Message from the OSDI '20 Program Co-Chairs

Dear colleagues,

Welcome to the 14th USENIX Symposium on Operating Systems Design and Implementation (OSDI '20)!

This year's program offers an unprecedented 70 exceptional papers. These papers represent the many strengths of our community and cover a wide range of topics, including file and storage systems, networking, scheduling, security, formal verification of systems, cluster management, system support for machine learning, hardware, consistency, consensus protocols, debugging, and, of course, operating systems design and implementation.

Our committee received a bumper crop of 400 submissions, an increase of more than 50% over OSDI '18. This growth demanded that we modify the review process and grow the committee at the last minute to handle the load. When you bump into a PC member, give them a huge thank you! Sixty-five members participated, including academics, industrial researchers, and industrial practitioners. Papers received two reviews in the first round; 305 advanced to round two, where they received an additional review. Of those, 177 advanced to round three, where they received three more reviews. For a small number of papers, where opinions were divided or where a paper was particularly specialized, we solicited additional expert reviews. In total, the PC and external reviewers wrote more than 1.6 million words in more than 1,600 thoughtful reviews.

After a rigorous online discussion across the full PC, the heavy PC members discussed 101 papers in a virtual 2-day PC meeting. The PC chairs strove to ensure that all the discussed papers received full and fair consideration, coming to a consensus agreement in almost every case. Papers were placed into high-level categories according to their main topic so that similar papers could be discussed together at the PC meeting. All discussed papers received a summary of the PC discussion written by a heavy PC member. In the end, the PC selected 70 papers for presentation at the conference, resulting in an 18% acceptance rate, similar to prior years. Each of the accepted papers was allocated an additional two pages and shepherded by a member of the heavy PC to help the authors address the reviewers' comments in their camera-ready versions.

After finalizing the program, we created a separate committee to decide the Jay Lepreau Best Paper Awards composed of PC members with no conflicts with the papers under consideration. PC members nominated papers for these awards. We selected four papers with at least two nominations for best paper as candidates for the award. After reading the nominated papers and considering the reviews from the full PC, the awards committee agreed on three Jay Lepreau Best Paper Awards.

As PC co-chairs, we stand on the shoulders of so many who did a tremendous amount of hard work to make OSDI '20 a success. First, we thank the authors of all submitted papers for choosing to send their work to OSDI. Thanks also to the program committee for their hard work in reviewing and discussing the submissions and in shepherding the accepted papers. We thank Vijay Chidambaram and James Mickens for organizing the Ask Me Anything sessions, and we thank Malte Schwarzkopf, Aastha Mehta, Natacha Crooks, and Brian Noble for organizing the student mentoring sessions. We are delighted that Anjo Vahldiek-Oberwagner, Eric Eide, and Ryan Stutsman have organized the artifact evaluation process. We are also grateful to the external reviewers who provided additional perspectives. We thank the USENIX staff, who have been fundamental in organizing OSDI '20 in an especially difficult year. Finally, OSDI wouldn't be what it is without our attendees—thank you for listening to our speakers, asking challenging and insightful questions, sharing your ideas with others, and networking with one another in Slack!

We hope you will find OSDI '20 interesting, educational, and inspiring!

Shan Lu, *University of Chicago*

Jon Howell, *VMware*

OSDI '20 Program Co-Chairs

Message from the OSDI '20 Artifact Evaluation Committee Co-Chairs

It is our pleasure to report on the artifact evaluation process conducted as part of OSDI '20. This year's conference represents the first time that OSDI has included an artifact evaluation committee (AEC), and it immediately follows the inaugural year for artifact evaluation at SOSP.

The goal of artifact evaluation is to incentivize authors to invest in the broader scientific community by producing artifacts that illustrate their claims, enable others to validate those claims, and accelerate future scientific progress. A paper with artifacts that have passed the artifact evaluation process is recognized in two ways: first by badges that appear on the paper's first page, and second by an appendix that details the artifacts.

Process

In designing the artifact evaluation process for OSDI, we aimed to bridge the processes from earlier USENIX conferences (USENIX Security) and the prior effort from ACM SOSP. USENIX previously used a single-badge process, whereas SOSP used a system based on the ACM's artifact review and badging policy. After deliberation, we decided on a three-badge approach to evaluation. This helps establish congruence between the processes for SOSP and OSDI, and the finer granularity of a multi-badge system encourages participation even when full artifacts cannot be shared or specific results are too challenging for the committee to reproduce. The three badges that we used for OSDI are:

- **Artifacts Available:** Have the artifacts associated with the paper been made available for retrieval both permanently and publicly?
- **Artifacts Functional:** Do the artifacts conform to the expectations set by the paper in terms of functionality, usability, and relevance?
- **Results Reproduced:** Can the AEC use the submitted artifacts to obtain the main results presented in the paper?

The criteria for each badge are independent; for example, an artifact does not need to be deemed available or functional in order to be considered for the "Results Reproduced" badge. The third badge corresponds to the "Results Replicated" badge at SOSP '19 but differs in name. The OSDI badge name matches terminology recommended by the National Information Standards Organization (NISO).

Evaluation

To form the artifact evaluation committee, we issued an open invitation to the systems community for self-nominations. From the self-nominations, we selected 40 early-career researchers and graduate students based on their levels of expertise.

After the decisions for OSDI '20 paper submissions were distributed, the authors of accepted papers were invited to submit artifacts for evaluation. (Thus, the artifact evaluation process had no effect on which papers were chosen to appear at OSDI.) Authors had one and a half weeks, until August 28, to respond to the call for artifacts. At artifact-submission time, authors were required to choose the badges for which their submission would be considered. The overwhelming majority of submissions applied for all three badges. Each artifact was accompanied by the accepted version of its associated paper so that the AEC could evaluate each artifact against its paper's claims.

A total of 49 artifacts were submitted for evaluation. The AEC members bid on artifacts, and we assigned two or three reviewers for each submission—three if the submission applied for the "Results Reproduced" badge, and two otherwise. After bidding, the AEC had five weeks, until October 9, to make judgments.

Evaluation started with an attempt to build the artifact (where appropriate). Next, AEC members tried to repeat some or all of the experiments described in the artifact's paper. AEC members were cognizant that it would be difficult to reproduce certain reported results, e.g., due to environmental or time limits. Reviewers were able to communicate with authors and regularly did so for clarifications and for help in debugging issues, with HotCRP preserving single-blind reviewing. Along the way, AEC members assessed each artifact's completeness, documentation, and apparent ease of reuse. After all reviews were submitted, the AEC held an online discussion to decide if—for each artifact—it met, exceeded, or fell below the expectations set by its paper.

Overall, the process generated 133 reviews and 1,180 comments with an average of about 3,000 words of combined review text and comments per artifact.

Results

OSDI '20 accepted 70 papers; in comparison, SOSP '19 accepted 38. Correspondingly, we received a greater number of submitted artifacts: 49 versus 23. We also saw an increase in the fraction of papers that chose to participate: 70%, up from 61% at SOSP '19. We hope that this trend will continue as artifact evaluation becomes a regular part of our community's conferences.

Of the 49 submitted artifacts, the AEC found that 48 met or exceeded expectations for at least one of the three badges. Per the choices of the authors, not all artifacts were considered for all badges.

- 47 artifacts received the **Artifacts Available** badge (96%).
- 46 artifacts received the **Artifacts Functional** badge (94%).
- 39 artifacts received the **Results Reproduced** badge (80%).

The papers that describe these artifacts can be easily recognized by the USENIX artifact evaluation badges that appear on their initial pages.

Takeaways

Cloud Resources: Increasingly, systems papers present experimental results that depend on large-scale pools of resources for reproduction. Based on feedback from the SOSP '19 efforts, we sought out resources to evaluate these types of artifacts, and Microsoft generously donated resource credits for running artifacts on Azure to help with this issue. Unfortunately, these resources were hard to leverage for the artifacts for which they would have been most useful. Several artifacts relied on access to high-end GPU resources; allocating these resources in Azure requires special approval and quota increases, which we were not able to secure. In some cases, the authors of these artifacts were able to provide reviewers with access to pre-existing resources that the AEC could use for reproduction. In the future, it may make sense to secure quotas for the use of specialized resources (specific GPUs, for example) before the start of the artifact evaluation process, based on types of resources required in the set of accepted papers.

Single vs. Multiple Badges: Of the 48 papers that received badges, 11 papers received a subset of the three available badges. We believe this is a strong outcome in favor of the multi-badge badge process we used. If we had opted to use a single badge that encompassed all of our evaluation criteria, it is likely that fewer papers would have received that badge, and consequently, fewer high-quality systems artifacts would have been recognized and documented.

Closing

We thank the authors of the 49 submitted artifacts for their hard work in creating these valuable accompaniments to their papers. We also thank the 40 AEC members, who collectively spent hundreds of hours evaluating and discussing these artifacts. Finally, we thank Microsoft for their generous support of the AEC through Microsoft Azure credits. Our hope is that the AEC effort has strengthened the work of the authors who participated, and that it will help facilitate work that builds on the papers that appear in the OSDI '20 proceedings.

The full results and badging for OSDI '20, as well as reports from other artifact evaluation processes within the systems community, can be found online at sysartifacts.github.io.

Abstract

This paper describes an operating system (OS) called Theseus. Theseus is the result of multi-year experimentation to redesign and improve OS modularity by reducing the states one component holds for another, and to leverage a safe programming language, namely Rust, to shift as many OS responsibilities as possible to the compiler.

Theseus embodies two primary contributions. First, an OS structure in which many tiny components with clearly-defined, runtime-persistent bounds interact without holding states for each other. Second, an intralingual approach that realizes the OS itself using language-level mechanisms such that the compiler can enforce invariants about OS semantics.

Theseus's structure, intralingual design, and state management realize live evolution and fault recovery for core OS components in ways beyond that of existing works.

1 Introduction

We report an experimentation of OS structural design, state management, and implementation techniques that leverage the power of modern safe systems programming languages, namely Rust. This endeavor was initially motivated by studies of *state spill* [16]: one software component harboring changed states as a result of handling an interaction from another component, such that their future correctness depends on said states. Prevalent in modern systems software, state spill leads to fate sharing between otherwise modularized and isolated components and thus hinders the realization of desirable computing goals such as evolvability and availability. For example, state spill in Android system services causes the entire userspace frameworks to crash upon a system service failure, losing the states and progress of all applications, even those not using the failed service [16]. Reliable microkernels further attest that management of states spilled into OS services is a barrier to fault tolerance [21] and live update [28].

Evolvability and availability of systems software are crucial in environments where reliability is necessary yet hardware redundancy is expensive or impossible. For example, systems software updates must be painstakingly applied without downtime or lost execution context in pacemakers [26] and space probes [25, 62]. Even in datacenters, where network switches are replicated for reliability, switch software failures and maintenance updates still lead to network outages [27, 48].

On the quest to determine to what extent state spill can be avoided in OS code, we chose to write an OS from scratch. We were drawn to Rust because its ownership model provides a convenient mechanism for implementing isolation and zero-cost state transfer between OS components. Our initial OS-building experience led to two important realizations. First, mitigating state spill, or better state management in general, necessitates a rethinking of OS structure because state spill (by definition) depends on how the OS is modularized. Second, modern systems programming languages like Rust can be used not just to write safe OS code but also to statically ensure certain correctness invariants for OS behaviors.

The outcome of our experimentation is Theseus OS, which makes two contributions to systems software design and implementation. First, Theseus has a novel OS structure of many tiny components with clearly-defined, runtime-persistent bounds. The system maintains metadata about and tracks interdependencies between components, which facilitates live evolution and fault recovery of these components (§3).

Second, and more importantly, Theseus contributes the *intralingual* OS design approach, which entails matching the OS's execution environment to the runtime model of its implementation language and implementing the OS itself using language-level mechanisms. Through intralingual design, Theseus empowers the compiler to apply its safety checks to OS code with no gaps in its understanding of code behavior, and shifts semantic errors from runtime failures into compile-time errors, both to a greater degree than existing OSes. Intralingual design goes beyond safety, enabling the compiler to statically check OS semantic invariants and assume resource bookkeeping duties. This is elaborated in §4.

Theseus's structure and intralingual design naturally reduce states the OS must maintain, reducing state spill between its components. We describe Theseus's state management techniques to further mitigate the effects of state spill in §5.

To demonstrate the utility of Theseus's design, we implement live evolution and fault recovery (for availability) within it (§6). With this, we posit that Theseus is well-suited for high-end embedded systems and datacenter components, where availability is needed in the absence of or in addition to hardware redundancy. Therein, Theseus's limitations of being a new OS and needing safe-language programs have a lesser impact, as applications can be co-developed with the OS in an environment under a single operator's control.

We evaluate how well Theseus achieves these goals in §7. Through a set of case studies, we show that Theseus can easily and arbitrarily live evolve core system components in ways beyond prior live update works, e.g., joint application-kernel evolution, or evolution of microkernel-level components. As Theseus can gracefully handle language-level faults (panics in Rust), we demonstrate Theseus’s ability to tolerate more challenging transient hardware faults that manifest in the OS core. To this end, we present a study of fault manifestation and recovery in Theseus and a comparison with MINIX 3 of fault recovery for components that necessarily exist inside the microkernel. Although performance is not a primary goal of Theseus, we find that its intralingual and spill-free designs do not impose a glaring performance penalty, but that the impact varies across subsystems.

Theseus is currently implemented on x86_64 with support for most hardware features, such as multicore processing, preemptive multitasking, SIMD extensions, basic networking and disk I/O, and graphical displays. It represents roughly four person-years of effort and comprises ~38000 lines of from-scratch Rust code, 900 lines of bootstrap assembly code, 246 crates of which 176 are first-party, and 72 unsafe code blocks or statements across 21 crates, most of which are for port I/O or special register access.

However, Theseus is far less complete than commercial systems, or experimental ones such as Singularity [33] and Barrelfish [8] that have undergone substantially more development. For example, Theseus currently lacks POSIX support and a full standard library. Thus, we do not make claims about certain OS aspects, e.g., efficiency or security; this paper focuses on Theseus’s structure and intralingual design and the ensuing benefits for live evolution and fault recovery.

Theseus’s code and documentation are open-source [61].

2 Rust Language Background

The Rust programming language [40] is designed to provide strong type and memory safety guarantees at compile time, combining the power and expressiveness of a high-level managed language with the C-like efficiency of no garbage collection or underlying runtime. Theseus leverages many Rust features to realize an intralingual, safe OS design and employs the *crate*, Rust’s project container and translation unit, for source-level modularity. A crate contains source code and a dependency manifest. Theseus does not use Rust’s standard library but does use its fundamental core and `alloc` libraries.

Rust’s *ownership* model is the key to its compile-time memory safety and management. Ownership is based on affine types, in which a value can be used at most once. In Rust, every value has an owner, e.g., the string value `"hello!"` allocated in L4 below is owned by the `hello` variable. After a value is moved, e.g., if `"hello!"` was moved in L5 from `hello` to `owned_string` (L14), its ownership would be transferred and the previous owner (`hello`) could no longer use it.

```

1 fn main() {
2     let hel: &str;
3     {
4         let hello = String::from("hello!");
5         // consume(hello); // → "value moved" error in L6
6         let borrowed_str: &str = &hello;
7         hel = substr(borrowed_str);
8     }
9     // print!("{}", hel); // → lifetime error
10 }
11 fn substr<'a>(input_str: &'a str) -> &'a str {
12     &input_str[0..3] // return value has lifetime 'a
13 }
14 fn consume(owned_string: String) {...}

```

When the owner’s scope ends, e.g., at the end of a lexical block, the owned value is *dropped* (released) by virtue of the compiler inserting a call to its destructor. Destructors in Rust are realized by implementing the `Drop` trait for a given type, in which a custom *drop handler* can perform arbitrary actions beyond freeing memory. On L8 above, the `hello` string falls out of scope and is auto-deallocated by its drop handler.

Values can also be *borrowed* to obtain references to them (L6), and the lifetime of those references cannot outlast the lifetime of the owned value. The syntax in L11 gives the name `'a` to the lifetime of the `input_str` argument, and specifies that the returned `&str` reference has that same lifetime `'a`. That returned `&str` reference is assigned to `hel` in L7, which would result in a lifetime violation in L9 because `hel` would be used *after* the owned value it was originally borrowed from (`hello`) was dropped in L8. Rust’s compiler includes a borrow checker to enforce these lifetime rules, as well as the core tenet of *aliasing XOR mutability*, in which there can be multiple immutable references or a single mutable reference to a value, but not both at once. This allows it to statically ensure memory safety for values on the stack and heap.

Theseus also extensively leverages Rust *traits*, a declaration of an abstract type that specifies the set of methods the type must implement, similar to polymorphic interfaces in OOP languages. Traits can be used to place *bounds* on generic type parameters. For example, the function `fn print_str<T: Into<String>>(s: T) { }` uses the underlined trait bound to specify that its argument named `s` must be of any abstract type `T` that can be converted into a `String`.

3 Theseus Overview and Design Principles

The overall design of Theseus specifies a system architecture consisting of many small distinct components, called *cells*, which can be composed and interchanged at runtime. A cell is a software-defined unit of modularity that serves as the core building block of the OS, much like their namesake of biological cells in an organism (no relation to Rust’s `std::cell`). Theseus enables all software written in safe Rust, including applications and libraries, to coexist alongside the core OS components in a single address space (SAS) and execute at a single privilege level (SPL), building upon language-provided type and memory safety to realize isolation instead of hardware protection. Everything presented herein is written in Rust and runs in the SAS/SPL environment.

Theseus follows three design principles:

- P1.** Require *runtime-persistent* bounds for *all* cells.
- P2.** Maximize the power of the language and compiler.
- P3.** Minimize *state spill* between cells.

The remainder of this section describes how Theseus satisfies the first principle and why it matters, while §4 and §5 discuss the second and third principles, respectively.

3.1 Structure of Runtime-Persistent Cells

Cells in Theseus have bounds that are clearly defined at implementation time and persist into and throughout runtime: a cell exists as a Rust *crate* at implementation time, a single object file at compile time, and a set of loaded memory regions with per-section bounds and dependency metadata at runtime. This applies to *all* cells, not just a select subset such as kernel extensions in monolithic and safe-language OSES or userspace servers in microkernels; there are no exemptions for components within a “base kernel” image. Explicit cell bounds identifiable at runtime are the foundation for strong data/fault isolation and state management in Theseus.

At runtime, Theseus loads and links *all* cells into the system on demand. Briefly, this entails finding and parsing the cell object file, loading its sections into memory, resolving its dependencies to write linker relocation entries, recursively loading any missing cells as needed, and adding new public symbols to a symbol map. In doing so, Theseus constructs detailed *cell metadata*, depicted in Figure 1, which is crucial knowledge for live evolution (§6.1) and fault recovery (§6.2). The set of loaded cells defines a *CellNamespace*, a true namespace containing all cells’ public symbols, used to quickly resolve dependencies between cells. Each loaded cell node tracks its constituent sections and the memory regions (§4.3.1) that contain them. The sections in each cell correspond to those in its crate’s object file, e.g., executable, read-only data, and read-write data sections. Each loaded section node tracks its size, location in memory, and bidirectional dependencies (incoming and outgoing); additional metadata exists to accelerate cell swapping and other system functions.

Persistence of Cell Bounds Reduces Complexity: Theseus’s persistent cell bounds provide a consistent abstraction of OS structure throughout all phases of their existence. This reduces the complexity of a developer’s mental model of the OS and simplifies fault recovery and evolution logic, as Theseus can introspect upon and manage its own code from the same cell-oriented viewpoint at runtime. The SAS/SPL environment augments this consistent view with *completeness*, in that everything from top-level applications and libraries to core kernel components are observable as cells. This enables Theseus to (i) implement a single mechanism, cell swapping, uniformly applicable to *any* cell, and (ii) jointly evolve cells from multiple system layers (e.g., applications and kernel components) in a safe manner.

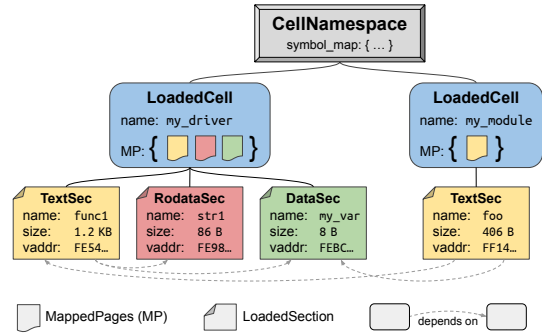

Figure 1: Theseus constructs detailed metadata that tracks runtime cell bounds in memory and bidirectional, per-section dependencies in order to simplify cell swapping logic.

Striking a Balance with Cell Granularity: Theseus cells are elementary in their scope; we follow separation of concerns to split functionality into many tiny crates, letting unavoidable circular dependencies between them halt further decomposition. We do not use Rust’s source-level module hierarchy in which one crate contains multiple Rust (sub)modules, as those module bounds are lost when the crate is built into an object file. Instead, we extract would-be modules into distinct crates, realizing hierarchy by organizing crates’ source files into folders in Theseus’s repository. This design offers both a programmer-friendly hierarchical view of source code and a simple system view of all cells as a flat set of distinct object files. It also strikes a balance between the complexity of needing to swap myriad tiny cells and the inefficiency and impracticality of swapping a large monolithic cell.

3.2 Bootstrapping Theseus with the nano_core

Theseus splits the compilation process at the linker stage, placing raw cell object files directly into the OS image such that linkage is deferred to runtime. From a practical standpoint, unlinked object files cannot run, so we must jump-start Theseus with the *nano_core*. The *nano_core* is a set of normal cells statically linked together into a tiny, executable “base kernel” image, comprising only components needed to bootstrap a bare-minimum environment that supports virtual memory and loading/linking object files. Because statically linking cells loses their bounds and dependencies, the *nano_core* fully replaces itself at the final bootstrap stage by dynamically loading its constituent cells one by one, using augmented symbol tables and other metadata burned into the OS image at build time. This meets the requirement of runtime-persistent bounds for *all* cells, allowing the *nano_core* to be safely unloaded after bootstrap.

4 Power to the Language

The second design principle Theseus follows is to leverage the power of the language by enabling the compiler to check safety and correctness invariants to the fullest extent possible. We term this approach *intralingual*, within the language, as it

involves matching Theseus’s execution environment to that of the language’s runtime model, and implementing OS semantics fully within the strong, static type system offered by modern languages like Rust. This extends compiler-checked invariants (e.g., no dangling references) to *all* types of resources, not just those built into the language.

Intralingual design offers two primary benefits. First, it empowers the compiler to take over resource management duties, reducing the states the OS must maintain, which in turn reduces state spill and strengthens isolation. Second, it enables the compiler to apply safety checks with no gaps in its understanding of code behavior, approaching end-to-end safety from applications to core kernel components and shifting semantic runtime errors into compile-time errors.

In contrast, traditional *extralingual* approaches rely on hardware protection and runtime checks to uphold invariants for safety, isolation, and correctness. These features are transparent to the compiler and require unsafe code. Even existing safe-language OSes [3, 13, 33, 44] have a gap between language-level safe code and the underlying unsafe core that implements the language’s required abstractions as a black box. Below, we describe how Theseus closes this gap and opens up such black boxes to the compiler.

4.1 Matching the Language’s Runtime Model

The compiler for many languages, including Rust, expects that its output will become (part of) an executable that runs within one address space and privilege level, e.g., a single userspace process. Thus, the compiler cannot holistically observe or check the behavior of independently-compiled components that run in different address spaces or privilege levels.

To address this shortcoming, we tailor Theseus’s OS execution environment to match Rust’s runtime model: (i) only a single address space (SAS) exists and thus a single set of addresses is visible, for which Theseus guarantees a one-to-one virtual-to-physical mapping; (ii) all code executes within a single privilege level (SPL), thus there is no other world or mode of execution; (iii) only a single allocator instance exists, matching the compiler’s expectation that a global heap serves all allocation requests. Note that Theseus does support multiple arbitrary heaps within that single instance (§7.3).

4.2 Intralingual OS Design

Matching the language’s runtime model only allows the compiler to *view* all Theseus components. For the compiler to *understand* those components and apply its safety checks to them, we must implement them in a manner that exposes their safety requirements, invariants, and semantics to the compiler. As an aside, Theseus uses safe code to the fullest extent possible at all layers of the system, prioritizing safety over all else, e.g., convenience, performance. It only descends into unsafety when fundamentally unavoidable: executing instructions *directly* above hardware and select functions within Rust’s foundational libraries, i.e., `core` and `alloc`.

Theseus goes beyond language safety to further empower the compiler to check our custom OS invariants as if they were built in. First, for each OS resource, Theseus identifies the set of invariants that prevent unsafety and incorrect usage. As the Rust compiler already checks myriad invariants for the usage of language-provided types and mechanisms, Theseus employs these existing mechanisms to allow its resource-specific invariants to be *subsumed* into those compiler invariants. For example, Theseus uses Rust’s built-in reference types, such as `&T` and `Arc<T>` (Atomic Reference-Counted pointer), to share resources (e.g., memory regions, channel endpoints) across multiple tasks in a safe language-level manner, instead of extralingual sharing mechanisms like raw pointers or mapping multiple pages to the same frame. This eliminates possible use-after-free errors by subsuming resource mismanagement checks into the compiler’s lifetime invariants.

Second, Theseus employs *lossless* interfaces for both external functions that export a resource’s semantics and internal functions that implement those semantics. An interface is lossless if crossing it preserves all language-level context, e.g., an object’s type, lifetime, or ownership/borrowed status. Furthermore, the *provenance* of that language-level context must be statically determinable, such that the compiler can authenticate that there was no broken link in the chain of calls and interface crossings when using a given resource. In other words, language-level knowledge must not be lost and then reconstituted extralingually. For example, invoking a system call in Linux loses the type and lifetime information of its arguments because they must be reduced to raw integer values to cross the user-kernel boundary.

Ensuring Resource Cleanup via Unwinding

One major invariant we enforce beyond default Rust safety is to prevent *resource leakage*, an acquired resource not being released even after no references to it remain. Although leakage does not violate safety, it is generally incorrect behavior. Theseus prevents resource leakage by (i) implementing all cleanup semantics in drop handlers (§2), a lossless language-level approach that allows the compiler to solely determine when it is safe to trigger resource cleanup, and (ii) employing *stack unwinding* to ensure acquired resources are always released in both normal and exceptional execution.

When tasks acquire resources in Theseus, they directly own objects representing those resources on their stack (§5.1). The Rust compiler tracks ownership of those objects to statically determine when a resource is dropped and, thus, where to insert its cleanup routine. Implementing all resource cleanup in only drop handlers frees developers from the burden of correctly ordering release operations or considering corner cases such as exceptional control flow jumps. Applying this to acquired locks allows Theseus to statically prevent many cases of deadlock: lock guards are auto-released during unwinding, and domain-specific locks automatically disable/re-enable preemption or interrupts, e.g., when modifying task runstates.

We implement Theseus’s *unwinder* from scratch in Rust, with custom unwinding logic based on the DWARF standard [1] but independent from existing unwind libraries; thus, it works in core OS contexts without a standard library or allocation. Theseus starts the unwinder only upon a software or hardware exception or a request to kill a task; it does not interfere with normal execution performance, unlike garbage collectors. This prevents failed or uncooperative tasks from jeopardizing resource release and reclamation, strengthening fault isolation. The unwinder uses compiler-emitted information along with cell metadata to locate previous frames in the call stack, calculate and restore register values present during that frame, and discover and invoke cleanup routines or exception-catching blocks. Cell metadata even enables the unwinder to traverse through nonstandard stack frames for hardware-entered asynchronous calling contexts, e.g., interrupts or CPU exception handlers.

Theseus supports intralingual resource revocation in two forms. First, Theseus can forcibly revoke generic resources by killing and unwinding an uncooperative task. This avoids isolation-breaking undefined behavior by ceasing to execute a task once its assumptions of safe resource access no longer hold. Second, Theseus can cooperatively revoke reclaimable resources, such as in-memory caches and buffer pools, which express the possibility of resource absence within their type definition, e.g., using `Option` or weak references. This design unifies system-level and language-level resource actions to guarantee that revoked resources are freed exactly once.

4.3 Examples of Intralingual Subsystems

We next describe how Theseus intralingually implements foundational OS resources, namely memory management and task management. Additional invariants, details, and examples, such as inter-task communication (ITC) channels, are omitted for brevity and available elsewhere [15].

4.3.1 Memory Management

Theseus intralingually implements virtual memory via the `MappedPages` type of Listing 2, which represents a region of virtually-contiguous pages statically guaranteed to be mapped to (optionally contiguous) real physical frames. `MappedPages` is the fundamental, sole way to map and access memory in Theseus, and serves as the backing representation for stacks, heaps, and arbitrary memory regions, e.g., device MMIO and loaded cells. The design of `MappedPages` empowers the compiler’s type system to enforce the following key invariants, extending Rust’s memory safety checks to *all* OS memory regions, not just the compiler-known stack and heap.

M.1: *The mapping from virtual pages to physical frames must be one-to-one, or bijective.* This prevents aliasing (sharing) from occurring beneath the language, forcing all shared memory access in Theseus to use *only* language-level mechanisms, such as references (`&MappedPages`). In Theseus’s SAS environment (§4.1), this is both possible and non-restrictive. In contrast, both conventional and existing safe-language OS

```
1 fn main() -> Result<()> {
2   let frames = get_hpet_frames()?;
3   let pages = allocate_pages(frames.count());
4   let mp_pgs = map(pages, frames, flags, pg_tbl)?;
5   {
6     let hpet: &HpetRegisters = mp_pgs.as_type(0)?;
7     print!("HPET device Vendor ID: {} ", hpet.caps_id.read() >> 16);
8   }
9   let (sender, receiver) = rendezvous::new_channel::<MappedPages>();
10  let new_task = spawn_task(receiver_task, receiver)?;
11  sender.send(mp_pgs)?;
12  Ok(()) // 'mp_pgs' not dropped, it was moved
13 }
14 fn receiver_task(receiver: Receiver<MappedPages>) -> Result<()> {
15   let mp: MappedPages = receiver.receive()?;
16   let hpet: &HpetRegisters = mp.as_type(0)?;
17   print!("Current HPET ticks: {} ", hpet.main_counter.read());
18   Ok(()) // 'mp' auto-dropped and unmapped here
19 }
20 struct HpetRegisters {
21   pub caps_and_id:   ReadOnly<u64>,
22   _padding:         [u64, ...],
23   pub main_counter:  Volatile<u64>,
24   ...
25 }
```

Listing 1: Example code that maps a memory region representing the HPET device, accesses the HPET vendor ID via MMIO, then spawns a new task and sends that memory region to it over a channel. The new task receives that memory region and uses it to read the HPET counter. This refers to code continued in Listing 2 and 3.

designs allow different virtual pages to map the same physical frame, an extralingual approach that renders sharing transparent to the compiler and thus uncheckable for safety.

We realize this invariant via the `map()` function (L26), which leverages type safety to take ownership of the allocated pages and frames in order to return a new `MappedPages` object. The lossless `map()` interface statically ensures the provenance of this relationship between `AllocatedPages`, `AllocatedFrames`, and `MappedPages`, guaranteeing they cannot be reused for duplicate mappings.

M.2: *Memory must not be accessible beyond the mapped region’s bounds.* To access a memory region, one must use `MappedPages` methods like `as_type()` (L45) or `as_slice()` (L52) that overlay a statically-sized struct or dynamically-sized slice atop it; mutable versions exist, see M.4 below. The in-bounds invariant (L46) is checked dynamically unless elided when the size and offset are statically known, as in some MMIO cases. These access functions are lossless because they return sized types that preserve the lifetime relationship described below.

M.3: *A memory region must be unmapped exactly once, only after there remain no outstanding references to it.* `MappedPages` realizes its release and cleanup semantics only within its drop handler (L38), ensuring that a `MappedPages` object, such as `mp` in L15 of Listing 1, is unmapped in both normal execution (L18) and exceptional execution. Correspondingly, memory must not be accessible after it has been unmapped. The above access methods tie the lifetime of the re-typed borrowed reference `&'m T` to the lifetime of its backing `MappedPages` memory region, allowing compiler lifetime checks to statically prevent use-after-free. As such, obtaining ownership of an overlaid struct is impossible by design, as

```

26 pub fn map(pages: AllocatedPages, frames: AllocatedFrames,
    flags: EntryFlags, ...) -> Result<MappedPages> {
27     for (page, frame) in pages.iter().zip(frames.iter()) {
28         let mut pg_tbl_entry = pg_tbl.walk.to(page, flags)?
                .get_pte_mut(page.pte_offset());
29         pg_tbl_entry.set(frame.start_addr(), flags?);
30     }
31     Ok(MappedPages { pages, frames, flags })
32 }
33 pub struct MappedPages {
34     pages: AllocatedPages,
35     frames: AllocatedFrames,
36     flags: EntryFlags,
37 }
38 impl Drop for MappedPages {
39     fn drop(&mut self) {
40         // unmap here: clear page table entry, invalidate TLB.
41         // AllocatedPages/Frames are auto-dropped and deallocated.
42     }
43 }
44 impl MappedPages {
45     pub fn as_type<'m, T>(&'m self, offset: usize) -> Result<'m T> {
46         if offset + size_of::<T>() > self.size_in_bytes() {
47             return Error::OutOfBounds;
48         }
49         let typed_mem: &'m T = unsafe {
50             &*((self.pages.start_addr() + offset) as *const T);
51             Ok(typed_mem)
52         }
53     }
54     pub fn as_slice<'m, T>(&'m self, offset: usize, count: usize)
55         -> Result<'m T> { ... }
56 }

```

Listing 2: The basic `MappedPages` type (L33) exposes an interface (L44-53) for safely accessing its underlying memory region. The `map()` function (L26) maps a range of virtual pages to physical frames and returns a new `MappedPages` instance that represents that memory region. Sanity checks and details omitted for brevity.

that would lossily discard the above lifetime relationship.

M.4: A memory region must only be mutable or executable if mapped as such. We ensure this using dedicated types, `MappedPagesMut` and `MappedPagesExec`, that offer `as_type_mut()` and `as_function()`, which statically prevents page protection violations as described elsewhere [15].

In summary, `MappedPages` bridges the semantic gap between the compiler’s and OS’s knowledge of memory, guaranteeing at compile time that unexpected invalid page faults cannot occur. Note that the necessary unsafe code in L49 is *innocuous* (see §8) as it merely indicates that the compiler cannot ensure the overlaid struct type has valid contents. Correctness of struct contents (e.g., `HpetRegisters` in L20) is unavoidably left to the developer. Regardless of developer mistakes, the compiler can still check that this unsafe code does not violate fault or data isolation because other invariants ensure it cannot produce dangling references (M.3) or access out-of-bounds addresses (M.2) beyond the reach of safe code. All other memory management code is safe down to the lowest level, where page table walks require extralingual code to accommodate hardware-defined page table formats.

4.3.2 Task Management

While `MappedPages` is the center of intralingual memory management, the `Task` struct in Theseus is minimized in both content and significance. Rather, task management centers around intralingual functions that leverage a consistent set of generic type parameters to handle each stage of the task life-

```

54 pub trait TFunc<A,R> = FnOnce(A) -> R;
55 pub trait TArg = Send + 'static;
56 pub trait TRet = Send + 'static;
57 pub fn spawn_task<F,A,R>(func: F, arg: A, ...) -> Result<TaskRef>
    where A: TArg, R: TRet, F: TFunc<A, R> {
58     let stack = alloc_stack(stack_size?);
59     let mut new_task = Task::new(task_name, stack, ...)?;
60     let trampoline_offset = new_task.stack.size_in_bytes() -
        size_of::<usize>() - size_of::<RegisterCtx>();
61     let initial_context: &mut RegisterCtx = new_task.stack
        .as_type_mut(trampoline_offset?);
62     *initial_context = RegisterCtx::new(task_wrapper::<F,A,R>);
63     new_task.saved_stack_ptr = initial_context as *const RegisterCtx;
64     let func_arg: &mut Option<F, A> = new_task.stack.as_type_mut(0?);
65     *func_arg = Some((func, arg));
66     Ok(TaskRef::new(new_task))
67 }
68 fn task_wrapper<F,A,R>() -> ! where A: TArg, R: TRet, F: TFunc<A,R> {
69     let opt: &mut Option<F, A> = current_task.stack
        .as_type(0).unwrap();
70     let (func, arg) = opt.take().unwrap();
71     let res: Result<R, KillReason> = catch_unwind_with_arg(func, arg);
72     match res {
73         Ok(exit_value) => task_cleanup.success::<F,A,R>(exit_value),
74         Err(kill_reason) => task_cleanup.failure::<F,A,R>(kill_reason),
75     }
76 }
77 fn task_cleanup_success<F,A,R>(exit_value: R) -> !
    where A: TArg, R: TRet, F: TFunc<A,R> {
78     current_task.set_as_exited(exit_value);
79     task_cleanup_final::<F,A,R>()
80 }
81 fn task_cleanup_failure<F,A,R>(kill_reason: KillReason) -> !
    where A: TArg, R: TRet, F: TFunc<A,R> {
82     current_task.set_as_killed(kill_reason);
83     task_cleanup_final::<F,A,R>()
84 }
85 fn task_cleanup_final<F,A,R>(curr_task: TaskRef) -> !
    where A: TArg, R: TRet, F: TFunc<A,R> {
86     runqueue::remove_task(current_task());
87     scheduler::schedule(); // task is descheduled, will never run again
88     loop { }
89 }

```

Listing 3: The interface to spawn a task (L57) creates a new task and sets up its stack such that it will jump to `task_wrapper()` upon first context switch, which will then invoke its entry function normally. Every function that handles a task lifecycle stage is parameterized with the same set of trait bounds (L54-56), ensuring that a task’s type information (function, argument, return type) is losslessly preserved across its entire lifecycle. Code simplified for brevity.

cycle, as shown in Listing 3: spawning and entering new tasks (L57,68), modifying task runstates as they run, and exiting and cleaning up tasks (L77,81,85). Theseus enforces the following invariants to empower the compiler to uphold memory safety and prevent resource leaks throughout the task lifecycle.

T.1: Spawning a new task must not violate memory safety. Rust already ensures this for multiple concurrent userspace threads, as long as they were created using its standard library thread type. Instead of using the standard library, Theseus provides its own task abstraction, overcoming the standard library’s need to extralingually accommodate unsafe, platform-specific thread interfaces, e.g. `fork()`. Theseus does not offer `fork` because it is known to be unsafe and unsuitable for SAS systems [7], as it extralingually duplicates task context, states, and underlying memory regions without reflecting that aliasing at the language level.

Theseus’s task abstraction preserves safety similarly to and as an extension of Rust threads. The `spawn_task()` interface (L57) requires specifying the exact type of the entry

function F , argument A , and return type R , with the following constraints: (i) the entry function must be runnable only once (`FnOnce` in L54), (ii) the argument and return type must be safe to transfer between threads (`Send` in L55-56), and (iii) the lifetime of said three types must outlast the duration of the task itself. All task lifecycle functions are lossless and have identical type parameters (F, A, R) , allowing the compiler to naturally extend its safety guarantees to concurrent execution across multiple Theseus tasks and to statically prevent invalidly-typed task entry functions, arguments, and return values.

T.2: *All task states must be released in all possible execution paths.* Releasing task states requires special consideration beyond simply dropping a `Task` object to prevent resource leakage (§4.2). Task states such as the stack are used during unwinding and can only be cleaned up once unwinding is complete, and task cleanup comprises multiple stages that each permit varying levels of resource release. For example, a task's stack and saved register context can be released when it is exited (L78) or killed (L82), but its runstate and exit value must persist until it has been reaped (not shown).

In addition, there exist multiple potential paths in the end stages of the task lifecycle that each require different cleanup actions. When a task runs to completion, its entry function naturally returns execution to the `task_wrapper` (L73), which can then safely mark the task as exited with its exit value. When a task crashes, the exception handler starts the unwinding procedure to release all task-held resources, after which it invokes the task failure function (L81) that marks the task as crashed. Both normal and exceptional execution paths invoke a final task cleanup function (L85) that removes the task from runqueues and deschedules it. All of these functions are parameterized with $\langle F, A, R \rangle$ types, a key part of intralingual fault recovery mechanisms like restartable tasks (§6.2).

T.3: *All memory transitively reachable from a task's entry function must outlive that task.* Although all memory regions in Theseus are represented by `MappedPages`, which prevents use-after-free via lifetime invariants, it is difficult to use Rust lifetimes to sufficiently express the relationship between a task and arbitrary memory regions it accesses. This is because a Rust program running as a task cannot specify in its code that its variables bound to objects in memory are tied to the lifetime of an underlying `MappedPages` instance, as they are hidden beneath abstractions like stacks, heaps, or program sections. Even if possible, this would be highly unergonomic and inconvenient, rendering ownership useless. For example, all local stack variables would need to be defined as borrowed references with lifetimes derived from that of the `MappedPages` representing the stack.

Thus, to uphold this invariant, we instead establish a chain of ownership: each task owns the cell that contains its entry function, and that cell owns any cells it depends on, given by the per-section dependencies in the cell metadata (§3.1). As such, the `MappedPages` regions containing all functions and data reachable from a task's entry function are guaranteed

to outlive that task itself. This avoids littering lifetime constraints across all program variables, and allows Rust code to be written normally with the standard assumption that the stack, heap, data, and text sections will always exist.

In contrast, conventional task management leaves the enforcement of these invariants to the OS programmer, an extralingual approach. In Theseus, only swapping stack pointer registers during a context switch is not intralingual.

5 State Management in Theseus

The third design principle Theseus follows is to minimize and ideally eliminate state spill in its cells. As Theseus's component structure is based on cells, state spill can only occur in interactions (e.g., function calls) that cross a cell boundary and result in changed state(s) in the receiving cell.

5.1 Opaque Exportation through Intralinguality

Theseus employs *opaque exportation* to avoid state spill in client-server interactions: each client is responsible for owning the state that represents its progress with the server, hence *exportation*, but cannot arbitrarily introspect into or modify that server-private state due to type safety, hence *opaque*. Opaque exportation is only possible because Theseus's safe, intralingual design enables shifting the burden of resource/progress bookkeeping from the OS into the compiler. This allows bookkeeping states to be *distributed*, or offloaded to each client, e.g., held only on a client task's stack. Theseus's unwinder can still find and invoke cleanup routines without needing OS knowledge about which resources a client has acquired, thus the server and OS at large need not maintain bookkeeping states for each client.

Conversely, Theseus eschews traditional state encapsulation, in which a server holds all states representing its clients' progress and resource usage [16, 17]. Such encapsulation constitutes state spill and causes fate sharing that breaks isolation: when a server crashes and loses its state, its clients will also fail. Opaque exportation still preserves *information hiding* [52], a primary benefit of encapsulation.

A corollary of opaque exportation is *stateless communication* (à la RESTful web architectures [24]), which dictates that everything necessary for a given request to be handled should be included in that request. Servers that employ stateless communication need not store intermediary states between successive client interactions, as future interactions will be self-sufficient, containing previously-exported states.

Opaque exportation enables Theseus to avoid common spillful abstractions such as handles. Client-side handles to server-owned data forces the server to maintain a global table that associates each client's handle with its underlying resource object, a form of state spill. Theseus rejects handles in favor of a client directly owning the underlying resource object; for example, an application task owns a `MappedPages` object instead of a virtual address handle, as shown by `mp_pgs` in L4 of Listing 1. This relieves the server (`mm` cell) from

the burden of maintaining a handle table, e.g., a list of virtual memory areas (VMAs) that correspond to the virtual addresses given to clients as handles for mapped regions. Note that clients are only responsible for owning, not cleaning up, objects that represent resources they acquired; when said object falls out of scope (or during unwinding), it is cleaned up via compile-time insertion of a server-provided cleanup routine, i.e., the object's drop handler. Thus, Theseus decouples the duty of owning and holding a state from the responsibility of implementing and invoking its cleanup functionality.

Accommodating Multi-Client States: Server-defined resources may pertain to or be shared across more than one client. Thus, Theseus extends opaque exportation to enable all pertinent clients to jointly own that resource state, i.e., *multi-client states*. Joint ownership and resource sharing in general can be realized via heap-allocated objects with automatic reference counting (e.g., Arc); while this can be viewed as state spill into the heap, considering spill into the allocator itself is not useful for two reasons. First, heap allocations are represented by owned objects elsewhere that point back to the heap, e.g., types like Box or Arc. Therefore, it suffices to consider only the propagation of those owned objects when determining where state spill occurred, rather than observing the internal state of the heap itself. Second, state spill into the heap is unavoidable; every basic action from creating a new local string variable to invoking a function would constitute state spill into the heap or stack, rendering it a useless metric.

5.2 Management of Special States in Theseus

Theseus cells often hold *soft states*, those that can be lost or discarded without error [19,55]. Soft states exist for the sake of convenience or performance, e.g., an in-memory cache of a clock source's period read from hardware. Although soft states technically constitute state spill, they can be idempotently re-obtained or recalculated with no impact on correctness. Therefore, Theseus permits soft states as harmless state spill with no adverse effects on evolution or availability.

We identify *unavoidable states* in two general forms: (i) *clientless states*, those that hardware requires the OS to maintain on its behalf, and (ii) states needed to handle asynchronous, hardware-invoked entry points that do not provide sufficient context. The former renders opaque exportation impossible and the latter violates stateless communication. In the first case, we cannot modify the behavior or capacity of underlying hardware to accommodate exported states. Thus, Theseus must hold these states to ensure they persist throughout all execution. Examples include low-level x86 structures like the Global Descriptor Table (GDT), Task State Segment (TSS), Interrupt Descriptor Table (IDT). In the second case, Theseus must store necessary contextual states with a static lifetime and scope that exceeds that of the asynchronous hardware event's entry function, e.g., an interrupt handler.

To preserve the interchangeability of server cells in both such cases, Theseus assigns their states a well-defined owner

and static lifetime by moving them into `state_db`, a state storage facility with minimal semantics akin to key value databases. Any singleton cell can move its static state into `state_db` and get a weak reference in return, a form of soft state. The `state_db` retains interchangeability despite harboring states spilled from other cells, as it uniquely must cooperate in its own swapping process by hardening itself via serialization to nonvolatile storage. The only other similar cell is the cell manager, which must also serialize its cell metadata. This design decouples a hardware state's lifetime from that of the server cell interacting with it, enabling said cell to be evolved without losing mandatory system-wide states.

5.3 Intralinguality and Spill Freedom: Examples

We further illustrate the relationship between intralingual design and state spill freedom with two example subsystems: memory and task management.

Memory Management: Theseus's MappedPages type (§4.3) eliminates state spill through opaque exportation: the client requesting the mapping owns the resultant MappedPages object, e.g., `mp_pgs` on L4, rather than the server (mm cell) that created it. In contrast, mm entities in existing OSes harbor state spill in the form of metadata representing each memory mapping, e.g., a list or table of virtual memory area (VMA) objects; clients must blindly trust that the underlying mapping and VMA persist throughout the usage of their virtual address handle. Importantly, we consider page tables to be hardware-required MMU states, much like x86's GDT or TSS. Page table entries are not language-level objects with lasting variable name bindings in Theseus; thus, writing to a page table is a hardware-externalized side effect rather than state spill. Crucially, the state representing this side effect — the transition from “unmapped” to “mapped” — is not lost, but reflected in the client-side MappedPages object rather than a hidden server-side state change.

Task Management: Theseus's intralingual design and its ensuing opaque exportation *significantly* reduce the scope and size of its Task struct, thus avoiding most instances of state spill from other subsystems into its task management cells. This is possible because the unwinder and compiler together retain the ability to fully clean up a task's acquired resources, even those shared across tasks, without needing to consult its task structure for resource bookkeeping states. Theseus also moves task-related states specific to other OS features, e.g., runqueue and scheduler information, out of the task struct and into those components themselves. This better follows separation of concerns than conventional OSes that hoard a huge list of OS states needed for manual resource bookkeeping and task cleanup into a centralized, all-encompassing task struct. Such a task struct design causes myriad OS operations to spill state into the task management entities and results in cross-cutting dependencies that closely entangle entities together, hindering their evolution or recovery. Thus, Theseus's task struct can contain only the bare necessities, e.g., the task's

runstate, stack, and saved execution context (register values). Correspondingly, it excludes lists of open files, open sockets, memory mappings, wait queues, etc.

6 Realizing Evolvability and Availability

To demonstrate the utility of Theseus’s design, we implement mechanisms inside it to realize challenging computing goals: live evolution and fault recovery.

6.1 Live Evolution via Cell Swapping

The fundamental evolutionary mechanism in Theseus is *cell swapping*, a multi-stage procedure that replaces O “old” existing cells with N “new” ones; O need not equal N . (i) First, Theseus loads all new cells into a new empty `CellNamespace` (§3.1), an isolated linking environment. (ii) Theseus then verifies dependencies bidirectionally: new cells must satisfy existing dependencies fulfilled by the old cells, and existing cells must satisfy the new cells’ dependencies. Isolated loading allows this to occur before making invasive changes to the running system. (iii) Theseus redirects all cells that depend on the old cells to depend on the corresponding new cells, which involves rewriting their relocation entries and dependency metadata, updating on-stack references to the old cells, and transferring states if necessary. (iv) Finally, Theseus atomically removes the old cells and symbols from the `CellNamespace` whilst moving in the new cells.

Evolving a running instance of Theseus is as easy as committing to its repository, which triggers our build server tool to re-compile Theseus and generate an evolution manifest file specifying which new cells shall replace which old ones. Maintainers can also select individual cells to evolve, and all others that must be evolved alongside them are automatically included to ensure a well-formed evolution manifest.

Theseus’s design facilitates cell swapping and simplifies known live update techniques like quiescence and state transfer. In stage (i), runtime cell bounds let Theseus’s dynamic loader ensure that a cell’s sections will not overlap or be interleaved in memory with those of another, allowing each cell to claim sole ownership of its memory regions and be cleanly removable in stage (iv). Dynamic loading also produces precise dependency information, needed in stages (ii) and (iii).

Spill-free design of cells in Theseus simplifies state transfer. As previously mentioned, opaque exportation allows a server cell to be more easily swapped because it need not maintain state between successive interactions with clients, increasing its quiescent periods. Stateless communication reduces a given function’s dependencies on other cells because it receives necessary states and function callbacks or closures via its arguments. Overall, this hastens the dependency rewriting and state transfer steps in stage (iii).

The *cell metadata* accelerates cell swapping. In stage (ii), dependency verification amounts to a quick search for fully-qualified symbols in the `CellNamespace`’s symbol map. In stage (iii), Theseus need not scan every task’s stack, rather

only a limited subset for which the old cells’ public functions or data are reachable from the task’s entry function; reachability is trivially determined by following dependency links in the metadata. Compile-time ownership semantics allow Theseus’s cell manager to fearlessly remove old cells and their symbols in stage (iv) without first checking for their usage elsewhere, as the compiler has already ensured a removed old cell will not be actually dropped and unloaded until it is no longer referred to by any other cells; this avoids a computationally-complex graph traversal over all metadata.

Theseus’s intralingual design extends to *transfer functions* needed for evolving a data structure in stage (iii). We allow and require such functions to be implemented intralingually using Rust’s type conversion traits, e.g., `Into`. Generation of transfer functions is ongoing work, thus the results reported in §7.1 use manually-implemented transfer functions.

6.2 Availability via Fault Recovery

We next describe how Theseus recovers from language-level exceptions (Rust panics) and hardware-induced faults like CPU exceptions. Theseus follows a multi-stage, cascading approach towards fault recovery, taking increasingly drastic measures until normal execution is recovered. A system-wide fault log records fault context (e.g., instruction pointer, current task) and the recovery action taken in order to track progression through recovery stages and avoid recurring fault loops.

The first recovery stage is to simply tolerate the fault by fully cleaning up a failed task via unwinding. This form of fault isolation allows other tasks that depend on resources shared with the failed task to continue running.

The second recovery stage is to respawn a new instance of the failed task. We extend the existing task infrastructure (Listing 3) to provide a fully intralingual implementation of *restartable tasks*, in which the spawn interface further constrains the $\langle F, A, R \rangle$ type parameters to enable the compiler to check that tasks are well-formed and safely restartable. The augmented trait bounds are $F: \text{Fn}(A) \rightarrow R + \text{Clone}$ and $A: \text{Send} + \text{Clone} + \text{'static}$, which require that the entry function can be safely executed multiple times ($F: \text{Fn}$, not FnOnce) and the argument can be safely duplicated (`Clone`).

The most significant recovery stage reuses the cell swapping mechanism (§6.1) to replace corrupted cells with freshly-loaded instances at different memory locations. This approach addresses faults that occur on invalid accesses of cell data or text sections, indicating they have been corrupted (e.g., due to a hardware memory failure). This represents the simplest possible case of cell swapping, with no possibility of missing dependencies or changes to code or data types. Following this, the failed task is restarted (as above), which allows it to successfully execute atop the new cell instance(s).

Notably, Theseus’s fault recovery mechanisms operate with few dependencies, allowing it to tolerate faults in the lowest system layers in the face of multiple failed subsystems. The fault-critical TCB of components for each recovery stage are

as follows: (i) cleanup of a failed task's states relies upon the unwinder, which only needs a basic execution environment to access the stack and invoke functions; (ii) restartable tasks rely upon task spawning; (iii) cell replacement relies upon object file parsing, loading, and linking. All of this can safely execute within the context of a CPU exception handler in Theseus. In comparison, fault recovery approaches in reliable microkernels like MINIX 3 [30] require support for context switches, interrupts, IPC, and userspace to work properly.

7 Evaluation

We evaluate Theseus to show that it achieves easy and arbitrary live evolution and increases system availability through fault recovery. We assess the impact of intralingual, state spill-free designs on memory and task management performance and compare Theseus's base performance with that of Linux through a series of benchmarks. All experiments were conducted on an Intel NUC 6i7KYK [2] with 4 (8 SMT) 2.6 GHz cores and 32 GB memory, unless otherwise stated.

7.1 Live Evolution

Theseus's evolutionary mechanisms are implemented in-band, that is, within the OS core and using its own features, which differs from existing works that implement live update functionality out-of-band or on a mature OS. As such, it is difficult to conduct a statistical analysis showing which historical commits can be supported by Theseus's live evolution. Instead, we use case studies (as in Baumann et al. [9]) to demonstrate that Theseus is able to evolve core system components in unique manners beyond prior live update works. Figure 2 shows the time scale of evolutionary stages for three case studies: (a) ITC channels, (b) scheduler and runqueue infrastructure, and (c) an Ethernet driver and network update client.

Inter-Task Communication (ITC) Channels: We show how Theseus can evolve its ITC channel layer (the equivalent of IPC) from an existing synchronous, unbuffered rendezvous channel into a new asynchronous buffered channel. We chose this because the histories of MINIX 3, seL4, and QNX Neutrino reveal significant, necessary evolution in their microkernel cores, most notably the addition of or change from synchronous to asynchronous IPC [4, 22]; all require a standard reboot to apply the change. Here, Theseus advances the state of the art by live evolving (i) a fundamental OS primitive that must be implemented within a microkernel, (ii) a kernel API that necessitates joint evolution of dependent userspace and kernel entities, and (iii) a widely-used component whilst preserving the execution context of those that depend on it.

During this experiment, we spawn multiple applications that exchange messages with each other over multiple synchronous channels, in addition to system tasks (e.g., input event manager) that already use said channel. We then issue a live evolution command at a random point while messages are in flight. Because Theseus can evolve cells independently

from execution contexts, it can swap the channel implementation out from underneath a running application without having to kill it. As shown in Figure 2(a), this improves availability by reducing median downtime to 385 μ s because it preserves the application's runtime progress, avoiding the domino effect of needing to restart multiple other dependent tasks transitively.

Scheduling and Runqueue Subsystems: In this experiment of Figure 2(b), we replace the existing round-robin scheduler with a new priority scheduler and the existing deque-based runqueue with a priority queue. All the while, Theseus runs multiple tasks of varying priorities that print messages, illustrating the visible difference in task execution order and frequency before and after evolution. This showcases Theseus's ability to evolve at runtime the modularity of the OS itself (by changing multiple cell bounds) and core cells used incessantly by many others.

At first glance, this appears trivial because existing OSes can already switch between multiple schedulers at runtime. The key distinction is that Theseus booted as an OS that did not originally contain *a priori* knowledge of or in-band support for multiple schedulers, whereas existing OSes require a scheduler infrastructure with a pre-defined common interface to accommodate multiple scheduler policies. This illustrates a significant benefit: subsystems in Theseus need not incorporate a special design or interface to support multiple versions of a given component, e.g., functions like `schedule()` or `task_switch()` can be unaware of multiple schedulers. Instead, Theseus components can rely upon an arbitrary, out-of-band cell swapping mechanism to evolve or flexibly switch between multiple alternatives, resulting in a simpler design.

Ethernet Driver and Network Update Client: In this experiment of Figure 2(c), we evolve Theseus to fix unreliable network downloads, comprising two cells that must be evolved simultaneously: (i) the core Ethernet driver underneath the network stack, and (ii) Theseus's evolution client application that sits atop the network stack to communicate with the build update server. This demonstrates Theseus's capacity for coordinated, multi-part evolution (as does the above scheduler case) versus small-scope live updates that only patch one driver function. The new Ethernet driver fixes an insidious bug that caused inconsistent connectivity due to incorrectly setting head and tail registers for the ring buffer of received packets; the new evolution client fixes its HTTP layer usage to properly recover from unexpected remote socket disconnections. We achieve this without losing any NIC configuration settings or packet data progress, tested by downloading files during the evolution and verifying them with checksums.

This case shows that Theseus can provide *availability without redundancy*, e.g., for solitary embedded systems in the field, and better availability atop hardware redundancy, e.g., for datacenter network switches that must be brought down during driver updates. Moreover, it shows that Theseus can perform "meta-evolution," i.e., loading a new evolution client

Figure 2: The time taken for each step in Theseus’s live evolution procedure, with cell swapping stages marked (*i-iv*) (§6.1). The first two steps are performed in isolation and do not affect the running system. Only the middle two steps (shaded) are critical and may impact execution by requiring atomicity, i.e., a system pause, but this can be avoided when the evolved components robustly handle state unavailability errors, as in the scheduler (b) case. The last two steps must lock the cell metadata to prevent overlapping evolution, but do not affect execution.

using that client’s own evolutionary features. This procedure is facilitated by state spill freedom that results in network states being owned by the application task, except for minimal states necessary to handle asynchronous receive buffers.

7.2 Fault Recovery

We demonstrate Theseus’s ability to tolerate faults within low-level core components, e.g., those that necessarily exist inside a microkernel. We focus on stress-testing whether Theseus can recover from unexpected hardware-induced faults beneath the language, as Theseus can recover from language-level faults easily because the compiler understands and can account for them, guaranteeing that unwinding will work.

Our *fault injection method* is to run Theseus atop the QEMU emulator [11] to enable us to automate arbitrary changes to hardware state, including randomly flipping one bit or overwriting full quadwords in memory, and randomly incrementing the instruction pointer register to skip instructions. We inject faults while running a workload of graphical rendering, task spawning, in-memory FS access, and ITC channel usage, and monitor the workload/OS behavior to determine if and how the fault manifests. This follows common practices in the literature [21, 30, 65]. As found in other fault injection works [30], very few randomly injected faults (<0.5%) manifest into observable failures; thus, we augment our fault injector to target specific regions in memory where faults are likely to manifest, namely a given task’s working set of stack, heap, and cell memory (text, data, and rodata sections).

Theseus Recovers from Microkernel-level Faults: Literature on fault-tolerant microkernels, e.g., MINIX 3 [31] and CurriOS [21], only evaluate recovery from faults injected into *userspace* system servers, not the microkernel itself. To show that Theseus supports recovery from faults in such low-level components, we inject faults into both MINIX 3’s IPC layer and Theseus’s ITC channels and evaluate their ability to recover. To ensure a fair comparison, we manually inspect all layers of MINIX 3’s IPC implementation and Theseus’s ITC channel implementation to discover 13 faults [45] that cause deterministic failures in both systems.

Out of the 13, Theseus recovers correctly in all but two cases, in which the receiver and sender tasks hang but do not crash; this can be solved via timeouts or resetting the channel.

MINIX 3 fails to recover correctly in all 13; its kernel crashes in 11 cases and loses a message in the other two. For example, corrupting the pointer to a passed message that is accessed in the IPC receive routine manifests as an invalid page fault in both Theseus and MINIX 3; MINIX 3’s kernel crashes and reboots whereas Theseus unwinds and properly restarts the ITC receiver task, allowing the sender to progress.

General Fault Recovery: To comprehensively assess Theseus’s fault recovery, we injected 800,000 faults into subsystems actively used by the above workloads, of which 0.083% manifested as observable failures. Table 1 shows that Theseus successfully recovered from 69% of total manifested faults. Restarting the failed task sufficed in 11% of cases, indicating corrupted stack or heap values; in the remaining 89%, Theseus needed to reload one or more cells, indicating corruption of text or data sections. The observable downtime of Theseus’s fault recovery mechanisms is evaluated elsewhere [15].

Theseus failed to recover from 31% of manifested faults, primarily due to the lack of asynchronous unwinding in Rust/LLVM. The compiler generates *synchronous* unwinding tables that only cover instructions where language-level exceptions (Rust panics) may occur. As hardware faults can occur at any instruction, Theseus’s unwinder may only find an inexact match for a faulted instruction pointer in the unwinding table, with a cleanup routine that may not completely release all resources acquired at the point of failure. Note that only local variables in the excepted stack frame may be missed, all other stack frames are properly handled. Though the known solution of asynchronous unwinding is unsupported, we are exploring OS and compiler solutions to augment coverage of unwinding information, beyond the scope of this work.

In another 30 cases, the fault caused the system or workload task to hang, recoverable via complementary hardware mechanisms like watchdog timers. In the remaining 18 and 62 cases respectively, Theseus failed to reload a new cell to replace the corrupted cell or suffered a fault in the unwinder’s code path itself, for which recovery failures are expected. Collectively, these represent the limitations of Theseus’s fault recovery.

7.3 Cost of Intralinguality & State Spill Freedom

Though performance is not a primary goal of Theseus, its intralingual and spill-free designs naturally raise performance

Successful Recovery	461
Restart task	50
Reload cell	411
Failed Recovery	204
Incomplete unwinding	94
Hung task	30
Failed cell replacement	18
Unwinder failure	62
Total manifested faults	665

Table 1: Theseus recovers from 69% of manifested faults in our fault injection trials that emulate hardware failures.

questions. In general, we observe and expect a trend in which many spill-free designs incur mild overhead, such as task and heap management, while some perform better, such as MappedPages. We compare multiple versions of Theseus with controlled differences to tease out the performance impact of these specific design choices. We also compare against Linux by porting LMBench microbenchmarks to Rust and running them on both Linux and Theseus; as Theseus is experimental and lacks POSIX support, results should be regarded as *informative* rather than conclusive. Overall, we do not observe any glaring performance penalties herein.

MappedPages: Better Performance and Scalability: Figure 3 compares our MappedPages design with a conventional spillful memory mapping implementation that encapsulates a red-black tree of VMAs, carefully modeled after and optimized to match Linux’s behavior. MappedPages performs slightly better because (i) clients directly own MappedPages objects, a form of distributed bookkeeping that obviates the need to search the VMA tree for the memory region that contains a given virtual address, and (ii) memory safety invariants are upheld at compile-time. Overall, this difference is unlikely to significantly impact real system workloads.

Avoiding Task State Spill has Negligible Overhead: As described in §5.3, Theseus eliminates runqueue and scheduler states spilled into the task struct, subverting the conventional all-inclusive task struct. This imposes the overhead of iterating through and removing a dead task from *all* runqueues rather than just the runqueue(s) it is known to be on. We evaluate the worst case in which a task is known to be on only *one* runqueue; the more runqueues a task is on, the less relative overhead Theseus has. We run Theseus on a 36-core (72 SMT) Supermicro 119u-7 server with one runqueue per hardware thread, to accurately reflect caching effects when searching through runqueues on other cores. The experiment of Figure 4(a) repeatedly removes a non-running task from its runqueue; while this is a contrived scenario impossible in any OS workload, it does show that overhead increases with the number of runqueues. The experiment of Figure 4(b) spawns and runs a dummy task that immediately exits, measuring the worst possible *realistic* overhead. Here, the impact is negligible because the prerequisite of spawning a task dominates the overhead of removing it from every runqueue.

Heap Designs	<i>threadtest</i>	<i>shbench</i>
unsafe	20.27 ± 0.009 s	3.99 ± 0.001 s
partially-safe	20.52 ± 0.010 s	4.54 ± 0.002 s
safe	24.82 ± 0.006 s	4.89 ± 0.002 s

Table 2: Heap microbenchmark results for various design points. Threadtest [12] allocates and deallocates 100 million 8-byte objects; shbench [34] does so for 20 million objects of size 1 to 1000 bytes.

Intralingual Heap Bookkeeping causes Overhead: Table 2 shows that an intralingual, safe heap implementation can impose up to 22.5% overhead in bookkeeping costs over an unsafe version. Each heap design variant is based on Theseus’s slab [14] allocator that tracks available memory as lists of MappedPages, one per slab, which serves allocation requests of a specific size. Multiple heap instances exist within a single alloc/dealloc interface, matching Rust’s language model (§4.1). The unsafe heap design maintains raw pointers to allocation metadata and neither owns its backing MappedPages nor knows of their lifetimes. The partially-safe heap owns its backing MappedPages but embeds raw pointers to them within the allocation metadata, discarding lifetime information. The safe heap maintains a collections type (e.g., red-black tree) that maps a virtual address to its allocation metadata and its backing MappedPages, allowing the compiler to observe and check that the association between an allocation and its backing MappedPages is never lost. This is crucial for Theseus to safely exchange memory between multiple per-core heaps, but causes overhead during deallocation when looking up the allocation metadata for a given address.

Microbenchmark Comparisons with Linux: We reimplement select LMBench benchmarks [47] in safe Rust on both Linux and Theseus, omitting those irrelevant to core OS components or with no equivalent in Theseus (e.g., RNG latency, futexes), and those that test subsystems still rudimentary in Theseus (e.g., networking, filesystems). Table 3 shows the results of each benchmark as the mean value across 100,000 iterations; full details are available elsewhere [15]. We do not claim that Theseus generally outperforms existing OSes like Linux, as larger-scale workloads may reveal different trends, but our results do not indicate significant performance drawbacks. The differences shown stem from eliminating the overhead of switching between hardware protection modes and address spaces; these are known benefits of SAS/SPL OSes [33].

In addition, we compare against microkernel IPC fastpaths by implementing an ITC fastpath within Theseus that bypasses the disconnection semantics of Theseus’s channels. We realize this fastpath in fully safe code via shared references to an atomic type that holds a small message, achieving a 1-byte RTT of 687 cycles compared to seL4’s [41] *one-way* IPC fastpath latency of 401 cycles on the same hardware (without Meltdown mitigations). For reference, Theseus’s asynchronous channel has an RTT of 1664 cycles, close to Singularity’s reported 1415-cycle channel RTT [5].

Figure 3: The time to map, remap, and unmap a 4 KiB page is constant for Theseus’s spill-free MappedPages approach, slightly better than a traditional spillful approach based on a red-black VMA tree.

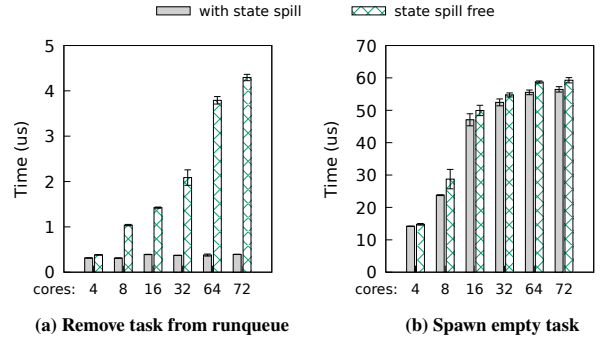

Figure 4: (a) The time to remove a task from the runqueue(s) increases when eliminating runqueue states from the task struct, but is minor in the worst realistic case of (b) spawning an empty task.

LMBench Benchmark	Ported behavior on Theseus; (Linux behavior, if different)	Linux (Rust)	Theseus	Theseus (static)
null syscall	call <code>curr_task()</code> function; (invoke <code>getpid()</code> syscall in vDSO)	0.28 ± 0.01	0.02 ± 0.00	0.02 ± 0.00
context switch	switch between two threads that continuously yield	0.61 ± 0.06	0.35 ± 0.00	0.34 ± 0.00
create process	spawn “Hello, World!” application; (fork + exec)	567.78 ± 40.4	242.11 ± 0.88	244.35 ± 0.06
memory map	map, write, then unmap 4KiB page; (use <code>MAP_POPULATE</code> flag)	2.04 ± 0.15	1.02 ± 0.00	0.99 ± 0.00
IPC	1-byte RTT over async ITC; (non-blocking pipe between threads)	3.65 ± 0.35	1.06 ± 0.00	1.03 ± 0.00

Table 3: Microbenchmark results in microseconds, smaller is better. *Linux (Rust)* is LMBench benchmarks reimplemented in safe Rust on Linux, *Theseus* is those benchmarks on Theseus, and *Theseus (static)* is those benchmarks on a statically-linked build of Theseus. Standard deviations of zero indicate values smaller than the timer period of 42 ns, and cannot be accurately measured.

Finally, the rightmost column of Table 3 shows that the *overhead of runtime-linked code* due to dynamic cell loading in Theseus is generally negligible. For this, we run the same set of benchmarks atop a build of Theseus in which all kernel cells are statically linked into a monolithic kernel binary.

8 Limitations and Discussion

Unsafe Code is an Unfortunate Necessity in a low-level kernel environment, needed to interface with hardware because the compiler understandably lacks a model of hardware semantics. Not all unsafe code is equal; we distinguish between two types of unsafe code: *innocuous* and *infectious*, in which infectious code may violate isolation but innocuous cannot. Unsafe code is infectious if it can circumvent the type system to access data inside another component, thereby “infecting” it, e.g., by dereferencing arbitrary pointers, but is *innocuous* if it merely accesses data reachable from safe code, e.g., writing the address of a variable to an I/O port. Innocuous code can still cause incorrect behavior. As part of ongoing work, we develop a compiler plugin to automate checks for the reachability and type safety of addresses accessed in unsafe blocks; this currently supports language-level unsafe blocks, e.g., within MappedPages, but requires manual whitelisting of inline assembly, e.g., context switch routines.

Reliance on Safe Language: Theseus must trust the Rust compiler and its `core/alloc` libraries to uphold safety without soundness holes. Fortunately, the risk of trusting Rust is

continually decreasing as multiple ongoing works strive to improve and verify the Rust compiler and its base libraries by checking unsafe usage [36, 37, 53]. To enjoy Theseus’s benefits, components must be implemented in safe Rust. Legacy code in other safe or managed languages could be supported by implementing their VMs/runtimes in Rust, but unsafe languages require hardware protection or dynamic interposition on memory accesses (à la SFI [60]) if isolation was desired.

Spillful Abstractions: There is tension between achieving spill freedom and supporting existing abstractions that need or benefit from state spill. One example is each task’s runnability state that represents whether it is blocked. Choosing a fully spill-free implementation would remove that state altogether, resulting in wasted CPU cycles as tasks would have no alternative but to endlessly spin while waiting on unavailable resources (e.g., acquired locks). As this impacts performance and convenience, we resolve the tension by seeking the middle ground: a minimal boolean state is spilled into each task that represents its runnability. This avoids the high cost of fruitlessly spinning but stops short of a traditional, fully-spillful design that spills information into the task struct about who blocked it and why (the conditions). In Theseus, the state of that blocked condition exists in and is owned by each entity that blocked that task, as per intralingual design.

Similar tensions exist in other subsystems, such as filesystems (FS) and memory. A fully spill-free FS would break existing POSIX interfaces by granting sole ownership of a file

to the client currently accessing it, meaning that the file would appear to be absent until the client releases it. We have not yet deeply explored custom filesystems, so Theseus’s current tradeoff is to support legacy FS standards at the cost of accepting state spill in the FS cells. For memory mapping, Theseus fully embraces the spill-free design choice, `MappedPages`.

Limitations of Intralinguality go beyond the overhead imposed by select designs (§7.3) or runtime bounds checks [20]. First, integrating existing unsafe components or libraries into the system can break the chain of compiler knowledge, i.e., intermixed extralinguality limits the benefits of other intralingual components. Second, not all knowledge is available statically; runtime checks may be necessary for nondeterministic input, such as user-specified memory mapping flags. Third, additional design effort is needed to express invariants using the type system versus using simple runtime checks, though this quickly becomes advantageous in OS contexts with complex runtime conditions that are tricky to get right.

9 Related Work

Theseus draws inspiration from much prior work. Related to its use of *safe language*, i.e., Rust, numerous prior works use safe languages in OSes: Modula-3 in SPIN [13], Java in JX [29], C# in Singularity [33], Rust in Tock [44] and Redox [3], and Go in Biscuit [20]. Many recent works have specifically leveraged Rust’s safety to realize efficient isolation [42, 49, 51, 66]. Theseus’s intralingual design approach (§4.2) goes beyond using a safe language, empowering the compiler to subsume resource-specific invariants into existing ones and thus check safety and correctness to a greater extent.

Theseus’s use of a *single address space* and *single privilege level* was inspired by SPIN [13] and Singularity [33], but for a different purpose than performance: matching the OS’s runtime model to that of the language (§4.1).

Our work is motivated by recently diagnosed problems in systems software due to *state spill* [16] and the ensuing argument for a spill-free OS [17]. Other works have implicitly targeted symptoms of state spill, e.g., CuriOS [21] shows that holding client-relevant states in server processes complicates fault recovery. CuriOS moves said states into each client’s address space, temporarily mapping them into a given server’s address space during an interaction; this offers effective isolation but incurs overhead, and only works for userspace servers in a microkernel OS. Theseus isolates client and server states within the same SAS and SPL using type and memory safety.

Theseus employs dynamic loading for *runtime-persistent bounds* of its cells. Dynamic loading is common in OSes to support kernel extensibility [13, 50, 56, 64], but only to load new modules, such as drivers and extensions, alongside (not in place of) a large, monolithic kernel without clear runtime bounds. Jacobsen et al. embed a microkernel within the Linux kernel as an indirection layer to decompose Linux into lightweight capability domains [35]; this helps to isolate

kernel subsystems but not to evolve or recover them.

Microkernel OSes [21, 31, 41] have persistent bounds for OS services that run in hardware-isolated userspace processes. Genode [23] is a similarly-modularized OS framework that creates a hierarchical tree of processes for strong access control. These OS structures make it easier to recover from service failures or update an OS service by restarting its process, but modularizing along coarse-grained process bounds limits their ability to evolve and recover from faults in core microkernel components. Also, Theseus’s finer-grained components make hardware-enforced process bounds uneconomical.

Live update of systems software has been extensively studied. Many works retrofit live update into legacy OSes like Linux [6, 18, 39, 46, 54, 58, 63]. Existing solutions need deep kernel expertise or tedious manual effort to generate or apply an update [18, 46, 54]; some impose overhead due to intermediary layers of indirection [18, 32, 57] or full-system checkpointing [39]; others are unable change kernel APIs, internal data structures, or non-function entities [6, 54, 58]. Overall, these works target small, localized security patches. In contrast, Theseus can apply sweeping evolutionary changes to core kernel components, their modularity, and kernel APIs by virtue of its new OS structure and spill-free design.

K42 [9, 10, 32, 57] is an object-oriented OS that deeply explores live update via hot-swapping of objects, similar to Theseus’s cell swapping. Unlike Theseus, K42 requires a uniform indirection layer atop all objects and can swap *only* objects, not low-level code beneath the OOP language layer, e.g., exception handling or hardware interaction. Similarly, microkernel solutions like PROTEOS [28], based on MINIX 3, can accommodate complex system updates for userspace server processes. Theseus builds upon PROTEOS’s novel techniques for state transfer, but can evolve finer-grained components, including those within a microkernel.

Fault-tolerant OS literature spans a wide variety of approaches, including using software domains to isolate and recover from failures in drivers and select OS subsystems [43, 59, 60], hardware isolation between OS service processes in microkernels [21, 31], and checkpoint/restore of drivers [38] or OS services [30] for faster, stateful recovery. Theseus uses intralingual mechanisms like unwinding and restartable tasks to ensure that language-level safety assumptions and compiler-provided isolation are not violated by recovery actions. Theseus also distinguishes between recovering a component (cell) and an execution context (task), can recover and replace finer-grained components than processes, and leverages novel state management techniques to simplify recovery logic.

A Artifact Appendix

A.1 Abstract

The full source code and documentation for Theseus OS is available online as a GitHub repository [61], where we invite contributions from the public. All OS components, source artifacts, and experiments described in the paper are present in the repository, along with detailed instructions on how to run or use them.

A.2 Artifact check-list

- **Program:** The Theseus Operating System
- **Compilation:** Rust, Make, no_std, freestanding, bare-metal
- **Binary:** OS .iso images
- **Run-time environment:** x86_64 bare-metal
- **Hardware:** Virtual or real x86_64 machine with BIOS
- **Experiments:** microbenchmarks, live evolution, fault recovery
- **Required disk space:** under 1GB
- **Expected experiment run time:** 10-12 hours
- **Public link:** <https://github.com/theseus-os/Theseus/tree/osdi20ae/osdi20ae>
- **Code licenses:** MIT

A.3 Description

A.3.1 How to access

The Theseus repository is hosted on GitHub at <https://github.com/theseus-os/Theseus>. The top level README contains detailed instructions on building and running Theseus. The branch `osdi20ae` contains pre-built Theseus images with instructions that specify how to easily reproduce each evaluation experiment, available at <https://github.com/theseus-os/Theseus/tree/osdi20ae>. The source-level documentation and high-level Theseus book are hosted online at <https://theseus-os.github.io/Theseus/>, but is best viewed using the commands `make doc` and `make book`, as specified in our README.

A.3.2 Hardware dependencies

We have tested Theseus on a variety of real machines, including Intel NUC devices, various Thinkpad laptops, and Supermicro servers. Currently, the only known limiting factor is support for booting via USB or PXE using traditional BIOS rather than UEFI; support for UEFI is a work in progress.

A.3.3 Software dependencies

We have tested building and then running Theseus in QEMU atop of the following host OSes:

- Linux, 64-bit Debian-based distributions like Ubuntu, tested on Ubuntu 16.04, 18.04, 20.04.
- Windows, using the Windows Subsystem for Linux (WSL), tested on the Ubuntu version of WSL and WSL2.
- MacOS, tested on versions High Sierra (10.13) and Catalina (10.15.2).
- Docker container environments.

The specific set of package dependencies are listed in the top-level README. Additional packages needed for artifact evaluation only are specified in the READMEs for each experiment.

A.4 Installation

Standard installation procedures are not required; steps to build and run a functional Theseus OS image are listed in our README.

A.5 Experiment workflow

All experiments described in the paper are implemented directly within the source code of Theseus and gated by compile-time configuration settings, so they are straightforward to inspect and run. The experiments are divided into the following groups, each of which has an accompanying script and set of instructions describing how to run it within its respective artifact folder in the repository. To further simplify reproduction of results, we provide pre-built OS images that are properly configured for each experimental setup.

- Case studies of live evolution of core OS components
- General fault injection and recovery
- Comparison with IPC fault recovery in MINIX 3
- Overhead of state spill and intralingual designs
 - The cost of MappedPages for memory mapping
 - The cost of removing runqueue/scheduler state spill from the task struct
 - The cost of safety and intralinguality in heap allocation
- LMBench microbenchmarks ported to Theseus and Linux

The documentation as well as a pre-built image of Theseus for each experiment can be found in the subfolder with the same name in the `osdi20ae` folder: <https://github.com/theseus-os/Theseus/tree/osdi20ae/osdi20ae>. Some experiments require Theseus to be built with special flags or need to be passed certain parameters to match the test cases in the paper. The requirements for running each benchmark as it was run in the paper are given in the documentation.

A.6 Evaluation and expected result

Due to differences in hardware and execution environments, the exact results presented in the paper may differ from those reproduced on other machines. However, the relative performance trends and conclusions drawn in our evaluation should hold.

A.6.1 Live evolution case studies

In these case studies, which correspond to §7.1 and Figure 2 in the paper, we start with a standard build of Theseus and evolve it into a different version with completely different functionality. This process downloads a set of modified crates as specified by an evolution manifest generated by our build tool, and then applies them to the running system using the `upd` application. The experiments can either be reproduced using a host machine that runs our build server alongside a virtualized instance of Theseus within QEMU, or using two separate physical machines with network access, one for the build server and one for Theseus. We provide detailed instructions on how to set up and reproduce each case study, as well as screenshots that describe what new behavior is expected after the evolutionary procedure has completed. We also explain how to obtain the raw values and calculate the measurements in Figure 2; one expects a general trend in which the first step of loading and linking crate object files takes the longest, and the critical third and fourth steps are very fast, within tens of μ s to a few hundred μ s.

A.6.2 Fault injection and recovery

In this experiment, Theseus runs atop the QEMU emulator, and we attach GDB to the virtualized instance of Theseus and use a script to inject faults into it by modifying the contents of memory and other hardware components like the instruction pointer register. We provide pre-built images of Theseus that run two of the sample workloads described in §7.2: accessing an in-memory filesystem and using inter-task communication channels. Each image is accompanied by a script that will inject faults into the system components used by the workloads run in that image. At the end of the experiment, each script should output the number of successful recoveries and failed recoveries. We also provide a full CSV table listing every fault injected and its outcome in our own trials.

A.6.3 IPC fault comparison

In this experiment, we compare 13 deterministic faults injected into Theseus's ITC channels and MINIX 3's IPC channels. A table describing the nature of each fault and the expected response observed in both Theseus and MINIX 3 is given in the README in this experiment's folder. As described in that README, modified source code of MINIX 3 is available at https://github.com/theseus-os/minix_osdi_ae, which contains a separate branch for each fault and instructions on how to build and run both systems to reproduce said fault recovery behavior.

A.6.4 Evaluation of MappedPages

This experiment measures the time to map, remap, and unmap a 4KiB page in two configurations: using the state spill-free, intralingual MappedPages implementation in Theseus, and using a traditional spillful approach based on a red-black tree of VMAs (see Figure 3). We provide a pre-built image for automated use with QEMU, with an accompanying script that runs this benchmark multiple times, parses the results, and calculates the statistics given in the paper. One should expect to observe similar trends as Figure 3, in which the MappedPages approach scales to many concurrent mappings better than the VMA-based approach.

A.6.5 Evaluation of runqueue state spill in tasking

This experiment measures the overhead of eliminating state spill into the tasking subsystem from the runqueue and scheduler subsystems, i.e., the overhead measured in Figure 4. We provide two pre-built images of Theseus (and instructions to re-create them manually), one using our standard spill-free implementation of runqueue and task states and one with a traditional spillful approach of a large stateful task struct. One should expect to observe similar trends as Figure 4(a), in that simply removing an exited task in the spill-free version will scale roughly linearly with the number of total runqueues in the system, whereas the spillful version should remain constant. The more important trend to observe is that of Figure 4(b), in which the overall effect of runqueue-task state spill is relatively minor because the cost of spawning a task dominates that of searching runqueues to remove an exited task.

A.6.6 Heap microbenchmarks

In this experiment, we run the *threadtest* and *shbench* microbenchmarks to measure the performance of three different versions of heap allocators that vary in their levels of safety and intralinguality, as given in Table 2 of the paper. We provide pre-built images for each configuration and instructions on how to build them manually. Overall, the expected trend is that the unsafe heap is the fastest, followed by the partially-safe heap and then the safe heap; the absolute runtimes may change but the relative overhead should remain similar to the paper.

A.6.7 LMBench microbenchmarks

In this experiment, we port a core subset of LMBench benchmarks to safe Rust code and compare their execution times across three environments: as Linux userspace applications, as applications atop the standard dynamically-loaded version of Theseus, and as applications atop a statically-linked version of Theseus, as shown in Table 3. We provide pre-built images for both configurations of Theseus as well as the ported LMBench source code, plus scripts and instructions for building and running it. In these microbenchmarks, we expect Theseus to be generally faster than Linux due to its SAS/SPL design that avoids extra boundary crossings (address spaces and privilege levels) imposed by traditional hardware-protected systems like Linux.

A.7 Experiment customization

The test executables and scripts for each experiment in Theseus can be customized with command-line parameters, e.g., the number of iterations, the size of trial operations, etc. Running each test command with a solitary `-help` argument will output a help menu that describes those parameters, along with in-source documentation at the top of each test application.

Abstract

RedLeaf is a new operating system developed from scratch in Rust to explore the impact of language safety on operating system organization. In contrast to commodity systems, RedLeaf does not rely on hardware address spaces for isolation and instead uses only type and memory safety of the Rust language. Departure from costly hardware isolation mechanisms allows us to explore the design space of systems that embrace lightweight fine-grained isolation. We develop a new abstraction of a lightweight language-based isolation domain that provides a unit of information hiding and fault isolation. Domains can be dynamically loaded and cleanly terminated, i.e., errors in one domain do not affect the execution of other domains. Building on RedLeaf isolation mechanisms, we demonstrate the possibility to implement end-to-end zero-copy, fault isolation, and transparent recovery of device drivers. To evaluate the practicality of RedLeaf abstractions, we implement Rv6, a POSIX-subset operating system as a collection of RedLeaf domains. Finally, to demonstrate that Rust and fine-grained isolation are practical—we develop efficient versions of a 10Gbps Intel ixgbe network and NVMe solid-state disk device drivers that match the performance of the fastest DPDK and SPDK equivalents.

1 Introduction

Four decades ago, early operating system designs identified the ability to isolate kernel subsystems as a critical mechanism for increasing the reliability and security of the entire system [12, 32]. Unfortunately, despite many attempts to introduce fine-grained isolation to the kernel, modern systems remain monolithic. Historically, software and hardware mechanisms remain prohibitively expensive for isolation of subsystems with tightest performance budgets. Multiple hardware projects explored the ability to implement fine-grained, low-overhead isolation mechanisms in hardware [84, 89, 90]. However, focusing on performance, modern commodity CPUs provide only basic support for coarse-grained isolation of user applications. Similarly, for decades, overheads of safe languages that can provide fine-grained isolation in software

remained prohibitive for low-level operating system code. Traditionally, safe languages require a managed runtime, and specifically, garbage collection, to implement safety. Despite many advances in garbage collection, its overhead is high for systems designed to process millions of requests per second per core (the fastest garbage collected languages experience 20-50% slowdown compared to C on a typical device driver workload [28]).

For decades, breaking the design choice of a monolithic kernel remained impractical. As a result, modern kernels suffer from lack of isolation and its benefits: clean modularity, information hiding, fault isolation, transparent subsystem recovery, and fine-grained access control.

The historical balance of isolation and performance is changing with the development of Rust, arguably, the first practical language that achieves safety without garbage collection [45]. Rust combines an old idea of *linear types* [86] with pragmatic language design. Rust enforces type and memory safety through a restricted ownership model allowing only one unique reference to each live object in memory. This allows statically tracking the lifetime of the object and deallocating it without a garbage collector. The runtime overhead of the language is limited to bounds checking, which in many cases can be concealed by modern superscalar out-of-order CPUs that can predict and execute the correct path around the check [28]. To enable practical non-linear data structures, Rust provides a small set of carefully chosen primitives that allow escaping strict limitations of the linear type system.

Rust is quickly gaining popularity as a tool for development of low-level systems that traditionally were done in C [4, 24, 40, 47, 50, 65]. Low-overhead safety brings a range of immediate security benefits—it is expected, that two-thirds of vulnerabilities caused by low-level programming idioms typical for unsafe languages can be eliminated through the use of a safe language alone [20, 22, 67, 69, 77].

Unfortunately, recent projects mostly use Rust as a drop-in replacement for C. We, however, argue that true benefits of language safety lie in the possibility to enable practical, lightweight, fine-grained isolation and a range of mechanisms

that remained in the focus of systems research but remained impractical for decades: fault isolation [79], transparent device driver recovery [78], safe kernel extensions [13, 75], fine-grained capability-based access control [76], and more.

RedLeaf¹ is a new operating system aimed at exploring the impact of language safety on operating system organization, and specifically the ability to utilize fine-grained isolation and its benefits in the kernel. RedLeaf is implemented from scratch in Rust. It does not rely on hardware mechanisms for isolation and instead uses only type and memory safety of the Rust language.

Despite multiple projects exploring isolation in language-based systems [6, 35, 39, 85] articulating principles of isolation and providing a practical implementation in Rust remains challenging. In general, safe languages provide mechanisms to control access to the fields of individual objects (e.g., through *pub* access modifier in Rust) and protect pointers, i.e., restrict access to the state of the program transitively reachable through visible global variables and explicitly passed arguments. Control over references and communication channels allows isolating the state of the program on function and module boundaries enforcing confidentiality and integrity, and, more generally, constructing a broad range of least-privilege systems through a collection of techniques explored by object-capability languages [59].

Unfortunately, built-in language mechanisms alone are not sufficient for implementing a system that isolates mutually distrusting computations, e.g., an operating system kernel that relies on language safety for isolating applications and kernel subsystems. To protect the execution of the entire system, the kernel needs a mechanism that *isolates faults*, i.e., provides a way to terminate a faulting or misbehaving computation in such a way that it leaves the system in a clean state. Specifically, after the subsystem is terminated the isolation mechanisms should provide a way to 1) deallocate all resources that were in use by the subsystem, 2) preserve the objects that were allocated by the subsystem but then were passed to other subsystems through communication channels, and 3) ensure that all future invocations of the interfaces exposed by the terminated subsystem do not violate safety or block the caller, but instead return an error. Fault isolation is challenging in the face of semantically-rich interfaces encouraged by language-based systems—frequent exchange of references all too often implies that a crash of a single component leaves the entire system in a corrupted state [85].

Over the years the goal to isolate computations in language-based systems came a long way from early single-user, single-language, single-address space designs [9, 14, 19, 25, 34, 55, 71, 80] to ideas of heap isolation [6, 35] and use of linear types to enforce it [39]. Nevertheless, today the principles of language-based isolation are not well understood. Singularity [39], which implemented fault isolation in Sing#, relied

on a tight co-design of the language and operating system to implement its isolation mechanisms. Nevertheless, several recent systems suggesting the idea of using Rust for lightweight isolation, e.g., Netbricks [68] and Splinter [47], struggled to articulate the principles of implementing isolation, instead falling back to substituting fault isolation for information hiding already provided by Rust. Similar, Tock, a recent operating system in Rust, supports fault isolation of user processes through traditional hardware mechanisms and a restricted system call interface, but fails to provide fault isolation of its device drivers (capsules) implemented in safe Rust [50].

Our work develops principles and mechanisms of *fault isolation* in a safe language. We introduce an abstraction of a language-based isolation domain that serves as a unit of information hiding, loading, and fault isolation. To encapsulate domain's state and implement fault isolation at domain boundary, we develop the following principles:

- **Heap isolation** We enforce *heap isolation* as an invariant across domains, i.e., domains never hold pointers into private heaps of other domains. Heap isolation is key for termination and unloading of crashing domains, since no other domains hold pointers into the private heap of a crashing domain, it's safe to deallocate the entire heap. To enable cross-domain communication, we introduce a special *shared heap* that allows allocation of objects that can be exchanged between domains.
- **Exchangeable types** To enforce heap isolation, we introduce the idea of *exchangeable types*, i.e., types that can be safely exchanged across domains without leaking pointers to private heaps. Exchangeable types allow us to statically enforce the invariant that objects allocated on the shared heap cannot have pointers into private domain heaps, but can have references to other objects on the shared heap.
- **Ownership tracking** To deallocate resources owned by a crashing domain on the shared heap, we track ownership of all objects on the shared heap. When an object is passed between domains we update its ownership depending on whether it's moved between domains or borrowed in a read-only access. We rely on Rust's *ownership discipline* to enforce that domains lose ownership when they pass a reference to a shared object in a cross-domain function call, i.e., Rust enforces that there are no aliases into the passed object left in the caller domain.
- **Interface validation** To provide extensibility of the system and allow domain authors to define custom interfaces for subsystems they implement while retaining isolation, we validate all cross-domain interfaces enforcing the invariant that interfaces are restricted to exchangeable types and hence preventing them from breaking the heap isolation invariants. We develop an interface definition language (IDL) that statically validates definitions of cross-domain interfaces and generates implementations for them.

¹Forming in the leaf tissue Rust fungi turn it red.

- **Cross-domain call proxying** We mediate all cross-domain invocations with *invocation proxies*—a layer of trusted code that interposes on all domain’s interfaces. Proxies update ownership of objects passed across domains, provide support for unwinding execution of threads from a crashed domain, and protect future invocations of the domain after it is terminated. Our IDL generates implementations of the proxy objects from interface definitions.

The above principles allow us to enable fault-isolation in a practical manner: isolation boundaries introduce minimal overhead even in the face of semantically-rich interfaces. When a domain crashes, we isolate the fault by unwinding execution of all threads that currently execute inside the domain, and deallocate domain’s resources without affecting the rest of the system. Subsequent invocations of domain’s interfaces return errors, but remain safe and do not trigger panics. All objects allocated by the domain, but returned before the crash, remain alive.

To test these principles we implement RedLeaf as a microkernel system in which a collection of isolated domains implement functionality of the kernel: typical kernel subsystems, POSIX-like interface, device drivers, and user applications. RedLeaf provides typical features of a modern kernel: multi-core support, memory management, dynamic loading of kernel extensions, POSIX-like user processes, and fast device drivers. Building on RedLeaf isolation mechanisms, we demonstrate the possibility to transparently recover crashing device drivers. We implement an idea similar to *shadow drivers* [78], i.e., lightweight shadow domains that mediate access to the device driver and restart it replaying its initialization protocol after the crash.

To evaluate the generality of RedLeaf abstractions, we implement Rv6, a POSIX-subset operating system on top of RedLeaf. Rv6 follows the UNIX V6 specification [53]. Despite being a relatively simple kernel, Rv6 is a good platform that illustrates how ideas of fine-grained, language-based isolation can be applied to modern kernels centered around the POSIX interface. Finally, to demonstrate that Rust and fine-grained isolation introduces a non-prohibitive overhead, we develop efficient versions of 10Gbps Intel Ixgbe network and PCIe-attached solid state-disk NVMe drivers.

We argue that a combination of practical language safety and ownership discipline allows us to enable many classical ideas of operating system research for the first time in an efficient way. RedLeaf is fast, supports fine-grained isolation of kernel subsystems [57, 61, 62, 79], fault isolation [78, 79], implements end-to-end zero-copy communication [39], enables user-level device drivers and kernel bypass [11, 21, 42, 70], and more.

2 Isolation in Language-Based Systems

Isolation has a long history of research in language-based systems that were exploring tradeoffs of enforcing lightweight

isolation boundaries through language safety, fine-grained control of pointers, and type systems. Early operating systems applied safe languages for operating system development [9, 14, 19, 25, 34, 55, 71, 80]. These systems implemented an “open” architecture, i.e., a single-user, single-language, single-address space operating system that blurred the boundary between the operating system and the application itself [48]. These systems relied on language safety to protect against accidental errors but did not provide isolation of subsystems or user-applications (modern unikernels take a similar approach [2, 37, 56]).

SPIN was the first to suggest language safety as a mechanism to implement isolation of dynamic kernel extensions [13]. SPIN utilized Modula-3 pointers as capabilities to enforce confidentiality and integrity, but since pointers were exchanged across isolation boundaries it failed to provide fault isolation—a crashing extension left the system in an inconsistent state.

J-Kernel [85] and KaffeOS [6] were the first kernels to point out the problem that language safety alone is not sufficient for enforcing fault isolation and termination of untrusted subsystems. To support termination of isolated domains in Java, J-Kernel developed the idea of mediating accesses to all objects that are shared across domains [85]. J-Kernel introduces a special capability object that wraps the interface of the original object shared across isolated subsystems. To support domain termination, all capabilities created by a crashing domain were revoked hence dropping the reference to the original object that was garbage collected and preventing the future accesses by returning an exception. J-Kernel relied on a custom class loader to validate cross-domain interfaces (i.e., generate remote-invocation proxies at run-time instead of using a static IDL compiler). To enforce isolation, J-Kernel utilized a special calling convention that allowed passing capability references by reference, but required a deep copy for regular unwrapped objects. Without ownership discipline for shared objects, J-Kernel provided a somewhat limited fault isolation model: the moment the domain that created the object crashed all references to the shared objects were revoked, propagating faults into domains that acquired these objects through cross-domain invocations. Moreover, lack of “move” semantics, i.e., the ability to enforce that the caller lost access to the object when it was passed to the callee, implied that isolation required a deep copy of objects which is prohibitive for isolation of modern, high-throughput device drivers.

Instead of mediating accesses to shared objects through capability references, KaffeOS adopts the technique of “write barriers” [88] that validate all pointer assignments throughout the system and hence can enforce a specific pointer discipline [6]. KaffeOS introduced separation of private domain and special shared heaps designated for sharing of objects across domains—explicit separation was critical to perform the write barrier check, i.e., if assigned pointer belonged to a specific heap. Write barriers were used to enforce the follow-

ing invariants: 1) objects on the private heap were allowed to have pointers into objects on the shared heap, but 2) objects on the shared heap were constrained to the same shared heap. On cross-domain invocations, when a reference to a shared object was passed to another domain, the write barrier was used to validate the invariants, and also to create a special pair of objects responsible for reference counting and garbage collecting shared objects. KaffeOS had the following fault isolation model: when the creator of the object terminated, other domains retained access to the object (reference counting ensured that eventually objects were deallocated when all sharers terminated). Unfortunately, while other domains were able to access the objects after their creator crashed, it was not sufficient for clean isolation—shared objects were potentially left in an inconsistent state (e.g., if the crash happened halfway through an object update), thus potentially halting or crashing other domains. Similar to J-Kernel, isolation of objects required a deep copy on a cross-domain invocation. Finally, performance overhead of mediating all pointer updates was high.

Singularity OS introduced a new fault isolation model built around a statically enforced ownership discipline [39]. Similar to KaffeOS, in Singularity applications used isolated private heaps and a special “exchange heap” for shared objects. A pioneering design decision was to enforce *single ownership* of objects allocated on the exchange heap, i.e., only one domain could have a reference to an object on the shared heap at a time. When a reference to an object was passed across domains the ownership of the object was “moved” between domains (an attempt to access the object after passing it to another domain was rejected by the compiler). Singularity developed a collection of novel static analysis and verification techniques enforcing this property statically in a garbage collected Sing# language. Single ownership was key for a clean and practical fault isolation model—crashing domains were not able to affect the rest of the system—not only their private heaps were isolated, but a novel ownership discipline allowed for isolation of the shared heap, i.e., there was no way for a crashing domain to trigger revocation of shared references in other domains, or leave shared objects in an inconsistent state. Moreover, single ownership allowed secure isolation in a zero-copy manner, i.e., the move semantics guaranteed that the sender of an object was losing access to it and hence allowed the receiver to update the object’s state knowing that the sender was not able to access new state or alter the old state underneath.

Building on the insights from J-Kernel, KaffeOS, and Singularity, our work develops principles for enforcing fault isolation in a safe language that enforces ownership. Similar to J-Kernel, we adopt wrapping of interfaces with proxies. We, however, generate proxies statically to avoid the run-time overhead. We rely on heap isolation similar to KaffeOS and Singularity. Our main reason for heap isolation is to be able to deallocate the domain’s private heap without any seman-

tic knowledge of objects inside. We borrow move semantics for the objects on the shared heap to provide clean fault isolation and at the same time support zero-copy communication from Singularity. We, however, extend it with the read-only borrow semantics which we need to support transparent domain recovery without giving up zero-copy. Since we implement RedLeaf in Rust, we benefit from its ownership discipline that allows us to enforce the move semantics for objects on the shared heap. Building on a body of research on linear types [86], affine types, alias types [18, 87], and region-based memory management [81], and being influenced by languages like Sing# [29], Vault [30], and Cyclone [43], Rust enforces ownership statically and without compromising usability of the language. In contrast to Singularity that heavily relies on the co-design of Sing# [29] and its communication mechanisms, we develop RedLeaf’s isolation abstractions—exchangeable types, interface validation, and cross-domain call proxying—outside of the Rust language. This allows us to clearly articulate the minimal set of principles required to provide fault isolation, and develop a set of mechanisms implementing them independently from the language, that, arguably, allows adapting them to specific design tradeoffs. Finally, we make several design choices aimed at practicality of our system. We design and implement our isolation mechanisms for the most common, “migrating threads” model [31] instead of messages [39] to avoid a thread context switch on the critical cross-domain call path and allow a more natural programming idiom, e.g., in RedLeaf domain interfaces are just Rust traits.

3 RedLeaf Architecture

RedLeaf is structured as a microkernel system that relies on lightweight language-based domains for isolation (Figure 1). The microkernel implements functionality required to start threads of execution, memory management, domain loading, scheduling, and interrupt forwarding. A collection of isolated domains implement device drivers, personality of an operating system, i.e., the POSIX interface, and user applications (Section 4.5). As RedLeaf does not rely on hardware isolation primitives, all domains and the microkernel run in ring 0. Domains, however, are restricted to safe Rust (i.e., microkernel and trusted libraries are the only parts of RedLeaf that are allowed to use unsafe Rust extensions).

We enforce the heap isolation invariant between domains. To communicate, domains allocate shareable objects from a global *shared heap* and exchange special pointers, remote references (`RRef<T>`), to objects allocated on the shared heap (Section 3.1). The ownership discipline allows us to implement lightweight zero-copy communication across isolated domains (Section 3.1).

Domains communicate via normal, typed Rust function invocations. Upon cross-domain invocation, the thread moves between domains but continues execution on the same stack. Domain developers provide an interface definition for the

Figure 1: RedLeaf architecture

domain’s entry point and its interfaces. The RedLeaf IDL compiler automatically generates code for creating and initializing domains and checks the validity of all types passed across domain boundaries (Section 3.1.5).

RedLeaf mediates all cross-domain communication with trusted proxy objects. Proxies are automatically generated from the IDL definitions by the IDL compiler (Section 3.1.5). On every domain entry, the proxy checks if a domain is alive and if so, it creates a lightweight continuation that allows us to unwind execution of the thread if the domain crashes.

In RedLeaf references to objects and traits are capabilities. In Rust, a trait declares a set of methods that a type must implement hence providing an abstraction of an interface. To expose their functionality, domains exchange references to traits via cross-domain calls. We rely on capability-based access control [76] to enforce the principle of least privilege and enable flexible operating system organizations: e.g., we implement several scenarios in which applications talk to the device driver directly bypassing the kernel, and even can link against device driver libraries leveraging DPDK-style user-level device driver access.

Protection model The core assumptions behind RedLeaf are that we trust (1) the Rust compiler to implement language safety correctly, and (2) Rust core libraries that use unsafe code, e.g., types that implement interior mutability, etc. RedLeaf’s TCB includes the microkernel, a small set of

trusted RedLeaf crates required to implement hardware interfaces and low-level abstractions, device crates that provide a safe interface to hardware resources, e.g., access to DMA buffers, etc., the RedLeaf IDL compiler, and the RedLeaf trusted compilation environment. At the moment, we do not address vulnerabilities in unsafe Rust extensions, but again speculate that eventually all unsafe code will be verified for functional correctness [5, 8, 82]. Specifically, the RustBelt project provides a guide for ensuring that unsafe code is encapsulated within a safe interface [44].

We trust devices to be non-malicious. This requirement can be relaxed in the future by using IOMMUs to protect physical memory. Finally, we do not protect against side-channel attacks; while these are important, addressing them is simply beyond the scope of the current work. We speculate that hardware counter-measures to alleviate the information leakage will find their way in the future CPUs [41].

3.1 Domains and Fault Isolation

In RedLeaf domains are units of information hiding, fault isolation, and composition. Device drivers, kernel subsystems, e.g., file system, network stack, etc., and user programs are loaded as domains. Each domain starts with a reference to a microkernel system-call interface as one of its arguments. This interface allows every domain to create threads of execution, allocate memory, create synchronization objects, etc. By default, the microkernel system call interface is the only authority of the domain, i.e., the only interface through which the domain can affect the rest of the system. Domains however can define a custom type for an entry function requesting additional references to objects and interfaces to be passed when it is created. By default, we do not create a new thread of execution for the domain.

Every domain, however, can create threads from the `init` function called by the microkernel when the domain is loaded. Internally, the microkernel keeps track of all resources created on behalf of each domain: allocated memory, registered interrupt threads, etc. Threads can outlive the domain creating them as they enter other domains where they can run indefinitely. Those threads continue running until they return to the crashed domain and it is the last domain in their continuation chain.

Fault isolation RedLeaf domains provide support for *fault-isolation*. We define fault isolation in the following manner. We say that a domain *crashes* and needs to be terminated when one of the threads that enters the domain panics. Panic potentially leaves objects reachable from inside the domain in an inconsistent state, making further progress of any of the threads inside the domain impractical (i.e., even if threads do not deadlock or panic, the results of the computation are undefined). Then, we say that the *fault is isolated* if the following conditions hold. First, we can unwind all threads running inside the crashing domain to the domain entry point and return an error to the caller. Second, subsequent attempts to

Figure 2: Inter-domain communication. Domain A invokes method `foo()` of domain B. The proxy that interposes on the invocation moves the ownership of the object pointed by `x` between domains.

invoke the domain return errors but do not violate safety guarantees or result in panics. Third, all resources of the crashed domain can be safely deallocated, i.e., other domains do not hold references into the heap of the crashed domain (heap isolation invariant), and we can reclaim all resources owned by the domain without leaks. Fourth, threads in other domains continue execution, and can continue accessing objects that were allocated by the crashed domain, but were moved to other domains before the crash.

Enforcing fault isolation is challenging. In RedLeaf isolated subsystems export complex, semantically rich interfaces, i.e., domains are free to exchange references to interfaces and hierarchies of objects. We make several design choices that allow us to cleanly encapsulate domain’s state and yet support semantically rich interfaces and zero-copy communication.

3.1.1 Heap Isolation and Sharing

Private and shared heaps To provide fault isolation across domains and ensure safe termination of domains, we enforce *heap isolation* across domains, i.e., objects allocated on the private heap, stack, or global data section of the domain can not be reached from outside of the domain. This invariant allows us to safely terminate any domain at any moment of execution. Since no other domain holds pointers into the private heap of a terminated domain, it is safe to deallocate the entire heap.

To support efficient cross-domain communication, we provide a special, global *shared heap* for objects that can be sent across domains. Domains allocate objects on the shared heap in a way similar to the normal heap allocation with the Rust `Box<T>` type that allocates a value of type `T` on the heap. We construct a special type, *remote reference* or `RRef<T>`, that allocates a value of type `T` on the shared heap (Figure 2). `RRef<T>` consists of two parts: a small metadata and the value itself.

The `RRef<T>` metadata contains an identifier of the domain currently owning the reference, borrow counter, and type information for the value. The `RRef<T>` metadata along with the value are allocated on the shared heap that allows `RRef<T>` to outlive the domain that originally allocates it.

Memory allocation on the domain heap To provide encapsulation of domain’s private heap, we implement a two-level memory allocation scheme. At the bottom, the microkernel provides domains with an interface for allocating untyped coarse-grained memory regions (larger than one page). Each coarse-grained allocation is recorded in the *heap registry*. To serve fine-grained typed allocations on the domain’s private heap, each domain links against a trusted crate that provides the Rust memory allocation interface, `Box<T>`. Domain heap allocations follow the rules of the Rust’s ownership discipline, i.e., objects are deallocated when they go out of scope. The two-level scheme has the following benefit: allocating only large memory regions, the microkernel records all memory allocated by the domain without significant performance overheads. If the domain panics, the microkernel walks the registry of all untyped memory regions allocated by the allocator assigned to the domain and deallocates them without calling any destructors. Such untyped, coarse-grained deallocation is safe as we ensure the heap isolation invariant: other domains have no references into the deallocated heap.

3.1.2 Exchangeable Types

Objects allocated on the shared heap are subject to the following rule: they can be composed of only of *exchangeable* types. Exchangeable types enforce the invariant that objects on the shared heap cannot have pointers into private or shared heaps, but can have `RRef<T>`s to other objects allocated on the shared heap. RedLeaf’s IDL compiler validates this invariant when generating interfaces of the domain (Section 3.1.5). We define exchangeable types as the following set: 1) `RRef<T>` itself, 2) a subset of Rust primitive *Copy* types, e.g., `u32`, `u64`, but not references in the general case, nor pointers, 3) anonymous (tuples, arrays) and named (enums, structs) composite types constructed out of exchangeable types, 4) references to traits with methods that receive exchangeable types. Also, all trait methods are required to follow the following calling convention that requires them to return the `RpcResult<T>` type to support clean abort semantics for threads returning from crashing domains (Section 3.1). The IDL checks interface definition and validates that all types are well-formed (Section 3.1.5).

3.1.3 Ownership Tracking

In RedLeaf `RRef<T>`s can be freely passed between domains. We allow `RRef<T>`s to be moved or borrowed immutably. However, we implement an ownership discipline for `RRef<T>`s that is enforced on cross-domain invocations. Ownership tracking allows us to safely deallocate objects on the shared heap owned by a crashing domain. The metadata section of the

`RRef<T>` keeps track of the owner domain and the number of times it was borrowed immutably on cross-domain invocations.

Initially, `RRef<T>` is owned by the domain that allocates the reference. If the reference is *moved* to another domain in a cross-domain call, we change the owner identifier inside `RRef<T>` moving ownership from one domain to another. All cross-domain communication is mediated by trusted proxies, so we can securely update the owner identifier from the proxy. Rust's ownership discipline ensures that there is always only one remote reference to the object inside the domain, hence when the reference is moved between domains on a cross-domain call, the caller loses access to the object passing it to the callee. If the reference is *borrowed immutably* in a cross-domain call, we do not change the owner identifier inside `RRef<T>`, but instead increment the counter that tracks the number of times `RRef<T>` was borrowed.

Recursive references `RRef<T>`s can form hierarchies of objects. To avoid moving all `RRef<T>`s in the hierarchy recursively on a cross-domain invocation, only the root of the object hierarchy has a valid owner identifier (in Figure 2 only object *x* has a valid domain identifier *A*, object *y* does not). Upon a cross-domain call, the root `RRef<T>` is updated by the proxy which changes the domain identifier to move ownership of the `RRef<T>` between domains. This requires a special scheme for deallocating `RRef<T>`s in case of a crash: we scan the entire `RRef<T>` registry to clean up resources owned by a crashing domain. To prevent deallocation of children objects of the hierarchy, we rely on the fact that they do not have a valid `RRef<T>` identifier (we skip them during the scan). The `drop` method of the root `RRef<T>` object walks the entire hierarchy and deallocates all children objects (`RRef<T>`s cannot form cycles). Note, we should carefully handle the case when an `RRef<T>` is taken out of the hierarchy. To deallocate this `RRef<T>` correctly we need to assign it a valid domain identifier, i.e., *y* gets a proper domain identifier when it is moved out from *x*. We mediate `RRef<T>` field assignments with trusted accessor methods. We generate accessor methods that provide the only way to take out an `RRef<T>` from an object field. This allows us to mediate the move operation and update the domain identifier for the moved `RRef<T>`. Note that accessors cannot be enforced for the unnamed composite types, e.g., arrays and tuples. For these types we update ownership of all composite elements upon crossing the domain boundary.

Reclaiming shared heap Ownership tracking allows us to deallocate objects that are currently owned by the crashing domain. We maintain a global registry of all allocated `RRef<T>`s (Figure 2). When a domain panics, we walk through the registry and deallocate all references that are owned by the crashing domain. We defer deallocation if `RRef<T>` was borrowed until the borrow count drops to zero. Deallocation of each `RRef<T>` requires that we have a `drop` method for each `RRef<T>` type and can identify the type of the reference dynamically. Each `RRef<T>` has a unique type identifier generated by the

IDL compiler (the IDL knows all `RRef<T>` types in the system as it generates all cross-domain interfaces). We store the type identifier along with the `RRef<T>` and invoke the appropriate `drop` method to correctly deallocate any, possibly, hierarchical data structure on the shared heap.

3.1.4 Cross-Domain Call Proxying

To enforce fault isolation, RedLeaf relies on *invocation proxies* to interpose on all cross-domain invocations (Figure 2). A proxy object exposes an interface identical to the interface it mediates. Hence the proxy interposition is transparent to the user of the interface. To ensure isolation and safety, the proxy implements the following inside each wrapped function: 1) The proxy checks if the domain is alive before performing the invocation. If the domain is alive, the proxy records the fact that the thread moves between domains by updating its state in the microkernel. We use this information to unwind all threads that happen to execute inside the domain when it crashes. 2) For each invocation, the proxy creates a lightweight continuation that captures the state of the thread right before the cross-domain invocation. The continuation allows us to unwind execution of the thread, and return an error to the caller. 3) The proxy moves ownership of all `RRef<T>`s passed as arguments between domains, or updates the borrow count for all references borrowed immutably. 4) Finally, the proxy wraps all trait references passed as arguments: the proxy creates a new proxy for each trait and passes the reference to the trait implemented by that proxy.

Thread unwinding To unwind execution of a thread from a crashing domain, we capture the state of the thread right before it enters the callee domain. For each function of the trait mediated by the proxy, we utilize an assembly trampoline that saves all general registers into a *continuation*. The microkernel maintains a stack of continuations for each thread. Each continuation contains the state of all general registers and a pointer to an error handling function that has the signature identical to the function exported by the domain's interface. If we have to unwind the thread, we restore the stack to the state captured by the continuation, and invoke the error handling function on the same stack and with the same values of general registers. The error handling function returns an error to the caller.

To cleanly return an error in case of a crash, we enforce the following calling convention for all cross-domain invocations: every cross-domain function must return `RpcResult<T>`, an enumerated type that either holds the returned value or an error (Figure 3). This allows us to implement the following invariant: functions unwound from the crashed domain never return corrupted data, but instead return an `RpcResult<T>` error.

3.1.5 Interface Validation

RedLeaf's IDL compiler is responsible for validation of domain interfaces and generation of proxy code required for enforcing the ownership discipline on the shared heap. RedLeaf

```

pub trait BDev {
    fn read(&self, block: u32, data: RRef<[u8; BSIZE]>)
        -> RpcResult<RRef<[u8; BSIZE]>>;
    fn write(&self, block: u32, data: &RRef<[u8; BSIZE]>)
        -> RpcResult<()>;
}

#[create]
pub trait CreateBDev {
    fn create(&self, pci: Box<dyn PCI>)
        -> RpcResult<(Box<dyn Domain>, Box<dyn BDev>)>
}

```

Figure 3: BDev domain IDL interface definitions.

IDL is a subset of Rust extended with several attributes to control generation of the code (Figure 3). This design choice allows us to provide developers with the familiar Rust syntax and also re-use Rust’s parsing infrastructure.

To implement an abstraction of an interface, we rely on Rust’s *traits*. Traits provide a way to define a collection of methods that a type has to implement to satisfy the trait, hence defining a specific behavior. For example, the `BDev` trait requires any type that provides it to implement two methods: `read()` and `write()` (Figure 3). By exchanging references to trait objects domains connect to the rest of the system and establish communication with other domains.

Each domain provides an IDL definition for the *create* trait that allows any domain that has access to this trait to create domains of this type (Figure 3). Marked with the `#[create]` attribute, the *create* trait both defines the type of the domain entry function, and the trait that can be used to create the domain. Specifically, the entry function of the `BDev` domain takes the `PCI` trait as an argument and returns a pointer to the `BDev` interface. Note that when the `BDev` domain is created along with the `BDev` interface, the microkernel also returns the `Domain` trait that allows creator of the domain to control it later. The IDL generates Rust implementations of both the *create* trait and the microkernel code used to create the domain of this type.

Interface validation We perform interface validation as a static analysis pass of the IDL compiler. The compiler starts by parsing all dependent IDL files creating a unified abstract syntax tree (AST), which is then passed to validation and generation stages. During the interface validation pass, we use the AST to extract relevant information for each type that we validate. Essentially, we create a graph that encodes information about all types and relationships between them. We then use this graph to verify that each type is exchangeable and that all isolation constraints are satisfied: methods of cross-domain interfaces return `RpcResult<T>`, etc.

3.2 Zero-copy Communication

A combination of the Rust’s ownership discipline and the single-ownership enforced on the shared heap allows us to provide isolation without sacrificing end-to-end zero-copy across the system. To utilize zero-copy communication, domains allocate objects on the shared heap with using the

`RRef<T>` type. On every cross-domain invocation a mutable reference (a reference that provides writable access to the object) is moved between domains, or an immutable reference can be borrowed. If the invocation succeeds, i.e., the callee domain does not panic, a set of `RRef<T>`s might be returned by the callee moving the ownership to the caller. In contrast to Rust itself, we do not allow borrowing of mutable references. Borrowing of mutable references may result in an inconsistent state in the face of a domain crash when damaged objects are returned to the caller after the thread is unwound. Hence, we require all mutable references to be moved and returned explicitly. If a domain crashes, instead of a reference an `RpcResult<T>` error is returned.

Zero-copy is challenging in the face of crashing domains and the requirement to provide transparent recovery. A typical recovery protocol re-starts the crashing domain and re-issues the failing domain call, trying to conceal the crash from the caller. This often requires that objects passed as arguments in the re-started invocation are available inside the recovery domain. It is possible to create a copy of each object before each invocation, but this introduces significant overhead. To recover domains without additional copies, we rely on support for immutable borrowing of `RRef<T>`s on cross-domain invocations. For example, the `write()` method of the `BDev` interface borrows an immutable reference to the data written to the block device (Figure 3). If an immutable reference is borrowed by the domain, Rust’s type system guarantees that the domain cannot modify the borrowed object. Hence, even if the domain crashes, it is safe to return the unmodified read-only object to the caller. The caller can re-issue the invocation as part of the recovery protocol providing the immutable reference as an argument again. This allows implementing transparent recovery without creating backup copies of arguments on each invocation that can potentially crash.

4 Implementation

While introducing a range of novel abstractions, we guide the design of RedLeaf by principles of practicality and performance. To a degree, RedLeaf is designed as a replacement for full-featured, commodity kernels like Linux.

4.1 Microkernel

The RedLeaf microkernel provides a minimal interface for creating and loading isolated domains, threads of execution, scheduling, low-level interrupt dispatch, and memory management. RedLeaf implements memory management mechanisms similar to Linux—a combination of buddy [46] and slab [16] allocators provides an interface for heap allocation inside the microkernel (the `Box<T>` mechanism). Each domain runs its own allocator internally and requests regions of memory directly from the kernel buddy allocator.

We implement the low-level interrupt entry and exit code in assembly. While Rust provides support for the *x86-interrupt* function ABI (a way to write a Rust function that takes the

x86 interrupt stack frame as an argument), in practice, it is not useful as we need the ability to interpose on the entry and exit from the interrupt, for example, to save all CPU registers.

In RedLeaf device drivers are implemented in user domains (the microkernel itself does not handle any device interrupts besides timer and NMI). Domains register threads as interrupt handlers for device-generated interrupts. For each external interrupt, the microkernel maintains a list of threads waiting for an interrupt. The threads are put back on the scheduler run queue when the interrupt is received.

4.2 Dynamic Domain Loading

In RedLeaf domains are compiled independently from the kernel and are loaded dynamically. Rust itself provides no support for dynamic extensions (except Splinter [47], existing Rust systems statically link all the code they execute [7, 50, 68]). Conceptually, the safety of dynamic extensions relies on the following invariant: types of all data structures that cross a domain boundary, including the type of the entry point function, and all types passed through any interfaces reachable through the entry function are the same, i.e., have identical meaning and implementation, across the entire system. This ensures that even though parts of the system are compiled separately type safety guarantees are preserved across domain boundaries.

To ensure that types have the same meaning across all components of the system, RedLeaf relies on a *trusted compilation environment*. This environment allows the microkernel to check that domains are compiled against the same versions of IDL interface definitions, and with the same compiler version, and flags. When a domain is compiled, the trusted environment signs the fingerprint that captures all IDL files, and a string of compiler flags. The microkernel verifies the integrity of the domain when it is loaded. Additionally, we enforce that domains are restricted to only safe Rust, and link against a white-listed set of Rust libraries.

Code generation Domain creation and loading rely on the code generated by the IDL compiler (Figure 4). IDL ensures safety at domain boundaries and allows support for user-defined domain interfaces. From the definitions of domain interfaces (Figure 4, ①) and its create function (②) the IDL generates the following code: 1) Rust implementations of all interfaces (③) and the create (④) trait, 2) a trusted entry point function (⑤) that is placed in the domain's build tree and compiled along with the rest of the domain to ensure that domain's entry function matches the domain create code, hence preserving safety on the domain boundary, 3) a microkernel domain create function that creates domains with a specific type signature of the entry point function (⑥), and 4) implementation of the proxy for this interface (⑦). By controlling the generation of the entry point, we ensure that the types of the entry function inside the microkernel and inside the domain match. If a domain tries to violate safety by changing the type of its entry function the compilation fails.

4.3 Safe Device Drivers

In RedLeaf device drivers are implemented as regular domains with no additional privileges. Like other domains they are restricted to the safe subset of Rust. To access the hardware, we provide device drivers with a collection of trusted crates that implement a safe interface to the hardware interface of the device, e.g., access to device registers and its DMA engines. For example, the `ixgbe` device crate provides access to the BAR region of the device, and abstracts its submit and receive queues with the collection of methods for adding and removing requests from the buffers.

Device driver domains are created by the `init` domain when the system boots. Each PCI device takes a reference to the PCI trait that is implemented inside the `pci` domain. Similar to other driver domains, the PCI driver relies on a trusted crate to enumerate all hardware devices on the bus. The trusted crate constructs `BARAddr` objects that contain addresses of PCI BAR regions. We protect each `BARAddr` object with a custom type, so it can only be used inside the trusted device crate that implements access to this specific BAR region. The `pci` domain probes device drivers with matching device identifiers. The driver receives a reference to the `BARAddr` object and starts accessing the device via its trusted crate.

4.4 Device Driver Recovery

Lightweight isolation mechanisms and clean domain interfaces allow us to implement transparent device driver recovery with shadow drivers [78]. We develop shadow drivers as normal unprivileged RedLeaf domains. Similar to proxy objects, the shadow driver wraps the interface of the device driver and exposes an identical interface. In contrast to the proxy which is relatively simple and can be generated from the IDL definition, the shadow driver is intelligent as it implements a driver-specific recovery protocol. The shadow driver interposes on all communication with the driver. During normal operation, the shadow passes all calls to the real device driver. However, it saves all information required for the recovery of the driver (e.g., references to PCI trait, and other parts of the device initialization protocol). If the driver crashes, the shadow driver receives an error from the proxy domain. The proxy itself receives the error when the thread is unwound through the continuation mechanism. Instead of returning an error to its caller, the shadow triggers the domain recovery protocol. It creates a new driver domain and replays its initialization protocol, by interposing on all external communication of the driver.

4.5 Rv6 Operating System Personality

To evaluate the generality of RedLeaf's abstractions, we implemented Rv6, a POSIX-subset operating system on top of RedLeaf. At a high-level, Rv6 follows the implementation of the xv6 operating system [73], but is implemented as a collection of isolated RedLeaf domains. Specifically, we implement Rv6 as the following domains: the core kernel, file system,

Figure 4: IDL code generation

network stack subsystem, network and disk device drivers, and collection of user domains. User domains communicate with the core kernel through the Rv6 system call interface. The core kernel dispatches the system call to either the file system or a network stack. The file system itself communicates with one of the RedLeaf block device drivers to get access to disk. We implemented three block device drivers: in-memory, AHCI, and NVMe. The file system implements journaling, buffer cache, inode, and naming layers. The network subsystem implements the TCP/IP stack and connects to the network device driver (we currently implement only one driver that supports a 10Gbps Intel Ixgbe device). We do not support the full semantics of the `fork()` system call as we do not rely on address spaces and hence cannot virtualize and clone the address space of the domain. Instead, we provide a combination of `create` system calls that allow user applications to load and start new domains [10]. Rv6 boots into a shell that supports pipes and I/O redirection and can start other applications similar to a typical UNIX system.

5 Evaluation

We conduct all experiments in the openly-available CloudLab network testbed [72].² For network-based experiments, we utilize two CloudLab c220g2 servers configured with two Intel E5-2660 v3 10-core Haswell CPUs running at 2.6 GHz, 160GB RAM, and a dual-port Intel X520 10Gb NIC. We run our NVMe benchmarks on a CloudLab d430 node that is configured with two 2.4 GHz 64-bit 8-Core E5-2630 Haswell CPUs, and a PCIe-attached 400GB Intel P3700 Series SSD. Linux machines run 64-bit Ubuntu 18.04 with a 4.8.4 kernel configured without any speculative execution attack mitigations as recent Intel CPUs address a range of speculative execution attacks in hardware. All RedLeaf experiments are performed on bare-metal hardware. In all the experiments, we disable hyper-threading, turbo boost, CPU idle states, and frequency scaling to reduce the variance in benchmarking.

5.1 Overheads of Domain Isolation

Language based isolation versus hardware mechanisms

To understand the benefits of language-based isolation over traditional hardware mechanisms, we compare RedLeaf’s

Operation	Cycles
seL4	834
VMFUNC	169
VMFUNC-based call/reply invocation	396
RedLeaf cross-domain invocation	124
RedLeaf cross-domain invocation (passing an <code>RRef<T></code>)	141
RedLeaf cross-domain invocation via shadow	279
RedLeaf cross-domain via shadow (passing an <code>RRef<T></code>)	297

Table 1: Language-based cross-domain invocation vs hardware isolation mechanisms.

cross-domain calls with the synchronous IPC mechanism implemented by the seL4 microkernel [27], and a recent kernel-isolation framework that utilizes VMFUNC-based extended page table (EPT) switching [62]. We choose seL4 as it implements the fastest synchronous IPC across several modern microkernels [58]. We configure seL4 without meltdown mitigations. On the c220g2, server seL4 achieves the cross-domain invocation latency of 834 cycles (Table 1).

Recent Intel CPU introduces two new hardware isolation primitives—memory protection keys (MPK) and EPT switching with VM functions—provide support for memory isolation with overheads comparable to system calls [83] (99-105 cycles for MPK [38, 83] and 268-396 cycles for VMFUNC [38, 58, 62, 83]). Unfortunately, both primitives require complex mechanisms to enforce isolation, e.g., binary rewriting [58, 83], protection with hardware breakpoints [38], execution under control of a hypervisor [54, 58, 62]. Moreover, since neither MPK nor EPT switching are designed to support isolation of privileged ring 0 code, additional techniques are required to ensure isolation of kernel subsystems [62].

To compare the performance of EPT-based isolation with language-based techniques we use in RedLeaf, we configure LVDs, a recent EPT-based kernel isolation framework [62] to perform ten million cross-domain invocations and measure the latency in cycles with the `RDTSC` instruction. In LVDs, the cross-domain call relies on the VMFUNC instruction to switch the root of the EPT and selects a new stack in the callee domain. LVDs, however, require no additional switches of a privilege level or a page-table. A single VMFUNC instruction takes 169 cycles, while a complete call/reply invocation takes 396 cycles on the c220g2 server (Table 1).

In RedLeaf, a cross-domain call is initiated by invoking

²RedLeaf is available at <https://mars-research.github.io/redleaf>.

the trait object provided by the proxy domain. The proxy domain uses a microkernel system call to move the thread from the callee to the caller domain, creates continuation to unwind the thread to the entry point in case the invocation fails, and invokes the trait of the callee domain. On the return path, a similar sequence moves the thread from the callee domain back into the caller. In RedLeaf, a null cross-domain invocation via a proxy object (Table 1) introduces an overhead of 124 cycles. Saving the state of the thread, i.e., creating continuation, takes 86 cycles as it requires saving all general registers. Passing one `RRef<T>` adds an overhead of 17 cycles as `RRef<T>` is moved between domains. To understand the low-level overhead of transparent recovery, we measure the latency of performing the same invocation via a shadow domain. In case of a shadow the invocation crosses two proxies and a user-built shadow domain and takes 286 cycles due to additional crossing of proxy and shadow domains.

Most recent Intel CPUs implement support for ring 0 enforcement of memory protection keys, protection keys supervisor (PKS) [3], finally enabling low-overhead isolation mechanism for the privileged kernel code. Nevertheless, even with low-overhead hardware isolation mechanisms, a zero-copy fault-isolation scheme requires ownership discipline for shared objects that arguably requires support from the programming language, i.e., either a static analysis [39] or a type system that can enforce single-ownership.

Overheads of Rust Memory safety guarantees of Rust come at a cost. In addition to the checks required to ensure safety at runtime, some Rust abstractions have a non-zero runtime cost, e.g., types that implement interior mutability, option types, etc. To measure the overheads introduced by Rust language itself, we develop a simple hash table that uses an open-addressing scheme and relies on the Fowler–Noll–Vo (FNV) hashing function with linear probing to store eight byte keys and values. Using the same hashing logic, we develop three implementations: 1) in plain C, 2) in idiomatic Rust (the style encouraged by the Rust programming manual), and 3) in C-style Rust that essentially uses C programming idioms but in Rust. Specifically, in C-style Rust, we avoid 1) using higher-order functions and 2) the `Option<T>` type that we utilize in the idiomatic code to distinguish between the occupied and unoccupied entries in the table. Without the `Option<T>` type that adds at least one additional byte to the key-value pair, we benefit from a tight, cache-aligned representation of key-value pairs in memory to avoid additional cache misses. We vary the number of entries in the hash table from 2^{12} to 2^{26} and keep the hash-table 75% full. On most hash table sizes, our implementation in idiomatic Rust remains 25% slower than the one in plain C, whereas C-style Rust performs equal to or even better than plain C, although by only 3-10 cycles (Figure 5). We attribute this to a more compact code generated by the Rust compiler (47 instructions on the critical get/set path in C-style Rust versus 50 instructions in C).

Figure 5: C vs Rust performance comparison

Figure 6: Ixgbe driver performance

5.2 Device Drivers

One of the critical assumptions behind RedLeaf is that Rust’s safety is practical for development of the fastest subsystems of a modern operating system kernel. Today, operating with latencies of low hundreds of cycles per I/O request, device drivers that provide access to high-throughput I/O interfaces, network adapters and low-latency non-volatile PCIe-attached storage, have the tightest performance budgets among all kernel components. To understand if overheads of Rust’s zero-cost abstractions allow the development of such low-overhead subsystems, we develop two device drivers: 1) an Intel 82599 10Gbps Ethernet driver (Ixgbe), and 2) an NVMe driver for PCIe-attached SSDs.

5.2.1 Ixgbe Network Driver

We compare the performance of RedLeaf’s Ixgbe driver with the performance of a highly-optimized driver from the DPDK user-space packet processing framework [21] on Linux. Both DPDK and our driver work in polling mode, allowing them to achieve peak performance. We configure RedLeaf to run several configurations: 1) `redleaf-driver`: the benchmark application links statically with the driver (this configuration is closest to user-level packet frameworks like DPDK; similarly, we pass-through the Ixgbe interface directly to the RedLeaf); 2) `redleaf-domain`: the benchmark application runs in a separate domain, but accesses the driver domain directly via a proxy (this configuration represents the case when the network device driver is shared across multiple isolated applications [38]); 3) `rv6-domain`: the benchmark application runs as an Rv6 program, it first enters the Rv6 with a system call and then calls into the driver (this configuration is analogous to a setup of a commodity operating system kernel in which user

Figure 7: Software-only nullnet driver performance

applications access I/O interfaces via a kernel network stack). Further, we run the last two configurations with and without the shadow driver (`redleaf-shadow` and `rv6-shadow`), which introduces an additional domain crossing into the shadow (these two configurations evaluate overheads of the transparent driver recovery). In all our tests, we pin the application thread to a single CPU core.

We send 64 byte packets and measure the performance on two batch sizes: 1 and 32 packets (Figure 6). For packet receive tests, we use a fast packet generator from the DPDK framework to generate packets at line-rate. On packet transmit and receive tests, Linux achieves 0.89 Mpps due to its overly general network stack and synchronous socket interface (Figure 6). On a batch of one, DPDK achieves 6.7 Mpps and is 7% faster than RedLeaf (6.5 Mpps) for both RX and TX paths (Figure 6). On a batch of 32 packets, both drivers achieve the line-rate performance of a 10GbE interface (14.2 Mpps). To understand the impact of cross-domain invocations, we run the benchmark application as a separate domain (`redleaf-domain`) and as an Rv6 program (`rv6-domain`). The overhead of domain crossings is apparent on a batch size of one, where RedLeaf can send and receive packets at the rate of 4 Mpps per-core with one domain crossing (`redleaf-domain`) and 2.9 Mpps if the invocation involves shadow domain (`redleaf-shadow`). With two domain crossings, the performance drops to 2.8 Mpps (`rv6-domain`) and 2.4 Mpps if the driver is accessed via a shadow (`rv6-shadow`). On a batch of 32 packets, the overhead of domain crossings disappears as all configurations saturate the device.

Nullnet To further investigate the overheads of isolation without the limits introduced by the device itself, we develop a software-only nullnet driver that simply returns the packet to the caller instead of queuing it to the device (Figure 7). On a batch of one, the overheads of multiple domain crossings limit the theoretical performance of nullnet driver from 29.5 Mpps per-core that can be achieved if the application is linked statically with the driver (`redleaf-driver`) to 5.3 Mpps when nullnet is accessed from the Rv6 application (`rv6-domain`). Adding a shadow driver lowers this number to 3.6 Mpps (`rv6-shadow`). Similarly, on a batch of 32 packets, nullnet achieves 94 Mpps if the application is run in the same domain as the driver. The performance drops to 67 Mpps when the benchmark code runs as an Rv6 application (`rv6-domain`), and to 55 Mpps if the Rv6 application involves a shadow driver (`rv6-shadow`).

Figure 8: Performance of the NVMe driver

5.2.2 NVMe Driver

To understand the performance of RedLeaf's NVMe driver, we compare it with the multi-queue block driver in the Linux kernel and a well-optimized NVMe driver from the SPDK storage framework [42]. Both SPDK and RedLeaf drivers work in polling mode. Similar to Ixgbe, we evaluate several configurations: 1) statically linked (`redleaf-driver`); 2) requiring one domain crossing (`redleaf-domain`); and 3) running as an Rv6 user program (`rv6-domain`). We run the last two configurations with and without the shadow driver (`redleaf-shadow` and `rv6-shadow`). All tests are limited to a single CPU core.

We perform sequential read and write tests with a block size of 4KB on a batch size of 1 and 32 requests (Figure 8). On Linux, we use `fio`, a fast I/O generator; on SPDK and RedLeaf, we develop similar benchmark applications that submit a set of requests at once, and then poll for completed requests. To set an optimal baseline for our evaluation, we chose the configuration parameters that can give us the fastest path to the device. Specifically, on Linux, we configure `fio` to use the asynchronous `libaio` library to overlap I/O submissions, and bypass the page cache with the `direct` I/O flag.

On sequential read tests, `fio` on Linux achieves 13K IOPS and 141K IOPS per-core on the batch size of 1 and 32 respectively (Figure 8). On a batch size of one, the RedLeaf driver is 1% faster (457K IOPS per-core) than SPDK (452K IOPS per-core). Both drivers achieve maximum device read performance. SPDK is slower as it performs additional processing aimed at collecting performance statistics on each request. On a batch size of 32, the RedLeaf driver is less than 1% slower (453K IOPS versus 454K IOPS SPDK). On sequential write tests with a batch size of 32, Linux is within 3% of the device's maximum throughput of around 256K IOPS. RedLeaf is less than one percent slower (255K IOPS). Since NVMe is a slower device compared to Ixgbe, the overheads of domain crossings are minimal for both batch sizes. With one domain crossing, the performance even goes up by 0.7% (we attribute this to a varying pattern of accessing the doorbell register of the device that gets thrashed between the device and CPU).

5.3 Application Benchmarks

To understand the performance overheads of safety and isolation on application workloads, we develop several applications that traditionally depend on a fast data plane of the op-

Figure 9: Performance of Maglev and Httpd

Figure 10: Key-value store

erating system kernel: 1) Maglev load balancer (maglev) [26], 2) a network-attached key-value store (kv-store), and 3) a minimal web server (httpd).

Maglev load-balancer Maglev is a load balancer developed by Google to evenly distribute incoming client flows among a set of backend servers [26]. For each new flow, Maglev selects one of the available backends by performing a lookup in a hash table, size of which is proportional to the number of backend servers (65,537 in our experiments). Consistent hashing allows even distribution of flows across all servers. Maglev then records the chosen backend in a hash table, a *flow tracking table*, that is used to redirect packets from the same flow to the same backend server. The size of the flow tracking table is proportional to the number of flows (we choose 1 M flows for our experiments). Processing a packet requires a lookup in the flow tracking table if it is an existing flow, or a lookup of a backend server and an insertion into the flow tracking table to record the new flow. To compare RedLeaf performance with both a commodity and the fastest possible setup, we develop C and Rust versions of the core Maglev logic. Moreover, we evaluate two C versions: one to run as a normal Linux program that uses the socket interface and another developed to work as a network function for the DDPK network processing framework [21]. In all versions we follow the same code logic and, if possible, apply the same optimizations. Again, on all setups, we restrict execution to one CPU core. Running as a Linux program, maglev is limited to 1 Mpps per-core due to the synchronous socket interface of the Linux kernel and a generic network stack (Figure 9). Operating on a batch of 32 packets, the maglev DDPK function is capable of achieving 9.7 Mpps per-core due to a well-optimized network device driver. Linked statically against the driver, RedLeaf

application (redleaf-driver) achieves 7.2 Mpps per-core. Performance drops with additional domain crossings. Running as an Rv6 application, maglev can forward at 5.3 Mpps per-core without and 5.1 Mpps with the shadow domain.

Key-value store Key-value stores are de facto standard building blocks for a range of datacenter systems ranging from social networks [64] to key-value databases [23]. To evaluate RedLeaf’s ability to support the development of efficient datacenter applications, we develop a prototype of a network-attached key-value store, kv-store. Our prototype is designed to utilize a range of modern optimizations similar to Mica [52], e.g., a user-level device driver like DDPK, partitioned design aimed at avoiding cross-core cache-coherence traffic, packet flow steering to guarantee that request is directed to the specific CPU core where the key is stored, no locks and no allocations on the request processing path, etc. Our implementation relies on a hash table that uses open addressing scheme with linear probing and the FNV hash function. In our experiments, we compare the performance of two implementations: a C version developed for DDPK, and a Rust version that executes in the same domain with the driver (redleaf-driver), i.e., the configuration that is closest to DDPK. We evaluate two hash table sizes: 1 M and 16 M entries with three sets of key and value pairs (<8B, 8B>, <16B, 64B>, <64B, 64B>). The RedLeaf version is implemented in a C-style Rust code, i.e., we avoid Rust abstractions that have run-time overhead (e.g., `Option<T>`, and `RefCell<T>` types). This ensures that we can control the memory layout of the key-value pair to avoid additional cache misses. Despite our optimizations, RedLeaf achieves only 61-86% performance of the C DDPK version. The main reason for the performance degradation is that being implemented in safe Rust, our code uses vectors, `Vec<T>`, to represent packet data. To create a response, we need to extend this vector thrice by calling the `extend_from_slice()` function to copy the response header, key, and value into the response packet. This function checks if the vector needs to be grown and performs a copy. In contrast, the C implementation benefits from a much lighter unsafe invocation of `memcpy()`. As an exercise, we implemented the packet serialization logic with unsafe Rust typecast that allowed us to achieve 85-94% of the C’s performance. However, we do not allow unsafe Rust inside RedLeaf domains.

Web server The latency of web page loading plays a critical role in both the user experience, and the rank of the page assigned by a search engine [15, 66]. We develop a prototype of a web server, httpd, that can serve static HTTP content. Our prototype uses a simple run-to-completion execution model that polls incoming requests from all open connections in a round-robin fashion. For each request, it performs request parsing and replies with the requested static web page. We compare our implementation with one of the de facto industry standard web servers, Nginx [63]. In our tests, we use the wrk HTTP load generator [1], which we configure to run with one thread and 20 open connections. On Linux, Nginx can serve

Figure 11: Block device recovery (FS write).

70.9 K requests per second, whereas our implementation of `httpd` achieves 212 K requests per second in a configuration where the application is run in the same domain as the driver (`redleaf-driver`) and network stack (Figure 9). Specifically, we benefit from low-latency access to the network stack and the network device driver. Running as an Rv6 domain, `httpd` achieves the rate of 181.4 K packets per second (178.9 K if it uses a shadow).

5.4 Device Driver Recovery

To evaluate the overheads introduced by the transparent device driver recovery, we develop a test in which an Rv6 program accesses the Rv6 file system backed by an in-memory block device. Running as an Rv6 program, the benchmark application continuously reads and writes files in the Rv6 file system using 4K blocks. The Rv6 file system accesses the block device via a shadow driver that can perform recovery of the block device in case of a crash. During the test, we trigger a crash of the block device driver every second (Figure 11). Automatic recovery triggers a small drop in performance. For reads, the throughput with and without restarts averages at 2062 MB/s and 2164 MB/s respectively (a 5% drop in performance). For writes, the total throughput averages at 356 MB/s with restarts and 423 MB/s without restarts (a 16% drop in performance).

6 Related Work

Several recent projects use Rust for building low-level high-performance systems, including data storage [33, 47, 60], network function virtualization [68], web engine [74], and several operating systems [17, 24, 50, 51], unikernels [49] and hypervisors [4, 36, 40]. Firecracker [4], Intel Cloud Hypervisor [40], and Google Chrome OS Virtual Machine Monitor [36] replace Qemu hardware emulator with a Rust-based implementation. Redox [24] utilizes Rust for development of a microkernel-based operating system (both microkernel and user-level device drivers are implemented in Rust, but are free to use unsafe Rust). The device drivers run in ring 3 and use traditional hardware mechanisms for isolation and system calls for communication with the microkernel. By and large, all these systems leverage Rust as a safe alternative to C, but do not explore the capabilities of Rust that go beyond type and memory safety.

Tock develops many principles of minimizing the use of unsafe Rust in a hardware-facing kernel code [50]. Tock is structured as a minimal core kernel and a collection of device drivers (capsules). Tock relies on Rust’s language safety for isolation of the capsules (in Tock user applications are isolated with commodity hardware mechanisms). To ensure isolation, Tock forbids unsafe extensions in capsules but does not restrict sharing of pointers between capsules and the main kernel (this is similar to language systems using pointers as capabilities, e.g., SPIN [13]). As a result, a fault in any of the capsules halts the entire system. Our work builds on many design principles aimed at minimizing the amount of unsafe Rust code developed by Tock but extends them with support for fault isolation and dynamic loading of extensions. Similar to Tock, Netbricks [68] and Splinter [47] rely on Rust for isolation of network functions and user-defined database extensions. None of the systems provides support for deallocating resources of crashing subsystems, recovery, or generic exchange of interfaces and object references.

7 Conclusions

“A Journey, not a Destination” [39], Singularity OS laid the foundation for many concepts that influenced the design of Rust. In turn, by enabling the principles of fault isolation in Rust itself, our work completes the cycle of this journey. RedLeaf, however, is just a step forward, not a final design—while guided by principles of practicality and performance, our work is, first, a collection of mechanisms and an experimentation platform for enabling future system architectures that leverage language safety. Rust provides systems developers the mechanisms we were waiting for decades: practical, zero-cost safety, and a type system that enforces ownership. Arguably, the isolation that we implement is the most critical mechanism as it provides a foundation for enforcing a range of abstractions in systems with faulty and mistrusting components. By articulating principles of isolation, our work unlocks future exploration of abstractions enabled by the isolation and safety: secure dynamic extensions, fine-grained access control, least privilege, collocation of computation and data, transparent recovery, and many more.

Acknowledgments

We would like to thank USENIX ATC 2020 and OSDI 2020 reviewers and our shepherd, Michael Swift, for numerous insights helping us to improve this work. Also, we would like to thank the Utah CloudLab team, and especially Mike Hibler, for his continuous support in accommodating our hardware requests. We thank Abhiram Balasubramanian for helping with RedLeaf device drivers and Nivedha Krishnakumar for assisting us with low-level performance analysis. This research is supported in part by the National Science Foundation under Grant Numbers 1837051 and 1840197, Intel and VMWare.

Specification and verification in the field: Applying formal methods to BPF just-in-time compilers in the Linux kernel

Luke Nelson, Jacob Van Geffen, Emina Torlak, and Xi Wang
University of Washington

Abstract

This paper describes our experience applying formal methods to a critical component in the Linux kernel, the just-in-time compilers (“JITs”) for the Berkeley Packet Filter (BPF) virtual machine. We verify these JITs using Jitterbug, the first framework to provide a precise specification of JIT correctness that is capable of ruling out real-world bugs, and an automated proof strategy that scales to practical implementations. Using Jitterbug, we have designed, implemented, and verified a new BPF JIT for 32-bit RISC-V, found and fixed 16 previously unknown bugs in five other deployed JITs, and developed new JIT optimizations; all of these changes have been upstreamed to the Linux kernel. The results show that it is possible to build a verified component within a large, unverified system with careful design of specification and proof strategy.

1 Introduction

Downloading application code into the OS kernel is a general approach to extensibility [26]. To extend the kernel, the application submits a program written in a dedicated language, and the kernel executes this program using an interpreter, or translates it into machine code for native execution via a *just-in-time (JIT) compiler* [3]. Berkeley Packet Filter (BPF) [31] is one such language, and it is used to implement a wide variety of extensions for the Linux kernel, including networking [38], security [79], and tracing [35], among many other services [18, 57].

Given the prevalence of BPF code and its execution in the OS kernel, the correctness of BPF JIT compilers (or simply “JITs”) is critical for the system. Compared to the BPF interpreter, using the JITs is both more efficient and more resistant to speculative attacks [84], leading major Linux distributions to remove the BPF interpreter from the kernel in favor of the JITs [9]. But the JITs are more susceptible to subtle correctness bugs due to their complexity (§3).

This paper presents a formal approach to building JITs in the kernel with high assurance of correctness. We develop Jitterbug, a framework for writing JITs and proving them

correct. Using Jitterbug, we design, implement, and verify a BPF JIT for RV32, the 32-bit RISC-V architecture [96]. We also port the existing JITs for Arm32, Arm64, RV64, x86-32, and x86-64 to Jitterbug, uncovering 16 previously unknown bugs. We write patches that fix these bugs and introduce new optimizations, all of which are verified to be correct. The BPF JIT for RV32, bug fixes, and optimizations have been upstreamed to the Linux kernel.

Jitterbug is designed to meet three competing requirements: *deployability* of verified JITs with minimal changes to the Linux kernel; *proof automation* to support rapid verification of JITs; and *separability* of verified JITs from any verification artifacts, making the resulting code auditable by kernel developers with no background in formal methods. Each of these requirements comes with its own challenges and trade-offs.

First, BPF JITs and their generated code interact with a monolithic kernel via an existing interface, which was not designed for verification. As Jitterbug emphasizes deployability, it cannot adopt the clean-slate design favored by previous verification efforts [33, 65, 81, 94] or change this interface to simplify verification. Therefore, it needs a correctness specification that is both capable of ruling out real-world bugs and amenable to verification. Developing such a specification is challenging even for clean-slate designs with strong simplifying assumptions, and it is the core technical challenge addressed by Jitterbug.

Second, verification needs to catch up with increasing functionality and optimization of BPF JITs. Jitterbug thus prioritizes proof automation to free developers from the burden of writing manual proofs and to enable rapid verification in the code review process. Prior work has shown success in scaling automated verification to systems whose code does not change in response to input [68, 70]. But verifying a JIT is particularly challenging, because it requires reasoning about not only the behavior of the JIT itself, but also that of the machine code generated by the JIT for input BPF programs.

Third, kernel development emphasizes the efficiency and clarity of source code, whereas formal development emphasizes managing code complexity to make verification tractable.

Jitterbug must resolve the tension and make the two development processes cleanly separable. While formal development can use specific tools and artifacts such as specifications, the final implementation of a JIT needs to be C code that can be reviewed assuming no knowledge of formal methods, and can be compiled using a standard toolchain.

To address these challenges, Jitterbug makes the following contributions:

- A precise stepwise specification for JIT correctness (§4). The specification models both BPF and target architectures as abstract machines, and it formulates JIT correctness as the behavioral equivalence of running the machines with a source BPF instruction and the target instructions produced by the JIT, respectively. The specification assumes that a JIT translates a single source instruction at a time. This assumption matches real-world BPF JIT implementations and obviates the need to reason about translating entire programs.

- An automated proof strategy that scales to practical BPF JITs (§5). Building on Serval [68], Jitterbug uses symbolic evaluation [10, 89] to produce a satisfiability query that encodes the semantics of a JIT implementation, the semantics of source BPF code, and the semantics of target machine code produced by the JIT. It then discharges the query using an SMT solver [21]. Since Serval was designed to reason about systems whose code is statically known, it cannot be used to verify *symbolic* instructions (e.g., with symbolic fields, at symbolic addresses) generated by the symbolic evaluation of a JIT. Jitterbug addresses this challenge with a symbolic evaluation strategy that can reason about such symbolic code.

- An approach to writing JITs in a domain-specific language (DSL) based on C (§6). The Jitterbug DSL is a *shallow embedding* of a structured subset of C in Rosette [88, 89], which extends Racket [29] for symbolic reasoning. That is, the Jitterbug DSL implements a subset of C as a Rosette library. We write new JITs in the DSL, which simplifies verification and enables synthesis of JIT optimizations [59, 82]. Jitterbug automates the step of translating JITs written in the DSL to C through an (unverified) extraction mechanism. We verify existing JITs by manually translating their C code to Rosette.

- Experience with using Jitterbug to build a BPF JIT for RV32, find and fix bugs in five existing BPF JITs, perform code review, develop optimizations, and port a JIT for a stack machine [65], all with low verification overhead (§7). One of the bugs has led to a clarification in the RISC-V instruction-set manual. We report on the iterative process of improving Jitterbug and upstreaming JIT code to the Linux kernel.

To our knowledge, Jitterbug is the first to provide a specification that rules out bugs in practical JIT implementations, and a proof strategy that scales automated verification to a class of compilers. It demonstrates the feasibility of building a verified component (i.e., the BPF JIT) within a large, unverified system under active development (i.e., the Linux kernel), through careful design of specification and proof strategy. This paper describes our design decisions and the rationale behind them (§8).

2 Related work

Code downloading for extensible systems. The Xerox Alto allows applications to customize and optimize the system through *microcode* [51, 85]. It pioneered the use of *packet filters* for demultiplexing, debugging, and monitoring.

The CMU/Stanford Packet Filter [62] introduced a *stack-based* virtual machine into the 4.3BSD kernel to interpret packet filters. To enable more efficient implementations, the Berkeley Packet Filter (BPF) [61] adopts a *register-based* virtual machine instead, which consists of two 32-bit registers and a scratch memory. BPF has gained a wide adoption in BSD and Linux kernels. Besides BPF, DTrace [12] and Lua on NetBSD [90] are two other in-kernel virtual machines.

A redesign of BPF in the Linux kernel started in 2014, first as an optimization of the internal representation of BPF instructions for 64-bit architectures [83]. It has since grown into a full RISC-like virtual machine, with 64-bit general-purpose registers, flexible control flow (e.g., bounded loops and BPF-to-BPF calls), and safe access to kernel memory. The generality and expressiveness have led to an explosion of tools and systems based on BPF, ranging from networking [38], security [79], tracing [35], to storage [7], virtualization [1, 71], and hardware offloading [43]. The new design is also called “extended BPF” or simply “BPF” in the Linux kernel, while the original design is referred to as *classic* BPF to avoid ambiguity. Unless otherwise noted, we follow this terminology and use BPF to refer to the new design. This paper focuses on building verified JITs for BPF.

More generally, the exokernels [26] demonstrate a diverse set of mechanisms for code downloading, such as accelerating packet filtering using JIT compilation [25], sandboxing machine code [92] using software-based fault isolation [77, 91], and analyzing file-system metadata using an in-kernel virtual machine [40]. Other extensibility mechanisms include using safe languages [6, 28, 55] and proof-carrying code [67].

Correctness of JIT compilation. Just-in-time compilation (JIT) is a well-studied dynamic code generation technique dating back to Lisp [3, 42] and regular expressions in the QED text editor [76, 87]. It has also been used for dynamically typed languages [14], emulators [5], and specialization [60, 73].

This paper considers JITs that are realized as *static* compilers, using static register allocation and performing no garbage collection for memory management. In contrast to sophisticated dynamic code generation systems such as those for Java or JavaScript, this simplicity makes static JITs applicable to a restricted environment such as the kernel [24].

There is a rich literature on compiler correctness. Readers may refer to Young [98] and Leroy [54] for overviews. Compilers, especially optimizing compilers, can have multiple intermediate representations and translation passes, whereas the JITs considered in this paper are much simpler and resemble a one-pass compiler. On the other hand, compilers usually

output assembly code, relying on a separate assembler and linker (e.g., GNU `as` and `ld`) to produce final machine code. The JITs run in the kernel and directly produce machine code, effectively combining a compiler, assembler, and linker.

The closest efforts in this area are the verified JITs by Myreen [65] and Jitk [94]. The former translates code in a simple stack-based instruction set to x86-32 (see §7), and is verified using the HOL4 theorem prover [80]. The JIT is implemented in HOL4 and translated to x86-32 machine code by a separate compiler [66]. Jitk builds on the CompCert verified compiler [53] to translate classic BPF to assembly, and is verified using the Coq theorem prover [86]. The JIT is implemented in Coq and extracted to OCaml code; it runs in user space rather than in the kernel due to the dependency on the OCaml runtime, an assembler, and a linker. Both efforts employ clean-slate designs, require manual proofs, and do not have a C implementation. Jitterbug is inspired by these efforts and shares the goal of building verified JITs, but prioritizes applicability to existing systems, proof automation, and implementation that can be reviewed independent of verification.

Compiler testing and fuzzing tools employ effective strategies to randomly generate input programs and check for miscompilation [58]. Csmith [97] and EMI fuzzers [52] have been used to find hundreds of bugs in GCC and LLVM. Kernel fuzzers such as syzkaller and trinity support generation of random BPF programs [23]. Serval [68] implements a bug finder for the compilation of BPF arithmetic and bitwise instructions. These tools generally do not exhaust all execution paths, thus providing no correctness guarantees for JITs.

Designing verified systems for deployment. Deployability is a desirable goal for formally verified systems, but it requires navigating an extra set of design trade-offs. As the first verified general-purpose microkernel, seL4 [46] pioneered many aspects of the design and deployment processes. For instance, it introduced a Haskell prototype as the bridge between formal methods and kernel developers, separating verification artifacts from the C implementation [45]. It has been deployed as a hypervisor to retrofit unverified, legacy software to power safety-critical systems [37, 47]. Another example is CompCert, the first verified C compiler. It has been integrated into the development process of control software for safety-critical systems [41, 53], replacing unverified compilers that were configured to disable optimizations due to risk concerns.

Cryptographic libraries are an attractive target for verification due to their essential role in security. For example, verified code from EverCrypt/HACL* [75, 99] and Fiat-Crypto [27] is used by Mozilla and Google, respectively. Amazon’s s2n TLS implementation [16] is verified via a combination of manual and automated proofs.

Jitterbug presents a case study in applying formal methods to the BPF JITs in the Linux kernel. It shares these design challenges and addresses them with a precise specification and a proof strategy that scales to practical JIT implementations.

Figure 1: Transitions during the execution of a BPF program.

3 Case study

This section presents a brief overview of BPF and a case study of the BPF JIT bugs in the Linux kernel, which helped motivate the design of Jitterbug.

3.1 An overview of BPF

The BPF virtual machine consists of 12 explicit 64-bit registers: general-purpose registers R0–R9, a frame pointer R10 that points to a stack memory region, and an internal register AX used by the kernel for rewrites (e.g., constant blinding against JIT spraying attacks [8]). It maintains a program counter PC and a tail-call counter TCC; the latter bounds the number of tail calls (to another BPF program without returning).

Currently, there are a total of 115 instruction opcodes, which can be categorized into the following:

- ALU (arithmetic and bitwise) instructions,
- JMP (unconditional and conditional jump) instructions,
- MEM (1-, 2-, 4-, and 8-byte memory access, and 4- and 8-byte atomic exchange-and-add) instructions,
- CALL to a kernel function or another BPF program; and
- TAIL_CALL and EXIT, which transfer control to another BPF program and the kernel, respectively.

Figure 1 depicts the execution of a BPF program. The input to a BPF program is provided by the kernel. Prologue and epilogue refer to initialization and cleanup code, respectively, for bridging the kernel. The BPF calling convention specifies that R0 holds the return value, R1–R5 pass arguments, and R6–R9 are preserved across the call.

User processes may share data with BPF programs by creating BPF *maps* in the kernel, which are key/value stores of different data types. Maps may be accessed concurrently by BPF programs and user processes. Though there have been discussions, BPF has so far chosen not to specify a memory consistency model to avoid performance penalties [19].

Each BPF program consists of a sequence of instructions in *bytecode* (GCC/LLVM can compile C code to BPF). Upon receiving a BPF program from user space, the kernel invokes a checker to analyze whether the program is safe (e.g., free of division by zero, unbounded loops, and uninitialized register accesses) [34]; we refer to it as the BPF *checker* (rather than “BPF verifier” as by the Linux kernel to avoid ambiguity). If the BPF checker deems the program safe, the kernel invokes the JIT for compilation and attaches the resulting machine

```

/* rd[0]: upper 32 bits of the destination register
   rd[1]: lower 32 bits of the destination register
   tmp2[1]: a temporary register */
if (val < 32) {
    /* tmp2[1] = rd[1] >> val */
    emit(ARM_MOV_SI(tmp2[1], rd[1], SRTYPE_LSR, val), ctx);
    /* rd[1] = tmp2[1] | (rd[0] << (32 - val)) */
    emit(ARM_ORR_SI(rd[1], tmp2[1], rd[0], SRTYPE_ASL,
                    32 - val), ctx);
    /* rd[0] = rd[0] >> val */
    emit(ARM_MOV_SI(rd[0], rd[0], SRTYPE_LSR, val), ctx);
} else if (val == 32) {
    /* rd[1] = rd[0] */
    emit(ARM_MOV_R(rd[1], rd[0]), ctx);
    /* rd[0] = 0 */
    emit(ARM_MOV_I(rd[0], 0), ctx);
} else {
    /* rd[1] = rd[0] >> (val - 32) */
    emit(ARM_MOV_SI(rd[1], rd[0], SRTYPE_LSR,
                    val - 32), ctx);
    /* rd[0] = 0 */
    emit(ARM_MOV_I(rd[0], 0), ctx);
}

```

Figure 2: Incorrect result with zero val for RSH64_IMM (Arm32).

instructions to various hook points in the kernel for execution; otherwise, the kernel rejects the program. The JIT therefore considers safe programs only.

3.2 Bugs in BPF JITs

We manually inspected every commit to the BPF JITs in the Linux kernel from May 2014 (when the new BPF design was introduced) to April 2020, and categorized those that fixed JIT correctness bugs for Arm32, Arm64, RV64, x86-32, and x86-64; those for RV32 will be discussed in §7. We consider “correctness bugs” as JITs producing erroneous machine instructions, and exclude non-correctness bugs (e.g., memory leaks during JIT compilation) from the study. In total, there are 41 commits that fixed 82 JIT correctness bugs during this period. See §A.2 for a complete list.

Below we describe some representative bugs we have found using Jitterbug. These bugs are difficult to find even for veteran developers, and were not caught by the existing test suite. They can lead to security vulnerabilities, since the resulting machine instructions run in the kernel and may process input from untrusted sources. For clarity, BPF instructions and registers are in uppercase, while target machine ones are in lowercase.

Subtle architectural semantics. Figure 2 shows an excerpt of the Arm32 JIT for RSH64_IMM, the BPF logical right shift instruction of a 64-bit register by an immediate. Since the target architecture is 32-bit, the JIT uses two machine registers, represented by rd[0] and rd[1], to hold the upper and lower 32 bits of a 64-bit BPF register, respectively. The BPF checker ensures that the shift amount val is within the range [0, 63]. The emitted instructions work as follows:

- when the shift amount val is less than 32, the result of the upper half is simply $rd[0] \gg val$, and the result of the lower half is $rd[1] \gg val$ combined with the bits shifted from the upper half, $rd[0] \ll (32 - val)$;

```

/* check if rvoff is in the range  $[-2^{31}, 2^{31} - 1]$  */
if (!is_32b_int(rvoff))
    return -ERANGE;
...
s64 upper = (rvoff + (1 << 11)) >> 12;
s64 lower = rvoff & 0xfff;
/* auipc t1, upper */
emit(rv_aupic(RV_REG_T1, upper), ctx);
/* jalr ra, lower(t1) */
emit(rv_jalr(RV_REG_RA, RV_REG_T1, lower), ctx);

```

Figure 3: Incorrect range check on rvoff for CALL (RV64).

- the result of the upper half is simply zero, as all the bits are shifted out, and the result of the lower half holds the bits shifted from the upper half.

One subtlety in Arm32 is that a zero immediate in the lsr (logical shift right) instruction means right-shift by 32 bits (i.e., shifting all bits out) [2: §F5.1.103]. Therefore, when the shift amount val is zero, the instructions produced by the JIT incorrectly set the destination register to zero, instead of behaving as a no-op. This is further complicated by inconsistent semantics in Arm32: a zero immediate in the shift left instruction means a no-op. We fixed the bug by changing the JIT to emit no instructions when val is zero.

Figure 3 shows another subtle bug in the RV64 JIT. Using a pair of auipc+jalr instructions is a standard way to support pc-relative call with a 32-bit offset on RISC-V [96]:

- auipc t1, imm20 appends 12 low-order zero bits to a 20-bit immediate, sign-extends the 32-bit value to 64 bits, adds the sign-extended value to the address of the instruction, and writes the result in register t1;
- jalr ra, imm12(t1) jumps to a target address obtained by adding a sign-extended 12-bit immediate to the register t1 and clearing the least-significant bit of the result for alignment; the address of the instruction following jalr is written to register ra.

One misconception is that auipc+jalr can reach any 32-bit offset in the range $[-2^{31}, 2^{31} - 1]$ on 64-bit RISC-V (RV64), by using certain imm20 and imm12 values. Part of the confusion stems from the “RV32I base integer instruction set” chapter in the RISC-V instruction-set manual indicating that auipc+jalr “can jump anywhere in a 32-bit pc-relative address range.” But the same does not hold on RV64: both auipc and jalr sign-extend their results to 64 bits, causing the reachable offset range to shift by -2^{11} . Therefore, the range check on rvoff in the JIT is incorrect, which can lead to an off-target jump.

Our report prompted the RISC-V instruction-set manual to add the following clarification: “Note that the set of address offsets that can be formed by pairing LUI with LD, AUIPC with JALR, etc. in RV64I is $[-2^{31} - 2^{11}, 2^{31} - 2^{11} - 1]$.” We fixed the bug in the JIT by using the clarified range for checking rvoff.

Subtle machine state. Figure 4 shows an excerpt of the x86-32 JIT for compiling BPF’s JSET64_REG and JSET32_REG (in the form BPF_JMP[32]|BPF_JSET|BPF_X in C). The semantics of “JSET64_REG DST, SRC, OFF” is to perform a conditional

```

case BPF_JMP | BPF_JSET | BPF_X:
case BPF_JMP32 | BPF_JSET | BPF_X:
    bool is_jmp64 = BPF_CLASS(insn->code) == BPF_JMP;
    u8 dreg_lo = dstk ? IA32_EAX : dst_lo;
    u8 dreg_hi = dstk ? IA32_EDX : dst_hi;
    u8 sreg_lo = sstk ? IA32_ECX : src_lo;
    u8 sreg_hi = sstk ? IA32_EBX : src_hi;

    if (dstk) {
        EMIT3(0x8B, add_2reg(0x40, IA32_EBP, IA32_EAX),
              STACK_VAR(dst_lo)); /* eax <- dst_lo */
        if (is_jmp64)
            EMIT3(0x8B, add_2reg(0x40, IA32_EBP, IA32_EDX),
                  STACK_VAR(dst_hi)); /* edx <- dst_hi */
    }

    if (ssk) {
        EMIT3(0x8B, add_2reg(0x40, IA32_EBP, IA32_ECX),
              STACK_VAR(src_lo)); /* ecx <- src_lo */
        if (is_jmp64)
            EMIT3(0x8B, add_2reg(0x40, IA32_EBP, IA32_EBX),
                  STACK_VAR(src_hi)); /* ebx <- src_hi */
    }

    /* and dreg_lo,sreg_lo */
    EMIT2(0x23, add_2reg(0xC0, sreg_lo, dreg_lo));
    /* and dreg_hi,sreg_hi */
    EMIT2(0x23, add_2reg(0xC0, sreg_hi, dreg_hi));
    /* or dreg_lo,dreg_hi */
    EMIT2(0x09, add_2reg(0xC0, dreg_lo, dreg_hi));
    goto emit_cond_jump; /* emit conditional jump */

```

Figure 4: Incorrect eflags value for JSET32_REG (x86-32).

jump when DST&SRC (“bitwise and” of two 64-bit BPF registers) is non-zero and fall through otherwise; the semantics of “JSET32_REG DST, SRC, OFF” is similar, using only the lower 32 bits of both DST and SRC.

Due to the limited number of registers on x86-32, the JIT spills some BPF registers on the stack. For simplicity, suppose that both DST and SRC are on the stack (i.e., both `dstk` and `ssk` are true). In this case, the JIT emits instructions to load the lower 32 bits of DST and SRC to `eax` and `ecx`, respectively. It also emits instructions to load the upper 32 bits to `edx` and `ebx` for JSET64_REG; the two registers are uninitialized for JSET32_REG.

One way to implement JSET32_REG is to emit a bitwise and of `eax` and `ecx`, followed by a conditional jump if the result is non-zero (i.e., the `zf` bit in the `eflags` register is clear). But the JIT emits extra `and` and `or` instructions that also use `edx` and `ebx`, which are uninitialized for JSET32_REG, incorrectly modifying `eflags`. The bug was not caught by the BPF selftests suite because none of the tests “polluted” `edx` and `ebx` with values that would cause the behavior to change. We fixed the bug by moving the last two EMIT2 statements under a condition that `is_jmp64` is true.

There are other bugs in the excerpt: when DST is mapped to x86 registers and not spilled on the stack (i.e., `dstk` is false), the emitted instructions incorrectly clobber the registers, while the semantics of the BPF instructions requires DST not to change. We fixed the bugs by loading DST to `eax` and `ecx`, regardless of whether DST is on the stack.

Subtle instruction encoding. Below is an encoding bug in the x86-32 JIT for the BPF LDXB instruction, which loads a byte from memory. As its semantics requires the result to be zero-

extended to 64 bits, the JIT attempts to emit “`mov dst_hi, 0`” to clear the upper 32 bits, using the following C code:

```
EMIT3(0xC7, add_1reg(0xC0, dst_hi), 0);
```

Notice that EMIT3 emits 3 bytes, but a correct “`mov dst_hi, 0`” expects 6 bytes: the opcode `0xC7`, the ModR/M byte formed by `add_1reg(0xC0, dst_hi)`, followed by 4 bytes of zeros as the immediate. The consequence is not merely an incorrect `mov`: it also “swallows” 3 bytes from the next instruction, breaking the instruction stream and altering the meaning of the subsequent instructions. We fixed the bug by emitting “`xor dst_hi, dst_hi`” instead, which is also shorter (2 bytes).

3.3 Summary

Compared to the bugs in *classic* BPF JITs [15, 94], those in today’s BPF JITs are more sophisticated due to the increased power of the BPF virtual machine. On the other hand, architecture-independent checks for BPF programs such as division by zero are now performed by the BPF checker, eliminating the need for the JITs to consider such cases.

While the Arm and RISC-V JITs emit instructions using well-defined macros (e.g., Figure 2) or functions (e.g., Figure 3), the x86 JITs directly emits raw bytes (e.g., Figure 4), partly due to the lack of a uniform instruction format on x86. Jitterbug therefore needs to model the semantics of their target architectures precisely; for x86, this means reasoning at the level of raw instruction bytes.

4 Specification

Jitterbug aims to rule out subtle bugs in BPF JITs through a formal specification, which is the focus of this section.

We begin with an intuitive description of what it means for a JIT to be correct. At a high level, running the machine code emitted by a JIT for a given source program should be equivalent to running a BPF interpreter with that source program. For example, both should compute the same return value and invoke the same kernel functions with the same arguments; any deviation indicates a bug. Jitterbug captures this intuition as a JIT correctness specification (§4.1).

Specifications like this are usually proved by induction, and the key to carrying out the proof is finding the right inductive invariant—a property preserved by the JIT translation of each individual source instruction. Inspired by the structure of the existing BPF JITs in the Linux kernel, Jitterbug introduces a *stepwise* specification that serves as our inductive invariant. As shown in Figure 5, this specification consists of a set of properties satisfied by individual translation steps, such as the generation of machine code for a single BPF instruction. Using the Lean theorem prover [22], we prove that any JIT that satisfies the stepwise specification implies our intuitive notion of correctness. This proof serves as the metatheory for

Figure 5: Jitterbug’s stepwise specification (rounded-corner boxes) implies JIT correctness, shown by [Theorem 1](#).

Jitterbug (§4.2). The stepwise specification itself is proved automatically for each JIT.

To illustrate how to apply the stepwise specification to prevent bugs, we use the BPF JIT for RV32 as an example. We also analyze alternative JIT implementations to demonstrate the generality of the specification (§4.3).

We end this section with a discussion of the limitations of Jitterbug’s specification and how it relates to prior compiler correctness specifications (§4.4).

4.1 JIT correctness

Formalizing JIT correctness requires formalizing the behavior of the JIT, source BPF programs, and target machine programs, as follows.

First, we model a JIT as a function `JITCompile`. It takes a source program $code_S$ and JIT context ctx as input, and returns either a target program $code_T$ on success, denoted as $JITCompile(code_S, ctx) = code_T$; or \perp , indicating compilation error. Both source and target programs are represented as partial maps from addresses to instructions; some addresses may be unmapped. We define $code \subseteq code'$ to mean that any address that maps to some instruction in $code$ maps to the same instruction in $code'$.

The JIT context ctx is an implementation-defined data structure. It usually contains compiler configurations (e.g., the base address of the target program allocated by the kernel, denoted by $ctx[base]$) and analysis results of the source program, which are used by the JIT for code generation. We assume that the JIT context is *well-formed* with respect to the source program; this assumption is captured using a predicate $wf(code_S, ctx)$ specified by JIT developers. For example, one may specify that $ctx[base]$ is properly aligned.

Next, we model the execution of both source and target programs as abstract machines, described by a set of states Σ and a state transition function $step$. Given a state $\sigma \in \Sigma$, we write $\sigma[\cdot]$ to refer to a specific component of the state. For example, $\sigma[pc]$ is the value of the program counter.

The step function takes as input a state σ , a program $code$, and an oracle denoted by nd . The oracle nd is an infinite sequence of nondeterministically chosen bytes, which are used for modeling external interactions with the kernel (e.g., values loaded from BPF maps or returned by calls to kernel

functions). Given these inputs, the step function produces the next state and a trace of externally visible *events* generated by executing the instruction at the program counter, $code[\sigma[pc]]$. The execution gets *stuck* if it triggers undefined behavior (e.g., the address $\sigma[pc]$ is unmapped in $code$). As shorthands, we write $\langle \sigma, code, nd \rangle \Rightarrow \langle \sigma', tr \rangle$ to mean $step(\sigma, code, nd) = \langle \sigma', tr \rangle$, and $\langle \sigma, code, nd \rangle \Rightarrow^* \langle \sigma', tr \rangle$ to mean that state σ' is reachable from zero or more applications of step starting from state σ , with concatenated trace tr .

The exact content of events is defined by each machine. For example, consider the BPF machine in Jitterbug. It defines the following events: `load(addr, val)`, `store(addr, val)`, `call(addr, args, val)`, `atomic_begin`, and `atomic_end`. It models each memory load as returning a fresh value provided by the oracle and producing a load event in the trace, since BPF maps may be modified outside the execution of a BPF program (§3.1). Each step may produce zero or more events. For example, the execution of `XADD32` (32-bit atomic exchange-and-add) produces `atomic_begin`, `load`, `store`, and `atomic_end`.

This model assumes read-only code, which prohibits JITs that produce self-modifying code [65]. It also assumes that the execution of a program is deterministic [53: §2.1], since the next state is uniquely determined by the current state, code, and oracle. Both assumptions match the BPF JITs in Linux.

In order to reason about the start and end of execution, each machine defines two predicates:

- $initial(x, ctx, \sigma)$, where σ is an initial state for input x and JIT context ctx ; and
- $final(\sigma', v)$, where σ' is a final state with return value v .

Recall that the JIT considers only *safe* source programs. For example, the Linux kernel rejects BPF programs that the BPF checker deems unsafe (§3.1). We capture this guarantee with a predicate $safe(code)$, which specifies that executing $code$ always reaches a final state (i.e., the execution terminates without triggering any undefined behavior):

$$\forall x, \sigma, nd. initial(x, ctx, \sigma) \rightarrow \exists \sigma', tr, v. \langle \sigma, code, nd \rangle \Rightarrow^* \langle \sigma', tr \rangle \wedge final(\sigma', v).$$

In addition, since a target program generated by the JIT runs within the kernel, it must behave like a regular function and preserve the corresponding calling convention: for example, stack pointer and callee-saved registers must hold the same values before and after the execution. We capture these requirements in the *architectural safety* predicate $\mathcal{A}(\sigma_T, \sigma'_T)$, which constrains the initial and final values of all preserved target registers r to be the same, i.e., $\sigma_T[r] = \sigma'_T[r]$.

Using our model, we define JIT correctness as follows.

Definition 1 (JIT correctness). A JIT is correct if for any safe source program $code_S$, well-formed JIT context ctx , and target program $code_T$ generated by the JIT such that $safe(code_S) \wedge wf(code_S, ctx) \wedge JITCompile(code_S, ctx) = code_T$, the following two conditions hold:

1. The execution of source program $code_S$ and that of target program $code_T$ produce the same trace and return value.

$$\begin{aligned} & \forall x, \sigma_S, \sigma_T, nd, tr, v. \\ & \text{initial}_S(x, ctx, \sigma_S) \wedge \text{initial}_T(x, ctx, \sigma_T) \rightarrow \\ & \left((\exists \sigma'_S. \langle \sigma_S, code_S, nd \rangle \Rightarrow^* \langle \sigma'_S, tr \rangle \wedge \text{final}_S(\sigma'_S, v)) \leftrightarrow \right. \\ & \left. (\exists \sigma'_T. \langle \sigma_T, code_T, nd \rangle \Rightarrow^* \langle \sigma'_T, tr \rangle \wedge \text{final}_T(\sigma'_T, v)) \right). \end{aligned}$$

2. Any final state reachable by executing target program $code_T$ satisfies architectural safety.

$$\begin{aligned} & \forall x, \sigma_T, \sigma'_T, nd, tr, v. \text{initial}_T(x, ctx, \sigma_T) \wedge \text{final}_T(\sigma'_T, v) \wedge \\ & \langle \sigma_T, code_T, nd \rangle \Rightarrow^* \langle \sigma'_T, tr \rangle \rightarrow \mathcal{A}(\sigma_T, \sigma'_T). \end{aligned}$$

The first property can be viewed as a *bisimulation* between source and target machines [54: §2]: the JIT produces a target program that preserves the behavior of the source program, and any behavior of the target program is permitted by the source program. Additionally, given that the source program is safe, this property implies that the target program produced by the JIT is safe (i.e., terminates without undefined behavior). The second property further requires the target program to correctly save and restore the corresponding architectural state. Both guarantees are critical for in-kernel execution.

4.2 Stepwise specification

Given [Definition 1](#), our goal is to devise a stepwise specification (i.e., an inductive invariant) that both implies JIT correctness and is amenable to automated verification. We achieve this goal by imposing structure on the JIT compilation process so that we can reason about the correctness of individual compilation steps, as follows.

Inspired by the existing BPF JITs in the Linux kernel, we suppose that the JIT generates a target program in a *per-instruction* fashion. Specifically, the target program consists of machine instructions for the prologue, each source instruction, and the epilogue ([Figure 1](#)). We do not assume any particular code layout. For example, one may produce the target program sequentially:

```
code_T = EmitPrologue(ctx)
for i in [0, |code_S| - 1]:
    code_T += EmitInstruction(ctx, i, code_S[i])
code_T += EmitEpilogue(ctx)
```

We formalize our assumptions about the JIT below.

Definition 2 (JIT assumptions). We assume that for any safe source program $code_S$, well-formed JIT context ctx , and target program $code_T$ produced by a JIT such that $\text{safe}(code_S) \wedge \text{wf}(code_S, ctx) \wedge \text{JITCompile}(code_S, ctx) = code_T$, the target program $code_T$ contains the machine instructions produced by each translation step:

- $\exists p. \text{EmitPrologue}(ctx) = p \wedge p \subseteq code_T$.
- $\forall i, insn. code_S[i] = insn \rightarrow$
 $\exists p. \text{EmitInstruction}(ctx, i, insn) = p \wedge p \subseteq code_T$.
- $\exists p. \text{EmitEpilogue}(ctx) = p \wedge p \subseteq code_T$.

With these assumptions, the stepwise specification boils down to the correctness of each translation step: `EmitPrologue`, `EmitInstruction`, and `EmitEpilogue`. Jitterbug allows developers to provide two relations as invariants maintained by their JIT implementations:

- $\sigma_S \sim_{ctx} \sigma_T$ relates source state σ_S and target state σ_T with respect to JIT context ctx . For example, it may specify that the value of a BPF register in σ_S is equal to that of the machine register the JIT uses to realize the BPF register in σ_T .
- $\mathcal{I}_{ctx}(\sigma_{T_0}, \sigma_T)$ relates initial target state σ_{T_0} and non-final target state σ_T with respect to JIT context ctx . For example, the prologue usually saves callee-saved registers to a designated memory region; \mathcal{I}_{ctx} may specify that the values of callee-saved registers in σ_{T_0} are equal to those in that region in σ_T .

Below we describe the correctness definition for each translation step. We denote the empty trace as ϵ .

Definition 3 (Prologue correctness). A JIT emits a correct prologue if executing the prologue results in a target state that establishes the invariants, and produces an empty trace:

$$\begin{aligned} & \forall code_S, ctx, p, x, \sigma_S, \sigma_T, nd. \text{wf}(code_S, ctx) \wedge \\ & \text{EmitPrologue}(ctx) = p \wedge \\ & \text{initial}_S(x, ctx, \sigma_S) \wedge \text{initial}_T(x, ctx, \sigma_T) \rightarrow \\ & \exists \sigma'_T. \langle \sigma_T, p, nd \rangle \Rightarrow^* \langle \sigma'_T, \epsilon \rangle \wedge (\sigma_S \sim_{ctx} \sigma'_T) \wedge \mathcal{I}_{ctx}(\sigma_T, \sigma'_T). \end{aligned}$$

Definition 4 (Per-instruction correctness). A JIT emits correct target instructions for a given source instruction if executing the emitted instructions results in a target state that preserves the invariants, and produces the same trace as executing the source instruction:

$$\begin{aligned} & \forall code_S, ctx, i, insn, p, \sigma_S, \sigma_T, \sigma_{T_0}, nd, tr. \text{wf}(code_S, ctx) \wedge \\ & code_S[i] = insn \wedge \sigma_S[pc] = i \wedge \\ & \text{EmitInstruction}(ctx, i, insn) = p \wedge \\ & \langle \sigma_S, code_S, nd \rangle \Rightarrow^* \langle \sigma'_S, tr \rangle \wedge (\sigma_S \sim_{ctx} \sigma_T) \wedge \mathcal{I}_{ctx}(\sigma_{T_0}, \sigma_T) \rightarrow \\ & \exists \sigma'_T. \langle \sigma_T, p, nd \rangle \Rightarrow^* \langle \sigma'_T, tr \rangle \wedge (\sigma'_S \sim_{ctx} \sigma'_T) \wedge \mathcal{I}_{ctx}(\sigma_{T_0}, \sigma'_T). \end{aligned}$$

Definition 5 (Epilogue correctness). A JIT emits a correct epilogue if executing the epilogue results in a final target state that satisfies architectural safety, and produces the same return value as in the source final state and an empty trace:

$$\begin{aligned} & \forall code_S, ctx, p, \sigma_S, v, \sigma_T, \sigma_{T_0}, nd. \text{wf}(code_S, ctx) \wedge \\ & \text{EmitEpilogue}(ctx) = p \wedge \\ & \text{final}_S(\sigma_S, v) \wedge (\sigma_S \sim_{ctx} \sigma_T) \wedge \mathcal{I}_{ctx}(\sigma_{T_0}, \sigma_T) \rightarrow \\ & \exists \sigma'_T. \langle \sigma_T, p, nd \rangle \Rightarrow^* \langle \sigma'_T, \epsilon \rangle \wedge \text{final}_T(\sigma'_T, v) \wedge \mathcal{A}(\sigma_{T_0}, \sigma'_T). \end{aligned}$$

Together, these three properties imply JIT correctness given the JIT assumptions. We prove the following theorem in Lean:

Theorem 1 (Stepwise soundness). JIT assumptions \wedge prologue correctness \wedge per-instruction correctness \wedge epilogue correctness \rightarrow JIT correctness.

With [Theorem 1](#) as a metatheory, Jitterbug proves the correctness of a JIT implementation by proving the properties in

Figure 6: Mapping from BPF state (upper half) to RV32 state (lower half). Rounded-corner boxes denote registers and rectangular boxes denote memory. Shaded regions are memory accessible by BPF programs and crosshatched regions for internal use.

Definitions 3, 4, and 5 via automated verification (see §5). The JIT context well-formedness wf and assumptions are assumed to be correct and trusted. The invariants (\sim_{ctx} and \mathcal{I}_{ctx}) are untrusted: if incorrect invariants are provided, verification fails.

4.3 Applying the stepwise specification

The stepwise specification is parameterized by assumptions (well-formedness of JIT context wf) and invariants (\sim_{ctx} and \mathcal{I}_{ctx}), which reflect how JIT developers intend to establish correctness. We illustrate how to apply the stepwise specification to the BPF JIT for RV32 by specifying the assumptions and invariants regarding registers, program counters, and memory. We also describe how one may specify them for the alternative JIT implementations we have considered.

Figure 6 shows the design of the BPF JIT for RV32. The upper half denotes the BPF state, including registers (R0–R10, AX), counters (tail-call counter TCC and program counter PC), a stack memory region, and maps of shared data (§3.1). The lower half denotes the RV32 state, including registers (fp, sp, a0–a7, s1–s6, t6; those not mapped to BPF registers are omitted), a machine program counter pc, and memory.

Registers. Since BPF registers are 64-bit and RV32 is a 32-bit architecture, the JIT realizes each BPF register using either a pair of RV32 registers (e.g., R1 using a0 and a1) or 64 bits in the “spilled registers” memory region (e.g., R6). This register mapping is static and pre-determined, eliminating the need for register allocation at compilation time. Other BPF JITs in the Linux kernel use similar register mappings.

The register mapping is handcrafted to achieve good performance. For instance, recall that BPF designates R1–R5 to pass function-call arguments, while the RISC-V calling convention uses a0–a7, plus the stack if needed [20]. To minimize register save and restore, the JIT realizes R1–R4 using a0–a7. For R5, the JIT emits instructions to push the corresponding s3, s4 to the “argument” memory region before the call.

To specify the relation $\sigma_S \sim_{ctx} \sigma_T$ between source and target states, let $\varphi_{reg}(ctx, \sigma_T, r)$ denote the value stored at the target location(s) to which a BPF register r is mapped (e.g., R1 mapped to a0, a1) with respect to JIT context ctx . A strawman approach is to require a strict equivalence: $\sigma_S[r] = \varphi_{reg}(ctx, \sigma_T, r)$ for every BPF register r . With this relation, the stepwise specification would require that if every BPF register and the mapped

locations contain equivalent values initially, their values remain equivalent after executing a BPF instruction, and the emitted machine instructions, respectively. One such example is the *partial* specification used by the BPF bug finder in Serval [68: §7]; the specification is partial because it does not support reasoning about control flow (e.g., program counters) or memory and cannot be used to prove JIT correctness.

While it is useful for finding bugs, the strawman relation is too restrictive for verification. First, if a BPF program does not use a certain register, it should be safe for the JIT to skip emitting code for initializing the corresponding target locations, but doing so violates the strict equivalence. Second, the relation is difficult to establish in the presence of calls. To see why, consider the BPF register R1, which is *not* preserved across a BPF CALL instruction (§3.1). R1 is thus considered *uninitialized* after the call as per the BPF semantics (the BPF checker ensures that R1 will be written to before any further use). On the other hand, R1 is mapped to a0, a1, both of which hold the return value after the call as per the RISC-V calling convention (the JIT emits instructions to further copy their values to s1, s2 to match the BPF calling convention for R0). Therefore, R1 and the corresponding a0, a1 do not hold equivalent values after the call, which violates the strict equivalence.

To relax the strict equivalence and give the JIT more freedom regarding uninitialized BPF registers, we augment the state of the BPF machine with an initialized set, which represents the set of registers that are initialized at this point; the set is updated based on the semantics of each BPF instruction. For example, DST is added to the set after “MOV64_IMM DST, IMM,” as it is written to by the instruction. Similarly, R1–R5 are removed from the set after CALL, as they are not preserved across the call and become uninitialized. In doing so, it suffices to require equivalence $\sigma_S[r] = \varphi_{reg}(ctx, \sigma_T, r)$ for every BPF register $r \in \sigma_S[\text{initialized}]$, effectively excluding uninitialized ones.

Program counters. Let $\varphi_{pc}(ctx, i)$ denote the target address to which the i -th BPF instruction is mapped in JIT context ctx . This is useful for a JIT to implement the compilation of jump instructions. It also allows us to relate program counters in BPF and machine states as an invariant $\varphi_{pc}(ctx, \sigma_S[pc]) = \sigma_T[pc]$.

To define φ_{pc} , one simple approach is to require the JIT to emit a *fixed* number of machine instructions for each BPF instruction (e.g., by padding with NOPs) [33]. In this case, we have $\varphi_{pc}(ctx, i) = ctx[\text{base}] + i \times N$, where $ctx[\text{base}]$

is the starting address of the emitted machine instructions determined by JIT context and N is a pre-determined number of machine instructions large enough to compile any BPF instruction. This is simple to specify and implement, but the emitted code wastes space and CPU cycles.

A more efficient approach is to emit a variable number of machine instructions for each BPF instruction. For example, the BPF JITs in the Linux kernel maintain an *offset table* in the JIT context to map each BPF instruction index to an offset into the emitted code; in this case $\varphi_{pc}(ctx, i)$ is defined by simply consulting the offset table. The JITs construct the offset table by repeating the compilation process until the table converges, or fail if an upper bound on the number of iterations is reached (e.g., 16 in the BPF JIT for RV32).

For flexibility, we choose not to specify how to construct the offset table in the JIT context. Instead, we specify the property a valid JIT context should satisfy. A key observation is that such JITs emit *consecutive* blocks of machine instructions, one block for each BPF instruction. As a result, the difference between the target addresses for a BPF instruction $code_S[i]$ and its successor $code_S[i+1]$ must be equal to the number of bytes emitted for $code_S[i]$. We capture the observation using the well-formedness predicate wf over source program $code_S$ and JIT context ctx for any i -th BPF instruction:

$$\begin{aligned} \text{EmitInstruction}(ctx, i, code_S[i]) = p \rightarrow \\ |p| = \varphi_{pc}(ctx, i+1) - \varphi_{pc}(ctx, i). \end{aligned}$$

Here $|p|$ denotes the length of machine instructions p (in bytes). This allows for both NOP-padding and the more sophisticated JIT implementations such as those in the Linux kernel. Note that this is an assumption on the validity of the JIT context, which does *not* rule out bugs in the construction of the offset table (see §4.4). A JIT may validate the offset table by checking that this predicate holds at compilation time.

Memory. One approach to relating the memory state of source and target machines, denoted by $\sigma_S[\text{mem}]$ and $\sigma_T[\text{mem}]$, respectively, is to require $\sigma_S[\text{mem}](a) = \sigma_T[\text{mem}](a)$ for every address a [65], where memory is modeled as a map from addresses to values. But this approach assumes a closed system (see §7 for such a JIT) and does not fit BPF. For example, both user processes and other BPF programs may concurrently modify memory to which a BPF program has access; therefore, consecutive loads from the same address in the BPF program may return different values. A further complication is that BPF does not specify a memory consistency model (§3.1), effectively assuming that of the underlying architecture.

We observe that a BPF JIT does not need to reason about the behavior of concurrent memory accesses [13, 56]. Instead, the goal is to faithfully translate BPF memory accesses to ones in the target machine, which is a simpler task. Based on this observation, we employ a hybrid approach to specify the invariants for BPF JITs using traces and maps, as follows.

Each target machine models memory as consisting of two disjoint parts, one corresponding to shared memory and the other for internal use (Figure 6). The memory layout used by a JIT determines which target addresses are shared and which are internal. The internal memory is simply a map from addresses to values, since it is private to each execution and the effects are not externally visible. The shared memory captures memory-related effects using events in a trace (§4.1). Since the BPF machine adopts the memory model of the underlying architecture, Jitterbug relates the traces of the BPF and target machines by using the same memory model for both; i.e., the BPF and target traces are drawn from the same set of all possible memory events. Given this correspondence, it suffices to require the traces produced by the BPF and target machines to be identical.

The requirement of having identical traces suffices for the BPF JITs. One exception is that older versions of the BPF JIT for Arm64 use Arm’s exclusive access instructions in a busy loop [2: §B2], which violates the requirement. Newer versions of the JIT have switched to using atomic instructions, which satisfies the requirement. We decide not to relax the requirement of having identical traces to keep the specification simple.

4.4 Discussion and limitations

Jitterbug’s JIT correctness (Definition 1), especially the use of traces, is inspired by the specification of CompCert [54]. Jitterbug’s specification differs in the following ways. First, in-kernel execution imposes stricter requirements on the source program (e.g., determinism, termination, and absence of undefined behavior), allowing us to prove stronger properties. Second, Jitterbug uses fine-grained models of target architectures to precisely reason about low-level state (e.g., program counter and stack pointer), whereas CompCert uses a more abstract semantics for assembly [64: §5] and relies on a separate assembler and linker. Third, the per-instruction compilation process of such JITs enables us to develop a stepwise specification amenable to automated verification.

Jitterbug trusts the correctness of the assumptions (§4.2). Therefore, it cannot catch bugs in the JIT context (e.g., offset-table construction) or layout of the target program. We manually examine the existing BPF JIT correctness bugs in the Linux kernel (§3.2), and determine that out of the 82 bugs, the specification can catch all but two bugs, both in offset-table construction. This shows the effectiveness of the specification.

Jitterbug’s specification permits “null” JIT implementations that fail on all source programs; we use existing test suites (e.g., the BPF selftests) to assess the feature completeness of JITs. It focuses on the JIT and cannot rule out bugs in the BPF checker, memory management for code images, or how the kernel uses the JIT. It does not model the instruction cache or memory permissions, relying on the kernel to correctly flush the cache and set up permissions. It does not provide any guarantees against microarchitectural timing channels [32, 48].

Figure 7: Jitterbug’s verification pipeline. Shaded boxes denote inputs provided by JIT developers.

5 Proving JIT correctness

Jitterbug extends automated verification to JIT correctness, a form of compiler correctness tailored for in-kernel execution. This section describes how Jitterbug achieves the automation.

As shown in Figure 7, Jitterbug provides the stepwise specification and the executable semantics (i.e., interpreters) for BPF and various architectures. It asks JIT developers for a JIT implementation, and assumptions and invariants regarding the implementation. All the inputs are written in the Rosette language (the JIT is written in the DSL described in §6).

Jitterbug builds on Serval for automated verification [68]. It invokes Rosette to reduce all the inputs to symbolic constraints via symbolic evaluation, and an SMT solver to check the satisfiability of these constraints. For symbolic evaluation to terminate, the JIT implementation and the execution of both interpreters must be free of unbounded loops [88]. The BPF JITs satisfy this requirement.

Below we highlight three key challenges in automated verification of JITs and how Jitterbug addresses these challenges.

Instantiation of existential quantifiers. To prove the stepwise specification, Jitterbug has to construct *some* execution of target instructions emitted by the JIT and show that the execution exhibits the same behavior as that of a source instruction. Automating the construction is challenging.

To see why, consider the specification for per-instruction correctness (§4.2). Letting \vec{x} stand for the universally quantified variables in Definition 4, the specification says that the target machine executes some finite number of steps, k , to produce a state σ'_T that satisfies the inductive invariant P . Making the number of steps k explicit, we can write the correctness formula as $\forall \vec{x}. \exists k. P(\vec{x}, k)$, or equivalently, $\exists f. \forall \vec{x}. P(\vec{x}, f(\vec{x}))$, where f is a Skolem function that computes the right k for each combination of the variables \vec{x} . The verification problem that Jitterbug solves therefore involves constructing f . In other words, Jitterbug must determine the number of steps to run symbolic evaluation with emitted instructions, and this value $f(\vec{x})$ may depend on the source program, JIT context, source and target states, etc.

In a restricted setting where the JIT emits straight-line code without any branches, $f(\vec{x})$ is simply the number of emitted instructions. The BPF bug finder in Serval and synthesis-based superoptimizers [72] all assume this setting and use the corresponding basic realization of f . But Jitterbug considers JITs that can emit code with branches, and when executing such code, the target machine can take a different number of steps depending on the input state. This rules out the straightforward realization of f that counts the number of emitted instructions.

To illustrate the challenge of computing f in our setting, consider the instructions emitted by the RV32 JIT for the BPF instruction “JNE64_REG DST, SRC, OFF” (jump to offset OFF if the values in DST and SRC differ). The JIT may emit different blocks of RV32 instructions, conditioned on whether it spills the registers (requiring `lw` to load from stack) or the offset requires a far jump (`jal` or `auipc+jalr`). Figure 8 shows three examples of these blocks and the $f(\vec{x})$ values for executing them, which vary depending on the register state and instructions. In general, constructing f requires human insight [63, 98], so Jitterbug allows JIT developers to provide a manually constructed f . In practice, however, Jitterbug can automate the construction of f for BPF JITs as follows.

To compute f , Jitterbug requires the target interpreter to maintain the symbolic program counter in the form $\text{base} + \text{offset}$, where base is the (symbolic) starting address of instructions. Maintaining this form is straightforward for most instructions. For instructions with subtler semantics, the interpreter achieves this by rewriting the program counter via *symbolic optimization* [68, 74]. For example, RISC-V’s `jalr` sets the least-significant bit of the program counter to zero (§3.2), causing it to take the form $(\text{base} + \text{offset}) \& \text{mask}$. The interpreter rewrites this expression by dropping the mask and checking that the resulting expression is equivalent (i.e., that the program counter is properly aligned).

Given a program counter of the form $\text{base} + \text{offset}$, Jitterbug provides a reusable procedure for constructing f through symbolic evaluation. It extracts the offset from the program counter expression and applies a simple rule: stop symbolic evaluation either if the offset is concrete but leaves the block of emitted instructions, or if the offset becomes symbolic. The intuition is that branching with a symbolic offset likely leaves the block, because the JIT generally produces such branching instructions by consulting the offset table in the JIT context (§4.3), which is considered symbolic for verification. Internal branching tends to have a concrete offset, for which symbolic evaluation continues.

This procedure guesses an f for verifying that the target machine reaches a desired state after taking $f(\vec{x})$ steps. It does not guarantee to find the right f if one exists, though it is sufficient for all the JITs we have studied and works well in practice. The procedure is untrusted: choosing a wrong f causes the target machine to either get stuck or enter a state that violates the inductive invariant, but it does not cause an erroneous JIT implementation to pass verification.

Figure 8: Emitted RV32 instruction blocks for BPF’s JNE64_REG with registers (a) R1, R2; (b) R1, R6; and (c) R6, R7 and with an offset of different ranges. R1 and R2 are realized using RV32 registers, and R6 and R7 are spilled on the stack (Figure 6). Straight and elbow arrows denote falling through and branching, respectively; those leaving the blocks are labeled with values of $f(\vec{x})$.

Symbolic evaluation of symbolic instructions. As shown in Figure 8, the JIT may emit different blocks of target instructions for a given source instruction opcode. When Jitterbug symbolically evaluates a JIT implementation, it produces a symbolic representation of all of these instruction blocks. This representation takes the form of *symbolic* instructions that may contain symbolic values in register and immediate fields. To verify the JIT, Jitterbug must then evaluate the target interpreter on both a symbolic input state *and* a symbolic program. This is in contrast to prior work on verifying systems code such as Serval, where the input state is symbolic but the program itself is concrete (e.g., all register and immediate fields are concrete bytes). Reasoning about symbolic programs both magnifies existing challenges to scaling verification and creates new ones. We discuss one example of each.

The first challenge is path explosion. While common to all tools based on symbolic evaluation, this problem becomes exponentially worse in the presence of symbolic code. For example, the BPF JIT for RV64 compiles LD64_IMM to a variable number of instructions to load a 64-bit immediate in chunks, selecting each instruction based on the chunk value and destination register. This amounts to reasoning about a total of 2,181 types of blocks of RV64 instructions for downstream stages, out of which 307 are feasible, applied to all possible input instructions (roughly, 2^{64}). *Symbolic execution* [17, 44], which explores individual paths separately, is thus not a good fit for this verification pipeline.

Jitterbug instead adopts Rosette’s strategy for symbolic evaluation [89: §4] to merge the program state at each control-flow join, but it forces a split on every possible (concrete) opcode of symbolic instructions. The intuition is that both the JIT and interpreters tend to handle each opcode separately; splitting on the opcode enables opportunities for concrete evaluation. This strategy works well in practice: it avoids path explosion and leads to easier-to-solve constraints.

The second challenge is that Jitterbug interpreters, unlike those in Serval, must be designed to work on both symbolic state and symbolic instructions. Failing to do so both causes state explosion and produces constraints difficult for SMT solving. For example, the interpreters in Serval represent the CPU state using a vector of bitvectors (one bitvector per register), and encode accessing register r_i as indexing into the

vector using integer i . This is suitable for concrete instructions, where i is concrete and the generated constraints are restricted to the theory of bitvectors. But with symbolic instructions, a symbolic register index i causes symbolic evaluation to produce constraints that also use the theory of (mathematical) integers. Mixing integers and bitvectors is expensive for solving and can lead to verification bottlenecks [39: §3].

We develop interpreters that account for symbolic instructions and thus can work with Jitterbug. For example, we carefully avoid integers in instruction semantics to restrict resulting constraints to the theories of equality with uninterpreted functions and bitvectors, a decidable fragment of first-order logic. Additionally, recall that the BPF JITs for x86 emit raw bytes (§3.2) and thus require a decoder for verification. We implement an x86 decoder that works on symbolic bytes. The development process is guided by using symbolic profiling to identify verification performance bottlenecks [10] and applying symbolic optimization to fine-tune symbolic evaluation [68: §4].

Axiomatization of expensive SMT operations. Both BPF and machine interpreters provide arithmetic instructions for multiplication, division, and remainder. Reasoning about these operations is expensive for SMT solvers [4, 49], and has been a source of timeouts in verification practice [30, 36].

To avoid such expensive reasoning, Jitterbug takes a standard *axiomatization* approach [50: §3.2] by replacing these bitvector operations with uninterpreted functions mul_n , div_n , and rem_n ($n = 32, 64$) in instruction semantics. For example, the BPF JIT for RV32 translates BPF’s DIV32_REG into using RISC-V’s `divu`; both instructions are encoded using uninterpreted function div_{32} (with variations for handling division by zero). Proving the correctness of this translation does *not* require the semantics of division, thereby scaling verification.

This approach is less general than using SMT’s built-in bitvector operations, because it ignores the semantics of these operations and might reject valid JIT implementations. For example, the JIT may reorder the operands of a multiplication in emitted instructions; for target architectures lacking native instructions for remainder or 64-bit multiplication, the JIT may emit instructions that emulate the behavior. Proving such a JIT correct requires additional properties about the operations.

Jitterbug captures these properties using the following axioms, which are sufficient to verify all the JITs we have studied:

- commutativity of mul_n : $\text{mul}_n(x, y) = \text{mul}_n(y, x)$;
- remainder: $\text{rem}_n(x, y) = x - \text{mul}_n(\text{div}_n(x, y), y)$;
- commutativity of mulhu : $\text{mulhu}_n(x, y) = \text{mulhu}_n(y, x)$; and
- decomposition of mul_{64} : $\text{mul}_{64}(x, y) = (\text{mulhu}_{32}(x_{\text{lo}}, y_{\text{lo}}) + \text{mul}_{32}(x_{\text{hi}}, y_{\text{lo}}) + \text{mul}_{32}(x_{\text{lo}}, y_{\text{hi}})) \oplus \text{mul}_{32}(x_{\text{lo}}, y_{\text{lo}})$.

Here x and y are bitvectors; subscripts “lo” and “hi” denote the lower and upper half bits, respectively; \oplus denotes bitvector concatenation; and mulhu is an auxiliary uninterpreted function for modeling the upper bits of a product. For example, x86’s 32-bit unsigned multiplication instruction stores a 64-bit product in registers `edx` and `eax`; the x86 interpreter encodes their values using mulhu_{32} and mul_{32} , respectively.

These axioms are shared by the verification of the BPF JITs across architectures. As a sanity check, we formalize and manually prove them using Lean [22].

6 Implementing a JIT

DSL. Figure 9 shows an excerpt of the BPF JIT for RV32, written in the Jitterbug DSL. The DSL is implemented as a Rosette library and reflects a structured subset of C: booleans, (machine) integers, array accesses (“@”), as well as conditional and switch statements. This subset is minimal and sufficient to support the development of the BPF JIT for RV32. It does not support address-of, dereference, or unstructured constructs (e.g., `goto` or `fallthrough` in `switch`).

Jitterbug extracts the final C code from JIT fragments written in the DSL, a code template (including glue code not covered by the DSL), and a type mapping (not shown here; both array accesses to `bpf2rv32` and calls to `bpf_get_reg64` return a value of type “`const s8 *`”). Jitterbug does not perform any type checking for the C code.

Using the DSL simplifies verification by avoiding the need to model the C semantics. One can also “escape” from the DSL to use the full Rosette language, though in that case Jitterbug is unable to perform C code extraction; we leverage this to simplify porting the existing BPF JITs from C to Jitterbug.

Synthesis. As an application of Jitterbug’s specification and verification, we use Rosette’s support for program synthesis to optimize the BPF JIT for RV32 [59]. We do so by synthesizing JIT fragments written in (a subset of) the DSL, where each fragment takes as input a BPF instruction with a given opcode (e.g., `ADD64_REG`) and emits a short sequence of RV32 instructions with equivalent behavior. We use the standard approach of writing program sketches [11, 82] to compactly define a space of JIT fragments for compiling ALU instructions. The synthesizer searches this space for the shortest fragment that satisfies per-instruction correctness (Definition 4), according to the Jitterbug verifier.

```
(func (emit_alu_r64 dst src ctx op)
  (var [tmp1 (@ bpf2rv32 TMP_REG_1)]
      [tmp2 (@ bpf2rv32 TMP_REG_2)]
      [rd (bpf_get_reg64 dst tmp1 ctx)]
      [rs (bpf_get_reg64 src tmp2 ctx)])
  (switch op
    [(BPF_ADD)
     (cond
      [(equal? rd rs)
       (emit (rv_srli RV_REG_T0 (lo rd) 31) ctx)
       (emit (rv_slli (hi rd) (hi rd) 1) ctx)
       (emit (rv_or (hi rd) RV_REG_T0 (hi rd)) ctx)
       (emit (rv_slli (lo rd) (lo rd) 1) ctx)]
      [else
       (emit (rv_add (lo rd) (lo rd) (lo rs)) ctx)
       (emit (rv_sltu RV_REG_T0 (lo rd) (lo rs)) ctx)
       (emit (rv_add (hi rd) (hi rd) (hi rs)) ctx)
       (emit (rv_add (hi rd) (hi rd) RV_REG_T0) ctx)]])
  ...))
```

(a) JIT implementation written in the DSL.

```
void emit_alu_r64(const s8 *dst, const s8 *src,
                 struct rv_jit_context *ctx, const u8 op)
{
  // clang-format on
  @|emit_alu_r64|
  // clang-format off
}
```

(b) C code template, where `@|...|` expands to generated code.

```
void emit_alu_r64(const s8 *dst, const s8 *src,
                 struct rv_jit_context *ctx, const u8 op)
{
  const s8 *tmp1 = bpf2rv32[TMP_REG_1];
  const s8 *tmp2 = bpf2rv32[TMP_REG_2];
  const s8 *rd = bpf_get_reg64(dst, tmp1, ctx);
  const s8 *rs = bpf_get_reg64(src, tmp2, ctx);

  switch (op) {
  case BPF_ADD:
    if (rd == rs) {
      emit(rv_srli(RV_REG_T0, lo(rd), 31), ctx);
      emit(rv_slli(hi(rd), hi(rd), 1), ctx);
      emit(rv_or(hi(rd), RV_REG_T0, hi(rd)), ctx);
      emit(rv_slli(lo(rd), lo(rd), 1), ctx);
    } else {
      emit(rv_add(lo(rd), lo(rd), lo(rs)), ctx);
      emit(rv_sltu(RV_REG_T0, lo(rd), lo(rs)), ctx);
      emit(rv_add(hi(rd), hi(rd), hi(rs)), ctx);
      emit(rv_add(hi(rd), hi(rd), RV_REG_T0), ctx);
    }
    break;
  }
  ...
}
```

(c) Final (extracted) JIT implementation in C.

Figure 9: Excerpt of the BPF JIT for RV32 for compiling the “`ADD64_REG DST, SRC`” instruction.

Using this approach, we found two JIT fragments better than our manual implementation for compiling `ADD64_REG` (Figure 9) and `SUB64_REG`. In each case, the synthesized fragment emitted four instructions, whereas our manual implementation emitted five. We adopted the synthesized fragments in the JIT.

7 Experience

Figure 10 shows the code size of the Jitterbug framework and the interpreters for verifying JITs, all written in Rosette. We wrote the interpreters in an idiomatic way [36: §3.3], adding instructions as needed. We borrowed part of the BPF and RV64 semantics from Serval [68], but rewrote the interpreters to support symbolic instructions (§5); we wrote the others from scratch. We developed the metatheory for JIT correctness and the bitvector axiomatization using 1,492 lines of Lean code.

Component (in Rosette)	Lines of code
Jitterbug framework	1,825
BPF interpreter	471
Arm32 interpreter	1,265
Arm64 interpreter	1,166
RISC-V interpreter (32- and 64-bit)	1,571
x86 interpreter (32- and 64-bit)	2,299

Figure 10: Line counts of Jitterbug’s components.

	JIT impl.		Spec.	Per-opcode verification time			
	C	DSL		Min	Max	Mean	Median
RV32	1,964	1,420	336	16	401	73	55
RV64	1,862	1,225	284	4	7,542	116	24
Arm32	1,620	839	192	23	925	130	99
Arm64	1,025	653	163	4	110	26	23
x86-32	1,683	1,074	185	24	488	122	109
x86-64	1,382	644	182	5	170	33	27

Figure 11: Line counts and per-opcode verification time (in seconds) of the BPF JITs for six architectures.

The primary application of Jitterbug is a new BPF JIT for RV32, which we wrote in the DSL, proved against the stepwise specification, and extracted to a C implementation. To validate the generality of Jitterbug, we ported the existing BPF JITs for RV64, Arm32, Arm64, x86-32, and x86-64 in the Linux kernel to Jitterbug for verification. Each port was line-by-line transcription from C to the DSL (and Rosette), emitting the same instructions as the original JIT. These ports did not cover the support for legacy instruction sets (e.g., those lacking atomic instructions mentioned in §4.3), compiling `TAIL_CALL`, or optimizing register saving.

Figure 11 lists the line counts for each BPF JIT. The specification effort comprises writing assumptions and invariants for the implementation (§5). Since Jitterbug performs verification for each source instruction opcode individually, we measured the per-opcode verification time, using an Intel Core i7-7700K CPU at 4.5 GHz, with Boolector 3.2.1 as the SMT solver [69]. Verification time across the JITs depends on many factors (e.g., the JIT implementation or solver), though architectural differences are a contributing factor. For example, the most time-consuming case is verifying the JIT for RV64 with BPF’s `LD64_IMM` (loading a 64-bit immediate), which emits 307 types of blocks of RISC-V instructions; the JIT for x86-64 emits six types for the same opcode.

Below we describe our experience using Jitterbug for the BPF JITs and a previously verified JIT for a stack machine [65].

The BPF JIT for RV32. We chose to implement a BPF JIT for RV32 because there was not one in the Linux kernel. The development took five iterations of code reviews.

The first two iterations occurred in June 2019. We sent an initial implementation to kernel developers to gather feedback and gauge interest. The implementation was written in Rosette

and manually translated to C, and was unverified. The feedback was positive, with suggestions to add support for eliminating zero extensions [93], an optimization BPF had just introduced.

We submitted the third implementation in February 2020. It was switched to using the DSL (§6), which was less prone to errors in manual translation. It passed the BPF selftests suite, and was verified against an early version of the specification. One of the suggestions from kernel developers was to factor out the common code to be shared among the JITs, such as the per-instruction structure (§4.2). We addressed the suggestions in the next two iterations, after which the JIT was accepted into the Linux kernel (see §A.1.1).

Throughout this process, we refined both the specification and the implementation. The early version of the specification missed two bugs that were also missed by testing. The first bug was an off-by-one error for `TAIL_CALL`: the emitted instructions limited the TCC (tail-call counter) to 32, rather than the correct value 33. The second bug was that the JIT did not maintain 16-byte alignment of the stack as per the calling convention. We found the two bugs once we completed the specification.

Automated verification supported this development process in two ways. First, it minimized the proof burden for developing the JIT, which must be feature-complete for deployability. Second, it enabled us to catch up with new features being introduced (e.g., support for eliminating zero extensions) and address code reviews by kernel developers in a timely manner.

Code review. As listed in §A.1.2, we found 16 new bugs in the existing BPF JITs, wrote patches that fix these bugs, and verified the fixed code. In addition, we found two new bugs in the Arm64 instruction encoding library, a core component shared by BPF and other kernel subsystems (e.g., KVM). We wrote new test cases to be included in the BPF selftests suite. This is useful for catching similar bugs across the JITs, as various “bots” are running selftests continuously for the Linux kernel. Finding subtle bugs in well-tested code shows the effectiveness of the specification and verification.

The main effort for porting and verifying these JITs was in writing the target interpreters for Jitterbug. Verifying the JITs for Arm32 and Arm64 took one week each. Verifying the JITs for x86-32 and x86-64 took three weeks in total, due to the complexity of the x86 interpreter (e.g., instruction decoding). Translating C code to Rosette was mechanical and straightforward, though mistakes in manual translation might hide bugs; extending Jitterbug to work on C code is future work. For specification, we adopted the assumptions and invariants for the JIT for RV32 and adjusted them accordingly.

In our experience, automated verification is key to rapid code review using formal methods. As an example, in December 2019, the developer of the BPF JIT for RV64 submitted patches to add support for far jumps. We ported the patches to Jitterbug and verified their correctness within days of the patch submission. We reported the verification results to kernel developers; the patches were accepted with our review.

Optimization. Another advantage of verification is that it enables developing complex optimizations by providing a high degree of confidence in their correctness. As listed in §A.1.3, we developed 12 patches optimizing the existing BPF JITs. Like code review, we verified the correctness of these optimizations by manually translating the C code to Rosette.

One of the optimizations adds support for RISC-V compressed instruction-set extension (RVC) to the BPF JIT for RV64. RVC improves code density and reduces instruction cache misses by adding short 2-byte instructions for common operations [95: §5], but it poses a challenge to verification: the JIT may choose either base (4-byte) or RVC (2-byte) for emitting each instruction, depending on the immediate value or registers. This leads to an exponential increase in the number of paths in the JIT, emitted instructions, and machine state (e.g., variable code lengths causing the program counter to take different values). Developing and verifying this optimization took approximately 3 weeks, following the proof strategy described in §5 to scale verification.

Beyond BPF JITs. While Jitterbug focuses on the BPF JITs, we also applied it to a JIT for a stack machine to x86-32. We ported the “version 1” JIT described by Myreen [65] to the Jitterbug DSL and extracted it to C code; the port emitted the same x86-32 instructions and was able to run the example as in the paper (Jitterbug does not support the “version 2” JIT that emits self-modifying code). For specification, we excluded registers from the invariants, since the stack machine had no registers; and modeled memory as a map from addresses to values without using traces, since the stack machine had no shared memory (§4.3). For verification, we wrote an interpreter for the stack machine and reused the x86 interpreter provided by Jitterbug. This process took one day.

Jitterbug reported two bugs in the JIT implementation: the offsets for two conditional jump instructions are given as 5 in the original paper, but we concluded that the correct value should be 8. We fixed the offsets and verification succeeded. We believe that both are typos in the paper, as our (fixed) JIT is consistent with the paper’s HOL4 code and proof.

8 Reflection and conclusion

Our work on Jitterbug was inspired by an earlier effort, started in 2015, to use the Coq theorem prover to develop a verified BPF JIT for x86-64. We chose to implement the JIT itself in x86-64 so as to minimize the trusted computing base. In hindsight, this was a mistake: doing so required reasoning about low-level machine state for both the compiler and emitted code, which hindered the completion of the proof; and the JIT implementation was impractical to audit and deploy due to the lack of C code and the optimizations seen in the Linux kernel. We suspended this effort two years later, in 2017.

Our interest in BPF JITs was revived with the development of symbolic profiling [10] and optimization [68, 74], which together demonstrated a systematic approach for scaling automated verification of low-level code. As an experiment, we wrote a bug finder for BPF JITs in Serval, which checked for strict equivalence of registers (§4.3) over straight-line instructions (§5). It enabled us to find 15 bugs regarding ALU instructions in two BPF JITs, although it was insufficient for verification or finding the bugs described in §3.2 due to the lack of a correctness specification and proof strategy (e.g., support for symbolic instructions).

For Jitterbug, we spent most of our effort devising a specification of JIT correctness that is general enough to cover a broad range of in-kernel JITs (e.g., without requiring padding emitted instructions), expressive enough to catch real bugs, and amenable to automated verification. We found the use of the Lean theorem prover valuable for navigating this trade-off, developing several iterations of the stepwise specification and a proof that implies the correctness of compiling entire programs. It also improved our confidence in the axiomatization of bitvector operations.

A key lesson from Jitterbug is that deciding what *not* to verify is as important as deciding what to verify. For instance, while ideally we would write and verify the BPF JIT for RV32 in C directly, the use of the DSL enabled us to fine-tune symbolic evaluation, which was critical for scaling verification. If we could not scale verification to JITs written in the DSL, verifying JITs written in C would surely be out of reach. Inspired by seL4 [78] and Ironclad [36], we bridged the resulting gap through validation, separately verifying that the instruction encoding functions in C emitted the same bytes as their original DSL code.

Through this paper, we presented our experience with specifying and verifying BPF JITs, a critical and rapidly evolving component in the Linux kernel. Our experience demonstrates, for the first time, the feasibility of extending automated verification to a restricted but practically important class of compilers. The source code of Jitterbug and the JITs is publicly available at <https://github.com/uw-unsat/jitterbug>.

Acknowledgments

A Artifact appendix

A.1 Patches to the Linux kernel developed using Jitterbug

The following tables list the upstreamed patches to the Linux kernel that we have developed using Jitterbug.

A.1.1 Development of the BPF JIT for RV32

Commit	Architecture	Description
5f316b65e99f	RV32	Add RV32G eBPF JIT
ca6cb5447cec	RV32	Factor common RISC-V JIT code
745abfaa9eaf	RV32	Fix tail call count off by one in RV32 BPF JIT
91f658587a96	RV32	Fix stack layout of JITed code on RV32

A.1.2 Bug fixes and new test cases

Commit	Architecture	Description
bb9562cf5c67	Arm32	Fix bugs with ALU64 RSH, ARSH BPF_K shift by 0
4178417cc535	Arm32	Fix offset overflow for BPF_MEM BPF_DW
579d1b3faa37	Arm64	Fix two bugs in encoding 32-bit logical immediates
1e692f09e091	RV64	Clear high 32 bits for ALU32 add/sub/neg/lsh/rsh/arsh
489553dd13a8	RV64	Fix offset range checking for auipc+jalr on RV64
6fa632e719ee	x86-32	Fix bug with ALU64 LSH, RSH, ARSH BPF_K shift by 0
68a8357ec15b	x86-32	Fix bug with ALU64 LSH, RSH, ARSH BPF_X shift by 0
80f1f8503635	x86-32	Fix bug with JMP32 JSET BPF_X checking upper bits
5fa9a98fb103	x86-32	Fix incorrect encoding in BPF_LDX zero-extension
50fe7ebb6475	x86-32	Fix clobbering of dst for BPF_JSET
aee194b14dd2	x86-64	Fix encoding for lower 8-bit registers in BPF_STX BPF_B
d2b6c3ab70db	—	Add test for BPF_STX BPF_B storing R10
93e5fbb18cec	—	Add test for JMP32 JSET BPF_X with upper bits set
ac8786c72eba	—	Add tests for shifts by zero

A.1.3 Optimizations for existing BPF JITs

Commit	Architecture	Description
cf48db69bdfa	Arm32	Optimize ALU64 ARSH X using orrpl conditional instruction
c648c9c7429e	Arm32	Optimize ALU ARSH K using asr immediate instruction
fd49591cb49b	Arm64	Optimize AND,OR,XOR,JSET BPF_K using arm64 logical immediates
fd868f148189	Arm64	Optimize ADD,SUB,JMP BPF_K using arm64 add/sub immediates
46dd3d7d287b	RV64	Enable zext optimization for more RV64G ALU ops
0224b2acea0f	RV64	Enable missing verifier_zext optimizations on RV64
21a099abb765	RV64	Optimize FROM_LE using verifier_zext on RV64
ca349a6a104e	RV64	Optimize BPF_JMP BPF_K when imm == 0 on RV64
073ca6a0369e	RV64	Optimize BPF_JSET BPF_K using andi on RV64
bfabff3cb0fe	RV64	Modify JIT ctx to support compressed instructions
804ec72c68c8	RV64	Add encodings for compressed instructions
18a4d8c97b84	RV64	Use compressed instructions in the rv64 JIT

A.2 Bug-fixing commits in BPF JITs in the Linux kernel (May 2014–April 2020)

The following table lists bug-fixing commits in the BPF JITs in the Linux kernel for Arm32, Arm64, RV64, x86-32, and x86-64. The superscripts *J* and *S* mark those for fixing bugs found using Jitterbug and the BPF bug finder in Serval, respectively.

Commit	Architecture	Year	Description
ALU:			
bb9562cf5c67^J	Arm32	2020	Fix bugs with alu64 rsh, arsh bpf_k shift by 0
14e589ff4aa3	Arm64	2015	Fix mod-by-zero case
251599e1d690	Arm64	2015	Fix div-by-zero case
d63903bbc30c	Arm64	2015	Fix endianness conversion bugs
1e4df6b72081	Arm64	2015	Fix signedness bug in loading 64-bit immediate
1e692f09e091^S	RV64	2019	Clear high 32 bits for alu32 add/sub/neg/lsh/rsh/arsh
fe121ee531d1	RV64	2019	Clear target register high 32-bits for and/or/xor on alu32
6fa632e719ee^S	x86-32	2019	Fix bug with alu64 lsh, rsh, arsh bpf_k shift by 0
68a8357ec15b^S	x86-32	2019	Fix bug with alu64 lsh, rsh, arsh bpf_x shift by 0
b9aa0b35d878	x86-32	2019	Fix bug for bpf_alu64 bpf_neg
343f845b3759	x86-64	2015	Fix from_be16 and from_le16/32 instructions
JMP:			
2b589a7e2bd3	Arm32	2018	Correct check_imm24
ddc665a4bb4b	Arm64	2017	Fix jit branch offset related to ldimm64
8eee539ddea0	Arm64	2015	Fix out-of-bounds read in bpf2a64_offset()
50fe7ebb6475^J	x86-32	2020	Fix clobbering of dst for bpf_jset
80f1f8503635^J	x86-32	2020	Fix bug with jmp32 jset bpf_x checking upper bits
711aef1bbf88	x86-32	2019	Fix bug for bpf_jmp bpf_jsgt, bpf_jsle, bpf_jslt, bpf_jsge
7c2e988f400e	x86-64	2019	Fix x64 jit code generation for jmp to 1st insn
MEM:			
4178417cc535^J	Arm32	2020	Fix offset overflow for bpf_mem bpf_dw
ec19e02b343d	Arm32	2018	Fix ldx instructions
8968c67a82ab	Arm64	2019	Remove prefetch insn in xadd mapping
7005cade1bdb	Arm64	2017	Use separate register for state in stxr
5ca1ca01fae1	x86-32	2020	Fix logic error in bpf_ldx zero-extension
5fa9a98fb103^J	x86-32	2020	Fix incorrect encoding in bpf_ldx zero-extension
aee194b14dd2^J	x86-64	2020	Fix encoding for lower 8-bit registers in bpf_stx bpf_b
CALL:			
8c11ea5ce13d	Arm64	2018	Fix getting subprog addr from aux for calls
489553dd13a8^J	RV64	2020	Fix offset range checking for auipc+jalr on rv64
TAIL_CALL and EXIT:			
02088d9b392f	Arm32	2018	Fix register saving
f4483f2cc1fd	Arm32	2018	Fix tail call jumps
51c9fbb1b146	Arm64	2014	Lift restriction on last instruction
16338a9b3ac3	Arm64	2018	Fix out of bounds access in tail call
a2284d912bfc	Arm64	2018	Fix stack_depth tracking in combination with tail calls
d8b54110ee94	Arm64	2017	Fix faulty emission of map access in tail calls
96bc4432f5ad	RV64	2019	Limit to 33 tail calls
769e0de6475e	x86-64	2014	Fix epilogue generation for ebpf programs
90caccdd8cc0	x86-64	2017	Fix bpf_tail_call() x64 jit
2482abb93ebf	x86-64	2015	Fix general protection fault when tail call is invoked
Prologue and epilogue:			
d1220efd2348	Arm32	2018	Fix stack alignment
f1003b787c00	RV64	2019	Fix broken bpf tail calls
9e4e5b5c8666	x86-32	2018	Fix regression caused by commit 24dea04767e6
fe8d9571dc50	x86-64	2019	Fix stack layout of jited bpf code

COBRA: Making Transactional Key-Value Stores Verifiably Serializable

Cheng Tan, Changgeng Zhao, Shuai Mu*, and Michael Walfish

NYU Department of Computer Science, Courant Institute

*Stony Brook University

Abstract. Today’s cloud databases offer strong properties, including serializability, sometimes called the gold standard database correctness property. But cloud databases are complicated black boxes, running in a different administrative domain from their clients. Thus, clients might like to know whether the databases are meeting their contract. To that end, we introduce COBRA; COBRA applies to transactional key-value stores. It is the first system that combines (a) black-box checking, of (b) serializability, while (c) scaling to real-world online transactional processing workloads. The core technical challenge is that the underlying search problem is computationally expensive. COBRA tames that problem by starting with a suitable SMT solver. COBRA then introduces several new techniques, including a new encoding of the validity condition; hardware acceleration to prune inputs to the solver; and a transaction segmentation mechanism that enables scaling and garbage collection. COBRA imposes modest overhead on clients, improves over baselines by 10 \times in verification cost, and (unlike the baselines) supports *continuous* verification. Our artifact can handle 2000 transactions/sec, equivalent to 170M/day.

1 Introduction and motivation

A new class of cloud databases has emerged, including Amazon DynamoDB and Aurora [2, 4, 133], Azure CosmosDB [7], CockroachDB [9], YugaByte DB [36], and others [16, 17, 21, 22, 69]. Compared to earlier generations of NoSQL databases (such as Facebook Cassandra, Google Bigtable, and Amazon S3), members of the new class offer the same scalability, availability, replication, and geo-distribution but in addition offer *serializable* transactions [55, 110]: all transactions appear to execute in a single, sequential order.

Serializability is the gold-standard isolation level [48, 77], and the correctness contract that many applications and programmers implicitly assume: their code would be incorrect if the database provided a weaker contract [137]. Note that serializability encompasses weaker notions of correctness, like basic integrity: if a returned value does not read from a valid write, that will manifest as a non-serializable result. Serializability also implies that the database handles failures robustly: non-tolerated server failures, particularly in the case of a distributed database, are a potential source of non-serializable results.

However, a user of a cloud database can legitimately wonder whether the database in fact provides the promised contract. For one thing, users often have no visibility into a cloud database’s implementation. In fact, even when the source code is available [9, 16, 17, 36], that does not necessarily yield visibility: if the database is hosted by someone else, you can’t really be sure

of its operation. Meanwhile, any internal corruption—as could happen from misconfiguration, operational error, compromise, or adversarial control at any layer of the execution stack—can cause a serializability violation. Beyond that, one need not adopt a paranoid stance (“the cloud as malicious adversary”) to acknowledge that it is difficult, as a technical matter, to provide serializability *and* geo-distribution *and* geo-replication *and* high performance under various failures [40, 78, 147]. Doing so usually involves a consensus protocol that interacts with an atomic commit protocol [69, 96, 103]—a complex combination, and hence potentially bug-prone. Indeed, today’s production systems have exhibited serializability violations [1, 18, 19, 25, 26] (see also §6.1).

This leads to our core question: *how can clients verify the serializability of a black-box database?* To be clear, related questions have been addressed before. The novelty in our problem is in combining three aspects:

(a) Black box, unmodified database. In our setting, the database does not “know” it’s being checked; the input to the verification machinery will be only the inputs to, and outputs from, the database. This matches the cloud context (even when the database is open source, as noted above), and contrasts with work that checks for isolation or consistency anomalies by using “inside information” [62, 86, 109, 123, 130, 141, 143], for example, access to internal scheduling choices. Also, we target production workloads and standard key-value APIs (§2).

(b) Serializability. We focus on serializability, in contrast to weaker isolation levels. Serializability has a strict variant and a non-strict variant [56, 110]; in the former, the effective transaction order must be consistent with real time. We attend to both variants in this paper. However, the weight is on the non-strict variant, as it poses a more difficult computational problem; the strict variant is “easier” because the real-time constraint diminishes the space of potentially-valid execution schedules.

On the one hand, the majority of databases that offer serializability offer the strict variant. On the other hand, checking non-strict serializability is germane, for two reasons. First, some databases claim to provide the non-strict variant (in general [11], or under clock skew [35], or for read-only workloads [32]), while others don’t specify the variant [3, 5]. Second, the strict case can degenerate to the non-strict case. Heavy concurrency, for example, means few real-time constraints, so the difficult computational problem re-enters. As a special case, clock drift causes otherwise ordered transactions to be concurrent (§3.5, §6.1).

(c) Scalability. This means, first, scaling to real-world online transactional processing workloads at reasonable cost. It also

means incorporating mechanisms that enable a verifier to work incrementally and to keep up with an ever-growing history.

However, aspects (a) and (b) set up a challenge: checking black-box serializability has long been known to be NP-complete [54, 110]. Recent work of Biswas and Enea (BE) [59] lowered the complexity to polynomial time, under natural restrictions (which hold in our context); see also pioneering work by Sinha et al. [124] (§7). However, these two approaches don’t meet our goal of scalability. For example, in BE, the number of clients appears in the exponent of the algorithm’s running time (§6, §7) (e.g., 14 clients means the algorithm is $O(n^{14})$). Furthermore, even if there were a small number of clients, BE does not include mechanisms for handling a continuous and ever-growing history.

Despite the computational complexity, there is cause for hope: one of the remarkable developments in the field of formal verification has been the use of heuristics to “solve” problems whose general form is intractable. This owes to major advances in solvers (advanced SAT and SMT solvers) [49, 57, 64, 73, 84, 99, 107, 128], coupled with an explosion of computing power. Thus, our guiding intuition is that it ought to be possible to verify serializability in many real-world cases. This paper describes a system called COBRA, which starts from this intuition, and provides a solution to the problem posed by (a)–(c).

COBRA applies to transactional key-value stores (everywhere in this paper it says “database”, this is what we mean). COBRA consists of a third-party, unmodified database that is not assumed to “cooperate”; a set of legacy database clients that COBRA modifies to link to a library; one or more *history collectors* that are assumed to record the actual requests to and responses from the database; and a *verifier* that comprehensively checks serializability, in a way that “keeps up” with the database’s (average) load. The database is untrusted while the clients, collectors, and verifier are all in the same trust domain (for example, deployed by the same organization). Section 2 further details the setup and gives example scenarios. COBRA solves two main problems:

1. *Efficient witness search* (§3). A brute-force way to validate serializability is to demonstrate the existence of a graph G whose nodes are transactions in the history and whose edges meet certain *constraints*, one of which is acyclicity (§2.3). From our starting intuition and the structure of the constraints, we are motivated to use a SAT or SMT solver [34, 50, 73, 127]. But complications arise. To begin with, encoding acyclicity in a SAT instance brings overhead [79, 80, 91] (we see this too; §6.1). Instead, COBRA uses a recent SMT solver, MonoSAT [52], that is well-suited to checking graph properties (§3.4). However, using MonoSAT alone on the aforementioned brute-force search problem is still too expensive (§6.1).

To address this issue, COBRA develops domain-specific pruning techniques and reduces the search problem size. First, COBRA introduces a new encoding that exploits common patterns in real workloads, such as read-modify-write transactions, to

efficiently infer ordering relationships from a history (§3.1–§3.2). (We prove that COBRA’s encoding is a valid reduction in Appendix B [132].) Second, COBRA uses parallel hardware (our implementation uses GPUs; §5) to compute *all-pairs reachability* over a graph whose nodes are transactions and whose edges are known precedence relationships; then, COBRA resolves some of the constraints efficiently, by testing whether a candidate edge would generate a cycle with an existing path.

2. *Scaling to a continuous and ever-growing history* (§4). Online cloud databases run in a continuous fashion, where the corresponding history is uninterrupted and grows unboundedly. To support online databases, COBRA verifies in rounds. From round-to-round, the verifier checks serializability on a portion of the history. However, the challenge is that the verifier seemingly needs to involve all history, because serializability does not respect real-time ordering, so future transactions can read from values that (in a real-time view) have been overwritten. To solve this problem, clients issue periodic *fence transactions* (§4.2). The epochs impose coarse-grained synchronization, creating a window from which future reads, if they are to be serializable, are permitted to read. This allows the verifier to discard transactions prior to the window.

We implement COBRA (§5) and experiment with it on production databases with various workloads (§6). COBRA detects all serializability violations we collect from real systems’ bug reports. COBRA’s core (single-round) verification improves on baselines by $10\times$ in the problem size it can handle for a given time budget. For example, COBRA finishes checking 10k transactions in 14 seconds, whereas baselines can handle only 1k or less in the same time budget. For an online database with continuous traffic, COBRA achieves a sustainable verification throughput of 2k txn/sec on the workloads that we experiment with (this corresponds to a workload of 170M/day; for comparison, Apple Pay handles 33M txn/day [6], and Visa handles 150M txn/day [33], admittedly for a slightly different notion of “transaction”). COBRA imposes modest overhead.

COBRA has several limitations (§8). First, there is no guarantee that COBRA terminates in reasonable time (though our experiments on real workloads do). Second, COBRA supports only a key-value API, and thus does not handle range queries and SQL operations such as “join” and “sum” (though one can translate these queries and operations to a key-value API, as commonly done in research on transactional key-value stores [100, 108, 129, 136, 140, 144]). Third, COBRA does not yet support async (event-driven) I/O patterns in clients (only multithreading). Fourth, COBRA mostly punts fault-tolerance of the verifier and collectors (though modular solutions exist). Finally, we have not identified serializability violations in the wild. Of course, that does not mean that databases unfaithfully execute correctly. Indeed, COBRA gives us a way, for the first time, to get confidence in the observed executions of these black box databases.

Figure 1: COBRA’s architecture. The dashed rectangle is a trust domain. The verifier is off the critical path but must keep up on average.

2 Overview and technical background

2.1 Setup and scenarios

Figure 1 depicts COBRA’s architecture. *Clients* issue requests to a *database* (a transactional key-value store) and receive results. The database is untrusted: the results can be arbitrary.

Each client request is one of five operations: start, commit, abort (which refer to *transactions*), and read and write (which refer to *keys*).

History collectors sit between clients and the database, capturing the requests that clients issue and the (possibly wrong) results delivered by the database. This capture is a *fragment of a history*. A *history* is a set of operations; it is the union of the fragments from all collectors.

A *verifier* retrieves history fragments from collectors and attempts to verify whether the history is *serializable*; we make this term precise below (§2.2).

The verifier proceeds in *rounds*; each round consists of a witness search, the input to which is logically the output of the previous round and new history fragments. The verifier must work against an online and continuously available database; however, the verifier performs its work in the background, off the critical path.

The verifier requires the full history including all requests to, and responses from, the database. COBRA assumes that neither the verifier nor the collectors crash (we revisit in §8).

Clients issue operations to a database through *sessions*; a client can have multiple simultaneous sessions. Within a session, transactions do not overlap (requests are blocking). Thus, a client can be multithreaded but not event-driven.

Clients, history collectors, and the verifier are in the same trust domain. This architecture is relevant in real-world scenarios. Consider for example an enterprise web application whose end-users are geo-distributed employees of the enterprise. The application servers run on the enterprise’s hardware while the back-end of the web application is a cloud database [27]. Note that our *clients* are the application servers, as clients of the database. A similarly structured example is online gaming, where the main program runs on company-owned servers while the user data is stored in a cloud database [24].

In these scenarios, the verifier runs on hardware belonging to the trust domain. There are several options, meanwhile, for the collectors. Collectors can be middleboxes situated at the

edge of the enterprise or gaming company, allowing them to capture the requests and responses between the database clients and the cloud database. Another option is to run the collector in an untrusted cloud, using a Trusted Execution Environment (TEE), such as Intel’s SGX. Recent work has demonstrated such a collector [46], as a TLS proxy that logs inbound and outbound messages, thereby ensuring (via the fact that clients expect the server to present a valid SSL/TLS certificate) that clients’ requests and responses are indeed logged.

Verifier’s performance requirement. The verifier’s performance will be reported as capacity (transactions/sec); this capacity must be at least the average offered load seen by the database over some long interval, for example a day. Note that the verifier’s capacity need not match the database’s *peak* load: because the verifier is off the critical path, it can catch up.

2.2 Verification problem statement

Preliminaries. We work within Adya’s canonical framework for specifying isolation levels [38], as summarized below.

First, assume that each database write creates a unique *version* for the given key, and each transaction reads and writes a key at most once; thus, any read can be associated with the transaction that issued the corresponding write. COBRA discharges this assumption in the client library (§5), which embeds a unique id in each write and consumes the id on a read.

In Adya’s formalism, a *history* is a set of operations performed by transactions (as in COBRA, §2.1), together with a *version order* [38, §3.1.2]: for each key, a total order of committed versions. The version order comes from within the database and is not exposed externally. In COBRA, history is collected outside the database so doesn’t contain a version order. (COBRA’s history is also known as a *multi-version log* [54], as discussed in Appendix B [132]).

A history is *serializable*, if there exists a total order on the committed transactions such that executing transactions in this order produces the same result as in the history (in Adya’s formalism, an additional requirement for serializability is that the aforementioned total order is consistent with the given version order). *Strictly serializable* [110] is the same as serializable, except that the total order must also obey real time: if a transaction T_i commits before T_j starts in real time, T_i appears earlier than T_j in the total order.

A history imposes *dependencies*. Specifically, a history (without a version order) induces *read-dependencies* (a transaction T_j reads the value written by transaction T_i , denoted $T_i \rightarrow T_j$). Adding a version order yields two other kinds of dependencies: *write-dependency* (T_i writes a key, and T_j overwrites it, so $T_i \rightarrow T_j$), and *anti-dependency* (T_i reads a value that is overwritten by T_j , so $T_i \rightarrow T_j$).

A *serialization graph* (of a history and a given version order) is a graph whose vertices are all transactions in the history and edges are all dependencies described above. Note that aborted and ongoing transactions are not in the serialization graph.

Figure 2: The verifier's process, within a round and across rounds.

The core problem. An important fact is that a history H is serializable iff there exists a version order such that the serialization graph arising from H and that version order is acyclic [54]. Based on this fact, the core problem is to identify such a serialization graph (that arises from H and some version order), or assert that none exists.

Notice that this problem would be straightforward if the database revealed its internal ordering, thus deciding a version order and all dependencies: one could construct the corresponding serialization graph, and test it for acyclicity. Indeed, that is a well-established family of techniques [65, 138]. But the version order is unavailable in our context, so we have to consider all possible version orders, and test whether any of the implied sets of dependencies yields an acyclic serialization graph.

2.3 Starting point: intuition and brute force

This section describes a brute-force solution, which serves as the starting point for COBRA and gives intuition. The approach relies on a data structure called a *polygraph* [110], which captures unknown dependencies.

In a polygraph, vertices (V) are transactions and edges (E) are read-dependencies. Note that read-dependencies are evident from the history because values are unique, by assumption (§2.2). There is a set, C , which we call *constraints*, that captures possible (but unknown) dependencies. Here is an example polygraph:

It has three vertices $V = \{T_1, T_2, T_3\}$, one known edge in $E = \{(T_1, T_3)\}$ from the known read-dependency $W_1(x) \rightarrow R_3(x)$, and one constraint $\langle (T_3, T_2), (T_2, T_1) \rangle$ which is shown as two dashed arrows connected by an arc. This constraint captures the fact that T_2 cannot happen in between T_1 and T_3 , because otherwise T_3 should have read x from T_2 instead of from T_1 . Hence T_2 has to happen either after T_3 or before T_1 , but it is unknown which option is the truth.

Formally, a *polygraph* $P = (V, E, C)$ is a directed graph (V, E) which we call the *known graph*, together with a set of *bipaths*, C ; that is, pairs of edges—not necessarily in E —of the form $\langle (v, u), (u, w) \rangle$ such that $(w, v) \in E$. A bipath of that form can be read as “either u happened after v , or else u happened before w ”. Now, define the *polygraph* (V, E, C) associated with a history, as follows [138]:

- V are all committed transactions in the history

- $E = \{(T_i, T_j) \mid T_j \text{ reads from } T_i\}$. Notation: $T_i \xrightarrow{\text{wr}(x)} T_j$, for some x .
- $C = \{ \langle (T_j, T_k), (T_k, T_i) \rangle \mid (T_i \xrightarrow{\text{wr}(x)} T_j) \wedge (T_k \text{ writes to } x) \wedge T_k \neq T_i \wedge T_k \neq T_j \}$.

The edges in E capture all read-dependencies, which as noted are evident from the history. C captures how uncertainty is encoded into constraints. Specifically, for each read-dependency in the history, all other transactions that write the same key happen either after the given read or before the given write.

A directed graph is called *compatible* with a polygraph if the graph has the same nodes and known edges in the polygraph, and the graph chooses one edge out of each constraint; one can think of such a graph as a solution to the constraint satisfaction problem posed by the polygraph. Formally, a graph (V', E') is *compatible* with a polygraph (V, E, C) if: $V = V'$, $E \subseteq E'$, and $\forall \langle e_1, e_2 \rangle \in C, (e_1 \in E' \wedge e_2 \notin E') \vee (e_1 \notin E' \wedge e_2 \in E')$.

A crucial fact (proved in Appendix B [132]) is: there exists an acyclic directed graph that is compatible with the polygraph associated to a history H , iff there exists an acyclic serialization graph G of H . Furthermore, we have seen that if there is such an acyclic serialization graph for H , then H is serializable (§2.2). Putting these facts together yields a brute-force approach for verifying serializability: first, construct a polygraph from a history; second, search for a compatible graph that is acyclic. However, not only does this approach need to consider $|C|$ binary choices ($2^{|C|}$ possibilities) but also $|C|$ is massive: it is a sum of quadratic terms, specifically $\sum_{k \in \mathcal{K}} r_k \cdot (w_k - 1)$, where \mathcal{K} is the set of keys in the history, and each r_k and w_k are the number of reads and writes of key k .

3 Verifying serializability in COBRA

Figure 2 depicts the major components of verification. This section covers one round of verification. As a simplification, assume that the round runs in a vacuum; Section 4 discusses how rounds are linked.

COBRA uses the MonoSAT SMT solver [52], which is geared to graph properties (§3.4). Nevertheless, the brute-force encoding (§2.3) would overwhelm even MonoSAT (§6.1).

COBRA refines that encoding in several ways. It introduces *write combining* (§3.1) and *coalescing* (§3.2). These techniques are motivated by common patterns that impose restrictions on the search space. COBRA’s verifier also does its own inference (§3.3) before invoking the solver. This is motivated by observing that (a) all-pairs reachability information (in the “known edges”) yields quick resolution of many constraints,

```

1: procedure CONSTRUCTENCODING(history)
2:    $g, readfrom, wwpairs \leftarrow \text{CreateKnownGraph}(\text{history})$ 
3:    $con \leftarrow \text{GenConstraints}(g, readfrom, wwpairs)$ 
4:    $con, g \leftarrow \text{Prune}(con, g)$  // §3.3, executed one or more times
5:   return  $con, g$ 
6:
7: procedure CREATEKNOWNGRAPH(history)
8:    $g \leftarrow \text{empty Graph}$  // the known graph
9:    $wwpairs \leftarrow \text{Map} \{ \langle \text{Key}, \text{Tx} \rangle \rightarrow \text{Tx} \}$  // consecutive writes
10:   $readfrom \leftarrow \text{Map} \{ \langle \text{Key}, \text{Tx} \rangle \rightarrow \text{Set}(\text{Tx}) \}$  // maps a write to its readers
11:  for transaction  $tx$  in  $history$ :
12:     $g.Nodes \mathrel{+}= tx$ 
13:    for read operation  $rop$  in  $tx$ :
14:       $g.Edges \mathrel{+}= (rop.read\_from\_tx, tx)$  // read-dependencies
15:       $readfrom[\langle rop.key, rop.read\_from\_tx \rangle] \mathrel{+}= tx$ 
16:
17:    // detect RMW (read-modify-write) transactions
18:    for all Keys  $key$  that are both read and written by  $tx$ :
19:       $rop \leftarrow$  the operation in  $tx$  that reads  $key$ 
20:      if  $wwpairs[\langle key, rop.read\_from\_tx \rangle] \neq \text{null}$ :
21:        REJECT // multiple consecutive writes, not serializable
22:       $wwpairs[\langle key, rop.read\_from\_tx \rangle] \leftarrow tx$ 
23:
24:  add session order edges to  $g$  // §4.2
25:  return  $g, readfrom, wwpairs$ 
26:
27: procedure GENCONSTRAINTS( $g, readfrom, wwpairs$ )
28:  // each key maps to set of chains; each chain is an ordered list
29:   $chains \leftarrow \text{empty Map} \{ \text{Key} \rightarrow \text{Set}(\text{List}) \}$ 
30:  for transaction  $tx$  in  $g$ :
31:    for write  $wrop$  in  $tx$ :
32:       $chains[wrop.key] \mathrel{+}= [tx]$  // one-element list
33:
34:  CombineWrites( $chains, wwpairs$ ) // §3.1
35:  InferRWEEdges( $chains, readfrom, g$ ) // infer anti-dependency
36:
37:   $con \leftarrow \text{empty Set}$ 
38:  for  $\langle key, chainset \rangle$  in  $chains$ :
39:    for every pair  $\{chain_i, chain_j\}$  in  $chainset$ :
40:       $con \mathrel{+}= \text{Coalesce}(chain_i, chain_j, key, readfrom)$  // §3.2
41:
42:  return  $con$ 
43:
44: procedure COMBINEWITES( $chains, wwpairs$ )
45:  for  $\langle key, tx_1, tx_2 \rangle$  in  $wwpairs$ :
46:    // By construction of  $wwpairs$ ,  $tx_1$  is the write immediately
47:    // preceding  $tx_2$  on  $key$ . Thus, we can sequence all writes
48:    // prior to  $tx_1$  before all writes after  $tx_2$ , as follows:
49:     $chain_1 \leftarrow$  the list in  $chains[key]$  whose last elem is  $tx_1$ 
50:     $chain_2 \leftarrow$  the list in  $chains[key]$  whose first elem is  $tx_2$ 
51:     $chains[key] \setminus = \{chain_1, chain_2\}$ 
52:     $chains[key] \mathrel{+}= \text{concat}(chain_1, chain_2)$ 
53:
54: procedure INFERRWEEdges( $chains, readfrom, g$ )
55:  for  $\langle key, chainset \rangle$  in  $chains$ :

85:       $g.Edges \leftarrow g.Edges \cup edge\_set_1$ 
86:       $con \mathrel{-}= c$ 
87:
88:  return  $con, g$ 

```

Figure 3: COBRA’s procedure for converting a history into a constraint satisfaction problem (§3). After this procedure, COBRA feeds the results (a graph of known edges G and set of constraints C) to a constraint solver (§3.4), which searches for a graph that includes the known edges from G , meets the constraints in C , and is acyclic. We prove the algorithm’s validity in Appendix B [132].

and (b) computing that information is amenable to acceleration on parallel hardware such as GPUs (§5).

Figure 3 depicts the algorithm that constructs COBRA’s encoding and shows how the techniques combine. Note that COBRA relies on a generalized notion of constraints. Whereas previously a constraint was a pair of edges, now a constraint is a pair of *sets of edges*. Meeting a constraint $\langle A, B \rangle$ means including all edges in A and excluding all in B , or vice versa. More formally, we say that a graph (V', E') is *compatible* with a known graph $G = (V, E)$ and generalized constraints C if: $V = V'$, $E \subseteq E'$, and $\forall \langle A, B \rangle \in C, (A \subseteq E' \wedge B \cap E' = \emptyset) \vee (A \cap E' = \emptyset \wedge B \subseteq E')$.

We prove the validity of COBRA’s encoding in Appx B [132]. Specifically we prove that *there exists an acyclic graph that is compatible with the constraints constructed by COBRA on a given history if and only if the history is serializable*.

3.1 Combining writes

COBRA exploits the read-modify-write (RMW) pattern, in which a transaction reads a key and then writes the same key. The pattern is common in real-world scenarios, for example shopping: in one transaction, get the number of an item in stock, decrement, and write back the number. COBRA uses RMWs to impose order on writes; this reduces the orderings that the verification procedure would otherwise have to consider. Here is an example:

There are four transactions, all operating on the same key. Two of the transactions are RMW, namely R_2, W_2 and R_4, W_4 . On the left is the basic polygraph (§2.3). It has four constraints (each in a different color), derived from the two read-dependencies.

COBRA goes further, inferring *chains*. A single chain comprises a *sequence of transactions whose write operations are consecutive*; in the figure, a chain is indicated by a shaded area. Notice that the only ordering possibilities exist at the granularity of chains (rather than individual writes); in the example, the two possibilities of course are $[W_1, W_2] \rightarrow [W_3, W_4]$ and $[W_3, W_4] \rightarrow [W_1, W_2]$. This is a reduction in the possibility space; for instance, the original version considers the possibility that W_3 is immediately prior to W_1 (the upward dashed black arrow), but COBRA “recognizes” the impossibility of that.

To construct chains, COBRA initializes every write as a one-element chain (Figure 3, line 32). Then, COBRA consolidates chains: for each RMW transaction t and the transaction t' that contains the prior write, COBRA concatenates the chain containing t' and the chain containing t (lines 22 and 44–51).

If a transaction t , which is *not* an RMW, reads from a transaction u , then t requires an anti-dependency edge to u ’s successor (call it v); otherwise, t could appear in the graph downstream of v , which would mean t actually read from v (or even from a later write), which does not respect history. COBRA creates the needed edge $t \rightarrow v$ in InferRWEdges (Figure 3, line 53). Note that in the brute-force approach (§2.3), analogous edges appear as the first component in a constraint.

3.2 Coalescing constraints

This technique exploits the fact that, in many real-world workloads, there are far more reads than writes. At a high level, COBRA combines all reads that read-from the same write. We give an example and then generalize.

In the above figure, there are five single-operation transactions, to the same key. On the left is the basic polygraph (§2.3), which contains three constraints; each is in a different color. Notice that all three constraints involve the question: which write happened first, W_1 or W_2 ?

One can represent the possibilities as a constraint $\langle A', B' \rangle$ where $A' = \{(W_1, W_2), (R_3, W_2), (R_4, W_2)\}$ and $B' = \{(W_2, W_1), (R_5, W_1)\}$. In fact, COBRA does not include (W_1, W_2) because there is a known edge (W_1, R_3) , which, together with (R_3, W_2) in A' , implies the ordering $W_1 \rightarrow R_3 \rightarrow W_2$, so there is no need to include (W_1, W_2) . Likewise, COBRA does not include (W_2, W_1) on the basis of the known edge (W_2, R_5) . So COBRA includes the constraint $\langle A, B \rangle = \langle \{(R_3, W_2), (R_4, W_2)\}, \{(R_5, W_1)\} \rangle$ in the figure.

To construct constraints using the above reductions, COBRA does the following. Whereas the brute-force approach uses all reads and their prior writes (§2.3), COBRA considers particular *pairs of writes*, and creates constraints from these writes and their following reads. The particular pairs of writes are the first and last writes from all pairs of chains pertaining to that key. In more detail, given two chains, $chain_i, chain_j$, COBRA constructs a constraint c by (i) creating a set of edges ES_1 that point from reads of $chain_i.tail$ to $chain_j.head$ (Figure 3, lines 71–72); this is why COBRA does not include the (W_1, W_2) edge above. If there are no such reads, ES_1 is $chain_i.tail \rightarrow chain_j.head$ (Figure 3, line 67); (ii) building another edge set ES_2 that is the other way around (reads of $chain_j.tail$ point to $chain_i.head$, etc.), and (iii) setting c to be $\langle ES_1, ES_2 \rangle$ (Figure 3, line 63).

3.3 Pruning constraints

Our final technique mines information that is encoded in paths in the known graph, to cull irrelevant possibilities en masse. The underlying logic is almost trivial. The interesting aspect is that the technique is enabled by a design decision to accelerate the computation of reachability on parallel hardware (§5 and Figure 3, line 77); this can be done since the computation is iterated (Boolean) matrix multiplication. Here is an example:

The constraint is $\langle (R_3, W_2), (W_2, W_1) \rangle$. Having precomputed reachability, COBRA knows that the first choice cannot hold, as it creates a cycle with the path $W_2 \rightsquigarrow R_3$; COBRA thereby concludes that the second choice holds. Generalizing, if COBRA determines that an edge in a constraint generates a cycle, COBRA throws away both components of the entire constraint and adds all the other edges to the known graph (Figure 3, lines 78–84). In fact, COBRA prunes multiple times, if necessary (§5).

3.4 Solving

The remaining step is to search for an acyclic graph that is compatible with the known graph and constraints, as computed in Figure 3. COBRA does this with a constraint solver. However, traditional solvers do not perform well on this task because encoding graph acyclicity as a set of SAT formulas is expensive (a claim by Janota et al. [91], which we also observed; §6.1).

COBRA instead uses MonoSAT, which is a particular kind of SMT solver [57] that includes SAT modulo *monotonic* theories [52]. This solver efficiently encodes and checks graph properties, such as acyclicity.

COBRA represents a verification problem instance (a graph G and constraints C) as follows. COBRA creates a Boolean variable $E_{(i,j)}$ for each vertex-vertex pair; True (resp., False) means the searched-for compatible graph has (resp., does not have) the given edge. For each edge in the known graph G , COBRA sets the corresponding Boolean variable to be True. For the

constraints C , recall that each constraint $\langle A, B \rangle$ is a pair of sets of edges, and represents a mutually exclusive choice to include either all edges in A or else all edges in B . COBRA encodes this in the natural way: $((\forall e_a \in A, e_a) \wedge (\forall e_b \in B, \neg e_b)) \vee ((\forall e_a \in A, \neg e_a) \wedge (\forall e_b \in B, e_b))$. (By abuse of notation, we have used e_a and e_b to refer to the corresponding E_{ij} variable.) Finally, COBRA enforces the acyclicity of the searched-for compatible graph (that is, the graph whose edges are given by the E_{ij} that are set to True); COBRA does so by invoking a primitive provided by the solver.

COBRA vs. MonoSAT. One might ask: if COBRA’s encoding makes MonoSAT faster, why use MonoSAT? Can we take the domain knowledge further? Indeed, in the limiting case, COBRA could re-implement the solver! However, MonoSAT, as an SMT solver, leverages many prior optimizations. One way to understand COBRA’s decomposition of function is that COBRA’s preprocessing exploits some of the structure created by the problem of verifying serializability, whereas the solver is exploiting residual structure common to many graph problems.

3.5 On strict serializability

COBRA’s verifier checks strict serializability [56, 110] by adding *real-order edges* [38]—which capture the order of non-overlapping transactions in real time—to the known graph. The verifier then performs the serializability checking algorithm of Figure 3; as a result, the serialization order (in the searched-for compatible graph) respects the real-time order.

To get real-order edges, the verifier needs *timestamps* for each operation. The verifier can get them either from the database if it exposes the relevant interface (for example, Google Spanner [69]) or else from COBRA’s collectors. A naive way to go from timestamps to real-order edges is to examine every pair of transactions, and create a real-order edge when one transaction’s commit timestamp is less than another’s start timestamp. But this approach runs in time quadratic in the number of transactions. Instead, COBRA borrows a prior algorithm [131, Fig. 6], which materializes the time precedence partial order in time $O(n + z)$, where n is the number of transactions and z is the minimum number of real-order edges needed.

A challenge is that clock drift in collectors makes it unsafe to infer real-time precedence relationships from timestamps. To tackle this problem, COBRA introduces a *clock drift threshold* (100ms [15] by default). COBRA assumes that clock differences among collectors do not exceed this threshold; if they do, COBRA may falsely reject a serializable history. With this assumption, COBRA increases transactions’ commit timestamps by the threshold. Thus, if two transactions have a real-order edge, one’s original commit timestamp is earlier than the other transaction’s start timestamp by at least the clock drift threshold. As a consequence, all transactions within a clock drift threshold are concurrent. Within such an interval, the verifier faces the computational expense that exists when there are no real-order edges, which calls for COBRA’s techniques (§3.1–§3.3) to accelerate verification (see §6.1 for relevant experiments).

4 Garbage collection and scaling

COBRA verifies in rounds. There are two motivations for rounds. First, new history is continually produced, of course. Second, there are limits on the maximum problem size (number of transactions) that the verifier can handle (§6.2); breaking the task into rounds keeps each solving task manageable.

In the first round, a verifier starts with nothing and creates a graph from `CREATEKNOWNGRAPH`, then does verification. After that, the verifier receives more client histories; it reuses the graph from the last round (the g in `CONSTRUCTENCODING`, Figure 3, line 5), and adds new nodes and edges to it from the new history fragments received (Figure 2).

The technical problem is to keep the input to verification bounded. So the question COBRA must answer is: which transactions can be deleted safely from history? Below, we describe the challenge (§4.1), the core mechanism of fence transactions (§4.2), and how the verifier deletes safely (§4.3). In this section, we describe the general rules and insights; a complete specification and correctness proof are in Appendix C [132].

4.1 The challenge

The core challenge is that past transactions can be relevant to future verifications; specifically, deleting a past transaction could cause the verifier to overlook future cycles.

Suppose a verifier saw three transactions (T_1, T_2, T_3) and wanted to remove T_2 (the shaded transaction) from consideration in future rounds. Later, the verifier observes a new transaction T_4 that violates serializability (and a fortiori, strict serializability) by reading from T_1 and T_3 . To see the violation, notice that T_2 is logically subsequent to T_4 , which generates a cycle ($T_4 \rightarrow T_2 \rightsquigarrow T_3 \rightarrow T_4$). Yet, if we remove T_2 , there is no cycle. Hence, removing T_2 is not safe: future verifications would fail to detect certain kinds of serializability violations.

Note that this example does not require malicious or exotic behavior. For example, consider a geo-replicated database: a client can retrieve a stale version from a local replica.

4.2 Epochs and fence transactions

COBRA addresses this challenge by creating *epochs* that impose a coarse-grained ordering on transactions; the verifier can then discard information from older epochs. To avoid confusion, note that epochs are a separate notion from rounds: a verification round includes multiple epochs.

To memorialize epoch boundaries in history, clients issue *fence transactions*. A fence transaction is a transaction that reads-and-writes a single key named “EPOCH” (a dedicated

key that is used by fence transactions only). Each client issues fence transactions periodically (for example, every 20 transactions).

What prevents the database from defeating the point of epochs by placing all of the fence transactions at the beginning of a notional serial schedule? COBRA leverages a property of practical serializable databases: preserved *session order*. That is, the serialization order must obey the execution order within each session (defined in §2.1). Many production databases (for example, PostgreSQL, Azure Cosmos DB, and Google Cloud Datastore) provide this property; for those which do not, COBRA requires clients to build the session order, for example, by mandating that all transactions from the same session include a read-modify-write to a distinguished (per-session) key. Since transactions' serialization order obeys the session order, the epoch ordering intertwines with the workload. Indeed, the verifier adds to the known graph *session-order edges* (Figure 3, line 24), which capture the transaction issuing order in each session; the verifier gets that per-session order from collectors, which observe it directly.

The verifier also assigns an *epoch number* to each transaction. To do so, the verifier traverses the known graph (g), locates all the fence transactions, chains them into a list based on the RMW relation (§3.1), and assigns their position in the list as their epoch numbers. Then, the verifier scans the graph again, and for each normal transaction in a session that is between fences with epoch i and epoch j ($j \geq i + 1$), the verifier assigns epoch number $j - 1$.

During the scan, the verifier keeps track of the largest epoch number that has been seen or surpassed by every session, called $epoch_{agree}$. Then we have the following guarantee.

Guarantee. For any transaction T_i whose epoch $\leq (epoch_{agree} - 2)$, and for any transaction (including future ones) T_j whose epoch $\geq epoch_{agree}$, the known graph g contains a path $T_i \rightsquigarrow T_j$.

To see why the guarantee holds, consider the path in three parts. First, for the fence transaction with epoch number $epoch_{agree}$ (denoted F_{ea}), g must have a path $F_{ea} \rightsquigarrow T_j$, through session-order edges. Similarly, for the fence transaction after T_i issued by the same session (denoted $F_{ea-\Delta}$), g has $T_i \rightsquigarrow F_{ea-\Delta}$. Finally, T_i has epoch $\leq (epoch_{agree} - 2)$, so $F_{ea-\Delta}$ must have epoch $\leq (epoch_{agree} - 1)$. Thus, $F_{ea-\Delta} \rightsquigarrow F_{ea}$ in g .

4.3 Garbage collection

COBRA takes a conservative approach. A transaction T can be safely deleted, if

- (i) T has been *superseded*, meaning that no future transactions can precede T or directly succeed T in the known graph; and
- (ii) T is not involved in any potential cycle that includes edges from constraints whose resolution could be affected by future transactions.

Below, we delve into condition (i), then motivate condition (ii), and finally describe COBRA's procedure for garbage collection.

Identifying superseded transactions. Define the *frontier* as the set of transactions that contain the most recent writes to keys among transactions with epoch number $\leq (epoch_{agree} - 2)$. The frontier captures the earliest transactions that future transactions can possibly read. A transaction T is *superseded* if: (1) T does not belong to the frontier, (2) T has epoch number $\leq (epoch_{agree} - 2)$, and (3) for any transaction T' that has a path to T in the known graph, T' has epoch number $\leq (epoch_{agree} - 2)$. Note that condition (2) does not subsume condition (3): we could have $T' \rightsquigarrow T$ with T' having a larger epoch than T (the Guarantee in §4.2 does not apply to transactions whose epochs differ by one).

At a high level, if a transaction T is superseded, the verifier can conclude that no future transactions should read from T ; such a future transaction would have to be ordered before some frontier transaction, which makes a cycle by having a path back to the future transaction, per the Guarantee (§4.2). Thus T is a *candidate* to delete. However, being superseded is not a sufficient condition for safe deletion, as we illustrate next.

Superseded does not imply disposable. Here is an example:

The shaded transaction (T_3) is superseded (T_3 and its predecessor T_2 have epochs $\leq epoch_{agree} - 2$, and T_3 does not belong to the frontier). Now consider the effect of future transactions T_7 and T_8 . T_8 operates on key c ; the other operations on this key are $W_4(c)$ and $W_5(c)$. By the guarantee (§4.2), both T_4 and T_5 happen before T_8 . Plus, $R_8(c)$ reads from $W_5(c)$, hence $W_4(c)$ must happen before $W_5(c)$ (otherwise, $R_8(c)$ should have read from $W_4(c)$). Consequently, the constraint $\langle (T_5, T_4), (T_4, T_3) \rangle$, which arises from key b , is solved: $T_4 \rightarrow T_3$ is chosen. Similarly, because of $R_7(d)$, the other constraint (concerning key a) is solved and $T_3 \rightarrow T_1$. Thus, there is a cycle ($T_1 \rightsquigarrow T_4 \rightarrow T_3 \rightarrow T_1$). Yet, deleting T_3 would make the cycle undetectable.

The core issue here is that future transactions can affect the resolution of constraints among “old” transactions.

Identifying safe transactions. To garbage collect, the verifier clones the known graph (g in Fig. 3) into g' . Then, for each constraint (con in Fig. 3), the verifier adds all edges in both edge sets to g' . Finally, for each superseded transaction T , if T does not belong to any cycles in g' or belongs to cycles consisting only of superseded transactions, the verifier deletes T . This approach meets conditions (i) and (ii), as argued in Appendix C [132].

COBRA component	LOC written/changed

history parser and others	1.2k lines of Java

Figure 4: Components of COBRA implementation.

5 Implementation

Figure 4 lists the components of COBRA’s implementation. COBRA’s client library wraps other database libraries: JDBC, Google Datastore library, and RocksJava. It enforces the assumption of uniquely written values (§2.2), by adding a unique id to a client’s writes, and stripping them out of reads. It also issues fence transactions (§4.2). Finally, we implement history collection (§2.1) in this library (the library writes operations to disk before sending them to the database); a better implementation would place this function in a proxy.

The verifier iterates the pruning logic within a round, stopping when it finds nothing more to prune or when it reaches a configurable maximum number of iterations (to bound the verifier’s work); a better implementation would stop when the cost of the marginal pruning iteration exceeds the improvement in the solver’s running time brought by this iteration.

Another aspect of pruning is GPU acceleration. Recall that pruning works by computing the transitive closure of the known edges (Figure 3, line 77). COBRA uses the standard algorithm: repeated squaring of the Boolean adjacency matrix [70, Ch.25] as long as the matrix keeps changing, up to $\log |V|$ matrix multiplications. ($\log |V|$ is the worst case and occurs when two nodes are connected by a $(\geq |V|/2 + 1)$ -step path; at least in our experiments, this case does not arise much.) The execution platform is cuBLAS [12] (a dense linear algebra library on GPUs) and cuSPARSE [13] (a sparse linear algebra library on GPUs), which contain matrix multiplication routines.

COBRA includes several optimizations. It invokes a specialized routine for triangular matrix multiplication (after testing the graph for acyclicity and then indexing the vertices according to a topological sort, creating a triangular matrix). COBRA also exploits sparse matrix multiplication (cuSPARSE), and moves to ordinary (dense) matrix multiplication when the density exceeds a threshold (namely, “5% of the matrix elements are non-zero”, the empirical cross-over point that we observed).

When COBRA’s verifier detects a serializability violation, it creates a certificate with problematic transactions: either a cycle in the known graph (detected by COBRA’s algorithms) or else a set of unsatisfiable clauses (produced by MonoSAT).

Figure 5: COBRA’s running time is shorter than other baselines’ on the BlindW-RW workload. The same holds on the other benchmarks (not depicted). Verification runtime grows superlinearly.

6 Experimental evaluation

We answer three questions:

- What are the verifier’s costs and limits, and how do these compare to baselines?
- What is the verifier’s end-to-end, round-to-round *sustainable capacity*? This determines the offered load (on the actual database) that the verifier can support.
- How much runtime overhead (in terms of throughput and latency) does COBRA impose for clients? And what are COBRA’s storage and network overheads?

Benchmarks and workloads. We use four benchmarks:

- *TPC-C* [31] is a standard. A warehouse has 10 districts with 30k customers. There are five types of transactions (frequencies in parentheses): new order (45%), payment (43%), order status (4%), delivery (4%), and stock level (4%). In our experiments, we use one warehouse, and clients issue transactions based on the frequencies.
- *C-Twitter* [8] is a simple clone of Twitter, according to Twitter’s own description [8]. Users can tweet a new post, follow/unfollow other users, and show a timeline (the latest tweets from followed users). Our experiments include 1000 users. Each user tweets 140-word posts and follows/unfollows other users based on a Zipfian distribution ($\alpha = 100$).
- *C-RUBiS* [30, 41] simulates bidding systems like eBay [30]. Users can register accounts, register items, bid for items, and comment on items. We initialize the market with 20k users and 200k items.
- *BlindW* measures COBRA’s performance in extreme scenarios, specifically those with many blind writes (that is, writes not preceded by a read of the same key in the same transaction); this pattern is the fundamental source of uncertainty in constraints (§3). This benchmark creates 10k keys, and runs read-only and write-only transactions, each with eight operations. It has three variants: (1) *BlindW-RM* (Read Mostly), with 90% read-only transactions; (2) *BlindW-RW* (Read-Write), evenly divided between read-only and write-only transactions; and (3) *BlindW-WM* (Write Mostly), with 90% write-only transactions.

Violation	Database	#Txns	Time
G2-anomaly [19]	YugaByteDB 1.3.1.0	37.2k	66.3s
Disappearing writes [1]	YugaByteDB 1.1.10.0	2.8k	5.0s
G2-anomaly [18]	CockroachDB-beta 20160829	446	1.0s
Read uncommitted [26]	CockroachDB 2.1	20*	1.0s
Read skew [25]	FaunaDB 2.5.4	8.2k	11.4s

Figure 6: Serializability violations that COBRA checks. “Violation” describes the phenomenon that clients experience. “Database” is the database (with version number) that causes the violation. “#Txns” is the size of the violation history. “Time” is the runtime for COBRA to detect the violation.

* The bug report only contains a small fragment of the history.

Databases and setup. We evaluate COBRA on Google Cloud Datastore [21], RocksDB [29, 74] (both provide a key-value API), and PostgreSQL [28, 114] (which only supports the SQL interface, COBRA translates SQL queries to key-value operations). In our experimental setup, clients interact with Google Cloud Datastore through the wide-area Internet, and connect to a PostgreSQL server through a local 1 Gbps network. One client starts one session.

Database clients run on two machines with a 3.3GHz Intel i5-6600 (4-core) CPU, 16GB memory, a 250GB SSD, and Ubuntu 16.04. For PostgreSQL, a database instance runs on a machine with a 3.8GHz Intel Xeon E5-1630 (8-core) CPU, 32GB memory, a 1TB disk, and Ubuntu 16.04. For RocksDB, the same machine hosts the client threads and RocksDB threads, which all run in the same process. We use a *p3.2xlarge* Amazon EC2 instance as the verifier, with an NVIDIA Tesla V100 GPU, a 8-core CPU, and 64GB memory.

6.1 One-shot verification

In this section, we consider “one-shot verification”: a verifier gets a history and decides whether that history is serializable. In our setup, clients record history fragments and store them as files; a verifier reads them from the local file system. In this section, the database is RocksDB (PostgreSQL and Google Cloud Datastore give similar results).

Baselines. We have four baselines:

- **A non-SAT serializability-checking algorithm (“nonSAT”):** To the best of our knowledge, the most efficient work for checking serializability that is not based on SAT or SMT solving is Biswas and Enea [59]. In our experiments, we use their Rust implementation [58].
- **SAT solver (“MiniSAT-BE”):** We use the same solving baseline that Biswas and Enea use for their own comparisons [59]: encoding serializability verification into SAT formulas, and feeding this encoding to MiniSAT [76], a popular SAT solver.
- **COBRA, subtracted (“MonoSAT-polygraph”):** We implement the original polygraph (§2.3), directly encode the constraints (without the techniques of §3), and feed them to the MonoSAT SMT solver [52].
- **SMT solver (“Z3-arith”):** An alternative use of SMT, and

Figure 7: Decomposition of COBRA runtime, on 10k-transaction workloads. Pruning dominates for read-mostly workloads, whereas solving dominates for workloads with many writes.

a natural baseline, is a linear arithmetic encoding: each node is assigned a distinct integer index, with read-from relationships creating inequality constraints, and writes inducing additional constraints (for a total of $O(|V|^2)$ constraints, as in §2.3). The solver is then asked to map nodes to integers, subject to those constraints [80, 91]. We use Z3 [73] as the solver (experiments below use Z3’s default configuration; we also experimented with all four builtin linear integer arithmetic tactics, which produce similar results).

As a special case, there is an alternative baseline for TPC-C that has the same performance as COBRA and beats other baselines. Namely, for RMW transactions, add inferred read-dependency and write-dependency edges to a candidate graph (without constraints, so potentially missing dependency information), topologically sort it, and check whether the result matches history; if not, repeat. This process has even worse order complexity than the brute-force approach (§2.3). However, it works for TPC-C because that workload has *only* RMW transactions. Effectively, all of history coalesces to a single, correctly-ordered chain (§3.1), yielding a serialization graph.

In the experiments below, the baselines and COBRA make use of session order edges (§4.2; also called *program order* in BE [59] and its implementation [58]).

Verification runtime vs. number of transactions. We compare COBRA to other baselines, on the various workloads. We use 24 clients. We vary the number of transactions in the workload, and measure the verification time. Figure 5 depicts the results on the BlindW-RW benchmark. On all five benchmarks, COBRA does better than MonoSAT-polygraph and Z3-arith, which do better than MiniSAT-BE and nonSAT.

Detecting serializability violations. We investigate COBRA’s performance on unsatisfiable instances: does COBRA search for an unacceptably long time on real-world workloads? We consider five workloads that are known to have serializability violations [1, 18, 19, 25, 26]. We experiment by downloading the reported histories from their bug repositories and feeding them to COBRA’s verifier. Figure 6 shows the results. COBRA detects all violations and finishes in reasonable time.

Figure 8: Differential analysis on several workloads, log-scale, with runtime above bars. Experiments time out at 10min (dotted line); no runtime is shown for timed-out experiments. On TPC-C, combining writes exploits the RMW pattern and solves all the constraints. On C-Twitter, each of COBRA’s components contributes meaningfully. On BlindW-RW, pruning is essential, because the workload has many blind writes which cannot benefit from the other two techniques.

Figure 9: COBRA’s running time is shorter than other baselines’ on checking strict serializability under clock drift. The workload is 2,000 transactions of BlindW-RW (clock drift threshold of 100 ms).

Decomposition of COBRA’s verification runtime. We measure the wall clock time of COBRA’s verification, broken into stages: *constructing*, which includes creating the known graph, combining writes, and creating constraints (§3.1–§3.2); *pruning* (§3.3), which includes the time taken by the GPU; and *solving* (§3.4), which includes the time spent within MonoSAT. We experiment with all benchmarks, with 10k transactions.

Figure 7 depicts the results. In benchmarks with RMWs only (the left one), there are no constraints, so COBRA doesn’t prune (see also the special case baseline, §6.1). In benchmarks with many reads and RMWs (the second to fourth bars), the dominant component is pruning not solving, because COBRA’s own logic identifies concrete dependencies. In benchmarks with many blind writes (the last two), solving is a much larger contributor because COBRA cannot eliminate as many constraints, leading to a larger search space, an effect that grows more pronounced as the fraction of blind writes increases. On the other hand, a majority of writes is not consistent with the patterns in common online transaction processing workloads (OLTP), where reads dominate.

Differential analysis. We experiment with four variants: COBRA itself; COBRA without pruning (§3.3); COBRA without pruning and coalescing (§3.2), which is equivalent to MonoSAT plus write combining (§3.1); and the MonoSAT baseline.

Figure 10: Verification throughput vs. round size ($\#tx_r$). The verification capacity for BlindW-RM (the dashed line) is 2.3k txn/sec when $\#tx_r$ is 5k; the capacity for C-RUBiS (the solid line) is 1.2k txn/sec when $\#tx_r$ is 2.5k.

Figure 11: Client and verifier throughputs with different fence frequencies. Client throughput (the solid line) is normalized to the workload without fence transactions. In BlindW-RM, each normal transaction has 8 operations (§6), and fence transactions have 1–2 operations.

We experiment with three benchmarks, with 10k transactions. Figure 8 depicts the results.

Checking strict serializability under clock drift. Clock drift adds complexity to strict serializability (§1, §3.5). To measure this effect, we experiment with COBRA, MonoSAT-polygraph, and Z3-arith, under different clock drifts, on the same workload. The workload has eight clients running BlindW-RW on 1k keys for one second with a throughput of 2k transaction/sec. To control computational overhead, the clients issue 20 transactions every 10ms. The maximum clock drift threshold is 100 ms [15]; similar thresholds can be found elsewhere [10, 37]. Figure 9 depicts the results; COBRA outperforms the baselines by 45× and 107× in verification time.

6.2 Scaling

What offered load (to the database) can COBRA support on an ongoing basis? To answer this question, we must quantify COBRA’s *verification capacity*, in txns/second. This depends on the characteristics of the workload, the number of transactions one round (§4) verifies ($\#tx_r$), and the average time for one round of verification (t_r). Note that the variable here is $\#tx_r$; t_r is a function of that choice. So the *verification capacity* for a particular workload is defined as: $\max_{\#tx_r} (\#tx_r / t_r)$.

To investigate this quantity, we run all our benchmarks on RocksDB with 24 concurrent clients, each configured to issue

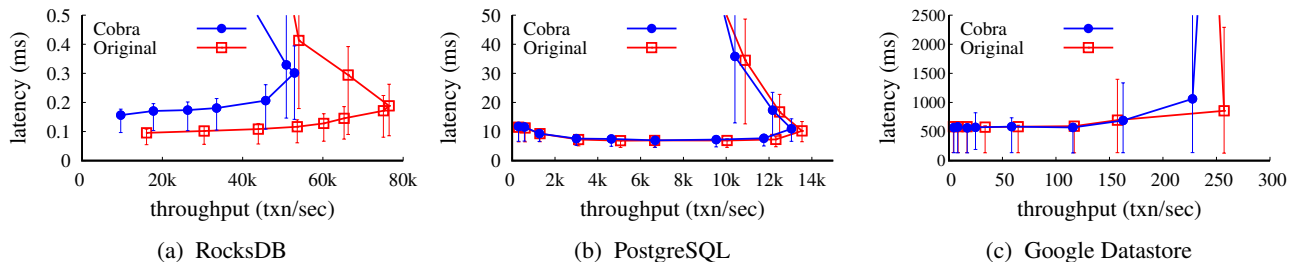

Figure 12: Throughput and latency, for C-Twitter benchmark. For our RocksDB setup, 90th percentile latency increases by $2\times$, with 50% throughput penalty, an artifact of history collection (disk bandwidth contention between clients and the DB). COBRA imposes minor overhead for our PostgreSQL. For Google Datastore, the throughput penalty reflects a ceiling (a maximum number of operations per second) imposed by the cloud service and the extra operations caused by fence transactions.

fence transactions every 20 transactions. We generate a 100k-transaction history ahead of time. For that same history, we vary $\#tx_r$, plot $\#tx_r/t_r$, and choose the optimum.

Figure 10 depicts the results for two benchmarks (C-RUBiS and BlindW-RM); C-Twitter and TPC-C have similar results (not depicted), but BlindW-RW and BlindW-WM run out of memory (we elaborate below). When $\#tx_r$ is smaller, COBRA does not have enough transactions to garbage collect, hence wastes cycles on redundantly analyzing transactions from prior rounds; when $\#tx_r$ is larger, COBRA suffers from a problem size that is too large (recall that verification time increases superlinearly; §6.1).

History eventually exceeds GPU memory on the BlindW-RW and BlindW-WM benchmarks because blind writes limit COBRA’s ability to garbage collect transactions: blind writes cannot benefit from combining writes (§3.1), hence many constraints remain, causing transactions to be involved in uncertain constraints, and thus not collectible (§4.3). Addressing this issue is future work (§8).

Fence frequency. The choice of fence frequency trades off verification capacity and peak client-side throughput. To quantify, we do the same BlindW-RM experiments as in Figure 10, this time fixing round size (at 5k transactions) and varying fence frequency.

Figure 11 depicts the results. The verifier has better throughput if clients issue fence transactions more frequently. The reason is that more fence transactions result in smaller epoch sizes, hence transactions can be garbage collected earlier, and the problem size for the verifier in each round is smaller. Moreover, with more fence transactions, the problem in each round is easier to solve because fence transactions add ordering constraints, which further reduce the number of possibly-valid execution schedules. However, more frequent fence transactions sacrifices peak client-side throughput because more resources are occupied by fence transactions.

The right setting of fence frequency depends on client offered load, peak:average throughput ratio, database capacity, and tolerance for latency. If the frequency is set too high (toward the left side of the x-axis), clients will no longer be able to offer the original workload with acceptable latency. On the

workload	network overhead		history size
	traffic	percentage	
BWrite-RW	227.4 KB	7.28%	245.5 KB
C-Twitter	292.9 KB	4.46%	200.7 KB
C-RUBiS	107.5 KB	4.53%	148.9 KB
TPC-C	78.2 KB	2.17%	1380.8 KB

Figure 13: Network and storage overheads per 1k transactions. The network overheads comes from fence transactions and the metadata (transaction ids and write ids) added by COBRA’s client library.

other hand, for too-low frequencies (toward the right side of the x-axis), the verifier will not be able to keep up with the database’s average load. Of course, if client load is constant, the fence frequency should be chosen as the point where verifier throughput equals client offered load.

6.3 Online overheads

The baseline in this section is the legacy system; that is, clients use the unmodified database library (for example, JDBC), with no recording of history.

Latency-versus-throughput. We evaluate COBRA’s client-side throughput and latency in the three setups, tuning the number of clients (up to 256) to saturate the databases. Figure 12 depicts the results. (Although these results include the overhead of collecting histories in the client library (§5), that overhead is negligible, as the log size is small and disk latency is lower than network latency.)

Network cost and history size. We evaluate the network traffic on the client side by tracking the number of bytes sent over the NIC. We measure the history size by summing sizes of the history files. Figure 13 summarizes.

6.4 Summary of experimental evaluation

COBRA improves by at least $10\times$ on baselines in verification cost (Figure 5), detects real-world issues (Figure 6), gains from its techniques versus the baseline (Figures 7 and 8), and imposes tolerable overhead (Figures 12 and 13).

Furthermore, its sustained throughput of 2k txn/sec (Figure 10) corresponds to large-scale real-world workloads. While 2k/sec might not sound large, recall that the verifier’s perfor-

mance requirement is to match *average* database load (§2.1). An average of 2k/sec corresponds to 170M/day, sufficient to handle Apple Pay [6] (33M txn/day), Visa [33] (150M txn/day), and others. Of course, a “transaction”, in the sense of a payment, might translate to several database transactions, so the comparison is inexact.

7 Related work

As stated earlier (§1), COBRA is the first system that verifies the executions of (a) black box databases, for (b) serializability, under (c) workloads of realistic scale.

Three works that we are aware of tackle (a) and (b) together. Biswas and Enea [59] was covered in Section 1 and compared in Section 6. Sinha et al. [124] use SMT solvers to analyze all possible interleavings for a concurrent program, to search for serializability violations. Finally, Gretchen [23] is an experimental checker that verifies the non-strict serializability of a COBRA-style history. Gretchen encodes the history as constraints [67] (similar to our MiniSAT-BE baseline; §6.1) and solves them with the fzn-gecode [20] solver.

A recent work that deserves special mention is Elle [94], which tests for isolation anomalies, and has found many isolation bugs in production databases. (Elle is part of the impactful Jepsen [14] project, which we discuss later in this section.) Elle has two modes for testing serializability. In one, it verifies Adya’s serializability (PL-3 [38]), the same goal as COBRA. But Elle in this mode requires a workload that makes the version order (§2.2) manifest; for example, clients invoke “append”, and writes become appends to a list (Elle in this mode also supports counters and sets). In relying on a specific API and a specific workload for testing, this mode does not meet our notion of black box (§1).

In the second mode, Elle works over arbitrary observations of key-value input/output, the same setup as COBRA. Without a determined version order, it applies heuristics to identify bugs. These heuristics are useful but not comprehensive, so this is not verification. For example, if a history contains a set of concurrent transactions that form a cycle through anti-dependencies, Elle’s current heuristics do not detect the non-serializability.

Checking consistency. Serializability is a particular *isolation* level in a transactional system—the I in ACID transactions. In shared memory systems and systems that offer replication (but do not necessarily support transactions), there is an analogous correctness contract, namely *consistency*. (Confusingly, the “C(onsistency)” in ACID transactions refers to something else [47].) Example consistency models are linearizability [88], sequential consistency [97], and eventual consistency [112]. Testing adherence to these models is an analogous problem to ours. In both cases, one searches for a total order of operations that fits the ordering constraints of both the model and the history [82]. As in checking serializability, the com-

putational complexity of checking consistency decreases if a stronger model is targeted (for example, linearizability vs. sequential consistency) [81], or if more ordering information can be (intrusively) acquired (by opening black boxes) [123, 139].

Concerto [43] uses *deferred verification*, allowing it to exploit offline memory checking [60] to check online the sequential consistency of a highly concurrent key-value store. Concerto’s design achieves orders-of-magnitude performance improvement compared to Merkle tree-based approaches [60, 106], but it also requires modifying the storage layer. (See elsewhere [75, 98] for algorithms related to Concerto.)

A body of work examines cloud storage consistency [39, 42, 83, 101, 102, 115, 135, 142]. These works rely on extra ordering information obtained through techniques like loosely- or well-synchronized clocks [39, 42, 82, 83, 93, 102, 115, 135, 142], or client-to-client communication [101, 122], or by guessing [143] (which risks falsely rejecting honest executions). As another example, a gateway that sequences the requests can ensure consistency by enforcing ordering [90, 113, 122, 125], thereby dramatically reducing concurrency.

Some of COBRA’s techniques are reminiscent of these works, such as its use of serialization graphs [42, 82]. However, a substantial difference is that COBRA neither modifies the “memory” (the database) to get information about the actual internal schedule nor depends on external synchronization. COBRA of course exploits epochs (§4.2), but this is for scaling, not core to the verification task, and invokes standard database interfaces.

Execution integrity. Our problem relates to the broad category of *execution integrity*—ensuring that a module in another administrative domain is executing as expected.

One approach is to use trusted components. For example, Byzantine fault tolerant (BFT) replication [66] (where the assumption is that a super-majority is not faulty) and TEEs (trusted execution environments, comprising TPM-based systems [68, 87, 104, 105, 111, 117, 119, 126] and SGX-based systems [44, 45, 51, 89, 95, 118, 121, 125]) ensure that the right code is running. However, this does not ensure that the code itself is right; concretely, if a database violates serializability owing to a bug, neither BFT nor SGX hardware helps.

Other examples are Verena [92], Orochi [131], AVM [85], and Ripley [134]. These systems provide end-to-end assurance that a whole stack is executing as it should, but they are not black box. COBRA is the other way around: it treats the database as a black box, but its purview is limited to the database.

A class of systems uses complexity-theoretic and cryptographic mechanisms [61, 120, 145, 146]. None of these works handle systems of realistic scale, and only one of them [120] handles concurrent workloads. An exception is Obladi [71], which remarkably provides ACID transactions atop an ORAM abstraction by exploiting a trusted proxy that carefully manages the interplay between concurrency control and the ORAM protocol; its performance is surprisingly good (as cryptographic-based systems go) but still pays 1-2 orders of magnitude over-

head in throughput and latency.

Detecting application anomalies caused by weak consistency. Several works [63, 109, 116] detect anomalies for applications deployed on weakly consistent storage. Like COBRA, these works use SAT/SMT solvers on graph-related problems. But the similarities end there: these works analyze application behavior, taking the storage layer as *trusted* input. As a consequence, the technical mechanisms are very different.

Testing distributed systems. There is a line of research on testing the correctness of distributed systems under various failures, including network partition [40], power failures [147], and storage faults [78]. Among these, Jepsen [14] is a very successful testing framework (the aforementioned Elle is one of Jepsen’s checkers) with active, ongoing innovation, which has detected large numbers of correctness bugs in production distributed systems. COBRA is complementary (and intended to be complimentary) to these works. Indeed, COBRA uses several of Jepsen’s traces in Figure 6 (§6.1).

Definitions and interpretations of isolation levels. COBRA of course uses dependency graphs, which are a common tool for reasoning about isolation levels [38, 56, 110]. However, isolation levels can be interpreted via other means such as excluding anomalies [53] and client-centric observations [72]; an open and intriguing question is whether the other definitions yield a more intuitive or more easily-implemented encoding and algorithm than the one in COBRA.

8 Discussion, future work, and conclusion

Applicability. COBRA cannot prevent misbehavior, only detect it. On the other hand, *no* system that we are aware of can detect and prevent serializability violations online. Meanwhile, COBRA could contribute to recovery: given a certificate (§5), the user could supply a candidate serialization order, enabling roll back and replay. See also Concerto’s eloquent case for deferred verification [43, §1.1].

Who would use COBRA? We covered some scenarios in Section 2.1. Another is to use COBRA as the checker of a testing framework (for example, Jepsen [14], §7). Then one could insert malfunctions into various layers of the system (OS, storage, network) and avoid instrumenting the database.

One might assume that the verifier needs to be at least as powerful as the database, so why have the database? While they must match in long-term average transactions/sec (§2.1), the two do different kinds of work per transaction. The database provides geo-replication, concurrency control, crash-atomicity, durability, load-balancing, and more; the verifier is a single machine and purely algorithmic.

Limitations and future work. COBRA can be slow for certain workloads (for example, when there are many unconstrained writes, as in the BlindW-WM benchmark; §6.1). In fact, COBRA’s worst-case running time is in principle exponential; fu-

ture work is to investigate whether there are real-world workloads that induce this behavior, or does it just happen under contrived problem instances as in the NP-reduction?

Consistent with our experiments, we expect “real-world” workloads not to trigger this behavior. For intuition, low contention on each key yields a relatively small number of constraints and a small search space; the extreme is that each key is touched once, yielding no dependencies. If there is high contention with sufficient reads, there are more dependencies among transactions, which imposes more ordering. An extreme case is that there is only one key, and transactions read and write this key, so that all transactions are ordered accordingly.

We have assumed that the verifier and the collectors operate fault-free. Future work is to make them fault-tolerant. To that end, COBRA could use standard techniques (for example, transparent state machine replication) or extend its protocols to handle failures. Note that even if some history fragments are lost, COBRA can (with minor modifications) produce meaningful results: a cyclic dependency (serializability violation) in a partial history is also a violation against the full history. Another idea is to use COBRA to infer what the missing transactions would have to be in order to ensure serializability.

COBRA focuses on serializability and strict serializability; future work is extending to other isolation levels. Relatedly, COBRA does not support range queries and other high-level operators (for example, sum and join); if applications want them, they have to rewrite queries (§1). Handling these queries “natively” would require the verifier to analyze both keys that are returned and keys that are *not* returned.

Making garbage collection more aggressive is another area of potential improvement, for example, by allowing the verifier to query the database to resolve certain constraints.

Conclusion. A final critique is that we lack a sensational headline, as we did not identify novel serializability violations. However, validation doesn’t always produce a gotcha: from our perspective, it’s equally significant to be able to report on a system that gives us confidence that cloud databases do meet serializability. This was something we used to have to *trust*; COBRA, however imperfect, helps us be *sure*.

Acknowledgments

Sebastian Angel, Miguel Castro, Pete Chen, Byron Cook, Andreas Haeberlen, Dennis Shasha, Ioanna Tzialla, Thomas Wies, and Lingfan Yu made helpful comments and gave useful pointers. We thank the anonymous reviewers (including at SOSP and NSDI) for careful and constructive comments, and likewise our shepherd Chris Hawblitzel. We thank the anonymous artifact evaluators for their patience and attention to detail. A Artifact Appendix

This artifact contains two parts: a COBRA verifier and COBRA clients. The COBRA verifier checks serializability of a set of transactions (called a history). COBRA clients include database clients and COBRA’s client library. Database clients are benchmark programs that interact with a black-box database (not part of COBRA) and generate histories. COBRA’s client library wraps database libraries, encodes and decodes values to and from the database, and records histories to logs.

COBRA’s artifact, including source code and comprehensive instructions for running the code and reproducing results, is released at: <https://github.com/DBCobra/CobraHome>. COBRA’s verifier requires an NVIDIA GPU to run, and COBRA depends on Linux (tested on Ubuntu 18.04), Java (1.8 or higher), CUDA (tested on 10.0.130), and MonoSAT (1.6.0).

Determinizing Crash Behavior with a Verified Snapshot-Consistent Flash Translation Layer

Institute of Information Science, Academia Sinica, Taiwan

Abstract

This paper introduces the design of a snapshot-consistent flash translation layer (SCFTL) for flash disks, which has a stronger guarantee about the possible behavior after a crash than conventional designs. More specifically, the flush operation of SCFTL also has the functionality of making a “disk snapshot.” When a crash occurs, the flash disk is guaranteed to recover to the state right before the last flush. The major benefit of SCFTL is that it allows a more efficient design of upper layers in the storage stack. For example, the file system built on SCFTL does not require the use of a journal for crash recovery. Instead, it only needs to perform a flush operation of SCFTL at the end of each atomic transaction. We use a combination of a proof assistant, a symbolic executor, and an SMT solver, to formally verify the correctness of our SCFTL implementation. We modify the xv6 file system to support group commit and utilize SCFTL’s stronger crash guarantee. Our evaluation using file system benchmarks shows that the modified xv6 on SCFTL is 3 to 30 times faster than xv6 with logging on conventional FTLs, and is in the worst case only two times slower than the state-of-the-art setting: the ext4 file system on the Physical Block Device (pbk) FTL.

1 Introduction

In modern computer systems, data storage usually needs to go through multiple layers, starting from a specific application, going through the file system, and eventually reaching the physical device. Usually, we refer to those layers as the *storage stack*. The design of a correct storage stack is non-trivial. For instance, in order to maintain efficiency, I/O operations sending from one layer can be reordered to reduce the overall waiting time. More importantly, under a sudden power loss or a system crash, a storage system should correctly recover the stored data. Due to the high complexity of the system design, in recent years, a significant amount of research effort is devoted to applying formal methods to provide rigorous correctness guarantees about storage stacks. Among those, one crucial direction is proving crash safety [3, 9, 10, 12, 13, 42].

Crash recovery is a critical issue; no one wants to lose important data after one accidental power loss. In the state-of-the-art system design, each component in the storage stack has its crash recovery mechanism and usually makes only minimal assumptions about its lower layers. For instance, the

file system usually assumes the underlying physical device follows the *asynchronous disk model*. The model provides only minimal guarantees about its possible behavior when the system crashes. As a result, the file system needs to implement a heavyweight crash recovery mechanism.

The more recent design of physical devices offers much stronger guarantees while maintaining similar performance. For instance, the *prefix-preserving* disk model [11] guarantees to recover to some state after the last flush operation without operation reordering. The *snapshot-consistent* disk model we propose in this paper provides an even stronger guarantee. The advance in the physical device design provides us with an excellent opportunity to rethink the design of the entire storage stack. The stronger guarantees of the physical device enable a cleaner and more efficient design of file systems, database systems, and applications built on top of them. For instance, the upper layer can remove some write barriers and data replication to achieve higher performance.

In this paper, we introduce the *snapshot-consistent flash translation layer* (SCFTL). The *flash translation layer* (FTL) is the interface between flash memory and upper layers in the storage stack, providing operations such as write, read, and flush. As the name suggests, SCFTL implements the snapshot-consistent disk model, which ensures that a crashed disk will recover to the state right before the last flush operation.

Our snapshot-consistent disk model has the benefit that the flush operation can be used to take a “disk snapshot.” The feature is particularly useful for upper layers to implement atomic operations/transactions—they only need to invoke a flush at the end of each operation/transaction. Upper-layer systems can utilize this feature to obtain a more efficient design, e.g., removing the journal from a file system.

Next, we compare the snapshot-consistent disk model with other disk models used in the literature. At first glance, one might think that the *synchronous disk model* can provide a similar crash guarantee, as it also confines the number of post-crash states to one. The synchronous disk model, however, can ensure only the atomicity of a single disk write, whereas our proposed snapshot-consistent disk model guarantees the atomicity of multiple writes between two consecutive flushes.

The asynchronous disk model guarantees only that writes before a flush are durable. For those after the last flush operation, even the order is not guaranteed. In the worst case,

it might have 2^n post-crash states, where n is the number of writes after the last flush. The *prefix-preserving disk model* guarantees that writes after the last flush will not be reordered, so the possible post-crash states reduce to, in the worst case, n . The post-crash states of the two disk models are “non-deterministic,” and the upper layers have to consider all possible scenarios in their crash recovery mechanisms.

Our SCFTL allows an efficient implementation (§3) utilizing the *out-of-place* update feature of FTLs. An FTL usually maintains an in-memory *logical-to-physical* address translation table (or L2P for short). On a write of data d to a logical address l , due to the physical constraint of the flash memory, the FTL cannot just update the value pointed to by l to d . Instead, it finds a new physical location, puts d there, and updates L2P to remap l to that new location. The old data pointed to by l remains there. The main idea of our implementation is to remember the L2P right before the last flush operation, which we refer to as the *stable L2P*. When the system crashes, we use the stable L2P to recover to the state before the last flush. Writing the entire L2P to the flash memory is an expensive operation, so we design a mechanism to store only the changes to the last stored L2P table, and store the full L2P to the flash memory only occasionally. We also designed a mechanism to ensure that the garbage collector will not erase the data pointed by the stable L2P.

We have formally verified the correctness of our SCFTL implementation using a combination of a proof assistant, a symbolic executor, and an SMT solver, which achieves a good balance between the degree of automation and the expressive power for stating and proving desired properties. The formal framework is set up manually using an interactive proof assistant, while the proof obligations involving the detail of SCFTL are discharged automatically with an SMT solver.

In the formal framework, we start with a simple mathematical specification of the snapshot-consistent disk model, which we briefly illustrate here using Figure 1. The state of the specification has two sector arrays, **stable** and **volatile**. The `flush()` operation copies **volatile** to **stable**; then the operation `write(0, x_9)` changes **volatile**[0] to x_9 and nothing else, while the `read(2)` operation returns **volatile**[2]; finally, the `recovery()` operation overwrites **volatile** with **stable**. In contrast to the specification, the SCFTL implementation stores the two arrays using more sophisticated data structures to achieve better performance and to satisfy the constraints of the flash memory. For instance, the **stable** array is implemented as an in-flash L2P and a list of L2P changes. Using a proof assistant, we reduce a *behavioral correctness* property over multiple FTL operations—which asserts that the SCFTL implementation behaves as the specification describes—to simpler *per-operation correctness* properties about each FTL operation (§4). We also prove that the behavioral correctness of SCFTL implies its snapshot consistency.

We then use more *automatic* tools to prove per-operation correctness (§5). More specifically, the relationship between

Figure 1. Illustration of the SCFTL operations.

the two arrays in the specification and the data structures in our implementation is described as a logical formula called the *abstraction relation*, and one type of the per-operation correctness formulae has the form “if the abstraction relation holds for the states before executing an operation, the relation will remain true for the states after executing the operation.” We use a *symbolic executor* [8, 32] to translate the C program of our SCFTL implementation to logical formulae describing how the states change after executing an SCFTL operation. Then we use an SMT solver to ensure that our implementation does satisfy the per-operation correctness formulae.

Our experimental results (§7) show that when a workload does not flush the disk too frequently, SCFTL is as efficient as an FTL implementing the asynchronous disk model. To understand the usefulness of SCFTL, we modify the xv6 [16] file system to support group commit and utilize the stronger crash guarantee granted by SCFTL. By changing less than 30 lines of code, we show that the modified xv6 on SCFTL outperforms xv6 with logging on conventional FTLs by 3 to 30 times using our file system benchmarks; the performance improvement is less obvious for workloads that frequently flush the disk (e.g., `smallfiles` repeatedly creates a file, writes 100 bytes of data to it, and calls `fsync`), and more obvious for workloads with lower flush frequency (e.g., `largefile` writes 4 MB of data to a file and calls `fsync` for every 1 MB). This observation suggests an important guideline for building systems and applications on top of SCFTL: reducing the flush frequency to extract more benefits from SCFTL. Finally, we use the same file system benchmarks to compare the performance of the modified xv6 on SCFTL with the state-of-the-art setting: the ext4 file system on the pblk [6] FTL. The result is encouraging. Although xv6 is a file system known to be simple but slow, our xv6 on SCFTL is in the worst case only two times slower than ext4 on pblk. Moreover, xv6 on SCFTL has a stronger crash guarantee than that of ext4 on pblk.

In summary, the main contributions of this paper are the design, specification, and verification of SCFTL:

- The design exploits the out-of-place update feature of FTLs and uses an efficient checkpointing algorithm to provide a stronger crash guarantee at the disk level (§3). We validate its efficiency with disk and file system benchmarks (§7).
- The specification is simple and useful as it involves only the manipulation of two arrays and a counter, and it naturally ensures the atomicity of multiple disk writes. We formalize snapshot consistency and show that the specification satisfies the property with a proof assistant (§4).

- We verify that our implementation of SCFTL meets its specification using automatic verification tools. To scale the verification of SCFTL, we propose a novel approach to model crash behavior and describe some techniques to simplify the proof obligations, including using ghost variables to craft efficient SMT encodings, categorizing invariants to remove unnecessary conditions, and partitioning the proofs to avoid non-determinism (§5).

SCFTL has several limitations. First, SCFTL does not allow concurrent SCFTL operations, although it does allow flash operations to be executed concurrently (more detail in §6.2). Second, SCFTL assumes the underlying flash memory is free of error. Finally, SCFTL does not implement standard optimizations of FTLs, such as hot-cold data separation and wear leveling, although its design does not prohibit them.

2 Related Work

We first discuss the recent advance of disk models; in particular, we will focus on *transactional* and *order-preserving* models. To the best of our knowledge, our work is the first to address the verification of the crash safety issue at the physical device layer. Most previous work on crash safety verification assumes a correct asynchronous disk is given and put their focus on other layers in the storage stack, e.g., the file system. We will discuss some recent work in this direction.

The *transactional models* [15, 17, 25, 38, 41] guarantee the atomicity of multiple write operations. They provide a non-standard disk interface, which has two consequences: (i) their semantics (e.g., isolated concurrent transactions and transaction abortion) is hard to formally specify or verify, and (ii) system developers have to learn a new interface, increasing the burden of porting existing or developing new software.

The *order-preserving disk models* [11, 45] guarantee the preservation of operation orders across a crash. They expose the standard read-write-flush disk interface, but with fewer possible post-crash states than the asynchronous disk model. Upper layers in the storage stack can utilize this feature to reduce the number of flushes invoked in their crash recovery mechanisms (e.g., copy-on-write and journaling).

Compared with the transactional models, the snapshot-consistent model uses the standard read-write-flush interface. It, moreover, guarantees the atomicity of multiple writes between two consecutive flushes and thus provides a stronger guarantee than the order-preserving models.

Recent research work has discovered many crash vulnerabilities in widely used applications such as LevelDB and Git [36], as well as ACID violations in many relational database systems [46]. These vulnerabilities mainly stem from the vague and weak crash guarantees provided by the underlying file systems. File systems themselves, even for mature ones such as ext4, btrfs [39] and F2FS [28], also contain bugs that may result in severe consequences [24, 27, 31].

In the past decades, a significant amount of research effort

is devoted to the development of a verified crash-safe storage stack. To name a few, the verified file systems Yxv6 [42], FSCQ [13], and DFSCQ [12] assume an asynchronous disk model and use a log-based design to guarantee crash safety. Instead of the asynchronous disk model, both the BilbyFS [3] and Flashix [19] file systems assume the underlying layer is a raw flash device (without an FTL) and implement an atomic transaction mechanism to ensure crash safety.

SCFTL differs from previous work on verifying the storage stack in that it targets the physical device layer. This approach has three notable benefits: First, the code and the data structure of an FTL are usually simpler and more manageable than that of a file system; thus it is easier to develop an efficient yet verifiable layer. Second, providing the standard disk interface is more modular than directly building file systems on a raw flash device; developers can build their own systems with various features and optimizations, and leave crash safety to the underlying verified disk. Finally, this approach allows us to exploit useful device characteristics (e.g., the out-of-place update feature of FTLs); it enables SCFTL to provide a stronger crash guarantee without compromising the performance.

Regarding the verification methodology and framework, the closest work to ours is Yggdrasil [42], which establishes a forward simulation and discharges the proof obligations using an SMT solver, achieving a high degree of automation. Compared with Yggdrasil, we have additionally formalized our simulation argument, snapshot consistency, and relevant theorems using a proof assistant, providing more correctness guarantees. The proof obligations have to be manually massaged into a form that can be handled by an SMT solver; strictly speaking, this leaves a gap in our formal proof (but we bridge the gap by pen-and-paper reasoning).

By contrast, there has been work on storage system verification [9, 10, 13, 19] where the entire proof is formally verified with a proof assistant and does not have any gaps, although their verification cost is also significantly higher since the whole proof structure has to be carefully designed and constructed by programmers. Our framework is not as sophisticated as Argosy [9], which treats layered storage systems, or Perennial [10], which supports concurrency; extending our framework to support these features are interesting future directions. There are also differences in modeling decisions between our framework and the others—for example, in Argosy a crash is modeled as an individual event whereas we incorporate crashes into operations, and in Yggdrasil the effect of a lower-level operation may not be visible at a higher level whereas we always relate such an operation to a corresponding higher-level operation that is specified not to change the state. These differences in modeling decisions do not lead to vital differences in correctness guarantees, however.

3 SCFTL Design and Implementation

SCFTL is designed with *high performance*, *strong crash guarantees*, and *provable correctness* in mind. Below we give an

Figure 2. Flash memory layout of SCFTL.

overview of flash disks and describe the techniques we use that set SCFTL apart from traditional FTLs.

3.1 Flash disk overview

Usually, a flash disk contains two main components, a fast *dynamic random-access memory* (DRAM) to store temporary data and a slower *flash memory* to store permanent data. In this paper, we use the keywords *in-memory* or *buffer* to mean the data is stored in the DRAM and *in-flash* to mean it is stored in the flash memory. Flash memory is usually structured as a list of *blocks*, each of which consists of multiple *pages*. A page further contains one or multiple *sectors*, the basic unit the upper layers (e.g., the file system) use to access data. One can access flash memory through commands such as READ and WRITE a page, ERASE a block, and SYNC to wait for the completion of all ongoing flash commands. Due to physical limitations, flash commands need to follow several intricate constraints. For instance, a *page* must be erased before being written. However, the basic unit for ERASE is a block, while that for WRITE is a page. It would be inefficient if we erase the entire block whenever we write to a page within it.

In order to free users from handling the intricate device characteristics of flash memory, a flash disk usually comes with a flash translation layer (FTL) to hide the complexity. Typical operations supported by an FTL include a write and a read operation to store and retrieve a sector of data, a flush operation to wait until all unprocessed changes is made to the flash memory, a recovery procedure that will be invoked after a crash, and a garbage collection (GC) procedure *gc* that will only be invoked by its internal garbage collector. Every FTL should at least support the main functionalities, namely *address translation*, *crash recovery*, and *garbage collection*. Below we introduce how SCFTL implements those functions.

3.2 Address translation

To comply with the *erase-before-write constraint* of flash memory, SCFTL maintains an in-memory logical-to-physical table (L2P) and writes data in a log-structured manner [40] to avoid in-place updates. Address translation can be done at the granularity of sectors, pages, blocks, or a mixture of them [26]. Often finer granularity leads to better performance, but at the cost of higher memory usage due to a larger L2P. SCFTL uses a sector-level L2P to achieve better performance.

SCFTL handles the request $\text{write}(la, d)$, i.e., writing a sector of data d to the logical sector address la , as follows. It first stores d into a page-sized *merge buffer* employed to resolve the size mismatch between a sector and a page. Then

SCFTL finds a new location pa for placing d using the triplet (blk, pg, sec) , called an *active pointer*, where the first two together point to the next free page to be written, and the last one points to the next free slot in the merge buffer. We call the block blk the *active block*. Then SCFTL also updates the in-memory L2P with the entry $la \mapsto pa$.

When the merge buffer is full, SCFTL invokes the command $\text{WRITE}(blk, pg, d)$ to write the buffered data to the flash memory, where d is the content of the merge buffer. Then SCFTL increases pg by one to follow the *sequential write constraint* (within one block) of flash memory, unless pg is already the last page in a block, in which case blk is assigned a new block address dequeued from the *free block queue* and pg is reset to 0. The free block queue is an in-memory data structure that SCFTL uses to track currently available blocks.

Finally, SCFTL would have to remember that the address storing old data (if any) is no longer valid, and the one for the new data is now valid. The garbage collector needs this information to relocate all valid data before erasing a block. In SCFTL, this is realized by an in-memory physical-to-logical table (P2L), which is the “reverse” mapping of L2P. Flash disks usually have more available physical locations than logical locations. So it can happen that a mapping $p \mapsto l$ is in P2L, but $l \mapsto p$ is not in L2P. In such a case, we know that this physical address p is invalid. We also use an in-memory table, called the *valid count table*, to remember the number of valid sectors in each block. The valid count table will be used by the garbage collector to select the *victim block* to recycle.

Handling a read(la) request is simpler: SCFTL first checks if the requested data is still stored in the merge buffer; if so, it directly returns the data in the merge buffer. Otherwise, SCFTL performs an L2P lookup to find the corresponding physical address p , followed by a $\text{READ}(p)$ command to retrieve the requested data stored in the flash memory. For a flush() request, SCFTL first stores the buffered data in the flash memory and advances the active pointer in the same way as handling a write request. Then it issues a SYNC command to ensure all data written before this point is persistent.

SCFTL maintains another L2P (the *stable L2P*) to reflect the state of the in-memory L2P right before the last flush for ensuring snapshot consistency. To distinguish the two kinds of L2P, we will call the in-memory L2P the *volatile L2P*. The cost of physically storing the stable L2P in the flash memory can be prohibitively high. Thus, SCFTL logically maintains the stable L2P through *checkpointing* in an efficient way.

Figure 2 shows the flash memory layout of SCFTL, including a *delta region* that records L2P differences, and a *full*

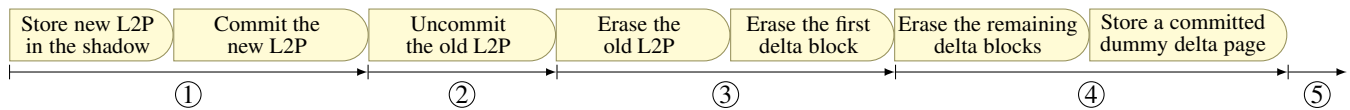

Figure 3. Full checkpoint protocol. The occurrence of crashes is partitioned to stages ① - ⑤.

checkpoint region that stores an entire L2P. SCFTL can create two kinds of checkpoints: a lightweight *delta checkpoint* and a heavyweight *full checkpoint*. SCFTL always creates a delta checkpoint when a flush is invoked. Under rare circumstances where the delta region nearly runs out of space, SCFTL creates a full checkpoint and clears the delta region.

Delta checkpoint Whenever a volatile L2P entry is modified due to a write or a gc operation, SCFTL also inserts a *delta pair*, which consists of a logical and a physical address, into the page-sized *delta buffer*. When the delta buffer is full, SCFTL invokes a WRITE command to store all buffered pairs along with a *tentative tag* into the in-flash delta region in a sequential manner and clears the buffer. We illustrate this operation in Figure 2.

On receiving a flush request, SCFTL first makes sure host data is safely stored in the flash memory. It then follows the same procedure above to store the buffered pairs in the flash memory, except here the delta page is tagged as *committed*. A committed delta page *activates* previous tentative delta pages, i.e., all delta pages before a committed one are treated as committed. When the committed delta page is safely kept in the flash memory, a delta checkpoint is successfully created.

Full checkpoint A full checkpoint of SCFTL consists of a complete L2P table and a commit flag. When making a full checkpoint, i.e., storing the volatile L2P together with a commit flag to the flash memory, we employ a *shadow* to prevent modification to the old L2P before the new one is settled. The detailed steps can be found in Figure 3. In short, we first store the new (volatile) L2P to the flash memory and start to erase the old L2P and the delta region only after the new L2P is committed. To ensure the correctness of our recovery procedure, we allow only flush operations to create a full checkpoint; write and gc operations are not allowed to create a full checkpoint. One potential issue is that the delta region might become full after a write or a gc operation. We address this issue by imposing upper bounds on the number of write and gc invocations (hence the number of created delta pairs) within an *epoch*, i.e., between two consecutive flushes. To ensure these bounds are respected, SCFTL uses a *write counter* and a *GC counter* to keep track of the number of write and gc invocations in the current epoch, respectively, and resets both counters on a flush or a recovery. If the upper layer calls a write after the write counter exceeds the bound, SCFTL simply treats that write as a no-op.

Systems that use SCFTL to implement atomic transactions should be aware of the write bound, to make sure an operation can fit into the current epoch before executing it. If an operation is too large to fit into an entire epoch (e.g., writing a large amount of data to a file), then it should be broken into multiple smaller ones. We believe that this requirement is not

too restrictive, given that some systems also face a similar situation; for example, because of the log size limit, ext4 always checks that the current running transaction has sufficient capacity left before atomically updating its metadata [35, §3.1]. Similarly, systems built on SCFTL can record the number of writes issued to SCFTL since the last flush, and *before* executing an operation, calculate the number of writes required to complete the operation. If the operation does not fit into the current epoch, then the system should call a flush to form a new epoch. This avoids calling a flush in the middle of an operation, which may expose intermediate states on a crash.

3.3 Crash recovery

The recovery procedure first recovers the volatile L2P with full and delta checkpoints. To explain how to reconstruct the L2P, we begin by specifying what is *visible* to the recovery procedure. A full checkpoint is visible if and only if it is committed. For the delta region, we treat its first page specially to ensure we can erase the entire delta region atomically. The only important information on the first page is the commit flag. All delta pairs on the first page are *dummy delta pairs* that will be ignored in the recovery procedure. Visibility of delta pairs can be determined by examining the commit flag of the first page of the delta region and, if the commit flag is on, performing a sequential scan over the entire delta region to find the last committed page.

In most cases, the recovery procedure simply restores a base L2P from a full checkpoint and applies all visible delta pairs in sequential order. The only exception is when a crash occurs during a full checkpoint. Below we analyze the behavior of the recovery procedure against each crash point during a full checkpoint, as shown in Figure 3:

- ①: The old L2P and all delta pairs are visible. Restoring the old L2P and applying each delta pair yields the new L2P.
- ②: Both the old and new L2P, and all delta pairs are visible. Although we do not leave other information (e.g., a timestamp) to distinguish the old L2P from the new one, our checkpoint design ensures that starting from either L2P and applying each delta pair restores the new L2P.
- ③: The new L2P and all delta pairs are visible. For the same reasoning in ②, it restores the new L2P and applies each delta pair, yielding the new L2P.
- ④: The new L2P is visible and all delta pairs are invisible. It simply restores the new L2P.
- ⑤: The new L2P and the dummy pairs are visible. It restores the new L2P and ignores all dummy delta pairs.

Selective persistence The idea of selective persistence [34] is to persistently keep only *primary data*, which is the minimal set of data structures required for correct crash recovery,

and rebuild non-primary data from the primary one. This way, the protocol to correctly maintain consistency between multiple data structures can be greatly simplified. In SCFTL, the primary data is simply the L2P. After restoring the volatile L2P, the recovery procedure proceeds to rebuild the *block queues* (explained later), P2L table, and valid counts table.

3.4 Garbage collection

The GC procedure of standard FTLs consists of the following steps: (i) find a *victim block*, (ii) relocate all valid sectors (those pointed to by the volatile L2P) in the victim block similarly to the write operation (the *relocation phase*), and (iii) erase the victim block (the *erasure phase*). In SCFTL, the standard GC procedure cannot be used, as the data pointed to by the stable L2P might be erased by a garbage collector.

To prevent such an issue, one design option is to keep additional information on what is allowed to be erased. This approach is taken by TxFash [38, §3.3] to prevent back pointers from being erased. The downside of this approach is that it can incur notable memory and performance overhead.

Another approach, adopted by OPTR [11, §3.4], is to invoke an internal flush (i.e., a flush operation issued by the FTL) before GC is activated. While an internal flush is allowed by the prefix-preserving guarantee that OPTR offers, it is not allowed by the snapshot consistency SCFTL is trying to achieve, as otherwise SCFTL might rollback to the state right before an internal flush on a recovery.

Two-phase garbage collection Instead, we use a simple protocol called *two-phase garbage collection* (2PGC), which delays the erasure phase until a flush is invoked. This is correct because after a flush operation, the old stable L2P will be discarded and hence all the previously selected victim blocks can be safely erased. To implement this idea, in the 2PGC mechanism, we use two functions gc_{rl} and gc_{es} to handle the relocation and erasure phases, respectively. We, moreover, maintain four queues to remember the status of blocks. Initially, all blocks are in the *free block queue*, except the active block, which does not belong to any of the state queues. When the active block is fully written, we add it to the *used block queue* and pick another block from the *free block queue* as the new active block.

When the garbage collector invokes the gc_{rl} function, it first removes a victim block from the used queue and performs the relocation of valid sectors. After all valid sectors are removed from the victim block, the gc_{rl} function adds the victim block to the *invalid block queue*. As the name suggests, all blocks in the invalid queue do not have any valid sector. Nevertheless, those blocks might still contain sectors pointed to by the stable L2P and hence cannot be immediately erased. All blocks in the *invalid* queue will be moved to the *erasable block queue* at the end of a flush operation. After a flush, the stable L2P will be updated, and all invalid blocks are no longer pointed to by the new stable L2P and are now erasable. All blocks in the erasable block queue can be safely erased. When the

garbage collector invokes the gc_{es} function, it finds a block b in the erasable queue, performs an $ERASE(b)$ command, and puts b in the free block queue.

The remaining problem of 2PGC is that garbage collected blocks cannot be immediately reused in the current epoch. To address this issue, SCFTL exploits the upper bounds on the number of write and gc_{rl} allowed in one epoch to ensure that there is sufficient space for newly written data and relocated data. These two bounds already exist to avoid overflowing the delta region (§3.2). Below we describe the constraints that need to be satisfied when picking the values for the two bounds, W (for write, in terms of sectors) and K (for gc_{rl} , in terms of blocks).

The first constraint ensures that write and gc_{rl} do not consume space more than what gc_{rl} can produce in one epoch:

$$\underbrace{W}_{\text{consumed by write}} + \underbrace{KN}_{\text{consumed by } gc_{rl}} \leq \underbrace{KS}_{\text{produced by } gc_{rl}} \quad (1)$$

where N is the maximum number of valid sectors in every victim block (we will explain how to obtain this bound later); S is the number of sectors per block. Each write occupies one sector and each gc_{rl} relocates at most N sectors; thus at most $W + KN$ sectors will be consumed in one epoch. Each gc_{rl} also turns one used block into one invalid block, which becomes an erasable block in the next epoch; thus at most KS sectors can be produced in one epoch.

To obtain the bound N , we introduce a GC threshold U : gc_{rl} can be activated only when the number of used blocks is larger than or equal to U . Let L be the number of entries of L2P (i.e., the number of logical sectors). Recall that a valid sector is a physical sector mapped by the volatile L2P. The *pigeonhole principle* states that there exists a used block (i.e., the hole) whose number of valid sectors (i.e., the pigeons) is no more than $\lfloor L/U \rfloor$. One design choice is to force gc_{rl} to always pick the block with the least number of valid sectors as the victim block (i.e., the greedy policy). A more flexible alternative allows gc_{rl} to pick any block providing the block has no more than $\lfloor L/U \rfloor$ valid sectors; the pigeonhole principle ensures the existence of such block. Either way, we obtain $N = \lfloor L/U \rfloor$.

The threshold may disable gc_{rl} before there is enough space for the next epoch; SCFTL would fail to proceed to the next epoch in this situation. To avoid such a situation, we can choose a proper U , W , and K such that gc_{rl} must be enabled when there is not enough space for the next epoch:

$$\underbrace{U}_{\text{GC threshold}} \leq \underbrace{P - 1 - \lceil (W + KN)/S \rceil}_{\text{lower bound of used blocks when not enough space}} \quad (2)$$

where P is the number of data blocks. First observe that free, erasable, and invalid blocks are all available to the next epoch as all invalid blocks become erasable after a flush. The condition of “not enough space” essentially means that the total number of these three kinds of blocks is less than $\lceil (W + KN)/S \rceil$. Given that the total number of free, erasable, invalid, and used blocks is equal to $P - 1$ (we always have

one active block), we know that the number of used blocks is more than $P - 1 - \lceil (W + KN)/S \rceil$ when there is not enough space for the next epoch.

We demonstrate a configuration that satisfies the above constraints: A 4-GB flash disk has 2^{20} logical sectors ($L = 2^{20}$); suppose each block has 512 sectors ($S = 512$) and we have 6 GB of flash memory for storing data, then the number of data blocks will be 3072 ($P = 3072$). We can set the GC threshold at 2500 ($U = 2500$) and we know the number of valid sectors in every victim block would not exceed 419 ($\lfloor L/U \rfloor = \lfloor 2^{20}/2500 \rfloor = 419$). Next we pick suitable values for W and K . Let $W = 4000$ and $K = 50$ and check whether they satisfy the above two constraints:

$$\begin{aligned} 24950 &= W + KN \leq KS = 25600 \\ 2500 &= U \leq P - 1 - \lceil (W + KN)/S \rceil = 3022 \end{aligned}$$

Both constraints are satisfied.

Recovery of block queues After the recovery procedure reconstructs the volatile L2P, it proceeds to reconstruct other data structures, including the aforementioned block queues. The recovery procedure simply scans through the blocks. If a block contains some sectors pointed to by the L2P, then it is a used block; otherwise, the recovery procedure treats it as an erasable block. Note that after the reconstruction of the volatile L2P, the stable and volatile L2Ps are identical and hence we do not have any invalid blocks. We do not have any free blocks after the recovery procedure; we do not have the information whether a block was in the erasable or free block queue before the crash. So we have to play it safe and put them in the erasable queue to follow the erase-before-write flash constraint.

4 Formal Verification Framework

The design of SCFTL (§3) is fairly sophisticated; to provide a strong guarantee of its reliability, we have formally verified its correctness. Our formal verification framework starts with the definition of a disk model \mathbb{S} (similar to Figure 1) that specifies the intended disk behavior. \mathbb{S} is defined as a particular kind of state transition system (§4.1) on which snapshot consistency can be formulated and proven (§4.2). As opposed to \mathbb{S} , which is merely an abstract, mathematical specification that is meant to be understood easily, the SCFTL implementation constitutes a more realistic transition system \mathbb{P} . We prove that \mathbb{P} is behaviorally correct with respect to \mathbb{S} , and moreover, this behavioral correctness is strong enough to imply the snapshot consistency of \mathbb{P} (§4.3). Behavioral correctness is a complicated property about sequences of state transitions, which cannot be easily verified with automatic verification tools. We can, however, reduce its proof to one about the behavior of individual operations (§4.4), the latter of which is more amenable to automatic verification (§5). The content of this section is formally verified with the Agda proof assistant [33], but here we provide only a high-level sketch.

4.1 Specification of disk behavior

To model the behavior of a disk as a state transition system, we should define the possible states of a disk and the operations that can be performed on the disk states. In \mathbb{S} , which is our abstract disk model that acts as a definition of intended behavior, a state t of a disk is a pair of arrays $t.volatile$ and $t.stable$ representing the volatile and stable copies of disk data respectively and a number $t.wcnt$ that counts the number of writes since the last flush. There is a set $\mathcal{N}_{\mathbb{S}}$ of states that represent the possible contents of a new disk, where only the *stable* array is initialized to some default value. Reading a disk state is just retrieving the data at a given address in the volatile part; since the operation does not change the disk state, we simply define it as a function $read(t, a) \triangleq t.volatile[a]$ rather than a kind of state transition.

Mirroring the FTL operations except read, the operations of \mathbb{S} are shown in Figure 4; they are classified as *regular*, *flush*, and *recovery* operations, and have a successfully executed version and a crashed version. Writing $t \xrightarrow{op} t'$ to mean that there is a transition from t to t' through the operation op , that is, t' is the state resulting from applying the operation op to the state t , we define the effect of an operation by specifying how t and t' are related: A write operation $w_{a,d}$, which writes the piece of data d to the address a in the volatile part, is defined by saying that $t \xrightarrow{w_{a,d}} t'$ amounts to

- $t'.volatile = t.volatile[a \mapsto d]$, where the right-hand side is the array whose values are the same as $t.volatile$ except at the address a , where the value is d ,
- $t'.stable = t.stable$, meaning that the stable data is not modified, and
- $t'.wcnt = t.wcnt + 1$, meaning that $wcnt$, the write counter mentioned at the end of §3.2, is incremented by one

when a and $t.wcnt$ are within bounds, or otherwise $t' = t$. The garbage-collecting operations rl and es do not change the (abstract) disk state. The flush operation f copies the volatile data to the stable part, and the recovery operation r does the opposite; both operations reset the write counter to 0. The crashed operations $w_{a,d}^c$, rl^c , es^c , and r^c may disrupt the volatile data arbitrarily, and thus their definitions only specify that the stable data remains the same (and the transitions become non-deterministic); for f^c there are two kinds of post-crash state because the update to the flash disk may have finished, in which case the system behaves as if the flush operation is successfully executed.

4.2 Snapshot consistency

Snapshot consistency is essentially a property about *execution fragments* (or *fragments* for short), which are consecutive sequences of transitions $t_1 \xrightarrow{op_1} t_2 \xrightarrow{op_2} \dots \xrightarrow{op_n} t_{n+1}$; we often omit unimportant intermediate states and write $t_1 \xrightarrow{op_1, op_2, \dots, op_n} t_{n+1}$. Informally, snapshot consistency says that when recovered from a crash, reading the state after the recovery operation will be the same as reading the state right

	Regular		Flush	Recovery
	Write	Relocate/Erse (GC)	Flush	Recover
Successful	$t \xrightarrow{w_{a,d}} t' \triangleq$ $(InBounds(a, t.wcnt) \wedge t'.volatile = t.volatile[a \mapsto d]$ $\wedge t'.stable = t.stable \wedge t'.wcnt = t.wcnt + 1)$ $\vee (\neg InBounds(a, t.wcnt) \wedge t' = t)$	$t \xrightarrow{rl/es} t' \triangleq$ $t' = t$	$t \xrightarrow{f} t' \triangleq$ $t'.volatile = t.volatile$ $\wedge t'.stable = t.volatile$ $\wedge t'.wcnt = 0$	$t \xrightarrow{r} t' \triangleq$ $t'.volatile = t.stable$ $\wedge t'.stable = t.stable$ $\wedge t'.wcnt = 0$
Crashed	$t \xrightarrow{w_{a,d}^c} t' \triangleq$ $t'.stable = t.stable$	$t \xrightarrow{rl^c/es^c} t' \triangleq$ $t'.stable = t.stable$	$t \xrightarrow{f^c} t' \triangleq$ $t'.stable = t.volatile$ $\vee t'.stable = t.stable$	$t \xrightarrow{r^c} t' \triangleq$ $t'.stable = t.stable$

Figure 4. Definitions of operations in \mathbb{S} . GC stands for Garbage Collection. The definition of the predicate $\text{InBounds}(a, wcnt)$ is $a \leq a_{max} \wedge wcnt \leq wcnt_{max}$ where a_{max} and $wcnt_{max}$ are the upper bounds on the addresses and the write counter respectively. Note that in the definitions a write operation has no effect ($t' = t$) when the write counter exceeds the bound ($wcnt > wcnt_{max}$).

before the last flush operation prior to the crash. More precisely, the disk may have operated normally for some time before the crash happens, and the recovery may fail several times before it succeeds. This whole behavior is described as a *one-recovery fragment* of the form

$$t_1 \xrightarrow{a_1, \dots, a_{k-1}} t_2 \xrightarrow{a_k(=f), b_1, \dots, b_\ell} t_3 \xrightarrow{c, (r^c)^m, r} t_4$$

where a_1, \dots, a_k are a sequence of successful regular or flush operations ending with f (that is, $a_k = f$), b_1, \dots, b_ℓ are successful regular operations, c is a crashed regular or flush operation, and $(r^c)^m$ is the crashed recovery operation repeated m times; this is abbreviated to $t_1 \rightsquigarrow t_4$ later on. Writing $t \approx t'$ to mean that $\text{read}(t, a) = \text{read}(t', a)$ for all addresses a within bounds, snapshot consistency of a one-recovery fragment of the above form is defined as follows:

- if c is a crashed regular operation, then $t_2 \approx t_4$;
- if c is the crashed flush operation f^c , then either $t_2 \approx t_4$ or $t_3 \approx t_4$.

Note that in the definition k can be 0, in which case no flush is performed before the crash c , and the definition requires, for instance in the first case, that the disk be reverted to the first state t_1 (which equals t_2) observationally.

We can now formulate snapshot consistency of a disk model. The typical way of using a disk can be represented as a *multi-recovery fragment* of the form

$$t_0 \xrightarrow{(r^c)^\ell, r} t_1 \rightsquigarrow t_2 \rightsquigarrow \dots \rightsquigarrow t_n \rightsquigarrow t_{n+1} \xrightarrow{a_1, \dots, a_m} t_{n+2}$$

which starts with performing the recovery operation on a state $t_0 \in \mathcal{N}_{\mathbb{S}}$ (until it succeeds) to bring the disk to a usable state, and continues with an arbitrary number of one-recovery fragments and some trailing regular and flush transitions representing uses of the disk. We say that a multi-recovery fragment of this form is snapshot-consistent if all the one-recovery sub-fragments $t_1 \rightsquigarrow t_2, \dots, t_n \rightsquigarrow t_{n+1}$ are snapshot-consistent, and that a disk model is snapshot-consistent if its every multi-recovery fragment is snapshot-consistent. With the definitions in place, we can now state our first result (whose proof is straightforward and omitted here).

Lemma 1. \mathbb{S} is snapshot-consistent.

Note that the definitions of snapshot consistency make

sense for any disk model that has the same structure as \mathbb{S} , in particular for the model \mathbb{P} that we will describe next.

4.3 Behavioral correctness and snapshot consistency of SCFTL

\mathbb{S} is a simplistic transition system: it gives a concise definition of the intended disk behavior, but is unsuitable for direct implementation. In SCFTL (§3), we use more practical states that consist of various in-memory and in-flash data structures, and sophisticated operations implemented in C. All these give rise to another transition system \mathbb{P} , which has the same set of operations as \mathbb{S} (as well as a *read* function for reading the states of \mathbb{P}) and also a set $\mathcal{N}_{\mathbb{P}}$ of possible states of a new disk (where only the in-flash part is initialized). The definition of \mathbb{P} is a formal version of what has been presented in §3; the exact definition is not needed in this section though, and will be described later in §5.

We have proven that \mathbb{P} is *behaviorally correct* with respect to \mathbb{S} : if we perform a legitimate sequence of operations in \mathbb{P} to obtain a fragment and read the *normal* states, which are states that immediately follow a successful operation, the results will be the same as performing the same sequence of operations in \mathbb{S} and reading the corresponding states. This property allows the behavior of \mathbb{P} to be understood in terms of \mathbb{S} . More formally, we have the following theorem.

Theorem 1 (behavioral correctness of \mathbb{P}). *For every multi-recovery fragment $s_0 \xrightarrow{(r^c)^m, r} s_1 \xrightarrow{op_1} \dots \xrightarrow{op_n} s_{n+1}$ in \mathbb{P} , there exists a fragment $t_0 \xrightarrow{(r^c)^m, r} t_1 \xrightarrow{op_1} \dots \xrightarrow{op_n} t_{n+1}$ in \mathbb{S} (which has the same sequence of operations) such that $s_i \approx t_i$ for every corresponding pair of normal states s_i and t_i .*

We will see how Theorem 1 is proven in §4.4 and §5. Before we do so, we show that the behavioral correctness of \mathbb{P} is strong enough to allow \mathbb{P} to inherit snapshot consistency from \mathbb{S} .

Theorem 2. \mathbb{P} is snapshot-consistent.

Proof. We must show that any multi-recovery fragment in \mathbb{P} is snapshot-consistent, that is, the results of reading the states mentioned by the definitions of snapshot consistency are the same. Observe that all these states are normal, so reading these states in the fragment (in \mathbb{P}) is the same as reading the

corresponding states in the fragment in \mathbb{S} that is guaranteed to exist by the behavioral correctness of \mathbb{P} . This means that the \mathbb{P} -fragment is snapshot-consistent if the \mathbb{S} -fragment is, and the latter is indeed the case because \mathbb{S} is snapshot-consistent (Lemma 1). \square

4.4 Per-operation correctness

Theorem 1 is proven with a *forward simulation* argument [30], which, though fairly standard, is described below for the sake of completeness. Given a multi-recovery fragment in \mathbb{P} , we construct a fragment in \mathbb{S} with the same sequence of operations while ensuring that every corresponding pair of normal states in the two fragments is related by an *abstraction relation* AR (to be described below) such that $AR(s, t)$ implies $s \approx t$ for all s and t , and moreover, any corresponding pair of abnormal states is related by a weaker abstraction relation CR . This forms a stepwise relationship between the two fragments, as illustrated, for example, in

Intuitively, the abstraction relation AR captures how a normal state in \mathbb{P} is interpreted as a state in \mathbb{S} . For example, one part of AR describes where the current data at a logical address—i.e., an entry in the *volatile* array of an \mathbb{S} -state—can be found in a \mathbb{P} -state. On the other hand, for abnormal states in \mathbb{P} , only the in-flash data are reliable, and the crash abstraction relation CR describes only how the in-flash part of a \mathbb{P} -state is interpreted as the stable part of an \mathbb{S} -state. Back to diagram (3): The in-memory part of s_0 ($\in \mathcal{N}_{\mathbb{P}}$) is not yet initialized, and thus s_0 only satisfies CR with some t_0 ($\in \mathcal{N}_{\mathbb{S}}$). A successful recovery operation brings the disk to a normal \mathbb{P} -state that satisfies AR with an \mathbb{S} -state. This AR relationship is preserved by successful regular and flush operations, but deteriorates to CR when a regular or flush operation crashes. Recovery attempts may fail but CR is preserved, and the relationship is restored to AR after the recovery succeeds, from which point we can resume using the disk.

The stepwise relationship is established inductively by showing (i) that initially CR holds for all $s \in \mathcal{N}_{\mathbb{P}}$ and $t \in \mathcal{N}_{\mathbb{S}}$ (to establish, for example, the leftmost $CR(s_0, t_0)$ in diagram (3)), and (ii) that each operation preserves AR or CR , or transforms AR into CR or vice versa (giving rise to each of the squares in diagram (3)). The inductive cases (ii) are called *type A per-operation correctness*. For example, the type A per-operation correctness formula for the crashed flush operation f^c is

$$\begin{aligned}
 \forall s, t, s'. AR(s, t) \wedge RI(s) \wedge s \xrightarrow{f^c} s' \\
 \implies \exists t'. t \xrightarrow{f^c} t' \wedge CR(s', t') \quad (4)
 \end{aligned}$$

where RI is the *representation invariant* describing properties that should be satisfied by the various data structures in a

\mathbb{P} -state, and is needed in the antecedent to make per-operation correctness provable. For example, a part of RI states that the in-memory L2P should agree with the in-flash L2P in addition to all the delta pairs. Like AR and CR , there is also a weaker version of RI called CI that describes only the properties about the in-flash part of a \mathbb{P} -state, and is used in the relevant per-operation correctness formulae. Note that per-operation correctness is about the behavior of an operation in general, not about its effect on particular states. We have thus reduced reasoning about fragments, of which there is a myriad possibilities, to reasoning about operations, of which there is only a handful.

Finally, to make the induction go through, we need to establish RI on all normal states and CI on all abnormal states so that the RI and CI premises in the type A per-operation correctness formulae are satisfied. This is done by showing that the invariants are suitably preserved or transformed by each operation, for example,

$$\forall s, s'. RI(s) \wedge s \xrightarrow{f} s' \implies RI(s') \quad (5)$$

These formulae are called *type B per-operation correctness*.

Up to this point, what we have proven is that \mathbb{P} is behaviorally correct if (i) $AR(s, t)$ implies $s \approx t$ for all s and t , (ii) $CR(s, t)$ for all $s \in \mathcal{N}_{\mathbb{P}}$ and $t \in \mathcal{N}_{\mathbb{S}}$ and $CI(s)$ for all $s \in \mathcal{N}_{\mathbb{P}}$, and (iii) (type A and type B) per-operation correctness holds for each operation. The three conditions are discharged using automatic verification techniques described next in §5.

5 Verifying the SCFTL Implementation

We use the SMT solver Z3 [18] to prove the correctness of the aforementioned three conditions. The first two conditions are easy to check: once we have the formulae describing the invariants RI and CI and the abstraction relations AR and CR , we can easily construct the corresponding formulae and let Z3 prove their validity automatically. For the third condition, i.e., the per-operation correctness, we need to construct the formulae $s \xrightarrow{op} s'$ in \mathbb{P} from the C implementation for all operations op . We use the symbolic executor Serval [32] to build these formulae (§5.1). If we naively construct the per-operation correctness formulae, often the generated formulae would be too difficult for Z3 to solve. We explain in §5.2–§5.4 how to simplify the formulae so that Z3 can handle them.

5.1 Modeling flash states and crashes

To perform symbolic execution for SCFTL, we need to translate C statements into formulae describing how they update the \mathbb{P} -states. A \mathbb{P} -state includes a *memory state* and a *flash state*. The memory state is a mapping from variable names to their in-memory value. For example, it maps L2P to an in-memory table. Serval can handle the update of memory states and produce the corresponding formula automatically. We model a flash state as a function $content(bk, pg)$ that maps a *flash location*, which is a pair (bk, pg) where bk is a block address and pg is a page address, to the data stored in that

page, and modify Serval to support the flash commands SYNC, ERASE, READ, and WRITE. More concretely, we need to tell Serval how those commands update flash states.

The $\text{WRITE}(bk, pg, d)$ command updates the flash state $\text{content}(b, p)$ to $\text{ite}(bk = b \wedge pg = p, d, \text{content}(b, p))$, where $\text{ite}(g, e_1, e_2)$ is a shorthand for “if g then e_1 else e_2 .” The $\text{ERASE}(bk)$ command updates the flash state $\text{content}(b, p)$ to $\text{ite}(bk = b, \text{empty}, \text{content}(b, p))$, where *empty* is a page (which can be modeled as, e.g., an array) with all cells valued -1 . Neither the $\text{READ}(bk, pg)$ nor the SYNC commands change $\text{content}(b, p)$ in the flash state.

Handling asynchronous flash operations The flash commands are *asynchronous*, i.e., the invoked commands first wait in a queue and start to update the flash memory only when the scheduler selects them. Updates to the same page will be executed in the same order in which they come into the queue, but there is no restriction regarding when the updates happen for different pages. If the system crashes, it will lose all commands in the queue.

The flash command SYNC blocks the system until the queue becomes empty. If the system crashes right after a SYNC command, there will be only one possible flash state. However, when it happens between two SYNC commands, there can be multiple possibilities, because we do not know which of those queued commands are processed.

Example 1. Suppose the content at the location (b_1, p_1) is *empty* before invoking the sequence of flash commands $\text{WRITE}(b_1, p_1, d_1)$, $\text{ERASE}(b_1, p_1)$, $\text{WRITE}(b_1, p_1, d_2)$, SYNC. If the system crashes right before SYNC, the content at (b_1, p_1) can be either *empty*, d_1 , or d_2 .

One way to model crash behavior is to use *crash schedules* [42, §3.1], which are a set of boolean variables representing the occurrence of crash events during the execution of an operation. A special case where all the boolean variables are true indicates a successful execution, in which all the WRITES invoked by the operation are synchronized. If we adopted this approach, then SCFTL would have to issue a SYNC at the end of each operation, limiting concurrency within a single operation. However, in our SCFTL implementation, it often happens that a SYNC is invoked only after multiple operations. Thus, this modeling would reduce performance significantly.

An alternative approach represents each flash page as a *history of values* [13, §3.2], which are the values written asynchronously to the flash page since the last SYNC. The history can be implemented as a *list*, and a crash non-deterministically chooses a value from the list. This modeling does not require synchronization at the end of an operation, and therefore does not limit concurrency. However, lists are not well supported by SMT solvers.

We propose a novel approach to model crash behavior, which does not limit concurrency and is amenable to SMT reasoning. The main idea is to “over-approximate” possible flash states when they are affected by asynchronous up-

dates. We implement the idea by adding to the flash state a mapping $\text{sync}(b, p)$ that maps a flash location (b, p) to a boolean value denoting whether the page is synchronized, i.e., it is not affected by asynchronous updates since the last SYNC. The $\text{WRITE}(bk, pg, d)$ command updates $\text{sync}(b, p)$ to $\text{ite}(bk = b \wedge pg = p, \text{false}, \text{sync}(b, p))$ and the $\text{ERASE}(bk)$ command updates it to $\text{ite}(bk = b, \text{false}, \text{sync}(b, p))$. The $\text{READ}(b, p)$ command does not change $\text{sync}(b, p)$ and always returns $\text{content}(b, p)$ no matter $\text{sync}(b, p)$ is true or not. The SYNC command remaps all locations of sync to *true*.

If op is a successfully executed operation, we collect all \mathbb{P} -states produced after executing op symbolically and use them to construct the formula for $s \xrightarrow{op} s'$.

If op is a crashed operation, we collect all possible crash states in two steps. We first collect all flash states (i) right before every SYNC command and (ii) after executing op . We then update the $\text{content}(b, p)$ function of the collected states to $\text{ite}(\text{sync}(b, p), \text{content}(b, p), \text{any})$, where *any* means the content can be any value. We model *any* with *fresh variables*, whose values can be arbitrarily assigned. The formula $s \xrightarrow{op} s'$ can then be constructed from all the $\text{content}(b, p)$ functions of the collected states. We also designed a suitable crash representation invariant CI for SCFTL operations that records flash disk information that is just sufficient for the recovery operation. For instance, it states that “at least one of the two full checkpoints is committed.” The CI can be guaranteed even with the over-approximated flash state we just introduced.

As said, the formulae produced with the approach we just described may be too difficult for SMT solvers to solve. Below (§5.2–§5.4) we introduce the techniques we use to simplify the formulae and make automatic verification feasible. These techniques are very general and should be usable by other automatic verification projects.

5.2 Crafting the abstraction relations and representation invariants

To avoid overwhelming the SMT solvers, care must be taken to put the abstraction relations and representation invariants in a suitable form. Below we look at a concrete example. A part of the abstraction relations asserts that the stable L2P in \mathbb{S} should agree with its concrete representation in \mathbb{P} , which is the in-flash L2P stored in a committed full checkpoint, in addition to all the committed delta pairs stored in the delta region (Figure 2). As opposed to representing the assertion as a relation, we could define a *function* that computes the physical address for a given logical address la from a \mathbb{P} -state by starting with the in-flash L2P and then sequentially applying the delta pairs, and assert that the stable L2P in \mathbb{S} agrees with the results of the function. Serval compiles the assertion to the following constraint (assuming for simplicity that there are only two delta pairs (la_0, pa_0) and (la_1, pa_1)):

$$\begin{aligned} &\forall la. L2P_{\text{stable}}[la] \\ &= \text{ite}(la = la_1, pa_1, \text{ite}(la = la_0, pa_0, L2P_{\text{flash}}[la])) \end{aligned}$$

The number of *ites* is the same as the number of delta pairs, which in the implementation is set to be large enough to avoid frequent full checkpointing. The resultant formula turns out to be too large for the SMT solvers to handle, though.

We thus choose to represent the assertion as a relation, which is divided into two disjoint parts. The first part considers logical addresses that appear in the delta region, and the second part considers those that do not. In more detail:

- For every (\forall) logical address la that appears in the region, there exists (\exists) a pair (la, pa) in the region such that $L2P_{stable}[la] = pa$. Moreover, this pair should be the last one about la in the sense that for any (\forall) subsequent pair (la', pa') we have $la' \neq la$.
- For every (\forall) logical address la that does not appear in the region, we have $L2P_{stable}[la] = L2P_{flash}[la]$.

The first part of the relation is still not amenable to efficient SMT solving as it contains *quantifier alternation* of the form $\forall x. \exists y. \forall z. \dots$, which is often too hard for the SMT solvers [4, 44] to deal with. The key observation is that the existential quantifier \exists can be avoided with the *ghost variable* technique [20]: because pa is determined by la and the \mathbb{P} -state, we can extend the \mathbb{S} -states with an auxiliary array aux (along with some other ghost variables required to determine pa) and modify the transition relation of \mathbb{S} to keep track of the last pa associated with each la ; the formula can then simply use $aux[la]$ (instead of an existentially quantified variable) whenever it needs to refer to the last pa associated with la . Note that the transitions of the non-ghost variables (i.e., *volatile*, *stable*, and *wcnt*) must not depend on the ghost variables (e.g., aux), so that the specification of interest (Figure 4) is essentially a *projection* of the \mathbb{S} -states, in which ghost variables are removed from the state space.

5.3 Categorizing the invariants

We use the observation that, usually, the invariants and abstraction relations can be grouped into different categories and handled separately in verification. For example, the *RI* may include constraints for different components of SCFTL, e.g., checkpoint and garbage collection. To simplify the presentation, here we assume $RI(s) = RI_{chk}(s) \wedge RI_{gc}(s) \wedge RI_{other}(s)$, where $RI_{chk}(s)$ are invariants related to checkpoints, $RI_{gc}(s)$ are those related to garbage collection, and $RI_{other}(s)$ are other invariants. Now we can divide Formula 5 into three simpler formulae: $\forall s, s'. RI(s) \wedge s \xrightarrow{op} s' \implies RI_x(s')$, where $x \in \{chk, gc, other\}$, and prove their correctness separately. We can further simplify the formulae by using only a subset of the constraints in *RI* to show the preservation of invariants. The reason is that to show $RI_x(s')$ holds after the execution of *op*, we usually do not need the starting state s to also satisfy the invariants related to other components. Hence we can use the formula $\forall s, s'. RI_x(s) \wedge s \xrightarrow{op} s' \implies RI_x(s')$ instead.

5.4 Partitioning the proofs

Both the implementation and specification of SCFTL involve “non-determinism” when a flush operation crashes. In the implementation, we collect multiple flash states to produce the formula $s \xrightarrow{fc} s'$. In the specification (Figure 4), when a flash operation crashes, the stable data may remain unchanged ($t'.stable = t.stable$) or change to the volatile data ($t'.stable = t.volatile$). We found that such non-determinism induces verification bottlenecks. We tried to prove the correctness of flush using Z3 with the presence of such non-determinism, but the solver failed to solve it given a few days of time budget. In our experience, this usually means the problem is too difficult for Z3 and needs to be simplified. For SCFTL, such non-determinism can be avoided by *partitioning the proofs*. We need to figure out (i) which flash states of the implementation correspond to the specification $t'.stable = t.stable$ and (ii) which correspond to $t'.stable = t.volatile$. More concretely, assuming that we collect two flash states, represented as $f_1(s)$ and $f_2(s)$, during the execution of the crashed flush operation, we can substitute the transition relations in Formula 4 properly to obtain:

$$\begin{aligned} \forall s, t, s'. AR(s, t) \wedge RI(s) \wedge (s' = f_1(s) \vee s' = f_2(s)) \\ \implies \exists t'. \left(\begin{array}{l} t'.stable = t.stable \\ \vee t'.stable = t.volatile \end{array} \right) \wedge CR(s', t') \quad (6) \end{aligned}$$

Instead of directly proving Formula 6, which involves non-determinism (\vee), we can use Z3 to prove the following two sufficient conditions separately—if we know that the first flash state corresponds to $t'.stable = t.stable$, and the second corresponds to $t'.stable = t.volatile$:

$$\begin{aligned} \forall s, t, s'. AR(s, t) \wedge RI(s) \wedge s' = f_1(s) \\ \implies \exists t'. t'.stable = t.stable \wedge CR(s', t') \quad (7) \end{aligned}$$

$$\begin{aligned} \forall s, t, s'. AR(s, t) \wedge RI(s) \wedge s' = f_2(s) \\ \implies \exists t'. t'.stable = t.volatile \wedge CR(s', t') \quad (8) \end{aligned}$$

Although this technique requires manual inspection of each crash state generated during an operation, it significantly improves the scalability of the verification of SCFTL.

6 Discussion

Using an SMT solver has the advantage that once the formulae are constructed, their proofs are done fully automatically. If some of the constructed formulae cannot be solved in a reasonable time, we apply the techniques mentioned above to simplify them systematically. In total, the representation invariant (*RI*) and the abstraction relation (*AR*) contain 98 conditions; their weaker versions (*CI* and *CR*, respectively) contain 17 conditions. We also use *loop invariants* and an inductive proof rule [23] to handle large loops. With these, all but three conditions can be proven correct.

The three unverified conditions are: (i) after a successful recovery, the L2P table is an one-to-one mapping except for

invalid entries; (ii) after a successful recovery, there is sufficient space to accommodate the follow-up writes and gc_{rls} ; (iii) after a successful flush, there is sufficient space to accommodate the follow-up writes and gc_{rls} . For the three unverified conditions, we use the *validation* technique [37] to ensure their correctness. The validator itself is formally verified (explained in §6.1) and will notify the user when our SCFTL implementation violates the property. Such notification never occurs in all of our experiments.

The Z3 verification time is 4640 seconds for a 8 GB flash disk and 6302 seconds for a 256 GB flash disk. We choose to verify a particular flash disk size at a time (rather than for all sizes) to reduce the number of quantifiers and thus improve the verification time. We also tried to change other parameters (e.g., several write bounds ranging from 2048 to 20480), the verification time ranges from 1 hour to 2 hours; interestingly, a larger value does not imply a longer time.

Table 1. Lines of code for SCFTL.

Component	Lines of code
SCFTL implementation	950 (C)
Snapshot consistency theorems	652 (Agda [33])
SCFTL specification	22 (Rosette [43])
Invariants & Relations	2010 (Rosette)
Ghost variables	538 (Rosette)
Proof partitions	96 (Rosette)
Flash memory model	232 (Rosette)
Core framework	1048 (Rosette)
Total	3946 (Rosette)

Table 1 shows the lines of code for SCFTL. We count the specification, loop invariants, representation invariants, abstraction relations, ghost variables, and proof partitions as our proof, resulting in a proof-to-implementation ratio of 2.8:1. The total development effort is about 6 person-months; a significant part is devoted to finding (an efficient SMT encoding of) the required invariants and scaling the verification with the techniques we introduced in §5. For the trusted computing base, we assume that (i) the flash memory is free of error, (ii) the verification tools Z3, Agda, and Serval are correct, (iii) the translation from LLVM to machine code is correct, and (iv) the LightNVM [6] Linux kernel module, which we used to host our SCFTL, is correct.

6.1 Validating unverified conditions

For each of the unverified conditions, we implement a validator to monitor if the condition is indeed satisfied during runtime. More specifically, we add to the \mathbb{P} -states a set of *validation variables*, including a flag indicating whether the validation fails or succeeds. The validators are not allowed to modify the \mathbb{P} -states other than the validation variables. We prove that the validator establishes the following postcondition: if the flag indicates a successful validation, then the

condition holds. Although the validation approach is not as useful for storage systems as for compilers, we regard the approach as a last resort to circumvent the limitation of automatic verification.

Validation can also be used to incorporate unverified components into SCFTL. For example, an unverified block allocator may keep track of the block usage and allocate the block with the least amount of usage for wear leveling. A validator can then validate whether the allocated block is actually in the free block queue, and if so, returns the block. Otherwise, SCFTL falls back to the default verified behavior, e.g., allocating the first block in the free block queue.

6.2 Support for concurrency

Our verification methodology does not support concurrent SCFTL operations, and our specification has a sequential nature. However, both of them do not limit an implementation from exploiting the high degree of hardware parallelism commonly seen in modern flash disks (e.g., multiple channels and flash chips). More specifically, executing a single step (e.g., a write operation) in the specification corresponds to performing a top-level C function in the SCFTL implementation. The C function usually uses asynchronous flash commands to avoid waiting for slow flash operations to finish. This design allows multiple flash operations to be executed concurrently until a SYNC. Reordering due to the concurrency of flash operations can only be observed when a crash occurs. We describe our technique to capture reordering in §5.1.

7 Evaluation

To evaluate SCFTL, we conducted experiments designed to answer the following questions:

- Is SCFTL actually correct? (§7.1)
- How does SCFTL perform compared to other FTLs implementing different disk models? (§7.2)
- Is the guarantee of snapshot consistency provided by SCFTL useful to its upper layers? (§7.3)

All experiments were done on a host machine with a 12-core 3.2 GHz Intel i7-8700 CPU and 16 GB of DRAM. To emulate the flash memory, we run experiments on Linux 4.15 hosted by FEMU [29], a QEMU-based emulator that can emulate an Open-Channel SSD (OCSSD). We used liblightnvm [2] with the libaio [1] backend to access the underlying OCSSD in an asynchronous way. The original version of FEMU supports latency emulation for OCSSD commands, but as libaio can only issue NVMe base commands, we followed FEMU’s approach to emulate latency for NVMe base commands. We validated that the results produced by the two sets of commands are consistent. The OCSSD has 4 channels, 4 dies per channel, and a total of 8 GB flash memory. We reserved 16 MB of flash memory for the full checkpoint region, 256 MB for the delta region, and set the write bound to 2048.

Figure 5. Throughput of FTLs under random writes with different write intervals (WI).

7.1 Stress testing and crash state simulation

To validate the correctness of SCFTL, we designed a testing framework that allows fast stress testing and crash state simulation. The framework hosts SCFTL by emulating the flash memory with DRAM, and simulates a crash by overwriting all pages affected by asynchronous WRITE or ERASE since the last SYNC with garbage data. The framework uses a *workload generator* to issue a sequence of writes and flushes to SCFTL, and simulates a crash based on a given probability. We set a higher probability for configurations that are more likely to result in corner cases (e.g., crashes during recovery).

The framework maintains a pair of arrays, volatile and stable, as golden results, and changes their states according to Figure 4. A *result checker* is then periodically activated to read every sector of SCFTL and check whether the results produced by SCFTL is consistent with the volatile array. To speed up testing, the checker only compares the first few bytes of the read data. We ran the test with 4 configurations for about 8 hours. In total, the workload generator wrote more than 1.4 TB of data, issued about 12 millions of flushes and simulated about 10 thousands of crashes. SCFTL successfully recovered from every crash state and passed all checks.

7.2 Comparing SCFTL with other FTLs

Besides SCFTL, we implemented two additional FTLs with different crash guarantees. The two FTLs implement the asynchronous (denoted by *async*) and synchronous (denoted by *sync*) disk models respectively. *async* is implemented in a way similar to SCFTL, except *async* (i) does not do checkpointing, (ii) does not comply with 2PGC (i.e., victim blocks are erased immediately after all valid data is relocated), and (iii) has no write count constraint. *sync* is the same as *async*, except *sync* always uses synchronous operations to access the underlying flash memory. We assume the one-page merge buffer of *sync* is backed by a battery (i.e., data copied to the buffer is guaranteed to be persistent); thus *sync* can safely ignore any flush request. We also used the state-of-the-art FTL *pblk* [6], which has similar features to *async* (e.g., both of them implement the asynchronous disk model and use a sector-level L2P), to understand the quality of our FTL implementation.

We wrote a small program to randomly issue 4 KB writes to a disk, and periodically flush the disk after a fixed number of writes. We call this period the *write interval*. For *pblk*, we also used a concurrent version (employing 4 threads) of the same

Figure 6. Boot time of SCFTL.

program as a way to identify the limitation of SCFTL’s sequential nature. Figure 5 shows the average throughput. We first draw two conclusions: (i) Our baseline FTL, *async* (3rd bars), has a performance characteristic similar to *pblk* (2nd bars). (ii) Concurrent workloads (1st bars), in general, have higher total throughput than sequential workloads (2nd bars); but the improvement is less obvious when the write interval is higher (e.g., WI = 2048 and WI = 256) because the underlying flash memory has fewer idle resources to serve the concurrent requests. Next, we compare SCFTL with *async* and *sync*.

When the write interval is set to 2048, SCFTL throughput is within 5% of *async* on average; with the write interval set to 256, SCFTL throughput is still within 11%. In both settings, SCFTL outperforms *sync* by more than 14x. With the write interval set to 16, SCFTL throughput drops to 53% of *async*, but still outperforms *sync* by 3.8x. When the write interval is reduced to 1, SCFTL throughput is only one half of *async* and one quarter of *sync*, because SCFTL writes one additional delta page on receiving a flush. Note that the last setting is not a reasonable usage of SCFTL, but it shows the overhead of SCFTL under the worst-case scenario.

We also analyze the write and flush latency and make the following observations: (i) SCFTL has a slightly higher average flush latency (12 ms) than *async* (10 ms) because SCFTL writes an additional delta page during a flush. (ii) SCFTL has a higher maximum flush latency (398 ms) due to full checkpointing; we can reduce the latency with a hybrid setting (similarly to the WAFL file system [22] which puts a log of requests on non-volatile memory and other data on slower disks), in which the full checkpoints go to memory technologies with a lower latency (e.g., SLC flash and 3D XPoint memory [21]), and other data stays in ones with a higher latency but a lower cost (e.g., MLC and TLC flash).

Finally, Figure 6 shows the boot time of SCFTL. We have not yet implemented optimizations for recovery to reduce the boot time, so the boot time is nearly the same regardless of whether there is a graceful shutdown or where a crash occurs. In general, the boot time is directly proportional to the size of the delta region and the size of the logical address space.

7.3 Modifying xv6 with SCFTL

To understand the usefulness of snapshot consistency guaranteed by SCFTL, we used *xv6* [16], a simple *log-based* file system, as our example. In order to prevent any file system inconsistency (e.g., a directory entry pointing to a free inode)

Figure 7. Performance of xv6 on different FTLs. SQLite generates 1K insert transactions followed by 1K update transactions; smallfiles repeatedly creates a file, writes 100 bytes of data to it, and calls `fsync`; largefile writes 4 MB of data to a file and calls `fsync` for every 1 MB; mailbench models a mail server running on the xv6 operating system [14]. To ensure durability, mailbench invokes an `fsync` for each message. We ran each workload 5 times and reported the average. The standard deviation is less than 8%.

due to a crash occurring in the middle of a system call, xv6 uses a *write-ahead log* for atomically writing multiple sectors of data to its underlying disk. Such atomicity, however, can be easily achieved with SCFTL. We thus modified xv6 to bypass its log so that data does not need to be written twice, once to the log and once to its actual location. We further modified xv6 to support a common optimization known as *group commit*, which groups multiple system calls into one *transaction*, to reduce the number of flushes. With group commit, xv6 only issues a flush when a transaction is full or on receiving an `fsync`. The implementation is rather easy with SCFTL; we changed less than 30 lines of code of xv6. We compared the two modified versions of xv6 on SCFTL (denoted by xv6-xlog and xv6-group, respectively) with the original xv6 on the asynchronous and synchronous disks used in §7.2 (denoted by xv6/async and xv6/sync, respectively). We used existing file system benchmarks [14, 40] to evaluate the performance.

Figure 7 shows the results. The performance of xv6-xlog is only on par with that of xv6/async and xv6/sync. Although xv6-xlog has reduced the use of writes and flushes via bypassing the log, issuing a flush at the end of each system call would inevitably result in a small write interval, for which SCFTL does not perform very well as shown in Figure 5. xv6-group performs much better than the other three as the write interval becomes larger when multiple system calls are grouped together. The performance difference is particularly obvious for largefile, where `fsync`s are less frequent.

Note that while xv6/async, xv6/sync, and xv6-xlog guarantee *immediate durability*, that is, the result of a system call is successfully stored in the disk after the call returns, xv6-group only guarantees system calls before the last `fsync` are persisted, and system calls after the last `fsync` will not be reordered. This property is also known as *sequential crash consistency* [7]. In practice, sequential crash consistency is a very strong property and is what most application developers actually require [35].

Finally we compare our group commit version of xv6 with

Figure 8. xv6 on SCFTL vs. ext4 on pblk. When running mailbench on ext4-metadata that does not guarantee the ordering between data and metadata, we invoked one additional `fdatsync` on the temporary file [12, Figure 1].

the state-of-the-art storage stack: ext4 on pblk. We mounted ext4 with two configurations: The default metadata journaling mode `data=ordered` (denoted by ext4-metadata), and the data journaling mode `data=journal, journal_async_commit` (denoted by ext4-data). ext4-metadata does not journal data but it issues one more flush than ext4-data when committing an ext4 transaction.

Figure 8 shows the results. xv6-group performance is 7% to 49% lower than ext4-metadata. Compared with ext4-data, the performance difference is more divergent. For SQLite, xv6-group performance is only 43% of ext4-data; but for largefile, xv6-group is more than 1.4x of ext4-data. Such divergence can be explained by the behavior of the workloads: SQLite frequently issues `fsync`s and causes the performance of SCFTL to degrade; on the other hand, largefile issues much less `fsync`s and a huge amount of data is written in the journal of ext4-data. We believe the performance difference between our modified xv6 and ext4 is mainly owing to the simplicity of xv6. This can be improved by, e.g., optimizing xv6 with in-memory representations for file system operations [5].

8 Conclusion

We believe that our verified SCFTL brings new opportunities for the design of the storage stack. We demonstrate that starting at a lower-level of abstraction can make verifying crash safety easier while still resulting in an efficient system. Formal specification and verification give the user a clear picture and strong confidence of what he/she can assume while designing the upper layers of the storage stack. Our experimental results show that SCFTL can provide a strong crash guarantee without compromising its performance if upper layers can carefully reduce the flush frequency.

There are several avenues for future work. For instance, we would like to extend the work to cover upper layers, such as file systems or database systems, of the storage stack. With a careful design that fully utilizes the advantage of SCFTL, we believe it is likely that we can obtain a verified and yet efficient upper-layer system. The FTLs used in commercial products usually come with several optimizations, e.g., hot-cold data separation and wear leveling. We plan to extend SCFTL to use those optimizations.

Storage Systems are Distributed Systems (So Verify Them That Way!)

Travis Hance, Carnegie Mellon University

Abstract

To verify distributed systems, prior work introduced a methodology for verifying both the code running on individual machines and the correctness of the overall system when those machines interact via an asynchronous distributed environment. The methodology requires neither domain-specific logic nor tooling. However, distributed systems are only one instance of the more general phenomenon of systems code that interacts with an asynchronous environment. We argue that the software of a storage system can (and should!) be viewed similarly. We evaluate this approach in VeriBetrKV, a key-value store based on a state-of-the-art B^etree.

In building VeriBetrKV, we introduce new techniques to scale automated verification to larger code bases, still without introducing domain-specific logic or tooling. In particular, we show a discipline that keeps the automated verification development cycle responsive. We also combine linear types with dynamic frames to relieve the programmer from most heap-reasoning obligations while enabling them to break out of the linear type system when needed. VeriBetrKV exhibits similar query performance to unverified databases. Its insertion performance is 24× faster than unverified BerkeleyDB and 8× slower than RocksDB.

1 Introduction

Software verification promises a fundamentally better way of constructing critical systems: Instead of relying on the spotty coverage provided by run-time testing, verification can mathematically guarantee the functional correctness and even the reliability of software at compile time.

In the context of distributed systems, prior work on IronFleet [29] shows how to combine Hoare logic [23, 31], to reason modularly about the behavior of a single program, with TLA-based [40] state-machine reasoning to show that a collection of nodes running that program behaves according to a high-level functional spec when executing in a failure-prone, asynchronous distributed environment. Both techniques employ general-purpose logic, unlike other work in the area that relies on custom languages or logic [17, 18, 58]. The approach

is compatible with a reasonable level of automation, modest-scale implementations (2-3K LoC), and performance within a factor of 2 of unverified code.

We observe that the abstraction of a system as a program interacting with a failure-prone, asynchronous environment applies beyond the domain of distributed systems. Indeed, we argue that a very different domain – storage systems – fits quite naturally into this same abstraction, capturing the asynchrony and nondeterminism of crash safety in such systems. Hence we generalize the IronFleet methodology to this new domain, without introducing a domain-specific logic [12], creating a custom language [2], or changing our system’s API and implementation to accommodate verification [54].

We evaluate the success of this generalization by constructing VeriBetrKV, a key-value store based on a B^etree [7], a complex but asymptotically-compelling write-optimized data structure. Modern persistent key-value stores use write-optimized data structures, such as LSM-trees [19, 20, 26, 37, 43, 53] and B^etrees [50], in order to efficiently handle random-insertion workloads, which are common in many key-value-store applications. Write-optimized data structures outperform older key-value data structures, such as B-trees, by orders of magnitude. However, these performance gains come at the cost of a significant increase in code complexity.

TLA-based reasoning lets us prove VeriBetrKV’s correct behavior under process crashes and under disk sector corruptions, while Hoare logic allows us to reason independently about the implementation-level optimizations needed for performance.

The resulting system is significantly more complex than the closest prior work, a verified in-memory key-value store [29]. The implementation is over 3× larger, and proving it functionally correct and crash safe requires a multi-level (vs. single-level) refinement proof.

Hence, an important contribution of this work are the techniques we developed to apply automated verification at this new scale. To make verification practical for large-scale software development, we need to balance between exploiting automation and controlling it. Ideally, we want *decisive* automation; i.e., automation that quickly tells us whether our

code and proofs are correct or incorrect. Decisive automation keeps developers engaged and efficient. Unfortunately, since general-purpose verification is undecidable, most automation tools can also “time out”. This pessimal outcome takes longer (by definition) and provides less direction to the developer, harming morale and productivity [21, §9.1][29, §6.3.2].

To escape the plague of time outs, we present a concrete development discipline that rapidly squashes time-out prone code. This ensures developers spend the majority of their time in a tight verification development cycle. For example, 98.3% of the definitions in VeriBetrKV verify in less than 10s, enabling development of larger code bases with less effort.

Many verification frameworks reason only about code operating on immutable data structures [11, 49], leaving optimized code generation to a compiler such as Haskell’s. Most real systems code relies on explicit in-place updates for good performance to avoid data copies. Some verification frameworks enable reasoning about heap-manipulating code using various methodologies from the PL literature, from separation logic [12, 52] to dynamic frames [29, 30, 32]. These techniques rely on both programmer annotations and relatively heavy-weight automation (e.g., SMT solvers [16]) to determine whether a modification to one portion of the heap may have affected other objects on the heap. Despite our time-out-prevention discipline, we encountered challenges with such automation: while it works well in small instances, as the system grows more complex, the automation slows significantly, reducing developer productivity (in line with prior reports [29, §6.2]).

Drawing on ideas from commercial (Rust [33]) and research [2, 51, 59] languages, we integrate a lightweight linear type system that gives dramatic automation improvements with dynamic frames when additional flexibility is needed. We rewrote some core components of VeriBetrKV from dynamic frames into linearity, reducing our proof burden by 31–37% without impacting performance. We also leverage linear types to emit optimized C++ code.

Ultimately, our evaluation (§7) shows that VeriBetrKV is able to deliver much of the performance gains promised by sophisticated key-value store data structures. On insertions using a hard disk, it outperforms BerkeleyDB by 24×. However, there is still work to be done. Insertions in VeriBetrKV are about 8× slower than RocksDB, a highly-tuned commercial key-value store.

As with any research prototype, VeriBetrKV comes with limitations. One limitation of VeriBetrKV is that it is presently single-threaded; it can exploit I/O pipelining but not CPU concurrency. Second, the guarantees of verification are limited by the Trusted Computing Base (TCB): the top-level spec of a crash-robust key-value store, the spec of VeriBetrKV’s interface to the OS and runtime, and the verifier and compiler (Dafny [41] and Z3 [16]). Finally, we focus on safety and functional correctness: we guarantee that the system does not return incorrect results, but liveness (i.e., the guarantee that an

operation will complete in finite time) is out of scope.

In summary, this paper makes the following contributions:

1. A method of specifying crash safety in a clean and extensible way that generalizes a verification methodology for distributed systems. As a demonstration of its extensibility, we enhance the specification to include robustness to disk corruption.
2. A discipline for managing automation that supports scalable system development.
3. The integration of a lightweight linear type system within a general-purpose verification language, and a large-scale concrete case study quantifying the impact of the type system as compared to previous approaches.
4. A prototype key-value store demonstrating that our verification methodology can scale to handle the complexities of modern key-value-store data structures.

2 Assumptions and Background

We summarize the assumptions underpinning our verification results (§2.1), the verification techniques we employ (§2.2–2.3), and the prior work from which we take inspiration (§2.4).

2.1 Assumptions

Every verified system makes a guarantee that is predicated on a set of assumptions which can be divided into three categories. First, the user must trust the top-level application-facing specification of the contract provided by the system. We provide a succinct (283 lines) specification for VeriBetrKV in terms of a dictionary that, when it crashes, reverts to its state at the most recent client `sync` (§3.1.2).

Second, the system must specify an interface to the environment (i.e., the rest of the world) that codifies assumptions about how that environment behaves. VeriBetrKV’s interface is an asynchronous I/O bus that reorders but does not duplicate or, except during a crash, drop messages. VeriBetrKV’s environment models a block-level disk and the possibility of arbitrary crashes and torn writes (§3.1).

Finally, we assume the correctness of our verification tools, including the build system that runs our verifier, Dafny [41], on each file. We modify Dafny to emit C++ code (§5.2), so we also rely on the correctness of the C++ toolchain used to produce an executable. These trusted tools are comparable to those in other systems verification efforts; e.g., systems verified in Coq [15] trust Coq, Coq’s extraction to, say, OCaml, and the OCaml compiler and runtime. Prior research indicates that each element in such a toolchain can itself be verified [6, 35, 42, 44, 56].

Despite all of these assumptions, several studies indicate that verification is a qualitatively better way of developing software [22, 24, 63], compared with current state-of-the-art code development techniques. These studies found numerous defects in traditional software, but none in verified software, only in the (unverified) trusted components.

2.2 TLA+-Style State-Machine Refinement

State machine refinement is an important tool in verifying asynchronous systems [1, 25, 38]. A high-level, abstract state machine models the desired behavior of a system (say, a key-value dictionary) capturing essential features (inserts update the dictionary; queries probe it) and abstracting away irrelevant details (e.g., efficient indexing and data representation). A concrete state machine adds more details, showing one way to instantiate the abstract machine (e.g., using a hash table to implement the dictionary). A safety proof then shows that the concrete state machine *refines* the abstract state machine, meaning that every execution of the concrete state machine can be mapped to a possible execution of the abstract one. Hence, reviewing the abstract state machine tells the consumer what to expect from the concrete state machine’s behavior.

A strength of this approach is that the high-level machine can abstract over asynchrony. If the concrete machine has many concurrently-moving parts, but one can show a refinement (because most transitions in the concrete model do not change its abstract interpretation), then we know the concurrency is irrelevant to the abstract behavior.

2.3 Floyd-Hoare Verification

Floyd-Hoare reasoning [23, 31] is a popular technique for reasoning about the correctness of single-threaded imperative programs. The developer annotates the program’s functions with pre-/post-conditions about the program’s state when entering/leaving the function, and a verifier checks that these claims hold for all possible inputs and outputs.

Verification tools based on Floyd-Hoare reasoning typically do not consider asynchronous interactions with an environment, which makes it difficult to reason directly about, e.g., program crashes that might occur at arbitrary points during execution. Hence, prior work in storage-system verification introduced a novel version of Floyd-Hoare reasoning, Crash-Hoare logic, to cope with this particular flavor of asynchrony [12].

2.4 Verifying Distributed Systems

In their IronFleet work [29], Hawblitzel et al. show how to compose Hoare logic and TLA+-style state-machine refinement to reason about the safety and liveness of distributed systems. They use Hoare logic to reason locally about a single program’s behavior, showing that it conforms to an abstract state machine. They then model the distributed system as another state machine whose state consists of N replicas of the program state machine, along with a network represented as a set of in-flight messages. The system transitions by non-deterministically choosing to allow either one of the N program state machines to advance a step, or the network’s state to advance (e.g., by delivering a message). The model captures nodes that can fail-stop and a network that can duplicate, drop, and reorder messages. The top-level verification theorem proves that if the program (e.g., a sharded key-value store) runs in a distributed system as modeled, then its behavior

Figure 1: System and environment state machines express how a program interacts with the world to implement an application in IronFleet (left) and VeriBetrKV (right). Shaded shapes are trusted; unshaded shapes are untrusted code and proof.

matches a concise app spec – a centralized map.

3 Verifying Storage Systems

To verify storage systems, we observe that embedded within prior work on verifying distributed systems (§2.4) is a general-purpose framework for verifying code that interacts with an asynchronous environment, such as a storage system. This is exciting because it suggests we can use a common methodology to solve a broader class of systems verification problems, and it obviates the need to develop a specialized logic or proof framework for each environment. In this paper, we showcase an instantiation of this general methodology for an asynchronous environment with a single disk and a single processing node. However, we conjecture that the approach generalizes to a variety of systems including multi-node, multi-disk storage systems; indeed, our predecessor, IronFleet [29], has already shown how to model multiple nodes connected by an asynchronous network. Further systems applications might include heterogeneous hardware or device drivers.

In this general framework (Figure 1), the developer uses Hoare logic to prove that their optimized imperative program code, when run synchronously and without crashing, complies with an abstract *program state machine* (e.g., in prior work, this was the code running on each node in the distributed system). The program code uses a trusted API (e.g., for the network) to interact with the outside world, and an important aspect of the refinement proof is showing that the code’s interactions with this API match those specified by the program state machine. A second state machine, the *environment*, encodes assumptions about the rest of the world – the parts the program does not control (e.g., the network). A final state machine, the *IOSystem*, composes these two state machines (the program and the environment) and dictates how they interact (e.g., prior work composes N programs running asynchronously, communicating only via the environment’s network). The developers prove a top-level theorem showing

that the IOSystem state machine refines a simple, high-level application spec (e.g., the distributed key-value store behaves like a centralized map). This theorem guarantees correct execution in practice if the environment behaves as modeled, if the hosts run an executable matching the program, *and* if the combined elements interact as assumed by the system.

In this work, we instantiate this general framework to reason about storage systems by modeling an environment that contains a disk and in which crashes may occur.

3.1 An Environment Model with Crashes

Our model of a storage system is a special case of the IOSystem as described above. It contains two parts: (i) the program, which models the executable VeriBetrKV, and (ii) the environment: a model of the disk with an I/O bus. Together, these two components form a *StorageIOSystem* (Figure 1).

The state machine representing this *StorageIOSystem* can transition in three ways. First, the program state machine can transition forward a step, possibly interacting with the I/O bus. Second, the environment can transition, e.g., by having the disk process a read- or write-command from the I/O bus.

Third and finally (and unlike IronFleet DistributedIOSystems), the *StorageIOSystem* as a whole can perform a *crash*, which models, e.g., a power failure or a kernel panic. Crashing results in a disk state that remembers every write it has acknowledged, but the data at the address of any unacknowledged write may reflect the old value, the newly written value, or a corrupt value (§3.1.1). For the program, a crash simply resets its state machine to its initial (boot-up) condition.

Our top-level proof shows that the *StorageIOSystem* is a refinement of the application spec (§3.1.2), demonstrating that VeriBetrKV’s top-level guarantees are maintained despite an arbitrary number of crashes occurring at nondeterministic times (outside the program’s control).

3.1.1 Corruption

Our disk model allows the disk to corrupt its data at any time (i.e., not just during a system crash). There is only one constraint: corruption cannot produce a block with a valid checksum.¹ When VeriBetrKV detects an invalid checksum, it aborts the current query. This ensures correctness, since VeriBetrKV will not return an incorrect query result. This assumption about the disk’s behavior is what checksummed storage systems already (informally) assume. We formalize this assumption and make use of it in our correctness proof.

Using checksums means that VeriBetrKV protects against “torn writes”, where a block of the disk is changed to have neither its old value nor the value written, as well as random media corruptions. Of course, some disks do violate our checksum assumption. An adversarially-controlled disk could easily return corrupted data yet with valid checksums. Likewise, a disk which returns stale blocks would also not satisfy our

¹Therefore, our checksum routine, CRC32C [8], exists within our TCB, so that it can be referenced by our disk model.

checksum assumption. In either case, it would be impossible for *any* implementation to meet our application spec as written.

However, our methodology provides flexibility in specifying the precise assumptions made about the disk. In principle, an engineer could provide a weaker disk model, and in addition, either provide a cleverer implementation or a weaker application spec to match.

3.1.2 Application Specification

To achieve good performance, a practical storage system cannot afford synchronous writes. Instead, the application calls *sync* when it requires durability; data not synced is permitted to be lost during a crash. The nondeterministic relationship between nondeterministic *crash* and the application *sync* API must appear in the theorem; each is a transition in the application spec state machine.

Intuitively, the application spec of VeriBetrKV says that in the absence of crashes or block corruption, VeriBetrKV acts exactly like a dictionary, always returning the most-recently-written value. In the presence of a crash, VeriBetrKV is allowed to forget data, but no farther back than the most recent *sync*. Furthermore, “forgetting” is equivalent to the entire dictionary reverting to a consistent, previous snapshot; future crash-free operations proceed forward from this snapshot. Contrast this promise with a filesystem with crash-corrupted metadata: the data may appear complete and valid, but future operations may result in behaviors that violate the filesystem’s contract.

Our storage system specification is easy to state, clean, and easy to utilize from a client application. In contrast, contemporary file systems, for performance reasons, decouple *sync* operations on metadata from *sync* on file data. Such guarantees are very difficult to utilize from a client, and in fact difficult to even state precisely; much of DFSCQ is dedicated to stating such a guarantee precisely [11].

3.2 Refinement Verification Techniques

Our methodology requires a proof of a TLA-style state-machine refinement (§2.2) between a *StorageIOSystem* and our application spec. Due to the complexity of this proof, we break the refinement into a sequence of smaller refinements (§6.2.1). We use the following techniques to organize the proof, separating concerns between the caching subsystem, the journal subsystem, and B^etree manipulations.

State-machine composition. In many cases, we define a templated state machine $S\langle T \rangle$ in terms of an abstract subcomponent T . A refinement T' of the subcomponent T can be lifted to a refinement $S\langle T' \rangle$ of the larger state machine $S\langle T \rangle$. This allows us to build up our refinement in terms of refinement proofs for the subcomponents. For example, a B^etree tree refines a simple dictionary spec; therefore, a *crash-safe* B^etree refines a *crash-safe* dictionary spec.

IOSystem Refinement. Our proof re-uses the concept of an

IOSystem at several layers of abstraction. For example, at the lowest layer, we model the disk as storing sequences of bytes, but at higher layers, we model the disk in a “type-safe” way, as a collection of nodes. But at all layers, the overall system follows the rules of an IOSystem state machine.

Transposition. High in the abstraction stack, the disk is used in different ways by different modules. For example, the journal models the disk as an array of journal entries, whereas the B^etree models the disk as storing nodes. At a low level, all the modules together interact with a single, byte-oriented disk. Transposition arguments enable us to split up one StorageIOSystem into multiple, so each can be reasoned about independently.

4 Disciplined Automation

A productive verification workflow uses the developer’s time efficiently. This has two aspects: how much tedious typing the developer has to do, and how quickly the verifier replies to the developer’s proof attempts.

Functional verification of arbitrary software is undecidable, and hence requires either a limit to expressivity [49, 54, 64] or some degree of manual guidance. In interactive theorem provers [15, 47], developers manually use tactics to tell the prover which steps to take next.

A large verified system has a large number of definitions, such as invariants and state-machine transition relations. An automated program verifier is a great fit for systems verification because so much of the verification work is tedium amenable to automation. Exposing all the definitions to the theorem prover, however, gives the theorem prover a large search space, which can take a long time to explore.

The development cycle is a balance between exploiting automation and controlling it. Faced with a verification failure, the developer must first supply any guidance not provided by automation. That process terminates when the proof passes (because the failure was a weakness of the automation) or the developer discovers an actual flaw. If automation is too weak, the developer burns time tediously typing in the missing proof guidance. If the automation heuristics are too aggressive, the developer burns time waiting for replies from the verifier.

As the system grows, the risk of timeouts grows. We have found it essential to resolve timeouts as soon as they crop up, before there are so many they are difficult to sort out. If a developer observes a $> 20s$ response time, they are expected to stop work and instead resolve the timeout,

The key technique to remedy timeouts is to control how much information the prover has when trying to verify a method or lemma, typically by making fewer definitions visible to the theorem prover. Developers can mark Dafny definitions `opaque`, for example, so that the definitions are hidden by default, except where the developer chooses to explicitly `reveal` the definitions. We use a command-line SMT profiler to pinpoint problematic definitions, i.e., those the solver instantiates too many times in its attempts to construct a proof.

Table 7.1 shows that we have followed this discipline with some consistency, and timeouts in VeriBetrKV remain rare.

5 Language Improvements

Verifying low-level systems software means verifying stateful code with in-place updates. Unfortunately, reasoning about updates is painful in the presence of aliasing. Traditional verification tools like Dafny and VCC [13] rely on an SMT solver to reason about aliasing and ownership. For example, Dafny uses dynamic frames [32], where programmers annotate methods with `modifies` clauses to specify which objects each method may modify. With dynamic frames, programmers can write arbitrarily complex expressions to compute the set of modified objects. Programmers can also write arbitrarily complex preconditions and postconditions to specify non-aliasing, usually by specifying the disjointness of various sets of objects used in various `modifies` clauses. The SMT solver must then reason about these arbitrarily complex expressions, which provides programmers with great flexibility, but painfully slows verification [29, §6.2]. Furthermore, this reasoning is mixed with reasoning about functional correctness properties, often making it confusing for the developer to diagnose errors: does a verification failure indicate something deep about the invariants and states, or just a missing non-aliasing requirement?

Recent work on low-level type-safe languages like Rust [33] point to an alternate strategy, where the language’s type checker quickly takes care of memory safety and ensures non-aliasing. Full tools for verifying Rust-like programs [3] are still under development and are not yet as mature as tools like Dafny, Coq, and VCC. Therefore, we use Dafny as a starting point and extend it in a more Rust-like direction in two ways. First, rather than using Dafny’s existing high-level code-generation backends, we wrote a C++ backend for Dafny that generates efficient C++ code that does not require a garbage collector (§5.2). Second, we extended Dafny’s static type checker to support linear variables (§5.1), which allow us to reason purely functionally about data that can be mutated and manually deallocated. This extended type checking needs no SMT solving and therefore places no burden on the SMT solver. Section 6.1 describes the use of linearity in our implementation. Section 7 quantifies the dramatic reduction in proof code it produces and confirms that our use of linear reasoning has a negligible impact on run-time performance.

Our approach to linearity combines ideas from linear type systems [59] like Cogent [2], linear variables in CIVL [36, 51], and Rust’s ownership borrowing. Crucially, our extended type system integrates with Dafny’s existing dynamic frames, so that we can use linearity to speed verification where possible and fall back to dynamic frames when we need more flexibility. This allows us to verify the safety of highly-aliased code that would require run-time checks or unsafe code in Rust, or would fall outside Cogent’s linearity restrictions.

```

function method seq_get<A>(shared s:seq<A>, i:uint64) : (a:A)
function method seq_set<A>(linear s1:seq<A>, i:uint64, a:A)
  : (linear s2:seq<A>)
function method seq_free<A>(linear s:seq<A>)

method M(a:array<uint64>, o:seq<uint64>,
  linear l:seq<uint64>, shared s:seq<uint64>) ... {
  linear var l2:seq<uint64> := l; // ok: consumes l
  linear var l3:seq<uint64> := l; // error: l already consumed
  var n:uint64 := seq_get(l2, 10); // ok: borrows l2
  l2 := seq_set(l2, 10, 20); // ok: consumes l2, then restores l2
  seq_free(l2); // ok: consumes l2
  seq_free(l2); // error: l2 already consumed
}

class BoxedLinear<A> {
  function Has():bool
  method Give(linear a:A)
    modifies this; requires !Has(); ensures Has(); ...
  method Take() returns(linear a:A)
    modifies this; requires Has(); ensures !Has(); ...
  function method { :caller_must_be_pure } Borrow() : (shared a:A)
    requires Has(); ...
}

```

Figure 2: Using linearity in extended Dafny

5.1 Linear Variables

Since aliasing and mutation are expensive to reason about, we use linearity to express non-aliasing or non-mutation. Specifically, we extend Dafny with a keyword `linear` to express non-aliased, mutable values, and a keyword `shared` to express aliased, immutable values.

Figure 2 shows example code written in our extended version of Dafny. Dafny can express both purely functional code, with no heap modification, and imperative code that allocates and modifies heap data. A Dafny `method` can perform both functional and imperative operations, while a `function method` can perform only purely functional operations. The method `M` demonstrates various kinds of Dafny variables. The variables `a` and `o` use existing Dafny features: `a` is an ordinary pointer to a mutable array in the heap, and `o` is an ordinary immutable sequence. `a` and `o` rely on garbage collection (in C#) or reference counting (in C++) for memory management. The variables `l` and `s` use our extensions to Dafny: `l` is a linear (non-aliased) mutable sequence, and `s` is a shared (potentially aliased) immutable sequence temporarily borrowed from a linear sequence. `l` and `s` do not rely on garbage collection or reference counting. (The declarations `linear l:seq<uint64>` and `shared s:seq<uint64>` are similar in spirit to Rust’s declarations `l:&mut[u64]` and `s:&[u64]`, although in Rust’s semantics, `l` and `s` are references to sequences, while in Dafny’s semantics, `l` and `s` are sequence values, not references.)

The static type checker flags any attempt to duplicate or discard a linear variable like `l` as a type error. In Figure 2, for example, the attempts to assign `l` to both `l2` and `l3` is a type error, as is the attempt to free `l2` twice. The lack of duplication allows efficient in-place updates at run-time, as shown in the call to `seq_set`, which sets one element of a sequence. Despite its efficient implementation, though, the verifier can reason about the call to `seq_set` in a purely functional way [2, 59], without worrying about aliasing and the state of the heap. Like Rust and Cogent, our extension to Dafny allows temporary immutable borrowing from a linear variable, as shown in the call to `seq_get`. Borrowed values are tagged as `shared`, and `shared` variables cannot be returned out of the scope of borrowing.

We also extended Dafny to support linear fields in data structures and linear elements in sequences. In contrast to purely linear systems [2], our system can verify the interoperation between the linear data structures and ordinary heap data (like array). First, it supports linear-to-ordinary references: linear data structures can hold ordinary fields and sequence elements, such as Dafny heap pointers and arrays.

Second, to support ordinary-to-linear references, our extension provides a novel trusted class `BoxedLinear<A>`, shown in Figure 2, which stores linear values in ordinary objects. Each `BoxedLinear` object is an ordinary heap object, and references to the object can be freely duplicated, allowing complex aliasing. However, to take the linear value out of a `BoxedLinear` object, the program must prove that the object currently has the linear value. Taking the linear value sets `Has` to false, so that a program can’t take the same linear value more than once. This prevents the linear value from being duplicated. In addition, pure functional code (`function methods`) can `Borrow` directly from `BoxedLinear` without modifying `Has`. Restricting the scope of the borrowed value to functional code ensures that no imperative `method` can make `Has` false during the borrow. This approach shows the power of combining SMT solving with type system linearity: linear variables bring economy and clarity to the common cases, while SMT reasoning allows greater flexibility (e.g. using lemmas to prove `Has() == true`) when needed.

5.2 Compiling to C++

Dafny compiles its code to C#, Java, JavaScript, and Go. When building a storage system, however, we want more control over memory layout and management than what these high-level, garbage-collected languages offer.

Hence, we have added a new C++ backend to Dafny. We compile Dafny’s immutable datatypes to C++ `structs`, and Dafny’s classes and arrays to reference-counted pointers to their C++ equivalents. We implement Dafny’s immutable sequences using a C++ `struct` that contains a shared pointer to the underlying values, along with an offset and length into those values. This allows us to optimize operations that extract portions of a sequence; because sequences are immutable, it is

safe to implement such operations by returning a new `struct` pointing at the same underlying values but with a different offset and length, rather than copying the values.

When compiling linear variables, we perform updates in-place, rather than copying. Since linear variables cannot be silently discarded, we can rely on explicit deallocation (e.g., `seq_free`) and do not need to reference count them.

Finally, the backend deliberately does not compile Dafny’s mathematical integers; it expects the programmer to use Dafny’s refinement types to define machine integers that can be (provably) safely compiled to standard C++ integer types.

6 VeriBetrKV: A High-Performance, Verified Key-Value Store

We present a high-level overview of VeriBetrKV’s implementation (§6.1) and the structure of its safety proof (§6.2).

6.1 VeriBetrKV’s Implementation

VeriBetrKV implements a copy-on-write B^etree with a logical journal for efficient syncs.

6.1.1 B^eTree Background

A B^etree [7] is a write-optimized structure that combines ideas from B-trees and LSM-trees to dramatically improve insertion performance versus a B-tree.

For our purposes, B^etrees have two key properties:

- They support random insertions an order of magnitude faster than B-trees. They achieve this speedup by accumulating newly inserted key-value pairs high in tree and “flushing” items from parent to child in large batches.
- They typically use much larger nodes than a B-tree. B^etree nodes are often in the range of 1-4MiB, whereas B-tree nodes are in the range of 4-64KiB. This is because B^etrees perform node updates in batch, and hence can afford to update large nodes without incurring high write amplification. As a consequence, queries in an “off-the-shelf” B^etree are slower than in a B-tree, since each cache miss must read a larger node. Production B^etrees contain optimizations to overcome this problem.

See Bender, et al. [4, 5] for a full exposition of B^etrees and an analytical framework for analyzing their performance.

In VeriBetrKV, we use 2MiB nodes on hard disk, 128KiB nodes on flash, and a fanout of 8.

6.1.2 Node-Buffer Data Structures

Each node in a B^etree contains a buffer of key-value pairs. VeriBetrKV has two representations for in-memory nodes: a serialized format and an in-memory search-tree format. The former avoids marshaling and demarshaling costs for nodes low in the tree, which are updated through batch flushes. We use the search-tree representation only for the root node, which must support single insertions of new key-value pairs from the user.

The in-memory search tree is one of the VeriBetrKV’s most performance-critical components. Thus, we originally wrote

it using Dafny’s dynamic-frames heap reasoning, making it one of the most difficult pieces of code in our implementation.

We then rewrote it using our linear type system (§5). From the verifier’s perspective, this eliminated all heap-mutating code. Furthermore, the type system gave immediate feedback on linear typing errors, enabling rapid development. Section 7 quantifies the reduction in proof code and shows that the shift to linear reasoning had no noticeable impact on performance.

The in-memory search tree also demonstrates the utility of the integration between our linear type system and Dafny’s builtin Floyd-Hoare reasoning. Each node in our in-memory search tree maintains a linear sequence of linear (pointers to) children. When we split a node, we need to copy half of those child pointers to the new left-hand node, and half of them to the new right-hand node. In a standard linear type system, such as in Rust, we cannot “take” a subset of the values out of a linear array, and we would have to resort to unsafe code or incur the run-time overhead of using an `Optional` type for each array element.

With our linear type system, each linear sequence `s` has an associated boolean ghost² sequence, `lseq_has(s)`, that serves the same purpose as the `Has` predicate of the `BoxedLinear` class in Figure 2. When we remove the child pointers for the new left-hand node the ghost sequence becomes `false` for each index `i` that we take. However, this does not prevent taking the remaining children for the right-hand node, since Dafny infers that `lseq_has(children)[i]` is still `true` for those indices.

6.1.3 Caching, Copy-on-Write, and Indirection Tables

VeriBetrKV maintains a cache (BlockCache) of recently accessed nodes, using an LRU eviction policy. The cache is free to write back a node at any time, which is safe because VeriBetrKV uses copy-on-write. The BlockCache is oblivious to the data structure it caches. It resembles a kernel buffer-cache, except (a) its allocation unit is a type parameter so we can allocate tree nodes, (b) it tracks inter-block references and garbage collects blocks.

VeriBetrKV implements crash safety by maintaining three copy-on-write B^etrees: a *persistent* tree, a *frozen* tree, and an *ephemeral* tree. New inserts go into the ephemeral tree, the frozen tree is in the process of being made durable, and the persistent tree is the previous tree that was made durable.

Each tree is defined by an *indirection table*, which maps logical node IDs to physical disk addresses. Parents refer to children by logical node ID, and the cache is indexed by logical ID. Since nodes are large, the indirection table is small. For example, the indirection table for a 1TiB disk is only 24MiB.

To sync the tree to disk, we write out all dirty nodes, write the indirection table, and then write a superblock pointing to the indirection table. VeriBetrKV keeps two superblocks,

²i.e., a data structure used for proof purposes only, not compiled code

alternating between them, and using a counter to detect which one is newer. We call this process a *checkpoint*.

VeriBetrKV ensures that checkpoints capture a point-in-time-snapshot as follows. When we begin a checkpoint, all dirty nodes in the live indirection table are marked as “write-back-before-editing”. Since these nodes are now also referenced by the indirection table of the in-progress checkpoint, we must write them to disk before modifying them in cache. Note that we need not wait for the write to complete: if the system crashes before the write completes, then the system will boot from the previous checkpoint.

The indirection table in VeriBetrKV is implemented as a linear-probing hash table. As with the in-memory search tree, we initially implemented this using Dafny’s dynamic frames. In order to isolate the complexities of heap reasoning, we essentially wrote the hash table twice. The first version used immutable data structures, and served as a precise, low-level description of the hash table’s behavior. We then wrote it a second time using mutable arrays, proving that each step exactly followed the algorithm in the functional model. This approach separated the proof of functional correctness from the proof of correct heap manipulation, but it meant implementing the hash table twice.

We then reimplemented this hash table using our linear Dafny extensions. In this version, the low-level functional model of the algorithm, suitably annotated with `linear` and `shared` keywords, *is* the implementation, cutting the amount of code substantially (§7).

6.1.4 Optimizing Syncs with a Journal

When applications perform frequent syncs, writing out every dirty node for each sync becomes expensive. For example, if an app performs a sync after every insert, then each sync must write out the root node (2MiB) to persist a single insertion.

We solve this problem with a journal of logical operations. Each insertion is recorded in an in-memory journal as well as inserted into the B^e tree. When the application requests a sync, we simply write the in-memory journal to disk.

Journal space is reclaimed as part of a checkpoint.

6.2 VeriBetrKV’s Proof

VeriBetrKV weaves several modularity techniques together to manage the complexity of the code and its correctness argument. We use modular Hoare logic to reason about implementation code and reusable templated state machine models and IOSystem composition (§3.2) to reason about how that code behaves in an asynchronous environment. IOSystems generalize well to this new context of storage systems, and reuse well as we develop a correctness argument up through layers of abstraction. Overall, this blend of techniques is sufficient to modularize the complexity of a modern high-performance storage architecture.

6.2.1 VeriBetrKV’s Refinement Proof

Below, we describe how simple state-machine refinement suffices to reason about the correctness of our B^e tree assuming it existed in memory on a crash-free machine (§6.2.2).

To manage complexity, we modularize our proof by separating the reasoning about the journal subsystem and the crash-safe B^e tree storage subsystem. We further modularize the B^e tree proof by separating caching logic from B^e tree manipulation logic.

6.2.2 Simple State-Machine Refinement

State-machine refinement enables designers to organize high-level correctness arguments in isolation from its low-level details, and then ignore abstract concerns when writing implementation code [40]. For example, suppose we want to prove that a single, unfailing process correctly implements an in-memory B^e tree (① in Figure 3).

- The application spec is a *Map* that updates and queries a key-value relation.
- An *abstract B^e tree* inserts messages into nodes arranged in a tree, where each node is an infinite map. This model has enough detail to define query semantics over that tree, but the (unimplementable) nodes elide detail that is addressed below.
- The *B^e tree* defines the node data structure that clumps the infinite key range into finite buckets at pivot keys.
- *Impl B^e tree* is compilable real imperative code, organized with Hoare logic, with details like mutable data structures and 64-bit integer overflow (gray in the diagram because VeriBetrKV does not have a purely in-memory B^e tree).

The refinement arrow between the *B^e tree* and the *abstract B^e tree* concerns only the relationship between pivot nodes and infinite-map nodes; it ignores higher-level concerns (the tree shape) and lower-level concerns (efficient data structures). This application of refinement gives the developer the freedom to modularize the correctness argument.

6.2.3 VeriBetrKV’s IOSystem Refinement

Of course, VeriBetrKV’s B^e tree does not necessarily run without crashing, and it interacts with an asynchronous byte-level disk, so that the full data structure is stored on disk but cached in memory. Hence, to prove its safety, we repeatedly apply the techniques from §3.2 to prove that the storage IOSystem state machine (§3), when instantiated with VeriBetrKV’s program state machine, refines the application-facing specification (§3.1.2).

A good specification of a crash-safe system needs to be able to describe how data is recovered upon crash. Our specification has an *ephemeral* state and a *persistent* state. All user operations (e.g., queries and inserts) are applied to the ephemeral state; if there are no crashes, the user will observe the behavior of a simple dictionary. On a crash, the ephemeral state reverts to the persistent state; the persistent state therefore represents the state made persistent to disk. Background operations can

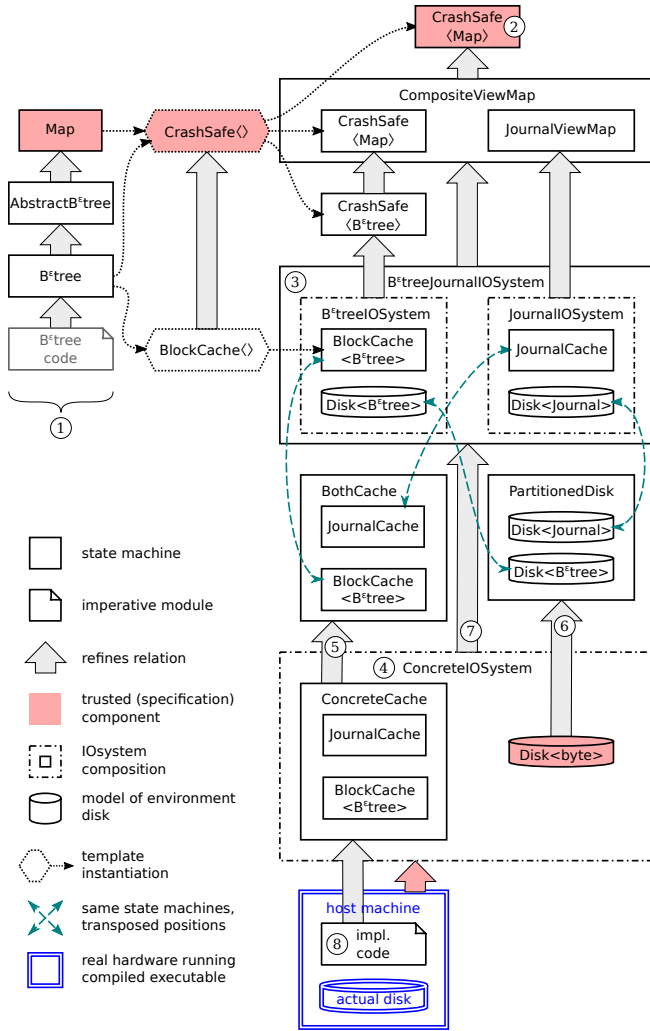

Figure 3: Structure of VeriBetrKV's correctness argument.

update the persistent state to a newer state. Two transitions, `sync_start` and `sync_end` are defined such that, when `sync_end` runs, the persistent state will have updated to the ephemeral state from the `sync_start` (or a newer version). We call this generic specification $\text{CrashSafe}\langle T \rangle$, parameterized over a state machine T . In our case, the top-level specification will be $\text{CrashSafe}\langle \text{Map} \rangle$.

The $\text{CrashSafe}\langle T \rangle$ template is an abstraction of our $\text{BlockCache}\langle T \rangle$ template state machine, which interacts with a disk but is oblivious to the data structure it caches. We prove generically that if concrete type T_{conc} refines an abstract type T_{abs} , then an IOSystem containing a $\text{BlockCache}\langle T_{\text{conc}} \rangle$ and a disk refines a $\text{CrashSafe}\langle T_{\text{abs}} \rangle$.

We apply this generic result at the next level down (3), where we instantiate the type-oblivious $\text{BlockCache}\langle T \rangle$ template with the IO-oblivious $B^e\text{tree}$ (§6.2.2). Leveraging refinement (1), this proves that $B^e\text{treeIOSystem}$ refines $\text{CrashSafe}\langle B^e\text{tree} \rangle$ and hence $\text{CrashSafe}\langle \text{Map} \rangle$.

In a sibling library, we prove that the JournalIOSystem

refines JournalViewMap , an abstract summary of journal behavior, including components for journal entries persisted to disk, journal entries being written, and journal entries in memory. Ordinary state machine composition pulls those together into the CompositeViewMap , an abstract summary of the state-machine composition $B^e\text{treeJournalIOSystem}$. The CompositeViewMap is shown to implement a $\text{CrashSafe}\langle \text{Map} \rangle$: an abstraction function applies updates in JournalViewMap 's journals to the map states in $\text{CrashSafe}\langle \text{Map} \rangle$ to obtain the application-spec $\text{CrashSafe}\langle \text{Map} \rangle$.

Thus, we have refined from the application spec to a model (3) of the VeriBetrKV's two main components, each modeled as separate systems, each of which uses a high-level "disk" that stores its client's internal datatype representation.

One layer down, the ConcreteIOSystem (4) introduces a real byte-level disk-IO interface. The program component of this IOSystem is the ConcreteCache , which includes marshaling and demarshaling functions on top of the JournalCache and $\text{BlockCache}\langle B^e\text{tree} \rangle$. The ConcreteCache refines (5) the BothCache . The disk component of the ConcreteIOSystem is our low-level disk model, the $\text{Disk}\langle \text{byte} \rangle$, which refines (6) PartitionedDisk via the same marshaling functions. This refinement relies on an invariant that $\text{Disk}\langle \text{Journal} \rangle$ and $\text{Disk}\langle B^e\text{tree} \rangle$ access mutually-disjoint regions of the disk. With these two refinements in place, we transpose the four subcomponents (dashed green arrows) and obtain a refinement (7) from ConcreteIOSystem to $B^e\text{treeJournalIOSystem}$. This rearrangement is crucial to allow us to reason about $B^e\text{treeIOSystem}$ and JournalIOSystem separately.

ConcreteCache is the lowest-level model of the program, including all of the components ($B^e\text{tree}$, journal, indirection table, byte-level IO interface). It remains to show that our imperative heap-mutating code (8) refines ConcreteCache . To do so, we show that each handler invocation in the code corresponds to a `Next` transition in the ConcreteCache state machine. Because ConcreteCache is a low-level model, this task decomposes nicely along Hoare-logic call-graph boundaries: calls to update the journal advance the JournalCache sub-component, leaving the $B^e\text{tree}$ unchanged, and vice versa.

6.2.4 VeriBetrKV's Floyd-Hoare Proof

The top-level API methods of VeriBetrKV's implementation (8) use Floyd-Hoare logic to show that their operations correspond to transitions of the ConcreteCache state machine. Of course, the ConcreteCache is only one component of the ConcreteIOSystem (4), and likewise, the implementation code interacts with the disk only via a trusted interface.

At the implementation level, we do not reason about the disk itself—we reason only about interactions via the trusted interface. Transitions of the ConcreteCache state machine are labeled with *disk ops*. Each disk op is either a *no-op* (i.e., no disk interaction), an *I/O request*, or an *I/O response*. The disk-op labels are "visible" to the ConcreteIOSystem : the ConcreteIOSystem state machine is defined in terms of the

Major component	spec	impl	proof

libraries	477	364	2847
total	1210	6373	44685

Table 1: Line counts [60] by major components in Figure 3.

	hash table		search tree	
	impl	proof	impl	proof
Aliasing reasoning				
Dynamic frames	289	1678	289	2220
Linear type system	289	1063	373	1531

Table 2: Line counts [60] of two subcomponents, comparing dynamic-frame implementations with our linear type system.³ Linear typing reduces the proof burden by 31–37%

ConcreteCache’s interaction with the disk via disk ops.

Thus, the Floyd-Hoare logic in our implementation does not need to reason about the disk proper. Rather, it only needs to show that each interaction with the trusted disk interface corresponds to a disk op which is valid according to the ConcreteCache state machine.

Overall, our proof shows that an executable built from our implementation’s code, if run on a real host with a real disk that meets our assumptions, will behave as the ConcreteSystem does, and hence as a CrashSafe⟨Map⟩. We have connected not just code, but a system with a disk and the possibility of the code crashing, up to the app spec.

7 Evaluation

Our evaluation addresses two main questions:

1. Do our automation-control techniques (§4) and language improvements (§5) improve the developer experience?
2. Can our verification methodology scale to the complexity of a modern key-value-store data structure, and can we deliver the performance gains of write optimization?

7.1 Developer Experience

Measuring Tedium. We estimate the amount of tedium (or conversely, the efficacy of automation) by the ratio of the lines of proof (e.g., lemmas, pre-/post-conditions, loop invariants) to the lines of executable implementation code. This is not a precise model, since it measures a completely verified artifact, where the developers may have cleaned up temporary lines of tedium that were typed in the course of resolving verification failures. However, the proof text in the “cleaned up” code at least reflects the tedium needed to bridge what automation could not manage by itself.

Table 1 gives line counts for VeriBetrKV, organized by

Figure 4: Cumulative distribution of verification times of function definitions, implementation methods, and proof lemmas. Most definitions—99.0%—verify in less than 20s, and 98.3%—verify in less than 10s.

the major components shown in Figure 3. We see that the proof ratio for the implementation code is 4:1, which grows to 7:1 when including all system refinement proofs (“total”). This is comparable to the distributed, in-memory key-value store verified in previous work [29], which also reports a 7:1 ratio. However, VeriBetrKV’s implementation is 3× larger, indicating that automated verification techniques can scale to larger systems without super-linear effort.

The results also show that VeriBetrKV’s implementation is more than 5× larger than its specification, giving us reason to hope that the specification is less likely to contain bugs than an unverified implementation. We have observed no correctness or data loss bugs at runtime; we have seen liveness and performance bugs.

Table 2 compares two VeriBetrKV components that we wrote using both dynamic frames and linear reasoning. The results show that switching to linear reasoning saves tedium, reducing proof overhead by 31–37%. Our qualitative experience was that development of linear code was much more pleasant than dynamic frames because the linear typechecker quickly and unambiguously identifies aliasing problems.

One interesting datum for tedium is the effort developers spend on test infrastructure in conventional development. RocksDB has a 0.99:1 ratio between test and production code (measuring its `db`, `java`, `utilities`, `third-party`, and `tools` directories). BerkeleyDB’s ratio is 0.45.

Measuring Proof-Attempt Latency. To assess the success of our discipline for keeping automation under control (§4), we measure the time to verify individual proof units (e.g., definitions, methods, or lemmas) where developers spend most of their time waiting for verification results. This estimates the developer’s perception of the latency of the verification-development cycle.

Figure 4 demonstrates that VeriBetrKV almost always exhibits interactive verification times, with 98.3% of definitions verifying in under 10 seconds, and 99.0% in under 20 seconds. This suggests that our timeout-averse development policy is

³The implementation of the hash table (with dynamic frames and the linear type system) and search tree (with dynamic frames) coincidentally have identical line counts, despite being unrelated.

Figure 5: VeriBetrKV manually hides 308 definitions (18% of all system definitions), revealing them 1403 times. This metric reflects the effort involved in explicitly managing automation.

effective. The figure reveals that we did not apply our policy with perfect consistency, as 37 proofs do take longer than 20s to verify. Of those, 54% involve dynamic frames.

It is difficult to capture every place we applied the policy. As a proxy, we can count places where we explicitly hid a definition. This both overestimates the cost of the policy (because sometimes we hid a definition based on intuition, before observing a timeout) and underestimates it (because automation can be controlled with other techniques).

These approximations aside, Figure 5 gives an idea of the burden of controlling automation. We hid 308 definitions, 18% of all definitions in the system. These hidden definitions are manually revealed 1403 times. Of the 308, 52 were never revealed: the salient properties of the definition could be exported as a postcondition without causing timeouts. 74% of hidden definitions are revealed no more than five times; their essential features are captured in lemmas or wrapped into higher-level definitions.

One of the motivations for introducing linear types into Dafny (§5) is to remedy slow verification of dynamic frames. For the fragment of VeriBetrKV we converted to linear reasoning, we compared interactive verification times (as in Figure 4) against the original dynamic frames code. The maximum method-level interactive verification time dropped 10s to 32s, and the 99th percentile dropped 1.3s to 4.8s.

Developers are typically less sensitive to the latency of continuous-integration builds that check that the system as a whole still verifies. For VeriBetrKV, these take 1.8 hours of CPU time, but thanks to the inherent parallelism of modular verification, complete in 11 minutes on 32 cloud machines.

7.2 Performance

Our performance evaluation addresses two questions:

1. Does VeriBetrKV demonstrate the insertion-performance gains of write-optimized data structures?
2. Does our linear extension produce code with performance comparable to hand-written code using dynamic frames?

All experiments were run on cloud instances with directly attached physical storage. The HDD experiments and sub-component microbenchmarks are run on AWS EC2 d2.xlarge instances, with 4x hardware hyperthreads on a 2.4 GHz Intel

Xeon E5-2676 v3. The SSD experiments are run on AWS EC2 i2.xlarge instances, with 4x hardware hyperthreads on a 2.5 GHz Intel E5-2670 v2 and a SATA SSD.

7.2.1 YCSB

Figure 6 shows throughput for VeriBetrKV, BerkeleyDB, and RocksDB on the YCSB benchmarks [14] on hard drive and SSD, including the load phase for workload A, and a uniformly random query workload (labeled as workload “U”). All systems are limited to a single core.

There are three main take-aways from these measurements. First, VeriBetrKV demonstrates the performance gains of using a write-optimized data structure. For the load phase on hard drive, which consists of a pure random insertion workload, VeriBetrKV is over $25\times$ faster than BerkeleyDB. Even on SSD, where random I/O is much cheaper, VeriBetrKV modestly outperforms BerkeleyDB on insertions.

In contrast, VeriBetrKV is roughly $8\times$ slower than RocksDB on hard disk and $4\times$ slower on SSD. Investigation identified three contributing factors: First, where Rocks relies on the kernel buffer cache, VeriBetrKV manages its own cache memory. Its effective cache size is reduced due to malloc fragmentation and conservative allocation to avoid violating the cgroup. Simulating an efficiently-allocated 1.8GiB B⁺tree node cache improves performance to over 13K insertions per second on HDD. Second, VeriBetrKV fails to overlap CPU with flush I/O: a twelve-minute run spends four minutes in CPU and eight minutes waiting for I/O, accounting for roughly a $2/3\times$ slowdown. Third, VeriBetrKV performs $1.5\times$ more I/O than Rocks in YCSB-Load; about half of the extra I/O is due to a suboptimal checkpointing policy.

The second main take-away is that queries in VeriBetrKV are about $4\times$ slower than on RocksDB. The fragmentation penalty again explains a $2\times$ factor; with a simulated 1.8GiB cache, VeriBetrKV and Rocks both perform 300K I/Os in serving 1M YCSB-C queries. Furthermore, we observed most Rocks I/Os are 4-8KiB (one or two buffer cache pages), whereas most VeriBetrKV I/Os are 1.5MiB (an entire B⁺tree node). This I/O size difference combined with the measured seek and read bandwidth of our hard drives explains the remaining gap. We plan to change our marshalling strategy to enable reading fields without fetching the entire node.

The final take-away is that at a macro-level our linear implementation has essentially the same performance as the version with hand-tuned code using dynamic frames reasoning.

Overall, we conclude that VeriBetrKV demonstrates that a verified system can achieve the performance gains of a write-optimized storage system, but it needs further optimization to match highly-tuned commercial implementations.

7.2.2 Linear Data Structures

Figure 7 shows the performance of our linear and dynamic-frames-based hash-table and search-tree implementations. The main take-away from both experiments is that, even in mi-

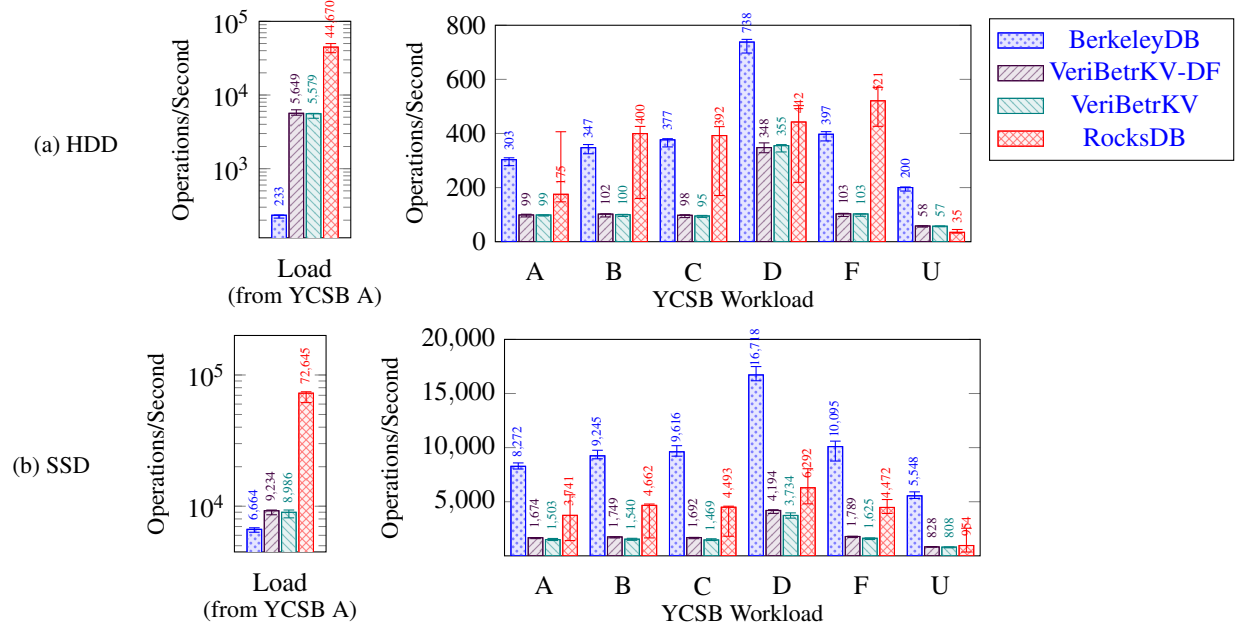

Figure 6: Median throughput of YCSB workloads values running on an HDD (a) and SSD (b) and 2GiB of RAM. VeriBetrKV-DF is a version of our system with hand-tuned code using dynamic frames reasoning. Load is 10M operations (≈ 5 GiB of data) and runs are 10000 operations each. Error bars indicate min/max of 6 runs. Higher is better. On an HDD (a), VeriBetrKV insertions are over $25\times$ faster than in BerkeleyDB, but lag RocksDB, by about $9\times$. VeriBetrKV queries are about $4\times$ slower than both. On an SSD (b), VeriBetrKV still beats BerkeleyDB on random insertions, but VeriBetrKV queries are slower than BerkeleyDB.

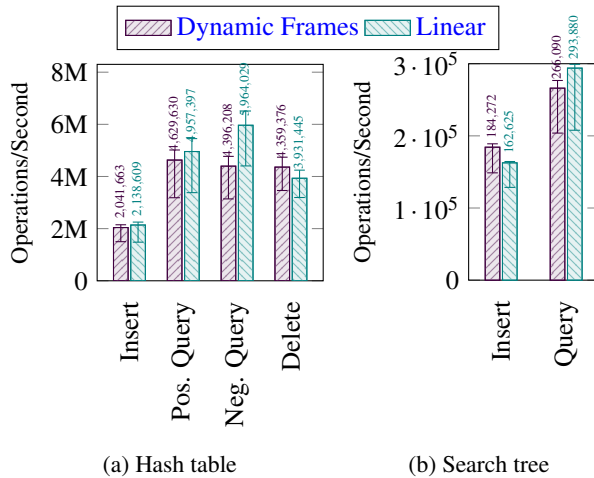

Figure 7: Median throughput of subcomponent microbenchmarks. Higher is better. Error bars are min/max of 6 runs.

crobenchmarks, the linear and non-linear implementations have very comparable performance.

The hash table benchmark inserts 64 million key-value pairs, performs 64 million positive and 64 million negative queries, and then deletes everything in the hash table. The keys are selected pseudo-randomly and are distributed uniformly in the 64-bit key space. The linear version is slightly faster than

the non-linear version, except for deletes, which are slightly slower. We suspect the speedup comes primarily from the lack of shared pointer overhead.

The search-tree benchmark measures the time to insert 8 million key-value pairs in pseudo-random order and then query them all in the same order. Performance for the linear version is close to the non-linear version, but slightly faster for queries and slightly slower for inserts. We believe queries are faster due to the elimination of shared pointer overheads, and the inserts are slower due to the overheads of destructing nodes on the way down the tree and reconstructing them on the way back up.

Our modifications to add linear types to Dafny consist of 1900 lines (3%); the C++ backend changes, which include linear features, add another 3100 lines (7.5%).

Overall, our linear type system enables us to construct performant code without the challenges of dynamic frame reasoning.

8 Related Work

IronFleet [29], VeriBetrKV’s most direct intellectual ancestor, verifies distributed systems of fail-stop nodes. Its verification strategy uses a refinement hierarchy with just two layers: one from imperative code to a protocol state machine, another from there to application spec. VeriBetrKV’s implementation contains more components (an in-memory B-tree and hash ta-

ble, a block cache, and a journal), and the B^etree, its core data structure, is substantially more complicated. Hence VeriBetrKV’s implementation is 3× larger than IronFleet’s sharded distributed key-value in-memory-only store.

8.1 Verified Storage Systems

FSCQ’s Crash Hoare Logic[12] modifies Hoare logic to explicitly reason about crashes, enabling crash reasoning to follow Hoare clauses up the implementation call graph. It does not employ refinement reasoning. FSCQ reasons about potentially repeated crashes during the recovery procedure; VeriBetrKV avoids such reasoning by virtue of a design whose recovery procedure requires no disk writes. FSCQ’s implementation is functional code extracted to Haskell, so the framework gives the developer less low-level control than VeriBetrKV.

DFSCQ [11] contributes an application spec for how crashes interplay with the separate `fsync` and `fdatasync` operations. Production file systems like ext4 provide these operations to offer greater performance at the cost of an application spec even more relaxed than the general `sync` operation that covers all updates (as in VeriBetrKV). DFSCQ’s implementation exploits this freedom to defer writes.

Yggdrasil uses refinement to show implementation functional correctness relative to a specification [54]. Crashes in the environment are implicit, and the app spec only promises linearity, requiring the implementation to sync on every mutating client operation (or group commit). It cannot exploit the performance benefit of deferring writes until an application-specified `sync`. Its disk model includes asynchronous I/O but has no concept analogous to an `IOSystem`. Its pushbutton approach to verification constrains the structure of the implementation and proof, but in exchange produces a very favorable proof:code ratio, reported at 1:300.

As discussed in §5, our linear extensions to Dafny are inspired by multiple sources [2, 33, 36, 51, 59]. Most relevant to systems verification is the Cogent language [2], which is a restricted functional language that certifiably compiles to C code. Amani et al. use Cogent to develop two file systems, each about 4K lines of native C. They verify two functional correctness properties of one of the file systems, with the aim of eventually proving both functional correctness and crash safety. The Cogent language is an impressive foundational effort and its certifying compiler provides a stronger guarantee than our simple but trusted changes to Dafny’s type system. Our type system’s linear variables are similar in spirit to Cogent’s linear types, but our work also integrates linearity directly with Dafny’s dynamic frames, enabling us to move smoothly back and forth between linear and non-linear reasoning about memory.

It is difficult to make meaningful performance comparisons between our durable key-value store and file systems: File systems provide richer semantics, such as bulk directory rename.

8.1.1 Concurrent Storage

AtomFS [66] is a compute-concurrent file system with fine-grained (per-inode) locks, but it does not reason about crash safety. CSPEC [9] verifies a compute-concurrent mail server absent crash safety. It verifies 215 lines of Coq implementation with 4,050 lines of proof. Perennial [10] verifies a compute-concurrent, crash-safe mail server. Perennial extends a capability separation logic with crash-safety-specific concepts, with which it builds a refinement argument. Perennial verifies 159 lines of concurrent Go with 3,360 lines of proof. Drawing on techniques from these systems would allow VeriBetrKV to scale further via parallelism.

8.2 Automation Strategies

A line of work on “push-button” verification [45, 46, 54, 55, 64, 65] accepts constraints on system structure in exchange for maximizing automation. The developer constrains their imperative code to bounded executions and writes invariants to span independent handler invocations. Such handlers could not walk down a tree of arbitrary depth, as happens in VeriBetrKV’s B^etree and search tree. Supporting longer bounded executions requires framework improvements [45] rather than creating a modularization job for the developer.

Taube et al. [57] employ a restricted fragment of logic [49] to verify distributed system implementations, including Raft [48] and Multi-Paxos [39]. By restricting the description of the protocol and its properties to a decidable logic, this approach guarantees that a solver can always return either a decisive answer. While the developer still must supply invariants, the remaining proof work is entirely automatic. The cost of this approach is that it force the developer to restate definitions unnaturally, and decidable verification is still subject to combinatorial slowdown as the scope of definitions grows.

The exploration of extreme points in the automation space is promising, but limitations on expressiveness and design motivate us to stick with developer-guided proofs, and instead use automation to make it as cheap as possible.

8.3 Additional Verified Systems

The seL4 verified microkernel is the seminal systems verification project [34], demonstrating the feasibility of verifying software at the scale of thousands of lines. C code refines a Haskell functional model of the implementation, which refines a high-level specification for the behavior of system calls.

CertiKOS [27] proves a concurrent microkernel implementation correct using refinement of state machines it calls “layers” expressed in a side-effect free subset of C. It introduces the notion of contextual refinement to reason about concurrent state machines in isolation [28].

Verdi [61] uses Coq to verify distributed systems by proving the correctness of a series of “system transformers” that take a high-level protocol description running in a friendly environment and transform it into a protocol that is safe in a more hostile environment (e.g., where packets can be dropped). The

signature transformer is a verified implementation of Raft [62]. In a sense, Verdi is a distributed systems analog to correctness-preserving compiler transforms.

9 Conclusion

In this work, we extracted a general methodology for verifying asynchronous systems from prior work and applied it to storage systems. In doing so, we developed a verification discipline and a novel integration of linearity with dynamic frame reasoning to reduce the burden of verifying systems code. Because we applied a generic methodology, we expect these improvements to apply equally well to the verification of other asynchronous systems. In future work, we would like to extend the methodology to also support thread-concurrent systems with shared memory, utilizing our linear type system to manage memory ownership.

Ultimately, our implementation and proof of crash safety for VeriBetrKV, a complex, modern storage system, show that automated verification techniques can scale to larger code bases without increasing the proof burden relative to simpler systems.

Acknowledgments

We thank the anonymous reviewers and our shepherd, Gernot Heiser, for useful feedback on the paper. Work at CMU was supported, in part, by grants from a Google Faculty Fellowship, the Alfred P. Sloan Foundation, and the NSF/VMware Partnership on Software Defined Infrastructure as a Foundation for Clean-Slate Computing Security (SDI-CSCS) program under Award No. CNS-1700521. Andrea Lattuada is supported by a Google PhD Fellowship.

A Artifact Appendix

A.1 Abstract

The evaluated artifact is provided as Docker images that contain the source code to VeriBetrKV, build instructions to run the verification as well as run the performance experiments and draw the graphs corresponding to those in §7 with the generated data.

A.2 Artifact check-list

- **Algorithm:** A verified B^etree-based key-value store.
- **Program:** VeriBetrKV as described in this paper.
- **Compilation:** Dafny/C++ compiler, included in Docker image.
- **Data set:** YCSB generated workload
- **Run-time environment:** Docker
- **Hardware:** Any x64; provide a data store directory on HDD or SSD as desired
- **Run-time state:** KV store backing files
- **Output:** PDFs containing graphs corresponding to §7
- **Required disk space:** 20GiB
- **Expected experiment run time:** Several hours

- **Public link:** <https://github.com/secure-foundations/veribetrkv-osdi2020/blob/master/README.md>

A.3 Description

A.3.1 How to access

Follow the README at <https://github.com/secure-foundations/veribetrkv-osdi2020/blob/master/README.md>. You can either run the binary Docker distribution, or build it yourself.

A.3.2 Hardware dependencies

You will need any x86 CPU, plus HDD and/or SSD storage devices for the performance measurements.

A.3.3 Software dependencies

All required dependencies are included in the Docker image.

A.3.4 Data sets

Performance experiments use the YCSB benchmark, for which the source and configuration are included in the Docker image.

A.4 Installation

You can either download the GitHub release, `veribetrkv-artifact-hdd`, and load the image with `docker load -i veribetrkv-artifact-hdd.tgz` or build it yourself with

```
cd docker-hdd
docker build -t veribetrkv-artifact-hdd .
```

A.5 Experiment workflow

The README explains how to launch the experiments by running scripts from outside Docker. The scripts will generate PDFs that reproduce the results from the paper.

A.6 Evaluation and expected result

The graphs in the output PDFs should correspond to those in §7, modulo variation in the experimental hardware.

A.7 Experiment customization

The README at the link above provides details on how to modify the experiment scripts in the Docker container.

A.8 AE Methodology

Submission, reviewing and badging methodology:

Fast RDMA-based Ordered Key-Value Store using Remote Learned Cache

Xingda Wei, Rong Chen, Haibo Chen

Engineering Research Center for Domain-specific Operating Systems, Ministry of Education, China
Institute of Parallel and Distributed Systems, Shanghai Jiao Tong University

Abstract

RDMA (Remote Direct Memory Access) has gained considerable interests in network-attached in-memory key-value stores. However, traversing the remote tree-based index in ordered stores with RDMA becomes a critical obstacle, causing an order-of-magnitude slowdown and limited scalability due to multiple roundtrips. Using index cache with conventional wisdom—caching partial data and traversing them locally—usually leads to limited effect because of unavoidable capacity misses, massive random accesses, and costly cache invalidations.

We argue that the machine learning (ML) model is a perfect cache structure for the tree-based index, termed *learned cache*. Based on it, we design and implement XSTORE, an RDMA-based ordered key-value store with a new hybrid architecture that retains a tree-based index at the server to perform dynamic workloads (e.g., inserts) and leverages a learned cache at the client to perform static workloads (e.g., gets and scans). The key idea is to decouple ML model re-training from index updating by maintaining a layer of indirection from logical to actual positions of key-value pairs. It allows a stale learned cache to continue predicting a correct position for a lookup key. XSTORE ensures correctness using a validation mechanism with a fallback path and further uses speculative execution to minimize the cost of cache misses. Evaluations with YCSB benchmarks and production workloads show that a single XSTORE server can achieve over 80 million read-only requests per second. This number outperforms state-of-the-art RDMA-based ordered key-value stores (namely, DrTM-Tree, Cell, and eRPC+Masstree) by up to $5.9\times$ (from $3.7\times$). For workloads with inserts, XSTORE still provides up to $3.5\times$ (from $2.7\times$) throughput speedup, achieving 53M reqs/s. The learned cache can also reduce client-side memory usage and further provides an efficient memory-performance tradeoff, e.g., saving 99% memory at the cost of 20% peak throughput.

1 Introduction

Network-attached in-memory key-value stores have become the foundation of many datacenter applications, including databases [47, 55], distributed file systems [7], web services [4, 37], and serverless computing [23, 42, 28], to name a few. With the prevalence of affordable high-performance networks in modern datacenters [46, 17, 20], such as InfiniBand, RoCE, or OmniPath, CPU quickly becomes the performance bottleneck and limits the scalability with the in-

crease of clients [31]. RDMA (Remote Direct Memory Access) has recently generated considerable interests in optimizing network-attached in-memory key-value stores (aka RDMA-based KVs) in both academia [34, 25, 52] and industry [16, 55, 31], as it enables direct access to the memory of remote machines with low latency and CPU/kernel bypassing. However, leveraging RDMA to ordered key-value stores encounters a significant obstacle—traversing tree-based index with one-sided RDMA primitives is costly and complex (e.g., $11\times$ slowdown in Fig. 2c). This is because it usually requires multiple network round trips (e.g., $O(\log N)$) and rapidly saturates bandwidth.

Many recent academic and industrial efforts [57, 17, 35] therefore proposed *index caching* to reduce RDMA operations. Yet, the conventional wisdom on implementing cache—replicating partial data and accessing them locally—does not work well with the tree-based index, and the drawbacks are amplified by maintaining the *tree-based* cache with RDMA primitives. First, the tree-based index can be large, so that the cache would suffer from unavoidable capacity misses. Second, the cache would aggravate random memory accesses and further increase the end-to-end latency. Third, updating the tree-based index may recursively invalidate the cache and cause false invalidation due to path sharing.

Inspired by recent research [29]—using machine learning (ML) models as an alternative index structure, we propose to leverage ML models as the (client-side) RDMA-based cache for the (server-side) tree-based index, termed *learned cache*. Specifically, the client uses learned cache to predict a small range of positions for a lookup key and then fetches them using one RDMA READ. After that, the client uses a local search (e.g., scanning) to find the actual position and fetches the value using another RDMA READ. Although using ML models as the index seems efficient (a few floating/int operations) and cheap (a small memory footprint) for static workloads (e.g., gets), it is also notoriously slow (frequently re-training ML models) and costly (keeping data in order) for dynamic workloads (e.g., inserts).

To address the above challenges, we propose a *hybrid* architecture that retains a tree-based index at the server to perform dynamic workloads (e.g., inserts) and leverages a learned cache at the client to perform static workloads (e.g., gets and scans). The hybrid architecture not only provides separate and appropriate execution paths for both workloads, but also simplifies the mechanism to guarantee the correctness of concurrent local and remote operations.

Based on this architecture, we further introduce a layer of indirection (i.e., a translation table) between the ML model and the tree-based index, which maps the logical position to the actual position of key-value pairs in the leaf-node granularity. The translation table decouples model retraining from index updating (e.g., node splits) and allows a *stale* learned cache (a combination of ML model and translation table) to continue predicting a *correct* position for a lookup key, as long as it is not overlapped with a leaf node split. It implies that the tree-based index can be concurrently updated in-place. Meanwhile, the ML model associated with its translation table can be retrained in the background and independently pulled by the clients on demand.

We have implemented XSTORE by extending a concurrent B+tree [50] with a well-tuned RDMA framework [51]. We evaluate XSTORE using the YCSB benchmarks [13] with two synthetic and one real-world [2] datasets, as well as two production workloads from Nutanix [30]. Our experimental results show that a single XSTORE server can achieve over 80 million read-only requests per second. This number outperforms state-of-the-art RDMA-based ordered key-value stores (i.e., DrTM-Tree [11], Cell [35], and eRPC+Masstree [24]) by up to $5.9\times$ (from $3.7\times$). For workloads with inserts, XSTORE still provides up to $3.5\times$ (from $2.7\times$) throughput speedup, achieving 53M reqs/s. The learned cache also reduces client-side memory usage significantly and further provides an efficient memory-performance tradeoff. For example, it can save 99% memory at the cost of 20% peak throughput, compared to caching the whole index.

In summary, this paper makes four contributions:

- The idea of *learned cache* that leverages machine learning (ML) models as index cache for RDMA-based, tree-backed KV stores;
- A hybrid architecture that combines (client-side) learned cache and (server-side) tree-based index to embrace static and dynamic workloads;
- A layer of indirection (translation table) that decouples ML model retraining from index updating and allows a *stale* learned cache to predict a *correct* position;
- A prototype implementation and an evaluation that demonstrates the advantage and efficacy of XSTORE.

2 RDMA-based Key-Value Store

In this paper, we focus on in-memory key-value (KV) stores that adopt the client-server model (network-attached) [34, 32, 25, 8] and range index structures (tree-backed) [33, 35, 57]. The server hosts both key-value pairs and indexes in main memory and handles requests from multiple clients concurrently. The client interacts with the server through a library that provides basic key-value interfaces, including GET(K), UPDATE(K,V), SCAN(K,N)¹, INSERT(K,V), and DELETE(K), as well as more complex operations built atop them.

¹SCAN(K,N) provides a form of range query that retrieves first (up to) N key-value pairs, where their keys are larger than or equal to K.

Fig. 1. The architecture of RDMA-based key-value stores: (a) server-centric RKV and (b) client-direct RKV.

RDMA (Remote Direct Memory Access) is an emerging feature—appearing in affordable high-performance networks (e.g., InfiniBand, RoCE, or OmniPath)—that enables direct access to the memory of remote machines with low latency and CPU/kernel bypassing. It has generated considerable interest in deploying the network in modern datacenters [17, 46, 20] and optimizing key-value stores (aka RDMA-based KVs) [34, 25, 16, 9, 8]. However, few prior systems consider *ordered* key-value stores that rely on tree-based indexes to handle range queries (i.e., SCAN(K,N)).

Server-centric design (S-RKV) [52, 26, 24]. An obvious design is to take a traditional KV store and reimplement the communication layer (e.g., RPC) using RDMA primitives. As shown in Fig. 1a, the clients ship their requests to the server via RDMA network using one round trip for each; the server traverses the tree-based index and performs the request locally. The *server-centric* design allows access to the server-side store with only two RDMA operations (one for sending and one for receiving), no matter how complex the index structures are, thereby avoiding multiple round trips and message size amplification [26]. However, this design exploits only high performance (low latency and high bandwidth) but not CPU efficiency (remote CPU bypassing) of RDMA network at the server, which limits the scalability of these KV stores with the increase of clients.

Client-direct design (C-RKV) [35, 17, 57]. The adoption of RDMA makes it practical to allow clients to access data hosted on the server directly, thereby permitting an alternative (*client-direct*) design that relaxes the burden on server CPUs. To simplify the mechanism for consistency, this design is restricted to read-only requests (i.e., GET and SCAN) in most systems [34, 16, 35]. This common choice is also motivated by the read-dominated nature of most applications [6]. As shown in Fig. 1b, the clients use one-sided RDMA operations to traverse the tree-based index and fetch the value directly for read-only requests; the server still needs to perform the rest of requests (i.e., UPDATE, INSERT, and DELETE) locally. The *client-direct* design can shift the CPU load on the server to the clients, which would alleviate the bottleneck (from CPU to network), especially on high-bandwidth networks (e.g., 100Gbps). However, it may consume extra network round trips for traversing the tree-based index due to the lack of richness of RDMA primitives, causing an order-

Fig. 2. A comparison of server-side (a) CPU and (b) network bandwidth utilization, (c) peak throughput, (d) end-to-end median latency at low load, and (e) throughput timeline for state-of-the-art server-centric (S-RKV) and client-direct (C-RKV) RDMA-based KV stores. **Workload:** YCSB C (100% read) and YCSB D (95% read and 5% insert), using 100M keys with a uniform distribution. **Testbed:** The server has two 12-core CPUs and two 100Gbps RNICs.

of-magnitude slowdown (e.g., $11\times$ slowdown in Fig. 2c). For example, recent work [35, 57] uses RDMA READs to traverse remote B+tree index and invariably incurs multiple network round trips ($O(\log N)$ [3]).

Recently, *index caching* has been proposed to reduce network round trips for index traversal by RDMA-based systems [52, 48, 17, 35, 38], namely, the client caches the server-side index locally. It aims at reducing RDMA READs for fetching the position of the value (aka *lookup*), instead of caching the value directly.² Thus, an *optimal* result with index caching only needs two RDMA operations per request (one for lookup and one for read).

3 Analysis of RDMA-based Ordered KVs

CPU is the primary scalability bottleneck in the server-centric design. Fig. 2 compares hardware resource utilization between S-RKV and C-RKV with the increase of clients. For S-RKV, the server rapidly saturates all CPUs (24 cores) but just consumes 11% of network bandwidth. It implies that CPU first becomes the performance bottleneck and limits the scalability with the increase of clients, especially when deploying fast networks. This also runs counter to the recent trend of building servers in modern datacenters with CPU-bypassing networks [17, 46, 20]. As shown in Fig. 2c, S-RKV reaches the peak throughput of around 24M reqs/s. Traversing tree-based index occupies most of CPU time, as it involves massive random memory accesses. On our testbed, we measured that one CPU core can perform 43 million 64-byte random reads per second at full speed. Thus, each core can only process up to 1.8M reqs/s for traversing a (8-level) B+tree with 100M keys, even putting other CPU and network costs aside.

Costly RDMA-based traversal is the key obstacle in the client-direct design. C-RKV allows the client to traverse the server-side index directly by using one-sided RDMA READs, which can thoroughly bypass server CPUs (see Fig. 2a). However, RDMA-based index traversal usually requires multiple network round trips (e.g., $O(\log N)$ for tree-

based index) and saturates the network bandwidth quickly. As shown in Fig. 2c, RDMA-based traversal limits the peak throughput of C-RKV to 7 million requests per second, even much lower than that of S-RKV. Using index caching at the clients can reduce RDMA operations by traversing index nodes locally. On our testbed, the throughput of C-RKV with index caching, similar to state-of-the-art design (Cell [35]), peaks at 14.5M reqs/s, as each request takes 4 RDMA READs (down from 8) for traversal.

Tree is not a proper structure for RDMA-based index cache.

To our knowledge, existing RDMA-based index caches use *homogeneous structures* to store *partial* index nodes, similar to the conventional design. For example, each client replicates tree nodes and traverses them locally before accessing the tree-based index hosted on the server [17, 35, 57].

First, the tree-based index can be large [56, 18, 26], and the traversal demands multiple random accesses from the root to the leaf node. Thus, each client can only cache nodes near the root (e.g., top four levels [35]) to minimize thrashing and maximize hits [35, 17]. Yet, the index cache still suffers from *unavoidable capacity misses* (bottom node levels). In Fig. 2c, for a read-only workload, the effect of RDMA-based caching for tree-based index is dominated by inner node levels cached. The *optimal* throughput (a *whole-index* cache) reaches 78M reqs/s using one RDMA READ for each traversal (fetch the position of value), $3.3\times$ better than S-RKV.

Second, traversing tree-based index is a memory-intensive but low-compute operation. The *homogeneous* index cache can just alter the type of memory accesses (i.e., remote and local), instead of reducing the number of memory accesses ($O(\log N)$). Hence, despite the index cache, traversing tree-based index would still incur *massive random accesses* and suffer from CPU cache misses, TLB misses, and RNIC's page translation cache misses. As shown in Fig. 2d, even caching the whole index, the end-to-end latency of C-RKV is still 80% higher than S-RKV, and the CPU cost on index cache (CPU_IDX) occupies close to 30%.

Third, updates to the tree-based index (i.e., inserts and deletes) might propagate the changes from the leaf level to the root node, so that the index updates would probably invalidate the cache *recursively* [57] and cause *false* invalidations

²Considering RDMA performance degradation with increasing payload size [25], the client will only cache internal nodes [35, 38] and not directly fetch a batch of keys and (inline) values to avoid bandwidth amplification [35, 3].

Fig. 3. An example of using ML models to predict the position within a sorted array for a given key.

(path sharing). It would result in frequent cache misses and RDMA READs to retrieve updated index nodes. Worse yet, the more tree nodes cached, the more performance degrades. Further, preserving traversal consistency for dynamic workloads demands sophisticated detection schemes (e.g., fence keys [19, 41]) and incurs additional overhead. In Fig. 2e, the *optimal* throughput significantly drops to 25M reqs/s with severe performance fluctuations, just because of 5% inserts.

4 Approach and Overview

Opportunity: ML Models. Our work is motivated by an attractive observation from the learned index [29]—a range index (e.g., B+tree) that finds the position of a given key inside a sorted array approximates the cumulative distribution function (CDF) of the keys in the index. As shown in Fig. 3, suppose the values have been sorted according to the lookup keys, the CDF (the red curve) is a mapping from the (sorted) keys to the (sorted) positions of their values, namely $CDF(K)$ returns the *actual* position of the value corresponding to K . Prior work [29] proposes to approximate the shape of a CDF using machine learning (ML) models, like neural nets (NN) and linear regression (LR), since they are able to learn a wide variety of distributions. As an alternative range index, the ML model is trained with every key to record the worst over- and under-prediction of a position (i.e., min- and max-error). In Fig. 3, given a lookup key (K), the model (the black curve) can predict a position (pos) with a min- and max-error (min_err and max_err), and a local search (e.g., scanning) around the prediction is used to get the *actual* position. To further reduce the prediction error, a hierarchy of simple models (e.g., recursive-model index [29]) is used to partition the key space, where the model at level L picks the model at level $L+1$ based on the key.

Our approach: Learned Cache. The key idea behind XSTORE is to leverage machine learning (ML) models as (client-side) RDMA-based cache for the (server-side) tree-based index, termed “*learned cache*”. The unique features of machine learning models can fundamentally overcome the drawbacks in the conventional wisdom for RDMA-based index caching (see §3). First, instead of using a *homogeneous* structure to cache a *partial* index, the ML model can cache the *whole* index at the cost of *accuracy*. Therefore, using the learned cache can completely avoid capacity misses, and each lookup only needs one RDMA READ. Further, the ML

Fig. 4. The hybrid architecture behind XSTORE: client-direct operations (left) and server-centric operations (right).

model is also famously memory-efficient (e.g., two parameters per LR model). Thus, the learned cache can match the *optimal* throughput of conventional design (a whole-index cache) but with practical memory consumption.

Second, instead of finding the *actual* position by traversing a tree-based index with $O(\log N)$ random memory accesses, the ML model can approximately predict a *range* of positions for a lookup key by performing a single multiplication and addition (e.g., linear regression). It implies that the learned cache might also reduce the end-to-end latency, even compared to a whole-index cache, due to fewer CPU cache and TLB misses at the clients.

Finally, instead of *fine-grained* and *recursive* invalidation in the tree-based cache for accurate predictions, the ML model can reduce and delay cache invalidations since it only needs to provide approximate predictions. Updates to the index might only decrease the accuracy of the (partial) ML model. Thus, the learned cache can significantly save invalidation cost in terms of network round trips and bandwidth usage, especially compared to a whole-index cache.

Challenge: Dynamic Workloads. Dynamic workloads (e.g., inserts and deletes) would violate an (unrealistic) assumption of ML-based approach that all key-value pairs are stored in sorted order by key [29]. However, retraining ML models and keeping data in order are slow and costly, which is hard to match the high performance of in-memory key-value stores (tens of millions of requests per second). An intuitive solution is to maintain a delta index (e.g., B+tree) for (in-place or buffer-based) inserts and then periodically compact it with the learned index (data merging and model retraining) [44, 18]. Unfortunately, it cannot work well with RDMA-based index caching. First, additional RDMA-based lookups on the delta index would incur more network round trips and severely increase the latency. Second, it is also hard to cache a fast-changing (tree-based) delta index at the clients. Finally, the data and model compaction definitely interrupts (RDMA-based) remote accesses and completely invalidates the learned cache. Hence, *how to make learned cache keep pace with dynamic workloads at low cost* becomes a key challenge.

Overview of XStore. XSTORE is an in-memory ordered key-value store using a client-server model, where the server and the clients are connected with a high-speed, low-latency net-

work with RDMA.³ Using ML models as the index (aka *learned index*) is famously efficient and cheap for static workloads (e.g., gets and scans), while it is notoriously slow and costly for dynamic workloads (e.g., inserts and deletes). It is because the inserts would amplify the prediction error and incur model retraining frequently. Prior work [29, 44, 15] relies more on the profit from efficiently handling static workloads to amortize the negative influence on dynamic workloads. We argue that the *learned cache* opens the opportunity to solve this dilemma. Unlike prior work [29, 44, 15, 14], which replaces or augments the tree-based index with the learned index, we propose a *hybrid architecture that retains the tree-based index at the server to handle dynamic workloads and uses the learned cache at the clients to handle static workloads*.

The architecture of XSTORE is shown in Fig. 4. The server hosts a B+tree index (XTREE) in the main memory and stores key-value pairs at the leaf level physically, like the common practice. Each client interacts with the server through a library, which hosts a local learned cache (XCACHE). XSTORE uses the client-direct design for read-only requests (i.e., GET(K) and SCAN(K,N)) and the server-centric design for the rest (i.e., UPDATE(K,V), INSERT(K,V), and DELETE(K)). For client-direct operations, like GET(K) in Fig. 4, the client first predicts a range of positions for the key K using XCACHE and then fetches them using one RDMA READ. Finally, the client uses a local search to find the actual position and fetches the value using another RDMA READ. For server-centric operations, like INSERT(K,V) in Fig. 4, the client uses RPC over RDMA to ship the request to the server. The server searches the lookup key k by traversing the B+tree index first and then inserts the new KV pair (k, v). XSTORE will partially retrain ML models for updated tree nodes in the background, and each client will individually fetch the models for XCACHE on demand.

5 Design and Implementation

5.1 Data Structures

XTree. At the server, XSTORE retains a B+tree index (XTREE) and stores key-value pairs at the leaf level physically, like the common practice, as illustrated in the left part of Fig. 5. XTREE follows the basic design of a concurrent B+tree [33, 50], except that the leaf node (LN) adopts the structure optimized for remote reads. The leaf node consists of a 24-bit incarnation (INCA), an 8-bit counter (CNT), a 32-bit right-link pointer to next sibling (NXT), keys with N slots ($K_0 \dots K_{N-1}$) and values with N slots ($V_0 \dots V_{N-1}$).

Every leaf node is allocated from an RDMA-registered memory region using a slab allocator and can store at most N key-value pairs in sorted order. For brevity, we assume fixed-length key-value pairs here.⁴ To save the size of RDMA

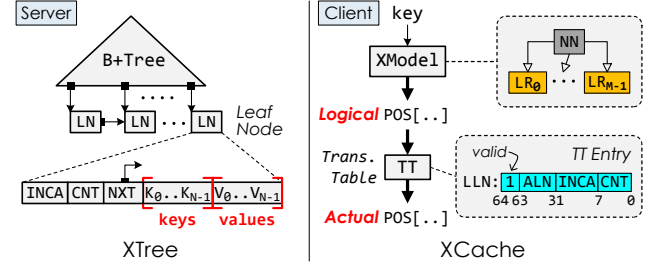

Fig. 5. The main structures in XSTORE: XTREE and XCACHE.

READ for lookup, XSTORE stores keys and values separately but continuously. It can avoid storing the address of the value. The client can fetch N keys from the leaf node and calculate the (remote) address of expected value locally (a fixed offset from its key). Moreover, XSTORE uses incarnation checks [16, 52] to guarantee the consistency of remote accesses. The incarnation in the leaf node is initially zero and is monotonically increased when the leaf node is reused (e.g., split or free). The number of slots (N) can be tuned for RDMA performance (e.g., 16).

XCache. Each client hosts a local learned cache (XCACHE), which consists of a 2-level recursive ML model (XMODEL) and a translation table (TT). As illustrated in the right part of Fig. 5, given a lookup key, XMODEL is used to predict a range of positions (POS[...]) within a sorted array (logically stitching together all leaf nodes of XTREE). Currently, XMODEL uses a linear multi-variate regression model at level 0 (top-model) and simple linear regression models at level 1 (sub-model), a common setup recommended in prior work [15, 29, 44].

The ML model demands the positions (virtual address) of leaf nodes are always sorted by the keys. It is almost impossible for dynamic workloads, since the insertion of key-value pairs may insert a new node at the leaf level and break the sorted order of leaf nodes. The server maintains an additional translation table (TT) for leaf nodes, from logical to actual positions, and each client caches a part of the table on demand. The entry of TT is located by the logical leaf-node number (LLN) and consists of a valid bit, a 31-bit actual leaf-node number (ALN), a 24-bit expected incarnation (INCA), and an 8-bit counter, as shown in Fig. 5. The client can calculate the (host) virtual address of the target leaf node using ALN and the base address of an RDMA-registered memory region. Further, the match of incarnation between TT's entry and target leaf node guarantees that the leaf node has not been reused.

Training models and TT. The server (re-)trains a 2-level ML model (XMODEL) with a translation table (TT) over XTREE's leaf nodes in the background, and each client (re-)fills the learned cache (XCACHE) on demand. Fig. 6 shows

³The client may not be the end user but the computation node or the front-end of RDMA-based datacenter applications [34, 35, 16, 17, 25, 55, 57].

⁴Similar to prior RDMA-enabled KVS [16, 52, 35], XSTORE currently al-

lows fixed-length key and fixed/variable-length value. For variable-length value, the leaf node should store a 64-bit fat pointer [16, 53] (the size and the position of value) instead of the value. We discuss how to support variable-length key in §6 and leave it to future work.

```

Fig. 6. Pseudo-code of training XMODEL and TT over XTREE.

the pseudo-code of training a complete XMODEL and TT. Starting from a sorted array of keys with logical positions (line 4), we first train the top model. Based on the prediction of the top model, we then evenly partition keys into M sub-models (line 9). Finally, we train each sub-model on a sorted array of its keys with a private logical position at a leaf node granularity (line 12-21) and calculate min- and max-error for every sub-model (line 22). Note that the keys in the leaf node across sub-models will be trained by both of sub-models. Moreover, each sub-model has independent logical positions and an own translation table, making it easy to retrain a sub-model individually when necessary.

In practice, training XMODEL is fast and low-cost, since (1) all of the models in XMODEL are simple linear/multivariate regression models, can be efficiently trained; (2) XMODEL can be partially retrained at a sub-model granularity; and (3) the top model can be trained over a sampled data. As an example, for 100M keys, XMODEL with 500K sub-models takes about 4 seconds to train the top-model and 8 microseconds for each sub-model using a single thread. Further, the client can fill a 500K sub-models XCACHE from scratch in less than one second.

```

Fig. 7. Pseudo-code of LOOKUP operation based on XCACHE.

A memory-performance trade-off. The ML model is famously memory-efficient. In XMODEL, the basic sub-models are 14B large and consist of two 32-bit floating-point model parameters⁵, two 8-bit min- and max-error, and a 32-bit TT size. Thus, XMODEL with 500K sub-models only needs less than 6.7MB. In contrast, TT might dominate the memory usage of XCACHE. For 100M keys, suppose each leaf node has 16 slots (N) and is half-full, TT requires nearly 100MB (15% of the tree-based index). In practice, each client could cache sub-models and TT entries on demand, and even just cache XMODEL to save 99% memory at the cost of 20% performance (using one RDMA READ to fetch a few TT entries).

5.2 Client-direct Operations

In the left part of Fig. 4, XSTORE uses the client-direct design for read requests, namely GET(K) and SCAN(K, N).

5.2.1 GET

Given a key, the client uses XCACHE to lookup the remote position of value using one RDMA READ commonly, replacing RDMA-based traversal in a tree-based index. As shown in Fig. 7, the client first uses XMODEL to predict leaf nodes that cover the lookup key (from *start* to *end*) and then calculates the actual (remote) address of these leaf nodes with TT (line 11). The client can use one RDMA READ with doorbell batching to fetch disjoint memory regions if necessary (line 13).⁶ Note that the unit of remote

⁵LR may use more floating-points for prediction.

⁶One RDMA READ can only read a continuous memory region. Yet, we can use an RDMA-aware optimization called doorbell batching [27] to read

read is a leaf node (N keys with a 64-bit header); it is the most likely to read just one leaf node due to the low prediction error of XMODEL. Next, the client uses a local search (e.g., scanning) to find the key from leaf nodes retrieved (line 20-23) and calculates the remote address of the value if it is found (line 22). Finally, the client uses another RDMA READ to fetch the value. Note that any invalid TT entry (line 9 and 17) would result in a fallback path, which ships the GET operation to the server and fetches updated models and TT entries using a single request (i.e., server-centric design).

5.2.2 SCAN

SCAN(K,N) implements a form of range query that returns first (up to) N key-value pairs (in order by key), starting with the next key at or after K. The client first uses the lookup operation with K to determine the remote address of the first key-value pair (larger than or equal to K) and then predicts the leaf nodes that contain the next N key-value pairs, with the help of TT. The translation table provides the number of key-value pairs (CNT) and the actual remote address (ALN) of adjacent leaf nodes (LLN) in sorted order by key. Thus, the client can use one RDMA READ with doorbell batching to fetch these leaf nodes, including keys and values. In general, XSTORE only requires two RDMA READs for each range query. In the rare case, the unexpected result, such as an invalid leaf node (incarnation mismatch) due to dynamic workloads, would cause a fallback path, similar to GET. Note that the range query in XSTORE is also not atomic with respect to updates and inserts as usual [33, 35]; it could be implemented by applications (e.g., transaction [17, 38]).

5.2.3 Non-existent Keys

Intuitively, the ML model guarantees to find all keys have been trained since it stores the worst over- and under-prediction for a CDF (i.e., min- and max-error). However, for non-existent keys, the model should be *monotonic* to guarantee the correct upper and lower bound of a prediction [21, 54], so that a local search could make sure the lookup key does not exist (see line 24 in Fig. 7). Hence, XMODEL adopts monotonic models (e.g., linear regression). As shown in Fig. 8, for a non-existent key (KEY=6), the sub-model LR0 can provide a proper prediction (LR0(6)=[3,4]) that covers the non-existent key (KEYS={5,7}).

However, a hierarchy of models might leave a gap of non-existent keys between neighboring models. Consequently, it still might provide a wrong prediction for these non-existent keys, even if every model is monotonic. For example, the top model selects LR0 for KEY=10 (non-existent), and then LR0 will return a wrong prediction (LR0(10)=[6,7]) that cannot determine whether the key does not exist or the model is out of date from the results (KEYS={17,18}). Worse yet, the non-existent key is common in the range query (e.g., SCAN(K,N)), which demands to retrieve first (up to) N keys larger than or equal to K. As illustrated in Fig. 8, the lookup (LR0(10)) for multiple disjoint memory regions in one network roundtrip.

Fig. 8. An example of the prediction for non-existent keys.

a range query SCAN(10,3) will miss a key (KEY=13), so the result (KEYS={17,18,20}) is also wrong.

Data augmentation. To remedy this, we augment the training set of sub-models to cover the gap of non-existent keys between neighboring models. However, data augmentation would increase the prediction error. We thus carefully add a boundary key to both sub-models, which can fill the gaps with minimal overlap between models. For example, in Fig. 8, we add a non-existent key in the gap (KEY=10) with the position of a previous KEY=4 into both sub-models (LR0 and LR1). After that, the lookup of non-existent keys would always return a correct prediction. Further, since the keys in the leaf node across sub-models have been trained by both, there is no need for data augmentation in most cases.

5.3 Server-centric Operations

As shown in the right part of Fig. 4, clients communicate with the server to perform UPDATE(K,V), INSERT(K,V), and DELETE(K) operations; the server updates XTREE concurrently and retrains XMODEL in the background.

Correctness. The correctness condition in XSTORE follows *no lost keys* [33]: the reader must return a correct value for a given key, regardless of concurrent writers. More specifically, when a reader and a writer run concurrently, the reader can return either the old or the new value, while both of them should be atomic.

Concurrency. The hybrid architecture behind XSTORE not only provides separate and appropriate execution paths for static and dynamic workloads (see Fig. 4), but also simplifies the mechanism to guarantee the correctness of concurrent operations. It is critical to the performance of RDMA-based systems due to the lack of richness of RDMA primitives [51]. In Fig. 9a, by using the learned cache (XCACHE), XSTORE restricts (client-direct) remote accesses to the leaf nodes (the dotted red arrow). Thus, we can avoid using sophisticated mechanisms to retrofit a concurrent tree-based index [35].

XTREE reuses an HTM-based concurrent B+tree [50]⁷ to support concurrent index updates (e.g., node splits) and

⁷The implementation is based on Intel's restricted transactional memory (RTM) that is available as a mature feature in Intel's CPUs (e.g., Skylake).

Fig. 9. (a) The access types of different operations for the main components in XSTORE. Red and blue arrows denote read and write accesses. (b) An example of model retraining for LR₈ due to a split of LN₁₀₁. The leaf node is named by its actual leaf-node number (ALN).

lookups on internal nodes, without the concern of RDMA-based remote accesses. For leaf nodes, XSTORE follows the technique proposed in DrTM+R [11]. Each tree operation at the server is enclosed within an HTM region, that provides strong atomicity in a single machine [5]. In addition, the strong consistency feature of RDMA (where an RDMA operation will abort an HTM transaction that accesses the same memory location [52]) further extends the atomicity when encountering remote accesses. Moreover, as the RDMA operation is only cache-coherent within a cache line, XSTORE adopts versioning [16] for consistent remote reads across multiple cache lines. For the data stored in the leaf node across multiple cache lines, a 16-bit version number is stored both in the header of data and at the start of each cache line. The remote reader matches these versions to detect inconsistent read and must retry if the versions differ. Note that XSTORE hides these versions to applications by automatically converting the data on reads and writes. Finally, the key is also stored in the header of its value, which guarantees consistent remote reads to the key and the value separately.

5.3.1 UPDATE

For UPDATE(K,V), the server first traverses XTREE to the leaf node and updates the value with V if the key (K) exists. Note that the update to the value will not change the index, so that it will also not influence the learned cache and belongs to static workloads.

Optimization: position hint. Although UPDATE(K,V) is a server-side operation, it can still benefit from the learned cache, especially when the server CPU becomes a bottleneck. The client could use XCACHE to predict a position (the remote address of leaf nodes) for the key (see line 1-12 in Fig. 7) and then ship the update request together with the position hint to the server. The server first checks the leaf nodes (by matching incarnation) according to the hint and updates the value if successful. It might skip index traversal and relax the burden on server CPUs. The optimization would increase the performance of update-heavy workloads, like YCSB A (50% update and 50% read).

5.3.2 INSERT and DELETE

INSERT(K,V) and DELETE(K) are shipped to the server and performed on XTREE, as is usual on B+tree. The *in-place* in-

serts and deletes require moving many key-value pairs within a leaf node to preserve the order of keys. Thus, XTREE chooses not to keep key-value pairs sorted within a leaf node, which can avoid moving key-value pairs and reduces working set in the HTM region. Note that the lookup based on the learned cache will not be affected since it fetches all keys (N) of a leaf node. For DELETE(K), we always overwrite the key and value slot for K with the last key-value pair in the leaf node and update the counter (CNT). Further, the empty leaf node will not be reclaimed to avoid thrashing and model retraining. For INSERT(K,V), we directly append K and V to the key and value slots in the leaf node if K does not exist (see K_A in Fig. 9b). Inserting a key-value pair into a full leaf node will result in a node *split* (see K_B in Fig. 9b). A new leaf node is allocated, and all key-value pairs (plus the new one) are evenly assigned to two leaf nodes in sorted order by key. The original leaf node should increment its incarnation, which makes the clients realize the split. The rest of the split process will execute on the tree index as well as usual.

Retraining and invalidation. The insert of a new leaf node (aka a split) will break the sorted (logical) order of leaf nodes and cause model retraining. An interesting observation behind our solution is that TT decouples model retraining from index updating and allows a *stale* combination of XMODEL and TT to provide a *correct* prediction for the lookup key as long as it is not overlapped with a split. This is because any insert will not cause data movement across leaf nodes, except the split node. For example, LR₈ initially maps K_A to logical node number LN₂, which stores the leaf's physical address 102. After leaf node LN₁ splits due to inserts (a new leaf node with physical address 327), the latest logical node number for K_A is LN₃ after retraining. Yet, the stale TT still maps K_A to physical address 102, the correct position of K_A. Thus, the client can still use a combination of stale models and TTs to find the keys as long as they are not overlapped with split leaf nodes.

Based on this, after a split, the server will *individually* retrain the sub-model and its translation table in the background (see TRAIN_SUBMODEL in Fig. 6) and perform all kinds of operations as usual based on XTREE. Meanwhile, the clients can still directly perform read-only operations based on XCACHE. The incorrect prediction can be detected

by incarnation mismatch between the leaf node and cached TT entry (line 17 in Fig. 7) and results in a fallback, which ships the operation to the server. The client will update XCACHE with a retrained model and its translation table fetched by the fallback. Noted that concurrent splits will not affect model retraining in progress and just make it stale. The new incarnation of the split leaf node ensures the client with this new (stale) model to realize the change of concurrent splits. Each split will issue a retraining task. The training thread currently does not merge or optimize the pending tasks to the same sub-model since it happens very rarely.

Optimization: speculative execution. A split of leaf node just moves the second half of key-value pairs (sorted by key) to its new sibling leaf node. Therefore, the prediction to the split node must still be mapped to this node or its new sibling, like LN_{101} and LN_{327} in Fig. 9b. Based on this observation, *speculative execution* is enabled to handle the lookup operation on a *stale* TT entry (i.e., incarnation check is failed). The client will still find the lookup key in the keys fetched from the split leaf node. If not found, the client will use its right-link pointer to fetch (the second half) keys from its sibling (one more RDMA READ). It means there is roughly half of the chance to avoid incurring a performance penalty. Currently, we only consider one sibling before using a fallback since a cascading split happens rarely. This optimization is important for insert-dominate workloads (e.g., YCSB D) since insert operations and retraining tasks might keep server CPUs busy; the fallbacks will also take server CPU time.

Model expansion. The growing size of key-value pairs in the ML model will likely increase the prediction error, resulting in performance degradation. Prior work [44] uses a sophisticated model split to adapt its learned structure for dynamic workloads, which demands physical data moving and atomic top-model replacement. In response to this problem, XSTORE supports *model expansion* that increases the number of sub-models in XMODEL at once (e.g., doubling) when necessary (e.g., exceeding a threshold of min- and max-error). The model expansion requires a complete training (see Fig. 6) on XTREE to build a new version of XMODEL and TT. Note that model expansion will not affect any requests performed by both the server and the client for several reasons. First, training models will not change or move data. Second, the top model can be trained over incomplete data. Third, the conflicting sub-model retraining could be made up later. Finally, the client can use the originally learned cache during model expansion. Moreover, after deleting a large number of key-value pairs, XSTORE can also resize XMODEL to shrink the number of sub-models using a similar process.

5.4 Durability

XSTORE should log writes (updates, inserts, and deletes) to log files stored in reliable storage for persistence and failure recovery (e.g., server's local disk). As RDMA-based remote accesses are restricted to reads (lookups, gets, and scans),

they will not involve in logging and recovery. In addition, XMODEL and TT are tightly associated with XTREE (e.g., virtual address). Thus, they should be rebuilt after recovery.

To ensure correct recovery from a machine failure, XSTORE can reuse the existing durability mechanism in the concurrent tree-based index extended by XTREE, like version numbers [50, 33]. Each worker thread at the server appends the log (key, value, and version) to its in-memory log buffer. A corresponding logging thread, sharing the same core with the worker thread, writes out the log buffer to its log file in the background. The logger batches the log entries to avoid the storage backend becoming the bottleneck. During recovery, XSTORE scans log files to sort logs of the same key by its version number and applies the latest log of keys in parallel. Finally, XSTORE rebuilds XMODEL and TT by training over recovered XTREE.

5.5 Scaling out XSTORE

XSTORE follows a coarse-grained scheme [57], the dominant solution, to distribute an ordered key-value store span multiple servers (scale-out). XSTORE first assigns key-value pairs to the servers based on a range-based partitioning function for the keys. Then each server constructs XTREE individually for its assigned key-value pairs and further trains a corresponding XMODEL and TT. Note that the boundary keys should be added to the training set to cover the gap of non-existent keys between neighboring servers.

The client maintains a separate learned cache for each server and uses the same partitioning function to decide which server should perform a given request. Based on it, the client can perform requests as mentioned in §5.2 and §5.3, with one exception—SCAN(K,N) reads a range of key-value pairs span multiple servers. After the lookup of K on a specified server, the client might find that the expected number (N) exceeds the remaining key-value pairs in this server. Starting from the first logical leaf node on the next server, the client can predict the leaf nodes that contain the rest of key-value pairs. Finally, the client uses one RDMA READ for each server involved to fetch these leaf nodes.

6 Discussion

Support variable-length keys. XSTORE currently supports fixed-length key and variable/fixed-length value. To support variable-length key, XSTORE should store a fat pointer in the leaf node of XTREE (instead of the actual key), which encodes the size and position of the key. This scheme can traverse variable-length key locally by CPUs (i.e., server-centric design), while it would be hard to do it efficiently by using one-sided RDMA READs (i.e., client-direct design). XSTORE has to retrieve the actual keys using an additional RDMA READ for each (Line 21 in Fig. 7). Therefore, XSTORE further stores a fixed hash code of the key within the fat pointer. Consequently, the client could directly compare the hash codes instead of keys, after fetching the leaf node for a given key. Note that the actual (variable-length) key should

Table 1: YCSB workload description. **R**, **U**, **I**, **M**, and **S** denote read, update, insert, read-modify-update, and scan, respectively. Scan accesses N values, where N is uniformly distributed in $[1, 100]$.

YCSB	A	B	C	D	E	F
Type	R : U	R : U	R	R : I	S : I	R : M
Ratio (%)	50 : 50	90 : 10	100	95 : 5	95 : 5	50 : 50

be checked to avoid a hash collision. For example, the client can fetch the value associated with the key. We plan to extend XSTORE to support variable-length keys in future work.

Data distribution. XSTORE assumes machine learning (ML) models can effectively learn various data distributions (e.g., log-normal [29, 44, 15]). Based on it, we believe there is a trade-off among the memory consumption of XCACHE, the retraining costs of XMODEL, and the performance of XSTORE. When using simple models (e.g., linear regression) for fast model retraining, XSTORE has to use many models to achieve high accuracy for irregular data distributions. For such a scenario, clients can only cache partial sub-models due to the increased model memory consumptions. On the other hand, XSTORE could use complex models (e.g., neural network (NN)) to achieve high accuracy with few models. Yet, NN is slow on model retraining and may impact the performance under dynamic workloads (e.g., inserts), since the client may fall back more often due to stale XCACHE.

7 Evaluation

7.1 Experimental Setup

Testbed. Without explicit mention, we use one server machine and (up to) 15 client machines. Each machine has two 12-core Intel Xeon CPUs, 128GB of RAM, and two ConnectX-4 100Gbps IB RNICs. Each RNIC is used by threads on the same socket and connected to a Mellanox 100Gbps IB Switch. The server registers the memory with huge pages to reduce RNIC’s page translation cache misses [16].

Workloads. We use YCSB [13] and two production workloads from Nutanix [30]. We mainly focus on YCSB as it contains various types of workloads [12]: update heavy (A), read mostly (B), read only (C), read latest (D), short ranges (E), and read-modify-write (F). Table 1 shows a summary of YCSB workloads (A-F). Since small requests dominate in real-life workloads [4], we evaluate KV stores with 100 million KV pairs initially (a 7-level tree-based index and a leaf level), where 8-byte key and 8-byte value are used, similar to prior work [33, 35, 24, 44]. Both Uniform and Zipfian key distributions are evaluated for all YCSB workloads. Note that YCSB D only has Uniform and Latest key distributions; the client is likely to query its recently inserted keys in Latest distribution. In addition, each client generates their insert key uniformly and randomly in YCSB D and E. The two production workloads both have a profile of 57:41:2 write:read:scan ratio, while the access patterns of them are relatively uniform (Prod1) and skewed (Prod2), respectively. Both of them have 500 million KV pairs with 8-byte key and 64-byte value. Fi-

Table 2: Data distribution description for evaluating datasets.

Name	Description	Workloads
L	Linear	YCSB[13], Nutanix[30]
NL	Noised linear	YCSB[13]
OSM	Longitude location	Open Street Map[2]

nally, besides the default data distribution of the above workloads, we also use two synthetic and one real-life datasets (see Table 2) to study the behavior of learned cache in depth.

Comparing targets. We compare XSTORE to three state-of-the-art RDMA-based ordered KV stores: DrTM-Tree [11] and eRPC+Masstree [24] (*server-centric* design), as well as Cell [35] (*client-direct* design). eRPC+Masstree (EMT) adopts eRPC [24] (RDMA-based RPC library) to extend Masstree [33] (in-memory ordered KV store). We implement DrTM-Tree and Cell in the same framework to provide an apple-to-apple comparison with two typical designs, but also because DrTM-Tree uses similar B+tree [50] and RDMA library [51] with XSTORE, and Cell is not open-source.⁸ We further consider RDMA-Memcached v0.9.6 [22] (RMC) in our experiments, which is an RDMA version of memcached [1], a widely used network-attached KV in industry.

All systems fully utilize all of the 24 CPU cores (with hyperthreading disabled) and two RNICs. As EMT and RMC cannot use multiple NICs simultaneously, we deploy two instances at the server on different sockets, and each instance uses the RNIC attached to that socket. This actually makes them faster during experiments since it avoids cross-socket synchronizations. XSTORE uses (up to) two auxiliary threads to train ML models in the background for dynamic workloads. XTREE is configured with a fanout of 16. XMODEL uses 500K sub-models for static workloads and 2M models for dynamic workloads to avoid model expansion during evaluation (because XSTORE can insert more than 150M KV pairs in 60s). In addition, logging is disabled in all systems, and the server hosts all data in main memory.

7.2 YCSB Performance

Fig. 10 compares the peak throughput of various RDMA-based key-value stores for YCSB with Uniform and Zipfian distributions, where all systems are saturated by up to 15 client machines. Note that RMC performs poorly in all experiments as it is bottlenecked by CPU synchronizations [43, 31]. Due to space limitations, we skip detailed discussion of experimental results on it.

Read-only workload (YCSB C). For Uniform distribution, XSTORE can achieve 82 million requests per second, even a little higher than the *optimal* throughput (a whole-index

⁸For DrTM-Tree, our experimental results were confirmed by the authors. For Cell, we follow the same caching strategy—the client caches nodes at least four levels above the leaf node at the clients with LRU policy to minimize churn and maximize hits. Based on a comparison against published numbers, we believe that the large performance difference between XSTORE and other systems (e.g., 27M reqs/s from our implementation vs. 0.95M reqs/s from Cell [35] for YCSB A with Zipfian distribution) offsets performance variations due to system and implementation details.

Fig. 10. Comparison of throughput on various RDMA-based KV systems using YCSB. Note that RMC does not support range queries.

cache), since it only uses one RDMA READ to fetch one leaf node per lookup; the payload is 16B smaller by avoiding a sophisticated mechanism for consistency (i.e., min-max fence keys [35]). The prediction error of XCACHE is just 0.74. This number outperforms EMT, DrTM-Tree, and Cell by $3.9\times$, $3.7\times$, and $5.9\times$, respectively. Both DrTM-Tree and EMT are bottlenecked by server CPUs, while Cell is bottlenecked by RDMA amplifications; it still needs four RDMA READs to traverse tree nodes even index caching is enabled.

For Zipfian distribution, XSTORE can still outperform EMT, DrTM-Tree, and Cell by $2.4\times$, $2.5\times$, and $4.6\times$, respectively. The systems with server-centric design perform better due to better CPU cache locality. However, the peak throughput of XSTORE drops by 18% since RDMA has relatively poor performance when massive clients read a small range of memory simultaneously. We suspect that our current RNIC (ConnectX-4) checks conflicts between one-sided RDMA operations based on request’s address [27], so that these operations may compete for NIC’s internal processing resources, even if there is no conflict.

Static read-write workloads (YCSB A, B, and F). For update-heavy workloads (YCSB A), XSTORE is still bottlenecked by server CPUs for handling updates. However, compared to server-centric KV systems (e.g., DrTM-Tree and EMT), the clients in XSTORE can directly perform read requests with the help of learned cache, which completely bypasses server CPUs. Therefore, XSTORE can still provide up to $2.2\times$ and $2.3\times$ (from $1.5\times$ and $2.0\times$) throughput improvements for Uniform and Zipfian distributions, respectively, compared to other KV systems. For read-mostly workloads (YCSB B), the speedup of throughput in XSTORE further reaches up to $5.3\times$ (from $3.1\times$). There are two reasons: (1) the read requests are less skewed interleaved with (10%) updates, compared to read-only workloads (YCSB C); (2) the server of XSTORE has not been saturated (less than 40% of CPU utilizations); thus it is still sufficient to perform updates, compared to update-heavy workloads (YCSB A). The performance of XSTORE on YCSB F is somewhere in between since it has about 75% reads.

Fig. 11. The performance timeline of YCSB D with (a) Uniform and (b) Latest workloads.

Dynamic workloads (YCSB D and E). The throughput of every system is impacted by dynamic workloads due to the contention between reads and inserts. For DrTM-Tree and EMT, the contention happens on the tree-based index. For XSTORE and Cell, the performance slowdown is mainly due to cache invalidations. However, Cell only caches the top four levels, where node split is rare. The overhead in XSTORE mainly comes from two parts: (1) cache invalidations would increase RDMA operations due to fallbacks (RDMA-based RPC) and speculative execution (50% one more RDMA READ); (2) a dynamic dataset is always harder to learn than a static dataset due to the randomly inserted new keys; the prediction error would stably increase to 8.3 for YCSB D.⁹ Fortunately, the clients can still use stale learned cache for most read requests, and model retraining is also very fast. Thus, for YCSB D, XSTORE can provide up to $3.5\times$ and $3.2\times$ (from $2.7\times$ and $1.9\times$) speedup and achieve 53M and 48M reqs/s throughput for Uniform and Latest distributions, respectively. For YCSB E, the performance is dominated by scanning a large range of KV pairs. Thereby the difference is relatively small, and XSTORE outperforms other systems by up to $1.8\times$ (from $1.4\times$).

Fig. 11 further shows the timelines for YCSB D with Uniform and Latest workloads. The optimal throughput of tree-based index cache can only achieve about 25M reqs/s, more than $3\times$ lower than its read-only throughput (78M reqs/s), and suffers from severe performance fluctuations due to frequent cache invalidations, especially for Uniform distribution. For Latest distribution, each client will focus on a small range of KV pairs (latest inserted by itself), which significantly reduces cache misses and invalidations due to accessing internal nodes split by other clients. XSTORE preserves relatively high throughput and has steady cache invalidation rates, 5% for Uniform, and 21% for Latest. It is mainly because stale learned cache can still provide a correct prediction for most read requests. The speculative execution also helps to halve the rate (from 10% to 5%). In addition, in Latest distribution, each client will frequently access KV pairs just inserted. If the insert incurs a node split, XSTORE might not fetch a new model immediately (wait for model retraining) and would increase cache misses.

CPU utilizations of XSTORE. Note that XSTORE uses two auxiliary threads to retrain XMODEL for dynamic work-

⁹The data distribution of dynamic workloads (i.e., YCSB D and E) is close to noised linear (NL). Hence, XSTORE can only achieve 61M reqs/s for YCSB D with 2M models even no inserts (see Fig. 14b and Fig. 15d).

Fig. 12. Comparison of (a) throughput-latency and (b) end-to-end median latency at low load for YCSB-C with a uniform distribution.

loads, causing increased server CPU usage. Yet, XSTORE still saves server CPUs compared to server-centric KV (e.g., DrTM-Tree) due to handling read requests in the clients. For example, DrTM-Tree saturates all CPUs ($24 \times 100\%$) for YCSB D, while XSTORE just consumes under half for serving insert requests and retraining sub-models.

End-to-end latency. Fig. 12a shows the throughput-latency curves for YCSB C with a uniform distribution. Due to space limitations, we omit other workloads that are similar. When using few clients (low load), server-centric KV has lower latency, as one RPC round trip is faster than two one-sided RDMA operations, namely DrTM-Tree (NIC_RPC) vs. XSTORE (NIC_IDX and NIC_VAL) in Fig. 12b. However, the throughput of them (e.g., DrTM-Tree) is saturated by CPUs much earlier (about 20M reqs/s), and the latency would rapidly collapse. On the other hand, the latency of Cell is limited by multiple RDMA READs for each lookup (NIC_IDX) even at low load. In contrast, XSTORE only needs one RDMA READ, thanks to the learned cache. As a reference, we provide the latency of using whole-index cache (Optimal) that also takes just one RDMA READ. However, traversing tree-based index locally still takes more time ($2.14\mu s$ in CPU_IDX) due to many random memory accesses, compared to XSTORE ($0.35\mu s$). Moreover, XSTORE can keep low latency at much high load (82M reqs/s with median latency of $16\mu s$) by eliminating CPU bottleneck at the server.

Fig. 13. (a) Performance comparison with production workloads. (b) Scalability of XSTORE on YCSB C with the increase of RNICs.

7.3 Production Workload Performance

Fig. 13a shows the peak throughput of XSTORE and other systems on two write-intensive production workloads, similar to YCSB A. The performance is also mainly bottlenecked by server CPUs due to 57% of writes. In the first workload (Prod1), XSTORE outperforms DrTM-Tree, EMT, and Cell by $1.44\times$, $1.55\times$, and $1.35\times$, respectively. The speedup in the second workload (Prod2) increases to $1.75\times$, $1.80\times$, and $1.60\times$ since this workload is more skewed.

Fig. 14. (a) Comparison between sub-model retraining and invalidation speed. (b) Performance of XSTORE with the increase of insertion speed. (c) Performance timeline with model expansion.

7.4 Scale-out Performance

Fig. 13b shows the scalability of XSTORE with up to 6 server RNICs (3 server machines). We scale XSTORE by range-based partitioning a YCSB dataset with 600M keys into different numbers of RNICs. The performance is measured using up to 13 client machines (26 RNICs) with a read-only workload. For a uniform request distribution, XSTORE achieve a peak throughput of 145M reqs/s, which is limited by the number of client machines. Note that, on our testbed, XSTORE needs about eight client RNICs to saturate one server RNIC. XSTORE scales to $1.97\times$ and $2.81\times$ by using 2 and 3 server RNICs, respectively. For a skewed request distribution (Zipfian), XSTORE just reaches 92M reqs/s by using 6 server RNICs since most requests (more than 35%) are sent to one RNIC. It throttles the entire system.

7.5 Model (Re-)Training and Expansion

Fig. 14a shows the throughput of training models using one or two threads and model invalidation speed for dynamic workloads (YCSB D and E). Empirically, using two threads for model retraining is sufficient for XSTORE to reach a throughput of 53M reqs/s (YCSB D). XSTORE can retrain sub-models individually and takes $8\mu s$ on average to retrain a model with 200 keys. Note that the insertion speed reaches about 2.65M reqs/s for YCSB D (5% inserts). For dynamic workloads, the throughput of XSTORE would decrease when stale sub-models can not retrained in time. To quantify the performance overhead, we evaluate XSTORE with the increase of insertion speed, similar to YCSB D (except that one client is dedicated to insert key-value pairs with a given speed, and the rest of clients still issue reads). As shown in Fig. 14b, the throughput drops below 40% (61M vs. 37M reqs/s) under the peak insertion speed (2.8M reqs/s , limited by server CPUs) when using a single retraining thread. Further, when using two threads, the performance degradation is limited to 13%.

Finally, the growing size of KV pairs in the ML model

Fig. 15. (a) Memory usage of learned cache (XCACHE). Comparison of peak throughput between learned cache and tree-based cache with different memory footprint at the client for YCSB C using (b) Uniform and (c) Zipfian distributions. Comparison of (d) peak throughput and (e) median latency on XSTORE with the increase of models for various data distributions (see Table 2).

will likely increase the prediction error, resulting in performance degradation. XSTORE supports model expansion to increase models in the background if needed. As shown in Fig. 14c, starting from 10M keys and 100K models, several clients continuously insert KV pairs, and the performance of XSTORE slowly degrades for read requests. When the average number of keys per model exceeds 200 (a user-defined threshold), the server starts to train a new XMODEL with double sub-models (200K) in the background from 0s to 4s, with negligible overhead. After that, the server will commit the new model, and clients could individually fetch new sub-models on demand. The performance resumes rapidly in 2s.

7.6 Memory Footprint of XCACHE

Fig. 15a presents the memory usage of XCACHE with the increase of sub-models for 100M KV pairs. Note that the entire XTREE has 654MB internal nodes. The size of TT depends on the number of leaf nodes. Since each leaf node has 16 slots for KV pairs, TT occupies around 98MB as the tree-based index is half-full. Thus, TT would dominate the memory usage for a small XMODEL since each sub-model is 14B large. To achieve peak throughput, XMODEL with 500K sub-models is enough for read-only workloads (YCSB C) with 100M KV pairs, while it needs 2M sub-models for dynamic workloads (YCSB D) with 250M KV pairs.

As shown in Fig. 15b and Fig. 15c, compared to conventional tree-based index cache, XSTORE can provide competitive performance with much lower memory footprint at the clients, even (almost) no memory footprint. XCACHE prefers to store XMODEL, which may only occupy 1% memory (6.8M vs. 654MB). It means that, for YCSB C with Uniform and Zipfian distributions, XSTORE can achieve 74% and 87% of optimal throughput (a whole-index cache), where the client uses one additional RDMA READ to fetch several 8-byte TT entries for each lookup. Even if the client only stores a 16-byte top model, XSTORE can still achieve about 40M reqs/s by using one RDMA READ to fetch a 14-byte sub-model first.

7.7 Data Distribution

We further evaluate XSTORE on a 100M-key dataset with different data distributions in Table 2 using a read-only workload (YCSB C). The throughput of XSTORE is sensitive to the prediction error due to bandwidth amplification for re-

trieving more keys. Thus, XSTORE requires more simple sub-models (e.g., LR) to learn complex data distributions (e.g., OSM) for the same prediction error. For example, as shown in Fig. 15d, XSTORE requires about 20M sub-models for OSM to achieve a peak throughput of 80M reqs/s. However, as shown in Fig. 15e, the median latency at a low load is relatively stable for various data distributions, as the latency of RDMA is insensitive to payload sizes when the network is not saturated [39].

Table 3: The impact of durability on throughput (M reqs/s).

YCSB /Uniform	A	B	C	D	E	F
w/o logging	41	80	82	53	10.2	36
w logging	31	78	82	51	9.9	33

7.8 Durability

To study the overhead of logging for durability, we evaluate the peak throughput of XSTORE for various YCSB workloads with logging to SSD enabled. As shown in Table 3, the performance drops by up to 24% for update-heavy workloads (e.g., YCSB A) due to additional writes to SSD for write operations (e.g., UPDATE). On the other hand, it does not degrade the performance of read-heavy workloads much (e.g., YCSB C). First, XSTORE executes read operations (e.g., GET) using one-sided RDMA primitives, bypassing the logging threads thoroughly. Second, XSTORE flushes the logs in a batched manner [33], which hides the impact of slow storage (§5.4).

7.9 Variable-length Value

By default, XSTORE directly stores the value in leaf nodes (*inline value*). To support variable-length values, XSTORE stores a 64-bit fat pointer (the size and the position of value) in leaf nodes (*indirect value*). Consequently, the client needs an additional RDMA READ to retrieve the variable-length value (Line 13 in Fig. 7). Fig. 16a shows the performance of XSTORE by using inline and indirect value. Using *indirect value* causes up to 43% (from 8%) performance degradation, compared to using *inline value*. The performance gap is closing with the increase of values (e.g., 1KB) since the cost of one additional RDMA READ becomes trivial.

7.10 Application Performance

To demonstrate the effectiveness of XSTORE in application workloads, we have integrated it into DrTM+H [51], a state-

Fig. 16. (a) Performance of XSTORE by using inline and indirect value. (b) Comparison of DrTM+H on TPC-C w/ and w/o XSTORE.

of-the-art distributed OLTP system that leverages RDMA-enabled KVS to store tuples. The vanilla DrTM+H only performs unordered index lookups (hash table) by using one-sided RDMA primitives [52]. DrTM+H with XSTORE (called DrTM+X) can further perform ordered index lookups (B+tree) through one-sided RDMA operations.

Experimental setup. We use TPC-C [45] to compare the performance of DrTM+H and DrTM+X. Note that both of them run in an asymmetric setting, which is widely adopted in cloud databases [55, 47, 7].¹⁰ More specifically, we deploy 96 warehouses on four data servers and use the rest of the machines in our testbed as clients. Both DrTM+H and DrTM+X rely on the data server to update tuples, while DrTM+X uses one-sided RDMA READs to retrieve tuples from the data server. Therefore, we use a read-heavy TPC-C workload in the experiment, which consists of NEW-ORDER transactions (10%) and ORDER-STATUS transactions (90%). NEW-ORDER transaction inserts a new order with five to fifteen order lines; ORDER-STATUS transaction retrieves the recently inserted orders first and then scans related order lines.

Performance. As shown in Fig. 16b, XSTORE improves the peak throughput of DrTM+H by 2.27 \times , reaching 490K reqs/s. DrTM+H is bottlenecked by server CPUs since the data server traverses the index and performs the read request locally. Consequently, the read requests of ORDER-STATUS transactions would compete CPUs with the write requests of NEW-ORDER transactions at the servers. Differently, DrTM+X relies on RNICs at the clients to lookup and retrieve tuples for ORDER-STATUS transactions. It relaxes the burden on server CPUs and improves performance significantly.

8 Related Work

RDMA-enabled key-value stores. XSTORE continues the line of research of RDMA-based in-memory key-value stores [31, 34, 25, 16, 52, 35, 43, 57, 8, 48], but explores a new design point, namely *learned cache*, that leverages machine learning (ML) models as index cache for RDMA-based, tree-backed key-value store. There have been many efforts to investigate RDMA-based unordered in-memory KVs which focus on such as improving the communication layer (e.g., RPC) [25, 24, 10], selecting appropriate hash tables [34, 16, 52], supporting index caching [52, 48], and enabling in-network processing [31, 40].

¹⁰Prior work [51] has shown that using (two-sided) RDMA-based RPC is a better choice for GET operations in a symmetric setting [17].

There is an increasing interest in optimizing tree-backed in-memory key-value stores with RDMA. Cell [35] allows clients to traverse server’s B+Tree using RDMA READs and caches the top three levels of tree index. FaRM B-Tree [17] caches B-tree’s internal nodes at each server to accelerate lookups using RDMA, while it is costly and error-prone for dynamic workloads [38]. Ziegler et al. [57] studies different RDMA-based design alternatives for tree-based index, including how the tree should be distributed and the choices of RDMA primitives for tree operations.

Learned indexes and their applications in systems. Kraska et al. [29] argue that all existing index structures can be replaced with machine learning (ML) models, which are termed “learned index”, and further propose several example learned indexes to replace various index structures, including tree-based range index. There have been several recent efforts of adapting learned indexes to handle dynamic workloads [44, 15, 36]. XIndex [44] adds a delta index to each sub-model in a learned index and proposes a new concurrent compaction scheme to split models. ALEX [15] uses a gapped array to accommodate new key-value pairs, similar to the leaf node of XTREE. However, it is non-trivial to enable the gapped array in a distributed system since it requires complex coordinations when expanding the array upon full. Bourbon [14] is a log-structured merge (LSM) tree that leverages the learned index to speedup lookups. FITING-TREE [18] is a form of a learned index to balance prediction error and memory cost. It uses extra sorted buffers to store inserts and merges them back when reaching a threshold. SIndex [49] is a concurrent learned index for variable-length string keys. Differently, XSTORE proposes a hybrid architecture to leverage ML models as RDMA-based index cache, instead of replacing or augmenting traditional index structures.

9 Conclusion

This paper presents XSTORE, an RDMA-based in-memory ordered key-value store with a new *hybrid* architecture to leverage ML model as RDMA-based index cache. Our experimental results show the high performance of XSTORE.

A Artifact Appendix

A.1 Abstract

This artifact provides the source code of XSTORE and scripts to reproduce the main experimental results. XSTORE is an RDMA-based ordered key-value store that adopts the client-server model (network-attached) and range index structures (tree-backed). To reproduce the results, we provide instructions to build binaries (§A.3) and run experiments (§A.4). The source code of XSTORE can be retrieved from a public open-source repository (§A.2.1). The repository also contains scripts to generate the main results in §7 (see Table 4). Though the scripts target our testbed (§7.1), readers can simply change them for other platforms (§A.6).

A.2 Artifact Check-list

- **Program:** fserver, ycsb, and micro.
- **Compilation:** g++ and cmake.
- **Hardware:** Intel CPU with RTM and Mellanox NIC with RDMA.
- **Execution:** Python scripts.
- **Metrics:** Throughput and median latency.
- **Expected experiment run time:** 1 minute each experiment.
- **Public link:**
<https://github.com/SJTU-IPADS/xstore>.
- **Code licenses:** Apache License 2.0.

A.2.1 How to Access

The artifact is publicly available at our Github repository.

```
$ git clone https://github.com/SJTU-IPADS/xstore
$ git checkout c9f38188
```

A.2.2 Hardware Dependencies

To reproduce the experiment results, each machine must have at least one Mellanox RDMA network card (e.g., Mellanox ConnectX-4 MT27700 100Gbps InfiniBand NIC), and the server machine must have Intel processors with Restricted Transactional Memory (RTM) (e.g., Xeon E5-2650 v4). It should be noted that the throughput of read operations (e.g., gets) is mainly bottlenecked by the RDMA network, while the throughput of write operations (e.g., updates) is mainly bottlenecked by the server CPU.

A.2.3 Software Dependencies

Operating system: Ubuntu ≥ 16.04 .

Compile toolchain: g++ $\geq 5.4.4$ and cmake $\geq 3.5.1$.

Other software dependencies: Intel MKL, Mellanox OFED, boost 1.6.1, and jemalloc.

A.3 Installation

Intel MKL (Math Kernel Library).

```
$ apt-get install -y intel-mkl-2019.1-053
```

Listing 1: A sample evaluating script (sample.toml).

```
[[pass]]
host = server_host    ## host name of the server
path = /cock/fstore
cmd = "./fserver -db_type ycsb -model_config=
ycsb-model.toml"

[[pass]]
host = client_host    ## host name of the client
path = /cock/fstore
cmd = "./ycsb -threads 1 -server_host
server_host"

[[pass]]
host = master_host    ## host name of the client
path = /cock/fstore
cmd = "./master -client_config cs.toml -epoch 60
-nclients 1"
```

Mellanox OFED.

```
$ wget latest_ofed_for_the_OS.
$ ./mlnxofedinstall -without-iser-dkms
-without-srp-dkms -without-srptools -force
```

Boost and jemalloc.

```
$ cd path_to_xstore
$ pip3 install -r requirements.txt
$ ./magic.py config -f build-config.toml
$ cmake .
$ cd deps/jemalloc
$ autoconf
$ cd path_to_xstore
$ make boost jemalloc
```

XSTORE.

```
$ make fserver ycsb micro master
```

A.4 Experiment Workflow

Launch XSTORE server.

```
$ ssh server_host
$ ./fserver -db_type ycsb -model_-
config=ycsb-model.toml
```

Launch XSTORE clients.

```
$ ssh client_host
$ ./ycsb -threads 1 -server_host server_host
```

Launch a master to collect results from clients.

```
$ ssh master_host
$ ./master -client_config cs.toml -epoch 60
-nclients 1
```

Automatic experiment workflow. Optionally, readers could use our script (bootstrap.py) to automate the above three steps. It takes a configuration file (e.g., Listing 1) to execute the above three steps required for the experiments. Specifically, the following command should launch the server, the clients, and the master accordingly:

```
$ ./bootstrap.py -f sample.toml
```

Table 4: The evaluating scripts to reproduce the results in §7. Note that the scripts are in the `ae_scripts` folder in our repository.

Figure	Description	Evaluating script
Fig. 10	YCSB A	<code>ycsba.toml</code>
Fig. 11	YCSB B	<code>ycsbb.toml</code>
Fig. 12	YCSB C	<code>ycsbc.toml</code>
	YCSB D	<code>ycsbd.toml</code>
	YCSB E	<code>ycsbe.toml</code>

Fig. 15b,c	Memory footprint	<code>cached_ycsbc.toml</code>

A.5 Evaluation and Expected Result

The experimental results mainly include throughput and median latency. By default, the `master` is responsible for printing the results. It should be noted that it is difficult to compare the performance results across different machines. Therefore, we only show the reported numbers on our testbed as an example here. For instance, to evaluate YCSB C on XSTORE, readers could run the script as follows:

```
$ ./bootstrap.py -f ae_scripts/ycsbc.toml
```

The `master` would print throughput (*thpt*) and median latency (*lat*) per second:

```
...
At epoch 1 thpt: 79.4M/s, ..., lat: 19.5 us
At epoch 2 thpt: 79.3M/s, ..., lat: 19.6 us
At epoch 3 thpt: 79.8M/s, ..., lat: 19.4 us
...
```

A.6 Experiment Customization

Table 4 lists the configuration files used to produce the experimental results in our paper. However, the scripts mainly target our testbed (§7.1). To execute them on other platforms, readers need to make minor changes to the scripts. The README in our repository provides detailed information about how to customize them for the experiments.

A.7 Notes

The source code and scripts for the artifact evaluation are used to reproduce the main results in XSTORE. To use XSTORE in your research, we recommend the `main` branch of our repository (§A.2.1), which would be maintained by members of the Institute of Parallel and Distributed Systems.

A.8 AE Methodology

Submission, reviewing and badging methodology:

Abstract

We design CrossFS, a cross-layered direct-access file system disaggregated across user-level, firmware, and kernel layers for scaling I/O performance and improving concurrency. CrossFS is designed to exploit host- and device-level compute capabilities. For concurrency with or without data sharing across threads and processes, CrossFS introduces a file descriptor-based concurrency control that maps each file descriptor to one hardware-level I/O queue. This design allows CrossFS's firmware component to process disjoint access across file descriptors concurrently. CrossFS delegates concurrency control to powerful host-CPU's, which convert the file descriptor synchronization problem into an I/O queue request ordering problem. To guarantee crash consistency in the cross-layered design, CrossFS exploits byte-addressable nonvolatile memory for I/O queue persistence and designs a lightweight firmware-level journaling mechanism. Finally, CrossFS designs a firmware-level I/O scheduler for efficient dispatch of file descriptor requests. Evaluation of emulated CrossFS on storage-class memory shows up to 4.87x concurrent access gains for benchmarks and 2.32x gains for real-world applications over the state-of-the-art kernel, user-level, and firmware file systems.

1 Introduction

We have finally entered an era where storage access latency is transitioning from milliseconds to microseconds [3, 52, 62, 68]. While modern applications strive to increase I/O parallelism, storage software bottlenecks such as system call overheads, coarse-grained concurrency control, and the inability to exploit hardware-level concurrency continues to impact I/O performance. Several kernel-level, user-level, and firmware-level file systems have been designed to benefit from CPU parallelism [65, 66], direct storage access [22, 31, 40], or computational capability in the storage hardware [33, 56]. However, these approaches are designed in isolation and fail to exploit modern, ultra-fast storage hardware.

Kernel-level file systems (Kernel-FS) satisfy *fundamental file system guarantees* such as integrity, consistency, durability, and security. Despite years of research, Kernel-FS designs continue to suffer from **three main bottlenecks**. First, applications must enter and exit the OS for performing I/O, which could increase latency by 1-4 μ s [31, 68]. Recently found security vulnerabilities have further amplified such costs [25, 39, 47]. Second, even state-of-the-art designs enforce unnecessary serialization (e.g., inode-level read-write lock) when accessing disjoint portions of data in a file leading to high concurrent access overheads [48]. Third, Kernel-FS designs *fail to fully exploit* storage hardware-level capabilities such as compute, thousands of I/O queues, and firmware-level scheduling, ultimately impacting I/O latency, throughput, and concurrency in I/O-intensive applications [5, 8, 9, 45, 69].

As an alternative design point, there is increasing focus towards designing user-level file systems (User-FS) for direct storage access bypassing the OS [17, 22, 31, 40, 52, 65]. However, satisfying the fundamental file system guarantees from untrusted user-level is challenging [33]. While these designs have advanced the state of the art, some designs bypass the OS only for data-plane operations (without data sharing) [17, 31, 52]. In contrast, others provide full direct access by either sidestepping or inheriting coarse-grained and suboptimal concurrency control across threads and processes [22, 40], or even compromise correctness [65]. Importantly, most User-FS designs fail to exploit the hardware capabilities of modern storage.

At the other extreme is the exploration of firmware-level file systems (Firmware-FS) that embed the file system into the device firmware for direct-access [33, 56]. The Firmware-FS acts as a central entity to satisfy fundamental file system properties. Although an important first step towards utilizing storage-level computational capability, current designs miss out on benefiting from host-level multi-core parallelism. Additionally, these designs inherit inode-centric design for request queuing, concurrency control, and scheduling, leading to poor I/O scalability.

In summary, current User-FS, Kernel-FS, and Firmware-FS

designs *lack a synergistic design across the user, the kernel, and the firmware layers*, which is critical for achieving direct storage access and scaling concurrent I/O performance without compromising fundamental file system properties.

Our Approach - Cross-layered File System. To address the aforementioned bottlenecks, we propose **CrossFS**, a cross-layered direct-access file system that provides scalability, high concurrent access throughput, and lower access latency. CrossFS achieves these goals by disaggregating the file system across the user-level, the device firmware, and the OS layer, thereby exploiting the benefits of each layer. The firmware component (FirmFS) is the heart of the file system enabling applications to directly access the storage without compromising fundamental file system properties. The FirmFS taps into storage hardware's I/O queues, computational capability, and I/O scheduling capability for improving I/O performance. The user-level library component (LibFS) provides POSIX compatibility and handles concurrency control and conflict resolution using the host-level CPUs (host-CPU). The OS component sets up the initial interface between LibFS and FirmFS (e.g., I/O queues) and converts software-level access control to hardware security control.

Scalability. File system disaggregation alone is insufficient for achieving I/O scalability, which demands revisiting file system concurrency control, reducing journaling cost, and designing I/O scheduling that matches the concurrency control. We observe that file descriptors (and not inode) are a natural abstraction of access in most concurrent applications, where threads and processes use independent file descriptors to access/update different regions of shared or private files (for example, RocksDB maintains 3.5K open file descriptors). Hence, for I/O scalability, in CrossFS, we introduce file descriptor-based concurrency control, which allows threads or processes to update or access non-conflicting blocks of a file simultaneously.

Concurrency Control via Queue Ordering. In CrossFS, file descriptors are mapped to dedicated hardware I/O queues to exploit storage hardware parallelism and fine-grained concurrency control. All non-conflicting requests (i.e., requests to different blocks) issued using a file descriptor are added to a file descriptor-specific queue. In contrast, conflicting requests are ordered by using a single queue. This provides an opportunity for device-CPU and FirmFS to dispatch requests concurrently with almost zero synchronization between host and device-CPU. For conflict resolution and ordering updates to blocks across file descriptors, CrossFS uses a per-inode interval tree [7], interval tree read-write semaphore (interval tree `rw-lock`), and global timestamps for concurrency control. However, *unlike current file systems that must hold inode-level locks until request completion*, CrossFS only acquires interval tree `rw-lock` for request ordering to FD-queues. In short, CrossFS concurrency design *turns the file synchronization problem into a queue ordering problem*.

CrossFS Challenges. Moving away from an inode-centric to a file descriptor-centric design introduces CrossFS-specific challenges. First, using fewer and wimpier device-CPU for conflict resolution and concurrency control impacts performance. Second, mapping a file descriptor to an I/O queue (a device-accessible DMA memory buffer) increases the number of queues that CrossFS must manage, potentially leading to data loss after a crash. Finally, overburdening device-CPU for serving I/O requests across hundreds of file descriptor queues could impact performance, specifically for blocking I/O operations (e.g., `read`, `fsync`).

Host Delegation. To overcome the challenge of fewer (and wimpier) device-CPU, CrossFS utilizes the cross-layered design and delegates the responsibility of request ordering to host-CPU. The host-CPU orders data updates to files they have access to, whereas FirmFS is ultimately responsible for updating and maintaining metadata integrity, consistency, and security with POSIX-level guarantees.

Crash-Consistency and Scheduler. To handle crash consistency and protect data loss across tens and possibly hundreds of FD-queues, CrossFS uses byte-addressable, persistent NVMs as DMA-able and append-only FD-queues from which FirmFS can directly fetch requests or pool responses. CrossFS also designs low-cost data journaling for crash-consistency of firmware file system state (§4.4). Finally, for efficient scheduling of device-CPU, CrossFS smashes traditional two-level I/O schedulers spread across the host-OS and the firmware into one FirmFS scheduler. CrossFS also equips the scheduler with policies that enhance file descriptor-based concurrency.

Evaluation of our CrossFS prototype implemented as a device-driver and emulated using Intel Optane DC memory [3] shows significant concurrent access performance gains with or without data sharing compared to state-of-the-art Kernel-FS [64, 66], User-FS [31, 40], and Firmware-FS [33] designs. The performance gains stem from reducing system calls, file descriptor-level concurrency, work division across host and device-CPU, low-overhead journaling, and improved firmware-level scheduling. The concurrent access microbenchmarks with data sharing across threads and processes show up to 4.87x gains. The multithreaded Filebench [59] macrobenchmark workloads without data sharing show up to 3.58x throughput gains. Finally, widely used real-world applications such as RocksDB [9] and Redis [8] show up to 2.32x and 2.35x gains, respectively.

2 Background and Related Work

Modern ultra-fast storage devices provide high bandwidth (8-16 GB/s) and two orders of lower access latency (< 20μsec) [15, 67] compared to HDD storage. The performance benefits can be attributed to innovation in faster storage hardware and access interface (e.g., PCIe support), increase in storage-level compute (4-8 CPU, 4-8 GB DRAM,

64K I/O queues) [27], fault protection equipped with capacitors [57, 58], and evolving support for storage programmability. In recent years, file systems have evolved to exploit high-performance modern storage devices. However, for applications to truly benefit from modern storage, file system support for scalable concurrency and efficient data sharing is critical [21, 26, 42]. Next, we discuss kernel, user-level, and firmware-level file system innovations and their implications.

Kernel-level File Systems (Kernel-FS). Several new kernel file systems have been designed to exploit the capabilities of modern storage devices [15, 23, 43, 64, 66]. For example, F2FS exploits multiple queues of an SSD and employs a log-structured design [43]. LightNVM moves the FTL firmware code to the host and customizes request scheduling [15]. File systems such as PMFS [23], DAX [64], and NOVA [66] exploit NVM’s byte-addressability; they support block-based POSIX interface but replace block operations with byte-level loads and stores. To improve concurrent access performance, file systems such as ext4 introduce inode-level read-write semaphores (`rw-lock`) for improving read concurrency when sharing files [24]. Alternatively, user-level storage access frameworks such as SPDK use NVMe-based I/O command queues to provide direct I/O operations. However, these frameworks only support simple block operations as opposed to a POSIX interface [29].

User-level File Systems (User-FS). There is a renewed focus to bypass the OS and directly access storage hardware from a user-level library. However, managing a file system from an untrusted library introduces a myriad of challenges, which include atomicity, crash consistency, and security challenges [40, 52, 60]. Some prior designs bypass the OS for data plane operations but enter the OS for control plane operations [31, 52, 60]. In contrast, approaches such as Strata [40] and ZoFS [22] provide direct access for control and data plane operations by managing data and metadata in a user-level library. For example, Strata [40] buffers data and metadata updates to a per-process, append-only log, which is periodically committed to a shared area using a trusted file system server. More recently, ZoFS, designed for persistent memory technologies, uses virtual memory protection to secure access to a user-level buffer holding data and metadata updates. Unfortunately, all these approaches require high-overhead concurrency control and use coarse-grained locks that do not scale [31]. For example, in Strata, a process must acquire an inode lease from the trusted file system server before accessing a file [40, 60].

Firmware File Systems (Firmware-FS). After two decades of seminal work on programmable storage [17, 33, 54, 56], prior research takes a radical approach of offloading either the entire file system [33] or a part of it [17, 54] into the device firmware. The firmware approach allows applications to bypass the OS for both control and data plane operations. Firmware-FS acts as a central entity to coordinate updates to

ext4-DAX	Strata	DevFS	CrossFS
21.38%	26.57%	27.06%	9.99%

Table 1: Time spent on inode-level lock.

file system metadata and data without compromising crash-consistency by using the device-CPU and the device-RAM for per-inode I/O queues. For security and permission checks, systems such as DevFS [33] rely on the host OS to update a device-level credential table with process permissions. For crash consistency, the power-loss capacitors could be used to flush in-transit updates after a system failure. Insider [56] explores the use of FPGAs for file system design, whereas other efforts have focused on using FPGAs [70] to accelerate key-value stores. Unfortunately, both DevFS and Insider handle concurrency using inode-level locks, limiting file system concurrency and scalability.

File System Scalability. Several kernel-level file system scalability designs have been explored in the past. SpanFS [32] shares files and directories across cores at a coarse granularity, requiring developers to distribute I/O. ScaleFS [13] decouples the in-memory file system from the on-disk file system and uses per-core operation logs to achieve high concurrency. FLEX [65] moves file operations to a user-level library and modifies the Linux VFS layer. Fine-grained locking mechanisms such as CST-semaphore [36] and range lock [42] are applied to current kernel-level file systems to improve concurrency. However, all the above approaches either lack direct access or require inode-level locks and fail to utilize host and device-level compute capabilities.

3 Motivation

Unfortunately, state-of-the-art Kernel-FS [64, 66], User-FS [31, 40], and Firmware-FS [33] designs suffer from three prominent limitations. First, they lack a synergistic design that could benefit from the combined use of host and device resources, such as host and device-level CPUs, and thousands of hardware I/O queues. Second, the use of an inode-centric design limits concurrent access scalability. Third, for file sharing across processes, applications must trap into an OS for control or data plane or both [60].

To briefly illustrate the poor concurrent access scalability in state-of-the-art file system designs, we conduct an experiment where readers and writers perform random-but-disjoint block accesses on a 12GB file. For our analysis, we compare User-FS Strata [40], Kernel-FS Linux ext4-DAX [64], Firmware-FS DevFS [33], and the proposed CrossFS. Figure 1a shows the aggregate write throughput when multiple writers concurrently update a shared file. The x-axis varies the writer thread count. In Figure 1b, we restrict the number of writers to 4 and increase readers in the x-axis.

Concurrent Write Performance: As shown in Figure 1a, when sharing files across concurrent writers, the throughput substantially reduces for all approaches except CrossFS. ext4-

Figure 1: Concurrent Write and Read Throughput. (a) shows the aggregated write throughput when concurrent writers update disjoint random blocks of a 12GB file; (b) shows aggregated read throughput when there are 4-concurrent writers.

DAX and NOVA use inode-level `rw-lock`, which prevents writers from updating disjoint blocks of a file. Strata does not scale beyond four threads because it uses an inode-level mutex. Additionally, Strata uses a private NVM log to buffer data and metadata (inode) updates, and the log fills up frequently, consequently stalling write operations.

Sharing across Reader and Writer Threads: Figure 1b and Table 1 show the aggregated read throughput and the execution time spent on an inode-level `rw-lock`. The read performance does not scale (in the presence of writers) even when accessing disjoint blocks, mainly due to the inode-level `rw-lock`. For Strata, by the time readers acquire a mutex for the private log, the log contents could be flushed, forcing readers to access data using Kernel-FS. We see similar performance bottlenecks when using concurrent processes instead of threads for ext4-DAX and NOVA due to their inode-centric concurrency control. For Strata, the performance degrades further; the reader processes starve until writers flush their private log to the shared area. These issues highlight the complexities of scaling concurrent access performance in Kernel-FS and User-FS designs. The observations hold for other user-level file systems such as ZoFS [22]. Finally, as shown in Figure 1a and Figure 1b, CrossFS outperforms other file systems with its fine-grained file descriptor-based concurrency. We will next discuss the design details of CrossFS.

4 Design of CrossFS

CrossFS is a cross-layered design that disaggregates the file system to exploit the capabilities of userspace, firmware, and OS layers. CrossFS also achieves high end-to-end concurrency in the user-level library, I/O request queues, and firmware-level file system, with or without file sharing across threads and processes. Finally, CrossFS reduces system call cost, provides lightweight crash consistency, and efficient device-CPU scheduling. We observe that applications that perform conflicting updates to the same blocks of files, automatically resort to protecting file descriptors with application-level locking [2, 5, 9]. Hence, for concurrency and file sharing, CrossFS uses file descriptors as a fundamental unit of synchronization, enabling threads and processes with separate file descriptors to update disjoint blocks of files concur-

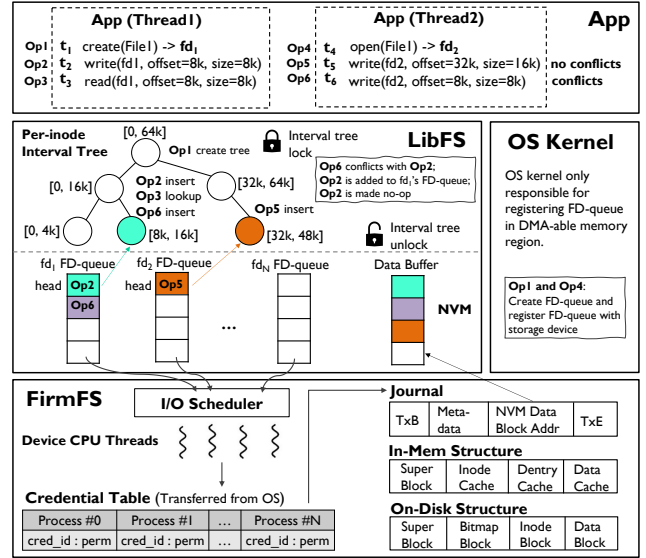

Figure 2: CrossFS Design Overview. The host-level LibFS converts POSIX I/O calls into FirmFS commands, manages FD-queues, and interval tree for checking block conflicts and ordering requests in FD-queues. FirmFS implements the file system, journaling, and scheduler and concurrently processes requests across FD-queues. The OS component is responsible for the FD-queue setup and updates the device credential table with host-level permission information. We show a running example of two instances sharing a file; Op1 to 6 show request execution with global timestamps t_1 to t_6 . Op6 conflicts with Op2, so Op6 is added to the same FD-queue as Op2 using an interval tree.

rently. CrossFS assigns each file descriptor a dedicated I/O queue (**FD-queue**) and adds non-conflicting (disjoint) block requests across descriptors to their independent FD-queue, whereas serializing conflicting block updates or access to a single FD-queue. Consequently, CrossFS converts the file synchronization problem to an I/O request ordering problem, enabling device-CPU to dispatch requests across FD-queues concurrently. We outline the design principles and then follow it up by describing the details of file descriptor-based concurrency mechanism, crash consistency support, I/O scheduling, and security.

4.1 CrossFS Design Principles

CrossFS adapts the following key design principles:

Principle 1: For achieving high performant direct-I/O, disaggregate file system across user-level, firmware, and OS layers to exploit host and device-level computing capabilities.

Principle 2: For fine-grained concurrency, align each file descriptor to an independent hardware I/O queue (FD-queue), and design concurrency control focused around the file descriptor abstraction.

Principle 3: To efficiently use device-CPU, merge software and hardware I/O schedulers into a single firmware scheduler, and design scheduling policies to benefit from the file-descriptor design.

Principle 4: For crash consistency in a cross-layered design,

protect the in-transit user data and the file system state by leveraging persistence provided by byte-addressable NVMe.

4.2 CrossFS Layers

CrossFS enables unmodified POSIX-compatible applications to benefit from direct storage access. As shown in Figure 2, CrossFS comprises of a user-level library (LibFS), a firmware file system component (FirmFS), and an OS component.

User-space Library Component (LibFS). Applications are linked to LibFS, which intercepts POSIX I/O calls and converts them to FirmFS I/O commands. As shown in Figure 2, when opening a file, LibFS creates an FD-queue by requesting the OS to allocate a DMA’able memory region on NVMe and registering the region with FirmFS. Each I/O request is added to a file descriptor-specific FD-queue when there are no block-level conflicts. In the presence of block conflicts, the conflicting requests are serialized to the same FD-queue. To identify block conflicts, in CrossFS, we use a per-inode interval tree with range-based locking. The conflict resolution using the interval tree is delegated to the host-CPU when sharing data across multiple threads, and for inter-process file sharing, interval tree updates are offloaded to FirmFS (and the device-CPU).

Firmware File System Component (FirmFS). FirmFS is responsible for fetching and processing I/O requests from FD-queues. Internally, FirmFS’s design is similar to a traditional file system with in-memory and on-disk metadata structures, including a superblock, bitmap blocks, and inode and data blocks. FirmFS also supports data and metadata journaling using a dedicated journal space on the device, as shown in Figure 2. FirmFS fetches I/O requests from FD-queues and updates in-memory metadata structures (stored in the device-level RAM). For crash-consistency, FirmFS journals the updates to the storage and then checkpoints them (§4.4). The mounting process for FirmFS is similar to a traditional file system: finding the superblock, followed by the root directory. To schedule requests from FD-queues, FirmFS also implements a scheduler (§4.5). Finally, FirmFS implements a simple slab allocator for managing device memory.

OS Component. The OS component is mainly used for setting up FD-queues by allocating DMA’able memory regions, mounting of CrossFS, and garbage collecting resources. The OS component also converts process-level access controls to device-level credentials for I/O permission checks without requiring applications to trap into the OS (§4.6).

4.3 Scaling Concurrent Access

We next discuss CrossFS’s file descriptor-based concurrency design that scales without compromising correctness and sharply contrasts with prior inode-centric designs.

4.3.1 Per-File Descriptor I/O Queues

Modern NVMe devices support up to 64K I/O queues, which can be used by applications to parallelize I/O requests. To exploit this hardware-level I/O parallelism feature, CrossFS aligns each file descriptor with a dedicated I/O queue (with a configurable limit on the maximum FD-queues per inode). As shown in Figure 2, during file open (*Op1*), LibFS creates an FD-queue (I/O request + data buffer) by issuing an IOCTL call to the OS component, which reserves memory for an FD-queue, and registers the FD-queue’s address with FirmFS. For handling uncommon scenarios where the number of open file descriptors could exceed the available I/O queues (e.g., 64K I/O queues in NVMe), supporting FD-queue reuse and multiplexing could be useful. For reuse, CrossFS must service pending requests in an FD-queue, and clear its data buffers. For multiplexing, CrossFS must implement a fair queue sharing policy. While CrossFS currently supports queue reuse after a file descriptor is closed, our future work will address the support for FD-queue multiplexing.

4.3.2 Concurrency Constraints

CrossFS provides correctness and consistency guarantees of a traditional kernel-level file system (e.g., ext4). We first define the constraints that arise as a part of CrossFS’s file-descriptor design, and then describe how CrossFS satisfies these constraints.

- Constraint 1: Read requests (commands) entering a device at timestamp T must fetch the most recent version of data blocks, which are either buffered in FD-queues or stored in the storage. The *timestamp* refers to a globally incrementing atomic counter added to an I/O command in the FD-queues.
- Constraint 2: For concurrent writes to conflicting (same) blocks across file descriptors, the most recent write at T_j can overwrite a preceding write at T_i where $i < j$.

4.3.3 Delegating Concurrency Control to Host-CPU

Handling conflict resolution across several threads that concurrently update a shared file could be compute-heavy. As a consequence, using fewer (or wimpier) device-CPU could pose a scalability challenge. Hence, in CrossFS, for data sharing across multiple threads (a common scenario in most applications), we exploit our cross-layered design and delegate concurrency control to host-CPU without impacting file system correctness. In the case of data sharing across processes, for simplicity and security, we offload concurrency control to FirmFS (discussed in §4.6). We first discuss the data structure support and then discuss CrossFS support for concurrent reader and writer threads with host-delegated concurrency control.

Request Timestamp. Before adding a request to an FD-queue, LibFS tags each I/O request with a globally incrementing hardware TSC-based timestamp. The timestamp is used to resolve ordering conflicts across writers and fetch the

most recent data for readers. The use of TSC-based timestamp for synchronization has been widely studied by prior research [35, 38, 46, 55].

Per-Inode Interval Tree. To resolve conflicts across concurrent writers and readers, we use a per-inode interval tree. An interval tree is an augmented red-black tree, indexed by interval ranges (low, high) and allows quick lookup for any overlapping or exact matching block range [7, 28].

In CrossFS, an inode-level interval tree is used for conflict resolution, i.e., to identify pending I/O requests in FD-queues that conflict with a newly issued I/O request. The OS allocates the interval tree in a DMA'able region during file creation and returns interval tree's address to LibFS. For each update request, LibFS adds a new interval tree node indexed by the request's block range. The nodes store a timestamp and a pointer to the newly added I/O request in the FD-queue. The interval tree's timestamp (TSC) is checked for following cases: (1) for writes to identify conflicting updates to block(s) across different FD-queues; (2) for reads to fetch the latest uncommitted (in-transit) updates from an FD-queue; and (3) for file commits (`fsync`). The interval tree items are deleted after FD-queue entries are committed to the storage blocks (discussed in 4.3.6).

Threads that share a file also share inode-level interval tree. For files shared within a process, interval tree is updated and accessed just by LibFS. The updates to interval tree are protected using a read-write lock (`rw-lock`), held only at the time request insertion to FD-queue.

4.3.4 Supporting Concurrent Readers and a Writer

CrossFS converts a file synchronization problem to a queue ordering problem. Hence, the first step towards concurrent write and read support for a file is to identify a file descriptor queue to which a request must be added. To allow concurrent readers and one writer to share a file, requests are ordered using a global timestamp.

For each write request, LibFS acquires an inode's interval tree `rw-lock` and atomically checks the interval tree for conflicts. A conflict exists if there are unprocessed prior FD-queue write requests that update the same block(s). After detecting a conflict, LibFS adds a global timestamp to the write request and orders it in the same FD-queue of the prior request. LibFS also updates the interval tree's node to point to the current request and releases the interval tree's `rw-lock`. For example, in Figure 2, for *Op6*, Thread 2's write to offset 8k conflicts with Thread 1's *Op2* buffered in *fd1*'s queue with an earlier timestamp. Hence, Thread 2's request is added to *fd1*'s FD-queue for ordering the updates.

Note that, while prior systems acquire the inode `rw-lock` until request completion, *CrossFS acquires inode-level interval tree `rw-lock` only until a request is ordered to the FD-queue*. This substantially reduces the time to acquire interval tree `rw-lock` compared to prior inode-centric designs (see §6). To reduce the latency when reading block(s) from a

file, LibFS uses the interval tree to identify conflicting writes to the same block(s) buffered in the FD-queue. If a conflict exists, LibFS (i.e., the host-CPU) returns the requested blocks from FD-queue, thereby reducing FirmFS work. For example, as shown in Figure 2, for *Thread 1*'s *Op3*, LibFS checks the file descriptors *fd1*'s FD-queue for a preceding write to the same block and returns the read from the FD-queue. Read operations also acquire interval tree `rw-lock` before lookup, and do not race with an on-going write or a FD-queue cleanup (which also acquires interval tree `rw-lock`).

4.3.5 Supporting Concurrent Writers

CrossFS supports concurrent writers to share files without enforcing synchronization between host and device-CPU's.

Non-conflicting Concurrent Writes. When concurrent writers share a file, non-conflicting (disjoint) writes to blocks across file descriptors are added to their respective FD-queues, tagged with a global timestamp, and added to an interval tree node for the corresponding block range. In Figure 2, non-conflicting *Op2* in *fd1* and *Op5* in *fd2* are added to separate FD-queues and can be concurrently processed by FirmFS.

Conflicting Concurrent Writes. The number of conflicting blocks across concurrent writers could vary.

(1) *Single-block conflict.* A single-block conflict refers to a condition where a conflict occurs for one block. When a current writer updates one block (say block k) at a timestamp (say j), the write request ($W_j B_k$) is atomically checked against the interval tree for preceding non-committed writes. If an earlier write (say $W_i B_k$, where $i < j$) exists, CrossFS adds the request ($W_j B_k$) to the queue, marks the earlier request ($W_i B_k$) as a *no-op*, and updates the interval tree to point to the new request ($W_j B_k$), thereby avoiding an extra write operation. For example, in Figure 2, the later request *Op6* is added to the FD-queue of *Op2*, and *Op2* is made a *no-op*.

(2) *Multi-block Write conflict.* CrossFS must handle multi-block conflicts for correctness, although uncommon in real-world applications. First, when a writer's request to update one block ($W_{i+1} B_k$) conflicts with an earlier write that updates multiple blocks (say $W_i B_k B_{k+1} B_{k+2}$), the prior request cannot be made a *no-op*. Hence, LibFS adds the new request ($W_{i+1} B_k$) to the same FD-queue of the prior request ($W_i B_k B_{k+1} B_{k+2}$) and inserts a child node (sub-tree) to the interval tree (B_k, B_{k+2} range) with a pointer to the newly added FD-queue request. This technique is used even for a multi-block request that conflicts with a prior single or multi-block request or when conflicting small writes update different ranges in the single block. Although this approach would incur multiple writes for some blocks, it simplifies handling multi-block conflicts that are uncommon. For rare cases, where multiple blocks of the new request ($W_i B_k B_{k+1} B_{k+2}$) conflicts with blocks across multiple FD-queues (say $W_j B_k$ and $W_n B_{k+2}$ with j and n in different queues), we treat these as an inode-level barrier operation, which we discuss next.

(3) *Multi-block Concurrent Reads.* Concurrent readers always fetch the most recent blocks for each update using the interval tree. For blocks with partial updates across requests, LibFS patches these blocks by walking through the sub-tree of an interval tree range.

Support for File Appends. Several classes of applications (e.g., RocksDB [9] evaluated in this paper) extensively use file appends for logging. In CrossFS, file appends are atomic operation. To process appends, FirmFS uses an atomic transaction to allocate data blocks and update metadata blocks (i.e., inode). We use and extend atomic transaction support for `O_APPEND` from the prior NVM-based file system [23].

4.3.6 File Commit (`fsync`) as a Barrier

File commit (`fsync`) operations in POSIX guarantee that a successful commit operation to a file descriptor commits all updates to a file preceding the `fsync` across all file descriptors. However, in CrossFS, requests across file descriptors are added to their own FD-queue and processed in parallel by FirmFS, which could break POSIX's `fsync` guarantee. Consider a scenario where a `fsync` request added to an empty FD-queue getting dispatched before earlier pending writes in other FD-queues. To avoid these issues, CrossFS treats file commit requests as a special **barrier** operation. The `fsync` request is tagged as a barrier operation and atomically added to *all FD-queues of an inode* by acquiring an interval tree `rw-lock`. The non-conflicting requests in FD-queues are concurrently dispatched by multiple device-CPU's to reduce the cost of a barrier. We study the performance impact of `fsync` operations in §6.

4.3.7 Metadata-heavy Operations

CrossFS handles metadata-heavy operations with a file descriptor (e.g., `close`, `unlink`, file rename) and without a file descriptor (e.g., `mkdir`, directory rename) differently. We next discuss the details.

Metadata Operations with a File Descriptor. Metadata-heavy operations include inode-level changes, so adding these requests to multiple FD-queues and concurrently processing them could impact correctness. Additionally, concurrent processing is prone to crash consistency bugs [18, 31, 53]. To avoid such issues, CrossFS maintains a LibFS-level pathname resolution cache (with files that were opened by LibFS). The cache maintains a mapping between file names and the list of open file descriptors and FD-queue addresses. CrossFS treats these metadata-heavy operations as barrier operations and adds them to all FD-queues of an inode after acquiring an interval tree `rw-lock`. The requests in FD-queues preceding the barrier are processed first, followed by atomically processing a metadata request in one queue and removing others.

Metadata Operations without a File Descriptor. For metadata operations without a file descriptor (e.g., `mkdir`), CrossFS uses a global queue. Requests in the global queue are processed in parallel with FD-queue requests (barring

some operations). Similar to kernel file systems, FirmFS concurrently processes non-dependent requests fetched from the global queue without compromising ordering. However, for complex operations such as a directory rename prone to atomicity and crash consistency bugs, CrossFS uses a system-wide ordering as used in traditional file systems [48]. Our current approach is to add a barrier request across all open FD-queues in the system. However, this could incur high latency when there are hundreds of FD-queues. Thus, we only add the rename request to the global queue and maintain a list of global barrier timestamps (`barrier_TSC`). Before dispatching a request, a device-CPU checks if request's `TSC < barrier_TSC`; otherwise, delays processing the request until all prior requests before the barrier are processed and committed. CrossFS is currently designed to scale data plane operations and our future work will explore techniques to parallelize non-dependent metadata-heavy operations.

4.3.8 Block Cache and Memory-map Support.

For in-memory caching, CrossFS uses FD-queue buffers (in NVM) as data cache for accessing recent blocks but does not yet implement a shared main memory (DRAM) cache. We evaluate the benefits of using FD-queue as data buffer in §6. Implementing a shared page cache could be beneficial for slow storage devices [23, 37]. Similarly, our future work will focus on providing memory-map (`mmap`) support in CrossFS.

4.4 Cross-Layered Crash Consistency

A cross-layered file system requires a synergistic lightweight crash consistency support at the host (LibFS) and the device (FirmFS) layers. We describe the details next.

FD-queue Crash Consistency. The FD-queues buffer I/O requests and data. For I/O-intensive applications with tens of open file descriptors, providing persistence and crash consistency for LibFS-managed FD-queues could be important. Therefore, CrossFS utilizes system-level hardware capability and uses byte-addressable persistent memory (Intel Optane DC Persistent Memory [3]) for storing FD-queues. The FD-queues are allocated in NVM as a DMA'able memory. LibFS adds requests to persistent FD-queues using a well-known append-only logging protocol for the crash consistency [55, 61], and to prevent data loss from volatile processor caches, issues persistent writes using CLWB and memory fence. A commit flag is set after a request is added to the FD-queue. After a failure, during recovery, requests with an unset commit flag are discarded. Note that the interval tree is stored in the host or device RAM and is rebuilt using the FD-queues after a crash. In the absence of NVM, CrossFS uses DRAM for FD-queues, providing the guarantees of traditional kernel file systems that can lose uncommitted writes.

Low-overhead FirmFS Crash Consistency. The FirmFS, which is the heart of the CrossFS design, provides crash consistency for the file system data and metadata state in the device memory. FirmFS implements journaling using a

REDO journal maintained as a circular log buffer to hold data and metadata log entries [23, 31]. When FirmFS dispatches an update request, FirmFS initiates a new transaction, appends both data and metadata (e.g., inode) entries to the log buffer, and commits the transaction. However, data journaling is expensive; hence most prior NVM file systems only enable metadata journaling [18, 23, 31]. In contrast, CrossFS provides lightweight journaling by exploiting the persistent FD-queues. Intuitively, because the I/O requests and data are buffered in persistent FD-queues, the FirmFS journal can avoid appending data to the journal and provide a reference to the FD-queue buffer. Therefore, CrossFS dedicates a physical region in NVM for storing all FD-queues and buffers using our in-house persistent memory allocator. LibFS, when adding requests (e.g., read or write) to a persistent FD-queue, tags the request with the virtual address and the relative offset from the mapped FD-queue NVM buffer. FirmFS uses the offset to find the NVM physical address and stores it alongside the journal metadata. For recovery, the physical address can be used to recover the data. Consequently, CrossFS reaps the benefits of *data+metadata* journaling at the cost of metadata-only journaling. The journal entries are checkpointed when the journal is full or after a two-second (configurable) interval similar to prior file systems [23]. After a crash, during recovery, the FirmFS metadata journal is first recovered, followed by the data in the NVM FD-queues.

4.5 Multi-Queue File-Descriptor Scheduler

In traditional systems, applications are supported by an I/O scheduler in the OS and the storage firmware. In CrossFS, applications bypass the OS and lack the OS-level I/O scheduler support. As a consequence, when the number of FD-queues increase, non-blocking operations (e.g., `write`) could bottleneck blocking operations (e.g., `read`, `fsync`), further exacerbated by the limited device-CPU count. To address these challenges, CrossFS exploits its cross-layered design and merges two-level I/O schedulers into a single multi-queue firmware-level scheduler (FD-queue-scheduler). The FD-queue-scheduler’s design is inspired by the state-of-the-art Linux *blk-queue* scheduler that separates software and hardware queues [14]. However, unlike the *blk-queue* scheduler, the FD-queue-scheduler (and FirmFS in general) is agnostic of process and thread abstractions in the host. Therefore, FD-queue-scheduler uses FD-queues as a basic scheduling entity and builds scheduling policies that decide how to map device-CPU to serve requests from FD-queues.

4.5.1 Scheduling Policies.

The FD-queue-scheduler currently supports a simple round-robin policy and an urgency-aware scheduling policy.

Round-robin Scheduling. The round-robin scheduling aims to provide fairness. We maintain a global list of FD-queues, and the device-CPU iterates through the global list to pick a queue currently not being serviced and schedule an

I/O request from the FD-queue’s head. To reduce scheduling unfairness towards files with higher FD-queue count, the round-robin scheduler performs two-level scheduling: first to pick an unserviced inode, and then across the FD-queues of the inode.

Urgency-aware Scheduling. While the round-robin scheduler increases fairness, it cannot differentiate non-blocking (e.g., POSIX `write`, `pwrite` return before persisting to disk) and latency-sensitive blocking (e.g., `read`, `fsync`) I/O operations. In particular, non-blocking operations such as `write` incur additional block writes to update metadata and data journals in contrast to read operations. Hence, in FirmFS, we implement an *urgency-aware* scheduling policy that prioritizes blocking operations without starving non-blocking operations. The device-CPU when iterating the FD-queue list, pick and schedule blocking requests at the head. Optionally, LibFS could also tag requests as blocking and non-blocking. To avoid starving non-blocking operations, non-blocking I/O requests from FD-queues that are either full or delayed beyond a threshold (100 μ sec by default, but configurable) are dispatched. Our evaluation in §6 shows that urgency-aware policy improves performance for read-heavy workloads without significantly impacting write performance.

4.6 Security and Permission Checking

CrossFS matches the security guarantees provided by traditional and state-of-the-art user-level file systems [31, 40] by satisfying the following three properties. First, in CrossFS, the filesystem’s metadata is always updated by the trusted FirmFS. Second, data corruptions are restricted to files for which threads and processes have write permission. Third, for files shared across processes, CrossFS allows only legal writers to update a file’s data or the user-level interval tree.

File System Permissions. CrossFS aims to perform file permission checks without trapping into the OS for data plane operations. For permission management, CrossFS relies on trusted OS and FirmFS. The FirmFS maintains a credential table that maps a unique process ID to its credentials. During the initialization of per-process LibFS, the OS generates a random (128-bit) unique ID [1, 6] for each process and updates the firmware credential table with the unique ID and the process credentials [4] and returns the unique ID to LibFS. FirmFS also maintains a FD-queue to per-process unique ID mapping internally. When LibFS adds a request to its private FD-queue, it also adds the request’s unique ID. Before processing a request, FirmFS checks if a request’s unique ID matches FD-queue’s unique ID (stored internally in FirmFS), and if they match, the I/O request’s permission (e.g., write access) is checked using the credentials in the firmware table. Any mismatch between an I/O request and FD-queue IDs are identified and not processed by FirmFS. As a consequence, accidental (unintended) writes to FD-queue could be identified by FirmFS. Further, a malicious process that succeeds in forging another process’s unique ID cannot use the ID in its

own FD-queue.

FD-queue Protection. First, FD-queues are privately mapped to a process address space and cannot be updated by other processes. Second, an untrusted LibFS with access permission to a file could reorder or corrupt FD-queue requests, but cannot compromise metadata. Finally, a malicious reader could add a file update request to FD-queue, but would not be processed by FirmFS.

Interval Tree. To reduce work at the device-CPU, CrossFS uses LibFS (and host-CPU) to manage inode-level interval tree and concurrency control. Because the interval tree is shared across writers and readers, an issue arises where a reader process (with read-only permission to a file) could accidentally or maliciously corrupt updates in the interval tree by legal writers (e.g., inserting a `truncate("file", 0)`).

To overcome such security complications, for simplicity, CrossFS provides two modes of interval tree updates: (a) FirmFS mode, and (b) LibFS delegation mode. In the FirmFS mode (enabled by default), the host-CPU add I/O requests to FD-queues, but FirmFS and device-CPU are responsible for updating the per-inode interval tree and managing concurrency control. This mode is specifically useful for cases where files are shared across multiple processes. As a consequence, file updates (e.g., `truncate("file", 0)`) by a malicious process with read-only access would be invalidated by the trusted FirmFS. This approach marginally impacts performance without compromising direct-I/O. In contrast, the LibFS delegation mode (an optional mode, which can be enabled when mounting CrossFS) allows the use of host-CPU for interval tree updates but does not allow inter-process file sharing. We observe that most I/O-intensive applications (including RocksDB analyzed in the paper) without file sharing could benefit from using host-CPU. We evaluate the trade-offs of both designs in §6.

Security Limitations. We discuss security limitations common to most User-FS designs [22, 33], and CrossFS.

Shared Data Structure Corruption. Sharing data and data-structures using untrusted user-level library makes CrossFS and other user-level file systems vulnerable to malicious/buggy updates or even DoS attacks. For example, in CrossFS, a user-level thread could corrupt the inode interval tree, impacting data correctness. Prior byte-addressable NVM designs such as ZoFS use hardware support such as Intel MPK ([22, 50]) to isolate memory regions across the file system library and application threads. Unfortunately, the isolation only protects against accidental corruption but not malicious MPK use [19].

Denial of Service (DoS) Attacks. CrossFS and most user-level designs do not handle DoS attacks, where a malicious LibFS could lock all intervals in the interval tree, perform many small updates to blocks, or force long interval tree merges for reads to those ranges. Recent studies have shown that lock-based attacks are possible for kernel file systems

too [51]. One approach in CrossFS could be to use OS-level monitors to revoke threads that hold interval tree locks beyond a threshold (e.g., Linux hard/soft-lockup detector). However, a more thorough analysis is required, which will be the focus of our future work.

5 Implementation

Due to the lack of programmable storage hardware, we implement and emulate CrossFS as a device driver. CrossFS is implemented in about 13K lines of code spread across LibFS (2K LOC), FirmFS with scheduler and journaling (9K LOC), and the OS (300 LOC) components. For storage, we use Intel Optane DC Persistent Memory attached to the memory bus. To emulate device-CPU, we use dedicated CPU cores, but also consider related hardware metrics such as device-level CPU speed, PCIe latency, and storage bandwidth (see §6). For direct-I/O, unlike prior systems that use high-overhead IOCTLs [33], the persistent FD-queues are mapped as shared memory between LibFS and the driver's address space.

LibFS. In addition to the details discussed in §4, LibFS uses a shim library to intercept POSIX operations and convert them to FirmFS compliant commands. We extend the NVMe command format that supports simple block (read and write) operations to support file system operations (e.g., open, read, write). The I/O commands are allocated using NVM, and LibFS issues the commands and sets a doorbell flag for FirmFS to begin processing. FirmFS processes a command and sets an acknowledgment bit to indicate request completion. Finally, for each file descriptor, LibFS maintains a user-level file pointer structure with a reference to the corresponding FD-queue, the file name, the interval tree, and information such as file descriptor offset. For persisting FD-queues, as described in §4.4, data updates are appended to NVM log buffers and persisted using CLWB and memory fence instructions.

FirmFS. The device-CPU are emulated using dedicated (kernel) threads pinned to specific CPUs, whereas FirmFS block management (superblock, bitmaps, inodes, and data block management) and journaling structures implemented by extending PMFS [23] ported to Linux 4.8.2 kernel. FirmFS extends PMFS's inode and dentry with a simplified dentry structure and dentry cache for path resolution. In our file descriptor-based design, path resolution involves mapping a path to an inode containing a list of all FD-queues. For FirmFS data + metadata journaling, we use REDO logs and substitute actual data with the physical address of data in NVM FD-queues.

OS Component. We primarily extend the OS for FD-queue setup and credential management. For FD-queue setup, we implement an IOCTL in the OS to allocate contiguous DMA-able memory pages using NVM memory, mapping them to process and FirmFS device driver address spaces. The OS

component also cleans up FD-queues after a file is closed. Next, for credential management, we modify Linux process creation mechanism in the OS to generate a per-process unique ID. The OS also updates the firmware-level credential table with this information.

6 Evaluation

We compare CrossFS with state-of-the-art User-FS, Kernel-FS, and Firmware-FS using microbenchmarks, macrobenchmarks, and real-world applications to answer the following questions.

- How effective is CrossFS in exploiting the cross-layered design and file descriptor-based concurrency?
- How effective is CrossFS's FD-queue scheduler?
- What is the impact of host configuration such as FD-queue depth and device configurations such as storage bandwidth, device-CPU frequency, and PCIe latency?
- Can CrossFS's cross-layered design scale for metadata-intensive workloads with no data sharing across threads?
- Does CrossFS benefit real-world applications?

6.1 Experimental Setup

We use a dual-socket, 64-core, 2.7GHz Intel(R) Xeon(R) Gold platform with 32GB memory and a 512GB SSD. For storage and FD-queues, we use a 512GB (4x128GB) Optane DC persistent memory with 8GB/sec read and 3.8GB/sec read-write bandwidth [30]. To emulate the proposed cross-layered file system, we reserve and use 2GB of DRAM for maintaining FirmFS in-memory state.

Besides, to study the implications of CrossFS for different storage bandwidths, PCIe latency, and device-CPU speeds, we use a CloudLab-based Intel(R) Xeon(R) CPU E5-2660 server that allows memory bandwidth throttling. We reserve 80GB memory mounted in a NUMA node for an emulated NVDIMM and vary bandwidth between 500MB/s to 10GB/s. To emulate PCIe latency, we add a 900ns software delay [49] between the time a request is added to the host's FD-queue and the time a request is marked ready for FirmFS processing. To emulate and vary device-CPU speeds, we apply dynamic voltage frequency scaling (DVFS). We enable persistence of NVM-based FD-queues and our proposed FirmFS data + metadata journaling that uses REDO logging.

For analysis, we compare CrossFS against state-of-the-art file systems in three different categories: User-FS Strata [40] and SplitFS [31], Kernel-FS ext4-DAX [64] and NOVA (a log structure NVM file system [66]), and finally, Firmware-FS DevFS [33]. To understand the benefits of avoiding system calls, for CrossFS, we compare an IOCTL-mode implementation with kernel traps but without VFS cost (CrossFS-ioctl) and a direct-mode without both kernel traps and VFS cost (CrossFS-direct).

6.2 Microbenchmarks

We first evaluate CrossFS using two microbenchmarks and then provide an in-depth analysis of how the host-side and the device-side configurations affect CrossFS performance.

6.2.1 Concurrency Analysis

In Figure 3a and Figure 3b, we vary the number of concurrent readers in the x-axis setting the concurrent writer count to four threads. For this multithreaded micro-benchmark, we use LibFS-level interval tree updates. We compare CrossFS-ioctl and CrossFS-direct against ext4-DAX, NOVA, DevFS, SplitFS, and Strata, all using Intel Optane DC persistent memory for storage.

ext4-DAX. First, ext4-DAX, a Kernel-FS, suffers from high system call and VFS cost, and locking overheads [31,63]. The inode `rw-lock` (read-write semaphore) contention between writers and readers increases with higher thread count. For the four concurrent reader-writer configuration, the time spent on locks is around 21.38%. Consequently, reader and writer throughputs are significantly impacted (see Figure 3b).

NOVA. Second, NOVA, also a Kernel-FS, exploits per-CPU file system data structures and log-structured design to improve aggregated write throughput compared to ext4-DAX. However, the use of inode-level `rw-lock` and system call costs impact write and read scalability.

DevFS. DevFS, a Firmware-FS, provides direct-access and avoids system calls, but uses per-inode I/O queues and inode-level `rw-lock`. Further, DevFS uses two levels of inode synchronization: first, when adding requests to an inode's I/O queue; second, when dispatching requests from the I/O queue for Firmware-FS processing. Consequently, the throughput does not scale with increasing thread count.

SplitFS. SplitFS, a User-FS, maps staging files to a process address space and converts data plane operations like `read()`, `write()` in the user-level library to memory loads and stores. Therefore, SplitFS avoids kernel traps for data plane operation (although metadata is updated in the kernel). As a result, SplitFS shows higher read and write throughputs over ext4-DAX, NOVA, and DevFS. However, for concurrent readers and writers, SplitFS gains are limited by inode-level locks.

Strata. Strata's low throughput is because of the following reasons: first, Strata uses an inode-level `mutex`; second, Strata uses a per-process private log (4GB by default as used in [40]). When using concurrent writers, the private log frequently fills up, *starving* readers to wait until the logs are digested to a shared area. The starvation amplifies for concurrent reader processes that cannot access private writer logs and must wait for the logs to be digested to a shared area.

CrossFS. In contrast, the proposed CrossFS-ioctl and CrossFS-direct's cross-layered designs with file descriptor concurrency allow concurrent read and write across FD-queues. Even though fewer than 1% of reads are fetched

Figure 3: Microbenchmark. Throughput of concurrent readers and 4 writers sharing a 12GB file. For CrossFS and DevFS, 4 device-CPU are used. CrossFS-iocctl uses IOCTL commands bypassing VFS but with OS traps, whereas CrossFS-direct avoids OS traps and VFS. Figure 3a and Figure 3b are random accesses. Figure 3c shows the impact on performance when varying the commit frequency with 4 concurrent writers.

Figure 4: Process Sharing. Results show aggregated read throughput (MB/s) of 8 reader processes when sharing a file varying number of writer processes. *CrossFS-direct-user-tree* refers to using user-level interval tree, and *CrossFS-direct-firm-tree* refers to FirmFS managed interval tree, as discussed in §4.6.

directly from the FD-queue, the performance gains are high. CrossFS-iocctl incurs kernel traps but avoids VFS overheads and low overhead journaling, resulting in 3.64x and 2.34x read performance gains over DAX and Strata, respectively. CrossFS-direct also avoids kernel traps achieving 3.38x and 4.87x write and read throughput gains over ext4-DAX, respectively. The read gains are higher because, for writes, the inode-level interval tree’s *rw-lock* must be acquired (only) for FD-queue ordering. In our experiments, this accounts for only 9.9% of the execution time. Finally, as shown in Table 2, CrossFS not only improves throughput but *also reduces latency* for concurrent access.

6.2.2 Multi-Process Performance

Figure 4 shows CrossFS performance in the presence of multiple writers and readers processes. We use the same workload used earlier in Figure 3. For CrossFS-direct approach, we evaluate two cases: first, as discussed in §4.6, with CrossFS-direct-user-tree, we maintain a shared interval tree in the user-level, and LibFS updates the interval tree. While this approach reduces work for device-CPU, a buggy or corrupted reader could accidentally or maliciously corrupt interval tree updates. In contrast, the CrossFS-direct-firm-tree approach avoids these issues by using FirmFS to update the interval tree, without impacting direct-I/O. As the figure shows, both approaches provide significant performance

	ext4-DAX	NOVA	DevFS	CrossFS-iocctl	CrossFS-direct
Readers	5.72	4.68	2.91	1.93	1.27
Writers	3.86	2.48	2.31	1.89	1.15

Figure 5: Urgency-aware Scheduler Impact. Results show aggregated throughput for reader and writer threads. The x-axis varies the number of reader and writer threads.

gains compared to other state-of-the-art designs. Besides, CrossFS-direct-firm-tree shows only a marginal reduction in performance due to an increase in device-CPU work.

6.2.3 Commit Frequency

To study the performance of CrossFS’s barrier-based commits, in Figure 3c, we evaluate *fsync* performance by running the random write benchmark with 4 concurrent writers. In the x-axis, we gradually increase the interval between successive *fsync*s. As shown, compared to ext4-DAX, CrossFS delivers 2.05x and 2.68x performance gains for *fsync*s issued at 4 write (worst-case) and 16 write (best-case) intervals, respectively. Although CrossFS adds a commit barrier to all FD-queues of an inode, device-CPU can concurrently dispatch requests across FD-queues without synchronizing until the barrier completion. Additionally, CrossFS avoids system call cost for both *fsync* and write operations.

6.2.4 Urgency-aware Scheduler

CrossFS’s cross-layered design smashes traditional OS-level I/O and firmware scheduler into a single firmware-level scheduler. To understand the implication of a scheduler, we evaluate two scheduling policies: (a) round-robin, which provides fairness, and (b) urgency-aware, which prioritizes

Figure 6: CrossFS Incremental Performance Breakdown. Results show aggregated throughput breakdown for 16 readers and 4 writers performing random access on a 12GB file. The baseline CrossFS approach (CrossFS-ioctli-lock) uses IOCTLs and coarse-grained inode-level lock.

blocking operations (e.g., read). We use the random-access micro-benchmark (discussed earlier) with an equal number of readers and writers performing random access on a shared 12GB file. Figure 5a and 5b show aggregated throughput for concurrent writers and readers, while varying the reader and writer count on the x-axis. First, the round-robin policy does not differentiate blocking reads and non-blocking writes; hence, it dispatches read and write requests with equal priority. Consequently, with 4 device-CPU and the use of interval tree `rw-lock`, blocking reads are delayed. The write throughput does not scale beyond 8 threads. In contrast, CrossFS’s urgency-aware scheduling prioritizes blocking reads without starving writes beyond a threshold, thereby accelerating reads by 1.22x.

6.2.5 CrossFS Performance Breakdown.

To decipher the source of CrossFS-direct performance gains, in Figure 6, we show the throughput breakdown of 4 writers, 16 readers configuration. CrossFS-ioctli-lock represents the CrossFS baseline that suffers from IOCTL (system call) cost and uses a coarse-grained inode `rw-lock`. Replacing the inode-level lock with fine-grained FD-queue concurrency (shown as Scalability Design) and eliminating system call cost (Kernel Bypass) provides significant performance benefits over the baseline. The urgency-aware scheduler improves the read throughput further.

6.2.6 Sensitivity Analysis - Host-side Configuration

We next study the performance impact of host-side configurations, which includes: (a) FD-queue depth (i.e., queue length), (b) read hits that directly fetch data from FD-queue, and (c) write conflicts with in-transit FD-queues requests. The values over the bars in Figure 7a and 7b show read hits and write conflicts (in percentage), respectively.

Read Hits. To understand the performance impact of FD-queue read hits, we mimic sequential producer-consumer I/O access patterns exhibited in multithreaded I/O-intensive applications such as Map-Reduce [20] and HPC "Cosmic Microwave Background (CMB)" [16]. The concurrent writers (producers) sequentially update specific ranges of blocks in a file, whereas the consumers sequentially read from specific ranges. Note that both producers and consumers use

separate file descriptors. The consumers start at the same time as producers. In Figure 7a, for CrossFS, we vary FD-queue depths to 32 (CrossFS-direct-QD32, the default depth) and 256 (CrossFS-direct-QD256) entries. For simplicity, we only show the results for CrossFS-direct, which outperforms CrossFS-ioctli. As expected, increasing the queue depth from 32 to 256 increases the read hit rate, enabling host threads to fetch updates from FD-queues directly. Consequently, read throughput for CrossFS-direct-QD256 improves by 1.12x over CrossFS-direct-QD32, outperforming other approaches.

Write Conflicts. A consequence of increasing the queue depth is the increase in write conflicts across concurrent writers. To illustrate this, we only use concurrent writers in the above benchmark, and the writers sequentially update all blocks in a file. As shown in Figure 7b, an increase in queue-depth increases write conflicts (27% for CrossFS-direct-QD256 with 8 threads), forcing some requests to be ordered to the same FD-queue. However, this does not adversely impact the performance because of our optimized conflict resolution and fewer host-CPU stalls with 256 FD-queue entries.

6.2.7 Sensitivity Analysis - Device Configuration

A cross-layered file system could be deployed in storage devices with different bandwidths, incur PCIe latency for host and device interaction, and use wimpier CPUs. To understand CrossFS’s performance sensitivity towards these device configurations, we decipher the performance by varying the storage bandwidth, adding PCIe latency, and reducing the frequency of device-CPU.

For varying the storage bandwidth, we use DRAM as a storage device and vary the storage bandwidth between 0.5GB/s to 10GB/s using thermal throttling. We use DRAM because Optane NVM cannot be thermal-throttled, and its bandwidth cannot be changed. In Figure 7c, we compare three CrossFS approaches: (1) CrossFS-noPCIELat-HighFreq - the default approach without PCIe latency and high device-CPU frequency (2.7GHz); (2) CrossFS-PCIELat-HighFreq - an approach that emulates *Gen 3 x8 PCIe*’s latency of 900ns [49] by adding software delays between the time a request is added to a FD-queue and the time when the request is processed by FirmFS; and finally, (3) CrossFS-PCIELat-LowFreq - an approach that reduces device-CPU frequency to 1.2GHz (the minimum frequency possible) using DVFS [41] in addition to added PCIe latency. The results show random write throughput when four concurrent writers and readers share a 12GB file. We also compare ext4-DAX, NOVA, and DevFS *without reducing CPU frequency or PCIe latency*.

At lower storage bandwidths (e.g., 500MB/s), as expected, CrossFS’s gains are limited by storage bandwidth. However, even at 2GB/s bandwidth, CrossFS-noPCIELat-HighFreq shows 1.96x gains over ext4-DAX. Next, the impact of 900ns PCIe latency (CrossFS-PCIELat-HighFreq) is overpowered by other software overheads such as file system metadata and

Figure 7: Performance Sensitivity towards Host and Device Configuration. Figure 7a and Figure 7b host configuration (FD-queue depth) sensitivity. Figure 7a shows read throughput with increasing in read hit rate for 32 and 256 entry FD-queue depth. Figure 7b shows write throughput and write conflict (%) when varying FD-queue depth across concurrent writers sequentially updating a file. Figure 7c shows device configuration sensitivity. The x-axis varies the storage bandwidth, and the graph shows write throughput for 4 concurrent writers when adding PCIe latency and reducing device-CPU frequency.

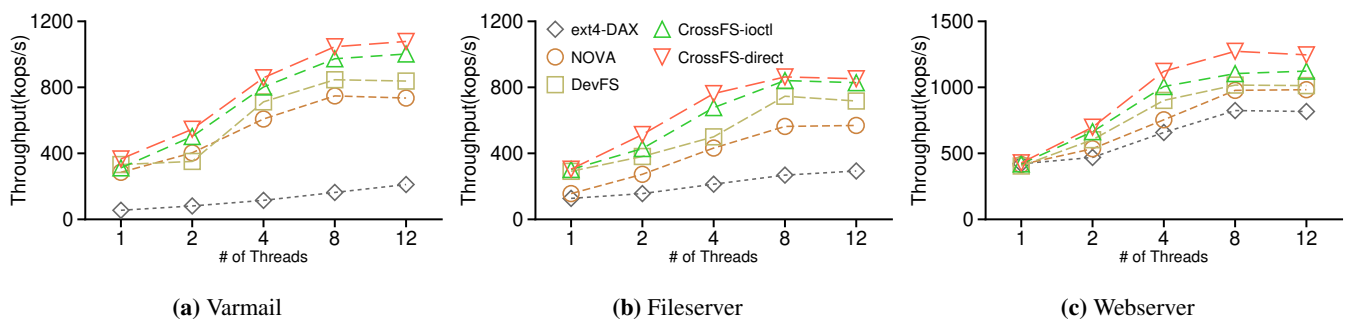

Figure 8: Filebench Throughput. The evaluation uses 4 device-CPU.

data management, journaling, and scheduling. While higher CPU frequency, storage bandwidth, and low PCIe latency would maximize gains when using a programmable storage, even when using 2.5x slower CPUs and 900ns PCIe latency, our cross-layered and concurrency-centric design provides 1.87x, 1.97x, 1.35x over ext4-DAX, NOVA, and DevFS that use high-frequency CPUs without PCIe latency, respectively.

6.3 Macrobenchmark: Filebench

Does CrossFS’s cross-layered design benefit multithreaded workloads without file sharing? To understand the performance, we evaluate well-known Filebench’s *Varmail* (metadata-heavy), *Fileserver* (write-heavy), and *Webserver* (read-heavy) workloads that represent real-world workloads [22, 23, 66]. The workloads are metadata-intensive and perform operations such as file create, delete, directory update, which contributes to 69%, 63%, and 64% in Varmail, Fileserver, and Webserver, respectively, of the overall I/O. The data read to write ratios are 1:1, 1:2, and 10:1 in Varmail, Fileserver, and Webserver, respectively.

We compare CrossFS-iocli and CrossFS-direct against ext4-DAX, NOVA, and DevFS. SplitFS does not yet support Filebench and RocksDB. Figure 8 shows the throughput for three workloads. The x-axis shows the throughput when increasing Filebench’s thread count. Without file sharing across threads, DevFS (without system calls) performs better

than NOVA and ext4-DAX. In contrast, CrossFS-direct, for *Varmail* and *Fileserver*, outperforms other approaches and provides 1.47x and 1.77x gains over NOVA, respectively. *Varmail* is metadata-intensive and (with 1:1 read-write ratio for data operations), and *fileserver* is highly write-intensive. For both these workloads, CrossFS-direct avoids system calls, reduces VFS cost, and provides fast metadata journaling at the cost of data journaling (aided by NVM-based FD-queues). With just 4 device-CPU and a metadata I/O-queue for operations without file descriptors, CrossFS-direct gains flat-ten. Finally, *Webserver* has a significantly higher read ratio. While CrossFS-direct improves performance, the throughput gains (1.71x) are restricted. First, blocking reads stress the available four device-CPU. Second, we notice OS scheduler overheads as a side-effect of emulating device-CPU with Linux kernel threads. The kernel threads in Linux periodically check and yield to the OS scheduler if necessary (i.e., `need_resched()`); the periodic yields negatively impact blocking random read operations for CrossFS and DevFS.

6.4 Real-World Applications

RocksDB. RocksDB [9] is a widely used LSM-based NoSQL database used as a backend in several production systems and frameworks [11, 12, 44]. RocksDB is designed to exploit SSD’s parallel bandwidth and multicore parallelism. As discussed earlier, we observe around 40% of I/O accesses to shared files across RocksDB’s foreground threads that share

Figure 9: Application throughput. Figure 9a and Figure 9b show random write and read performance for RocksDB by varying threads in *DBbench* workload. RocksDB internally creates background compaction threads. Figure 9c shows the *SET* benchmark for Redis by varying the number of Redis instances.

log files and background threads that compact in-memory data across LSM levels in the SST (string sorted) files [34]. However, conflicting block updates are negligible. In Figure 9a and Figure 9b, we vary the number of application (foreground) threads along the x-axis and set the device-CPU count to four. We compare ext4-DAX, NOVA, DevFS, CrossFS-ioctl, and CrossFS-direct’s throughput for random write and read operations. Note that RocksDB, by default, uses three background parallel compaction threads, which increases with increasing SST levels [10]. We use widely used *DBbench* [2], with 100B keys, 1KB values, and a 32GB database size. We set RocksDB’s memory buffer to 128MB [44].

CrossFS-direct and CrossFS-ioctl show up to 2.32x and 1.15x write and read throughput gains over ext4-DAX, respectively. The read and write performance benefits over DevFS are 1.33x and 1.21x, respectively. We attribute these gains to the following reasons. First, RocksDB threads do not update the same block (lower than 0.1% conflicts); hence, unlike other approaches, CrossFS-ioctl and CrossFS-direct avoid inode-level locks. Second, both CrossFS-ioctl and CrossFS-direct avoid VFS overheads. Additionally, CrossFS-direct also avoids system call costs. When increasing application threads, the burden on four device-CPU’s increases, impacting performance for the 16 application thread configuration. The blocking reads are impacted due to the use of kernel threads for device-CPU emulation (see §6.3).

Redis. Redis is a widely used storage-backed in-memory key-value store [8], which logs operations to append-only files (AOF) and checkpoints in-memory key-values asynchronously to backup files called RDB [40]. We run multiple Redis instances and the instances do not share AOF or RDB files. We use background write mode for Redis instances that immediately persist key-value updates to the disk. Figure 9c shows the Redis performance.

First, when increasing Redis instances, the number of concurrent writers increases. The server and the client (benchmark) instances run as separate processes, which increases inter-process communication, system call, and VFS costs. Although instances do not share files, CrossFS-direct provides considerable performance gains mostly stemming from direct storage access, avoiding VFS overheads, and lowering jour-

naled cost. Consequently, CrossFS provides 2.35x higher throughput over ext4-DAX.

7 Conclusion

This paper proposes CrossFS, a cross-layered file system design that provides high-performance direct-I/O and concurrent access across threads and applications with or without data sharing. Four key ingredients contribute to CrossFS’s high-performant design. First, our cross-layered approach exploits hardware and software resources spread across the untrusted user-level library, the trusted OS, and the trusted device firmware. Second, the fine-grained file descriptor concurrency design converts a file synchronization problem to the I/O queue ordering problem, which ultimately scales concurrent access. Third, our lightweight data + metadata journaling aided by NVM reduces crash consistency overheads. Finally, our unified firmware-level scheduler complements the file descriptor design, reducing I/O latency for blocking operations. Our detailed evaluation of CrossFS against state-of-the-art kernel-level, user-level, and firmware-level file system shows up to 4.87x, 3.58x, 2.32x gains on microbenchmarks, macrobenchmarks, and applications.

Abstract. We introduce BOURBON, a log-structured merge (LSM) tree that utilizes machine learning to provide fast lookups. We base the design and implementation of BOURBON on empirically-grounded principles that we derive through careful analysis of LSM design. BOURBON employs greedy piecewise linear regression to learn key distributions, enabling fast lookup with minimal computation, and applies a cost-benefit strategy to decide when learning will be worthwhile. Through a series of experiments on both synthetic and real-world datasets, we show that BOURBON improves lookup performance by $1.23\times$ – $1.78\times$ as compared to state-of-the-art production LSMs.

1 Introduction

Machine learning is transforming how we build computer applications and systems. Instead of writing code in the traditional algorithmic mindset, one can instead collect the proper data, train a model, and thus implement a robust and general solution to the task at hand. This data-driven, empirical approach has been called “Software 2.0” [26], hinting at a world where an increasing amount of the code we deploy is realized in this manner; a number of landmark successes over the past decade lend credence to this argument, in areas such as image [32] and speech recognition [24], machine translation [46], game playing [44], and many other areas [7, 15, 17].

One promising line of work, for using ML to improve core systems is that of the “learned index” [31]. This approach applies machine learning to supplant the traditional index structure found in database systems, namely the ubiquitous B-Tree [9]. To look up a key, the system uses a learned function that predicts the location of the key (and value); when successful, this approach can improve lookup performance, in some cases significantly, and also potentially reduce space overhead. Since this pioneering work, numerous follow ups [13, 20, 30] have been proposed that use better models, better tree structures, and generally improve how learning can reduce tree-based access times and overheads.

However, one critical approach has not yet been transformed in this “learned” manner: the Log-structured Merge

Tree (LSM) [37, 39, 42]. LSMs were introduced in the late ’90s, gained popularity a decade later through work at Google on BigTable [8] and LevelDB [22], and have become widely used in industry, including in Cassandra [33], RocksDB [18], and many other systems [21, 38]. LSMs have many positive properties as compared to B-trees and their cousins, including high insert performance [11, 37, 40].

In this paper, we apply the idea of the learned index to LSMs. A major challenge is that while learned indexes are primarily tailored for read-only settings, LSMs are optimized for writes. Writes cause disruption to learned indexes because models learned over existing data must now be updated to accommodate the changes; the system thus must re-learn the data repeatedly. However, we find that LSMs are well-suited for learned indexes. For example, although writes modify the LSM, most portions of the tree are immutable; thus, learning a function to predict key/value locations can be done once, and used as long as the immutable data lives. However, many challenges arise. For example, variable key or value sizes make learning a function to predict locations more difficult, and performing model building too soon may lead to significant resource waste.

Thus, we first study how an existing LSM system, WiscKey [37], functions in great detail (§3). We focus on WiscKey because it is a state-of-the-art LSM implementation that is significantly faster than LevelDB and RocksDB [37]. Our analysis leads to many interesting insights from which we develop five *learning guidelines*: a set of rules that aid an LSM system to successfully incorporate learned indexes. For example, while it is useful to learn the stable, low levels in an LSM, learning higher levels can yield benefits as well because lookups must always search the higher levels. Next, not all files are equal: some files even in the lower levels are very short-lived; a system must avoid learning such files, or resources can be wasted. Finally, workload- and data-awareness is important; based on the workload and how the data is loaded, it may be more beneficial to learn some portions of the tree than others.

We apply these learning guidelines to build BOURBON, a

learned-index implementation of WiscKey (§4). BOURBON uses piece-wise linear regression, a simple but effective model that enables both fast training (i.e., learning) and inference (i.e., lookups) with little space overhead. BOURBON employs *file learning*: models are built over files given that an LSM file, once created, is never modified in-place. BOURBON implements a cost-benefit analyzer that dynamically decides whether or not to learn a file, reducing unnecessary learning while maximizing benefits. While most of the prior work on learned indexes [13, 20, 31] has made strides in optimizing stand-alone data structures, BOURBON integrates learning into a production-quality system that is already highly optimized. BOURBON’s implementation adds around 5K LOC to WiscKey (which has ~20K LOC).

We analyze the performance of BOURBON on a range of synthetic and real-world datasets and workloads (§5). We find that BOURBON reduces the indexing costs of WiscKey significantly and thus offers $1.23\times - 1.78\times$ faster lookups for various datasets. Even under workloads with significant write load, BOURBON speeds up a large fraction of lookups and, through cost-benefit, avoids unnecessary (early) model building. Thus, BOURBON matches the performance of an aggressive-learning approach but performs model building more judiciously. Finally, most of our analysis focuses on the case where fast lookups will make the most difference, namely when the data resides in memory (i.e., in the file-system page cache). However, we also experiment with BOURBON when data resides on a fast storage device (an Optane SSD) or when data does not fit entirely in memory, and show that benefits can still be realized.

This paper makes four contributions. We present the first detailed study of how LSMs function internally with learning in mind. We formulate a set of guidelines on how to integrate learned indexes into an LSM (§3). We present the design and implementation of BOURBON which incorporates learned indexes into a real, highly optimized, production-quality LSM system (§4). Finally, we analyze BOURBON’s performance in detail, and demonstrate its benefits (§5).

2 Background

We first describe log-structured merge trees and explain how data is organized in LevelDB. Next, we describe WiscKey, a modified version of LevelDB that we adopt as our baseline. We then provide a brief background on learned indexes.

2.1 LSM and LevelDB

An LSM tree is a persistent data structure used in key-value stores to support efficient inserts and updates [39]. Unlike B-trees that require many random writes to storage upon updates, LSM trees perform writes sequentially, thus achieving high write throughput [39].

An LSM organizes data in multiple *levels*, with the size of each level increasing exponentially. Inserts are initially buffered in an in-memory structure; once full, this structure

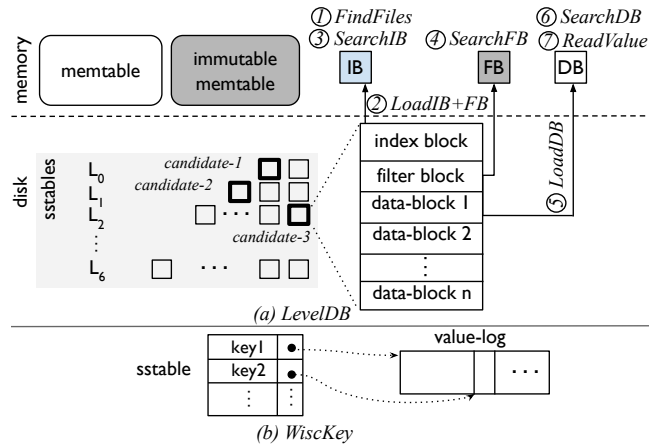

Figure 1: **LevelDB and WiscKey.** (a) shows how data is organized in LevelDB and how a lookup is processed. The search in in-memory tables is not shown. The candidate sstables are shown in bold boxes. (b) shows how keys and values are separated in WiscKey.

is merged with the first level of on-disk data. This procedure resembles merge-sort and is referred to as compaction. Data from an on-disk level is also merged with the successive level if the size of the level exceeds a limit. Note that updates do not modify existing records in-place; they follow the same path as inserts. As a result, many versions of the same item can be present in the tree at a time. Throughout this paper, we refer to the levels that contain the newer data as *higher* levels and the older data as *lower* levels.

A lookup request must return the latest version of an item. Because higher levels contain the newer versions, the search starts at the topmost level. First, the key is searched for in the in-memory structure; if not found, it is searched for in the on-disk tree starting from the highest level to the lowest one. The value is returned once the key is found at a level.

LevelDB [22] is a widely used key-value store built using LSM. Figure 1(a) shows how data is organized in LevelDB. A new key-value pair is first written to the *memtable*; when full, the memtable is converted into an immutable table which is then compacted and written to disk sequentially as *sstables*. The sstables are organized in seven levels (L_0 being the highest level and L_6 the lowest) and each sstable corresponds to a file. LevelDB ensures that key ranges of different sstables at a level are disjoint (two files will not contain overlapping ranges of keys); L_0 is an exception where the ranges can overlap across files. The amount of data at each level increases by a factor of ten; for example, the size of L_1 is 10MB, while L_6 contains several 100s of GBs. If a level exceeds its size limit, one or more sstables from that level are merged with the next level; this is repeated until all levels are within their limits.

Lookup steps. Figure 1(a) also shows how a lookup request for key k proceeds. ① *FindFiles*: If the key is not found in the in-memory tables, LevelDB finds the set of candidate sstable files that may contain k . A key in the worst case

may be present in all L_0 files (because of overlapping ranges) and within one file at each successive level. ② *LoadIB+FB*: In each candidate sstable, an index block and a bloom-filter block are first loaded from the disk. ③ *SearchIB*: The index block is binary searched to find the data block that may contain k . ④ *SearchFB*: The filter is queried to check if k is present in the data block. ⑤ *LoadDB*: If the filter indicates presence, the data block is loaded. ⑥ *SearchDB*: The data block is binary searched. ⑦ *ReadValue*: If the key is found in the data block, the associated value is read and the lookup ends. If the filter indicates absence or if the key is not found in the data block, the search continues to the next candidate file. Note that blocks are not always loaded from the disk; index and filter blocks, and frequently accessed data blocks are likely to be present in memory (i.e., file-system cache).

We refer to these search steps at a level that occur as part of a single lookup as an *internal lookup*. A single lookup thus consists of many internal lookups. A *negative internal lookup* does not find the key, while a *positive internal lookup* finds the key and is thus the last step of a lookup request.

We differentiate indexing steps from data-access steps; indexing steps such as *FindFiles*, *SearchIB*, *SearchFB*, and *SearchDB* search through the files and blocks to find the desired key, while data-access steps such as *LoadIB+FB*, *LoadDB*, and *ReadValue* read the data from storage. Our goal is to reduce the time spent in indexing.

2.2 WiscKey

In LevelDB, compaction results in large write amplification because *both* keys and values are sorted and rewritten. Thus, LevelDB suffers from high compaction overheads, affecting foreground workloads.

WiscKey [37] (and Badger [1]) reduces this overhead by storing the values separately; thesstables contain only keys and pointers to the values as shown in Figure 1(b). With this design, compaction sorts and writes only the keys, leaving the values undisturbed, thus reducing I/O amplification and overheads. WiscKey thus performs significantly better than other optimized LSM implementations such as LevelDB and RocksDB. Given these benefits, we adopt WiscKey as the baseline for our design. Further, WiscKey’s key-value separation enables our design to handle variable-size records; we describe how in more detail in §4.2.

The write path of WiscKey is similar to that of LevelDB except that values are written to a *value log*. A lookup in WiscKey also involves searching at many levels and a final read into the log once the target key is found. The size of WiscKey’s LSM tree is much smaller than LevelDB because it does not contain the values; hence, it can be entirely cached in memory [37]. Thus, a lookup request involves multiple searches in the in-memory tree, and the *ReadValue* step performs one final read to retrieve the value.

2.3 Optimizing Lookups in LSMs

Performing a lookup in LevelDB and WiscKey requires searching at multiple levels. Further, within each sstable, many blocks are searched to find the target key. Given that LSMs form the basis of many embedded key-value stores (e.g., LevelDB, RocksDB [18]) and distributed storage systems (e.g., BigTable [8], Riak [38]), optimizing lookups in LSMs can have huge benefits.

A recent body of work, starting with learned indexes [31], makes a case for replacing or augmenting traditional index structures with machine-learning models. The key idea is to train a model (such as linear regression or neural nets) on the input so that the model can predict the position of a record in the sorted dataset. The model can have inaccuracies, and thus the prediction has an associated error bound. During lookups, if the model-predicted position of the key is correct, the record is returned; if it is wrong, a local search is performed within the error bound. For example, if the predicted position is pos and the minimum and maximum error bounds are δ_{min} and δ_{max} , then upon a wrong prediction, a local search is performed between $pos - \delta_{min}$ and $pos + \delta_{max}$.

Learned indexes can make lookups significantly faster. Intuitively, a learned index turns a $O(\log n)$ lookup of a B-tree into a $O(1)$ operation. Empirically, learned indexes provide $1.5\times - 3\times$ faster lookups than B-trees [31]. Given these benefits, we ask the following questions: *can learned indexes for LSMs make lookups faster? If yes, under what scenarios?*

Traditional learned indexes do not support updates because models learned over the existing data would change with modifications [13, 20, 31]. However, LSMs are attractive for their high performance in write-intensive workloads because they perform writes only sequentially. Thus, we examine: *how to realize the benefits of learned indexes while supporting writes for which LSMs are optimized?* We answer these two questions next.

3 Learned Indexes: a Good Match for LSMs?

In this section, we first analyze if learned indexes could be beneficial for LSMs and examine under what scenarios they can improve lookup performance. We then provide our intuition as to why learned indexes might be appropriate for LSMs even when allowing writes. We conduct an in-depth study based on measurements of how WiscKey functions internally under different workloads to validate our intuition. From our analysis, we derive a set of learning guidelines.

3.1 Learned Indexes: Beneficial Regimes

A lookup in LSM involves several indexing and data-access steps. Optimized indexes such as learned indexes can reduce the overheads of indexing but cannot reduce data-access costs. In WiscKey, learned indexes can thus potentially reduce the costs of indexing steps such as *FindFiles*, *SearchIB*, and *SearchDB*, while data-access costs (e.g., *ReadValue*)

Figure 2: **Lookup Latency Breakdown.** The figure shows the breakdown of lookup latency in WiscKey. The first bar shows the case when data is cached in memory. The other three bars show the case where the dataset is stored on different types of SSDs. We perform 10M random lookups on the Amazon Reviews dataset [5]; the figure shows the breakdown of the average latency (shown at the top of each bar). The indexing portions are shown in solid colors; data access and other portions are shown in patterns.

cannot be significantly reduced. As a result, learned indexes can improve overall lookup performance if indexing contributes to a sizable portion of the total lookup latency. We identify scenarios where this is the case.

First, when the dataset or a portion of it is cached in memory, data-access costs are low, and so indexing costs become significant. Figure 2 shows the breakdown of lookup latencies in WiscKey. The first bar shows the case when the dataset is cached in memory; the second bar shows the case where the data is stored on a flash-based SATA SSD. With caching, data-access and indexing costs contribute almost equally to the latency. Thus, optimizing the indexing portion can reduce lookup latencies by about 2 \times . When the dataset is not cached, data-access costs dominate and thus optimizing indexes may yield smaller benefits (about 20%).

However, learned indexes are not limited to scenarios where data is cached in memory. They offer benefit on fast storage devices that are currently prevalent and can do more so on emerging faster devices. The last three bars in Figure 2 show the breakdown for three kinds of devices: flash-based SSDs over SATA and NVMe, and an Optane SSD. As the device gets faster, lookup latency (as shown at the top) decreases, but the fraction of time spent on indexing increases. For example, with SATA SSDs, indexing takes about 17% of the total time; in contrast, with Optane SSDs, indexing takes 44% and thus optimizing it with learned indexes can potentially improve performance by 1.8 \times . More importantly, the trend in storage performance favors the use of learned indexes. With storage performance increasing rapidly and emerging technologies like 3D Xpoint memory providing very low access latencies, indexing costs will dominate and thus learned indexes will yield increasing benefits.

Summary. Learned indexes could be beneficial when the database or a portion of it is cached in memory. With fast storage devices, regardless of caching, indexing contributes

to a significant fraction of the lookup time; thus, learned indexes can prove useful in such cases. With storage devices getting faster, learned indexes will be even more beneficial.

3.2 Learned Indexes with Writes

Learned indexes provide higher lookup performance compared to traditional indexes for read-only analytical workloads. However, a major drawback of learned indexes (as described in [31]) is that they do not support modifications such as inserts and updates [13, 20]. The main problem with modifications is that they alter the data distribution and so the models must be re-learned; for write-heavy workloads, models must be rebuilt often, incurring high overheads.

At first, it may seem like learned indexes are not a good match for write-heavy situations for which LSMs are optimized. However, we observe that the design of LSMs fits well with learned indexes. Our key realization is that although updates can change portions of the LSM tree, a large part remains immutable. Specifically, newly modified items are buffered in the in-memory structures or present in the higher levels of the tree, while stable data resides at the lower levels. Given that a large fraction of the dataset resides in the stable, lower levels, lookups to this fraction can be made faster with no or few re-learnings. In contrast, learning in higher levels may be less beneficial: they change at a faster rate and thus must be re-learned often.

We also realize that the immutable nature of sstable files makes them an ideal unit for learning. Once learned, these files are never updated and thus a model can be useful until the file is replaced. Further, the data within an sstable is sorted; such sorted data can be learned using simple models. A level, which is a collection of many immutable files, can also be learned as a whole using simple models. The data in a level is also sorted: the individual ssables are sorted, and there are no overlapping key ranges across ssables.

We next conduct a series of in-depth measurements to validate our intuitions. Our experiments confirm that while a part of our intuition is indeed true, there are some subtleties (for example, in learning files at higher levels). Based on these experimental results, we formulate a set of *learning guidelines*: a few simple rules that an LSM that applies learned indexes should follow.

Experiments: goal and setup. The goal of our experiments is to determine how long a model will be useful and how often it will be useful. A model built for a sstable file is useful as long as the file exists; thus, we first measure and analyze sstable lifetimes. How often a model will be used is determined by how many internal lookups it serves; thus, we next measure the number of internal lookups to each file. Since models can also be built for entire levels, we finally measure level lifetimes as well. To perform our analysis, we run workloads with varying amounts of writes and reads, and measure the lifetimes and number of lookups. We conduct our experiments on WiscKey, but we believe our results are

Figure 3: **SSTable Lifetimes.** (a) shows the average lifetime of sstable files in levels L_4 to L_0 . (b) shows the distribution of lifetimes of ssables in L_1 and L_4 with 5% writes. (c) shows the distribution of lifetimes of ssables for different write percentages in L_1 and L_4 .

Figure 4: **Number of Internal Lookups Per File.** (a)(i) shows the average internal lookups per file at each level for a randomly loaded dataset. (b) shows the same for sequentially loaded dataset. (a)(ii) and (a)(iii) show the negative and positive internal lookups for the randomly loaded case. (a)(iv) shows the positive internal lookups for the randomly loaded case when the workload distribution is Zipfian.

applicable to most LSM implementations. We first load the database with 256M key-value pairs. We then run a workload with a single rate-limited client that performs 200M operations, a fraction of which are writes. Our workload chooses keys uniformly at random.

Lifetime of SSTables. To determine how long a model will be useful, we first measure and analyze the lifetimes of ssables. To do so, we track the creation and deletion times of all ssables. For files created during the load phase, we assign the workload-start time as their creation time; for other files, we record the actual creation times. If the file is deleted during the workload, then we calculate its exact lifetime. However, some files are not deleted by the end of the workload and we must estimate their lifetimes.[†]

Figure 3(a) shows the average lifetime of sstable files at different levels. We make three main observations. First, the average lifetime of sstable files at lower levels is greater than that of higher levels. Second, at lower percentages of writes, even files at higher levels have a considerable lifetime; for example, at 5% writes, files at L_0 live for about 2 minutes on an average. Files at lower levels live much longer; files at L_4 live about 150 minutes. Third, although the average lifetime of files reduces with more writes, even with a high

amount of writes, files at lower levels live for a long period. For instance, with 50% writes, files at L_4 live for about 60 minutes. In contrast, files at higher level live only for a few seconds; for example, an L_0 file lives only about 10 seconds.

We now take a closer look at the lifetime distribution. Figure 3(b) shows the distributions for L_1 and L_4 files with 5% writes. We first note that some files are very short-lived, while some are long-lived. For example, in L_1 , the lifetime of about 50% of the files is only about 2.5 seconds. If files cross this threshold, they tend to live for much longer times; almost all of the remaining L_1 files live over five minutes.

Surprisingly, even at L_4 , which has a higher average lifetime for files, a few files are very short-lived. We observe that about 2% of L_4 files live less than a second. We find that there are two reasons why a few files live for a very short time. First, compaction of a L_i file creates a new file in L_{i+1} which is again immediately chosen for compaction to the next level. Second, compaction of a L_i file creates a new file in L_{i+1} , which has overlapping key ranges with the next file that is being compacted from L_i . Figure 3(c) shows that this pattern holds for other percentages of writes too. We observed that this holds for other levels as well. From the above observations, we arrive at our first two learning guidelines.

Learning guideline - 1: Favor learning files at lower levels. Files at lower levels live for a long period even for high write percentages; thus, models for these files can be used for a long time and need not be rebuilt often.

Learning guideline - 2: Wait before learning a file. A few

[†] If the files are created during load, we assign the workload duration as their lifetimes. If not, we estimate the lifetime of a file based on its creation time (c) and the total workload time (w); the lifetime of the file is at least $w - c$. We thus consider the lifetime distribution of other files that have a lifetime of at least $w - c$. We then pick a random lifetime in this distribution and assign it as this file's lifetime.

files are very short-lived, even at lower levels. Thus, learning must be invoked only after a file has lived up to a threshold lifetime after which it is highly likely to live for a long time.

Internal Lookups at Different Levels. To determine how many times a model will be used, we analyze the number of lookups served by the sstable files. We run a workload and measure the number of lookups served by files at each level and plot the average number of lookups per file at each level. Figure 4(a) shows the result when the dataset is loaded in an uniform random order. The number of internal lookups is higher for higher levels, although a large fraction of data resides at lower levels. This is because, at higher levels, many internal lookups are negative, as shown in Figure 4(a)(ii). The number of positive internal lookups is as expected: higher in lower levels as shown in Figure 4(a)(iii). This result shows that files at higher levels serve many negative lookups and thus are worth optimizing. While bloom filters may already make these negative lookups faster, the index block still needs to be searched (before the filter query).

We also conduct the same experiment with another workload where the access pattern follows a zipfian distribution (most requests are to a small set of keys). Most of the results exhibit the same trend as the random workload except for the number of positive internal lookups, as shown in Figure 4(a)(iv). Under the zipfian workload, higher level files also serve numerous positive lookups, because the workload accesses a small set of keys which are often updated and thus stored in higher levels.

Figure 4(b) shows the result when the dataset is sequentially loaded, i.e., keys are inserted in ascending order. In contrast to the randomly-loaded case, there are no negative lookups because keys of different sstable files do not overlap even across levels; the *FindFiles* step finds the one file that may contain the key. Thus, lower levels serve more lookups and can have more benefits from learning. From these observations, we arrive at the next two learning guidelines.

Learning guideline - 3: Do not neglect files at higher levels. Although files at lower levels live longer and serve many lookups, files at higher levels can still serve many negative lookups and in some cases, even many positive lookups. Thus, learning files at higher levels can make both internal lookups faster.

Learning guideline - 4: Be workload- and data-aware. Although most data resides in lower levels, if the workload does not lookup that data, learning those levels will yield less benefit; learning thus must be aware of the workload. Further, the order in which the data is loaded influences which levels receive a large fraction of internal lookups; thus, the system must also be data-aware. The amount of internal lookups acts as a proxy for both the workload and load order. Based on the amount of internal lookups, the system must dynamically decide whether to learn a file or not.

Lifetime of Levels. Given that a level as a whole can also be learned, we now measure and analyze the lifetimes of levels.

Figure 5: Changes at Levels. (a) shows the timeline of file creations and deletions at different levels. Note that $\#changes/\#files$ is higher than 1 in L_1 as there are more creations and deletions than the number of files. (b) shows the time between bursts for L_4 for different write percentages.

Level learning cannot be applied at L_0 because it is unsorted: files in L_0 can have overlapping key ranges. Once a level is learned, any change to the level causes a re-learning. A level changes when new ssables are created at that level, or existing ones are deleted. Thus, intuitively, a level would live for an equal or shorter duration than the individual ssables. However, learning at the granularity of a level has the benefit that the candidate ssables need not be found in a separate step; instead, upon a lookup, the model just outputs the sstable and the offset within it.

We examine the changes to a level by plotting the timeline of file creations and deletions at L_1 , L_2 , L_3 , and L_4 in Figure 5(a) for a 5%-write workload; we do not show L_0 for the reason above. On the y-axis, we plot the number of changes divided by the total files present at that level. A value of 0 means there are no changes to the level; a model learned for the level can be used as long as the value remains 0. A value greater than 0 means that there are changes in the level and thus the model has to re-learned. Higher values denote a larger fraction of files are changed.

First, as expected, we observe that the fraction of files that change reduces as we go down the levels because lower levels hold a large volume of data in many files, confirming our intuition. We also observe that changes to levels arrive in bursts. These bursts are caused by compactions that cause many files at a level to be rewritten. Further, these bursts occur at almost the same time across different levels. The reason behind this is that for the dataset we use, levels L_0 through L_3 are full and thus any compaction at one layer results in cascading compactions which finally settle at the non-full L_4 level. The levels remain static between these bursts. The duration for which the levels remain static is longer with a lower amount of writes; for example, with 5% writes, as shown in the figure, this period is about 5 minutes. However, as the amount of writes increases, the lifetime of a level reduces as shown in Figure 5(b); for instance, with 50% writes, the lifetime of L_4 reduces to about 25 seconds. From these observations, we arrive at our final learning guideline.

Learning guideline - 5: Do not learn levels for write-heavy workloads. Learning a level as a whole might be more appro-

priate when the amount of writes is very low or if the workload is read-only. For write-heavy workloads, level lifetimes are very short and thus will induce frequent re-learnings.

Summary. We analyzed how LSMs behave internally by measuring and analyzing the lifetimes of sstable files and levels, and the amount of lookups served by files at different levels. From our analysis, we derived five learning guidelines. We next describe how we incorporate the learning guidelines in an LSM-based storage system.

4 Bourbon Design

We now describe BOURBON, an LSM-based store that uses learning to make indexing faster. We first describe the model that BOURBON uses to learn the data (§4.1). Then, we discuss how BOURBON supports variable-size values (§4.2) and its basic learning strategy (§4.3). We finally explain BOURBON’s cost-benefit analyzer that dynamically makes learning decisions to maximize benefit while reducing cost (§4.4).

4.1 Learning the Data

As we discussed, data can be learned at two granularities: individualsstables or levels. Both these entities are sorted datasets. The goal of a model that tries to learn the data is to predict the location of a key in such a sorted dataset. For example, if the model is constructed for a sstable file, it would predict the file offset given a key. Similarly, a level model would output the target sstable file and the offset within it.

Our requirements for a model is that it must have low overheads during learning and during lookups. Further, we would like the space overheads of the model to be small. We find that piecewise linear regression (PLR) [4, 27] satisfies these requirements well; thus, BOURBON uses PLR to model the data. The intuition behind PLR is to represent a sorted dataset with a number of line segments. PLR constructs a model with an error bound; that is, each data point d is guaranteed to lie within the range $[d_{pos} - \delta, d_{pos} + \delta]$, where d_{pos} is the predicted position of d in the dataset and δ is the error bound specified beforehand.

To train the PLR model, BOURBON uses the Greedy-PLR algorithm [47]. Greedy-PLR processes the data points one at a time; if a data point cannot be added to the current line segment without violating the error bound, then a new line segment is created and the data point is added to it. At the end, Greedy-PLR produces a set of line segments that represents the data. Greedy-PLR runs in linear time with respect to the number of data points.

Once the model is learned, inference is quick: first, the correct line segment that contains the key is found (using binary search); within that line segment, the position of the target key is obtained by multiplying the key with the line’s slope and adding the intercept. If the key is not present in the predicted position, a local search is done in the range determined by the error bound. Thus, lookups take $O(\log s)$ time, where s is the number of segments, in addition to a

Workload	Baseline time (s)	File model		Level model	
		Time(s)	% model	Time(s)	% model
Mixed: Write-heavy	82.6	71.5 (1.16 ×)	74.2	95.1 (0.87 ×)	1.5
Mixed: Read-heavy	89.2	62.05 (1.44 ×)	99.8	74.3 (1.2 ×)	21.4
Read-only	48.4	27.2 (1.78 ×)	100	25.2 (1.92 ×)	100

Table 1: File vs. Level Learning. *The table compares the time to perform 10M operations in baseline WiscKey, file-learning, and level-learning. The numbers within the parentheses show the improvements over baseline. The table also shows the percentage of lookups that take the model path; remaining take the original path because the models are not rebuilt yet.*

constant time to do the local search. The space overheads of PLR are small: a few tens of bytes for every line segment.

Other models or algorithms such as RMI [31], PGM-Index [19], or splines [29] may also be suitable for LSMs and may offer more benefits than PLR. We leave their exploration within LSMs for future work.

4.2 Supporting Variable-size Values

Learning a model that predicts the offset of a key-value pair is much easier if the key-value pairs are the same size. The model then can multiply the predicted position of a key by the size of the pair to produce the final offset. However, many systems allow keys and values to be of arbitrary sizes.

BOURBON requires keys to be of a fixed size, while values can be of any size. We believe this is a reasonable design choice because most datasets have fixed-size keys (e.g., user-ids are usually 16 bytes), while value sizes vary significantly. Even if keys vary in size, they can be padded to make all keys of the same size. BOURBON supports variable-size values by borrowing the idea of key-value separation from WiscKey [37]. With key-value separation, sstables in BOURBON just contain the keys and the pointer to the values; values are maintained in the value log separately. With this, BOURBON obtains the offset of a required key-value pair by getting the predicted position from the model and multiplying it with the record size (which is $keysize + pointersize$.) The value pointer serves as the offset into the value log from which the value is finally read.

4.3 Level vs. File Learning

BOURBON can learn individualsstables files or entire levels. Our analysis in the previous section showed that files live longer than levels under write-heavy workloads, hinting that learning at the file granularity might be the best choice. We now closely examine this tradeoff to design BOURBON’s basic learning strategy. To do so, we compare the performance of file learning and level learning for different workloads. We initially load a dataset and build the models. For the read-only workload, the models need not be re-learned. In the mixed workloads, the models are re-learned as data changes. The results are shown in Table 1.

For mixed workloads, level learning performs worse than file learning. For a write-heavy (50%-write) workload, with level learning, only a small percentage of internal lookups are able to use the model because with a steady stream of incoming writes, the system is unable to learn the levels. Only a mere 1.5% of internal lookups take the model path; these lookups are the ones performed just after loading the data and when the initial level models are available. We observe that all the 66 attempted level learnings failed because the level changed before the learning completed. Because of the additional cost of re-learnings, level learning performs even worse than the baseline with 50% writes. On the other hand, with file models, a large fraction of lookups benefit from the models and thus file learning performs better than the baseline. For read-heavy mixed workload (5%), although level learning has benefits over the baseline, it performs worse than file learning for the same reasons above.

Level learning can be beneficial for read-only settings: as shown in the table, level learning provides 10% improvements over file learning. Thus, deployments that have only read-only workloads can benefit from level learning. Given that BOURBON's goal is to provide faster lookups while supporting writes, levels are not an appropriate choice of granularity for learning. Thus, BOURBON uses file learning by default. However, BOURBON supports level learning as a configuration option that can be useful in read-only scenarios.

4.4 Cost vs. Benefit Analyzer

Before learning a file, BOURBON must ensure that the time spent in learning is worthwhile. If a file is short-lived, then the time spent learning that file wastes resources. Such a file will serve few lookups and thus the model would have little benefit. Thus, to decide whether or not to learn a file, BOURBON implements an online cost vs. benefit analysis.

4.4.1 Wait Before Learning

As our analysis showed, even in the lower levels, many files are short-lived. To avoid the cost of learning short-lived files, BOURBON waits for a time threshold, T_{wait} , before learning a file. The exact value of T_{wait} presents a cost vs. performance tradeoff. A very low T_{wait} leads to some short-lived files still being learned, incurring overheads; a large value causes many lookups to take the baseline path (because there is no model built yet), thus missing opportunities to make lookups faster. BOURBON sets the value of T_{wait} to the time it takes to learn a file. Our approach is never more than a factor of two worse than the optimal solution, where the optimal solution knows apriori the lifetime and decides to either immediately or never learn the file (i.e., it is two-competitive [25]). Through measurements, we found that the maximum time to learn a file (which is at most ~4MB in size) is around 40 ms on our experimental setup. We conservatively set T_{wait} to be 50 ms in BOURBON's implementation.

4.4.2 To Learn a File or Not

BOURBON waits for T_{wait} before learning a file. However, learning a file even if it lives for a long time may not be beneficial. For example, our analysis shows that although lower-level files live longer, for some workloads and datasets, they serve relatively fewer lookups than higher-level files; higher-level files, although short-lived, serve a large percentage of negative internal lookups in some scenarios. BOURBON, thus, must consider the potential benefits that a model can bring, in addition to considering the cost to build the model. It is profitable to learn a file if the benefit of the model (B_{model}) outweighs the cost to build the model (C_{model}).

Estimating C_{model} . One way to estimate C_{model} is to assume that the learning is completely performed in the background and will not affect the rest of the system; i.e., C_{model} is 0. This is true if there are many idle cores which the learning threads can utilize and thus do not interfere with the foreground tasks (e.g., the workload) or other background tasks (e.g., compaction). However, BOURBON takes a conservative approach and assumes that the learning threads will interfere and slow down the other parts of the system. As a result, BOURBON assumes C_{model} to be equal to T_{build} . We define T_{build} as the time to train the PLR model for a file. We find that this time is linearly proportional to the number of data points in the file. We calculate T_{build} for a file by multiplying the average time to train a data point (measured offline) and the number of data points in the file.

Estimating B_{model} . Estimating the potential benefit of learning a file, B_{model} , is more involved. Intuitively, the benefit offered by the model for an internal lookup is given by $T_b - T_m$, where T_b and T_m are the average times for the lookup in baseline and model paths, respectively. If the file serves N lookups in its lifetime, the net benefit of the model is: $B_{model} = (T_b - T_m) * N$. We divide the internal lookups into negative and positive because most negative lookups terminate at the filter, whereas positive ones do not; thus,

$$B_{model} = ((T_{n.b} - T_{n.m}) * N_n) + ((T_{p.b} - T_{p.m}) * N_p)$$

where N_n and N_p are the number of negative and positive internal lookups, respectively. $T_{n.b}$ and $T_{p.b}$ are the time in the baseline path for a negative and a positive lookup, respectively; $T_{n.m}$ and $T_{p.m}$ are the model counterparts.

B_{model} for a file cannot be calculated without knowing the number of lookups that the file will serve or how much time the lookups will take. The analyzer, to estimate these quantities, maintains statistics of files that have lived their lifetime, i.e., files that were created, served many lookups, and then were replaced. To estimate these quantities for a file F , the analyzer uses the statistics of other files at the same level as F ; we consider statistics only at the same level because these statistics vary significantly across levels.

Recall that BOURBON waits before learning a file. During this time, the lookups are served in the baseline path. BOURBON uses the time taken for these lookups to estimate

$T_{n.b}$ and $T_{p.b}$. Next, $T_{n.m}$ and $T_{p.m}$ are estimated as the average negative and positive model lookup times of other files at the same level. Finally, N_n and N_p are estimated as follows. The analyzer first takes the average negative and positive lookups for other files in that level; then, it is scaled by a factor $f = s/\bar{s}_l$, where s is the size of the file and \bar{s}_l is the average file size at this level. While estimating the above quantities, BOURBON filters out very short-lived files.

While bootstrapping, the analyzer might not have enough statistics collected. Therefore, initially, BOURBON runs in an always-learn mode (with T_{wait} still in place.) Once enough statistics are collected, the analyzer performs the cost vs. benefit analysis and chooses to learn a file if $C_{model} < B_{model}$, i.e., benefit of a model outweighs the cost. If multiple files are chosen to be learned at the same time, BOURBON puts them in a max priority queue ordered by $B_{model} - C_{model}$, thus prioritizing files that would deliver the most benefit.

Our cost-benefit analyzer adopts a simple scheme of using average statistics of other files at the same level. While this approach has worked well in our initial prototype, using more sophisticated statistics and considering workload distributions (e.g., to account for keys with different popularity) could be more beneficial. We leave such exploration for future work.

4.5 Bourbon: Putting it All Together

We describe how the different pieces of BOURBON work together. Figure 6 shows the path of lookups in BOURBON. As shown in (a), lookups can either be processed via the model (if the target file is already learned), or in the baseline path (if the model is not built yet). The baseline path in BOURBON is similar to the one shown in Figure 1 for LevelDB, except that BOURBON stores the values separately and so *ReadValue* reads the value from the log.

Once BOURBON learns a sstable file, lookups to that file will be processed via the learned model as shown in Figure 6(b). ① *FindFiles*: BOURBON finds the candidate sstables; this step required because BOURBON uses file learning. ② *LoadIB+FB*: BOURBON loads the index and filter blocks; these blocks are likely to be already cached. ③ *ModelLookup*: BOURBON performs a look up for the desired key k in the candidate sstable's model. The model outputs a predicted position of k within the file (pos) and the error bound (δ). From this, BOURBON calculates the data block that contains records $pos - \delta$ through $pos + \delta$.[†] ④ *SearchFB*: The filter for that block is queried to check if k is present. If present, BOURBON calculates the range of bytes of the block that must be loaded; this is simple because keys and pointers to values are of fixed size. ⑤ *LoadChunk*: The byte range is loaded. ⑥ *LocateKey*: The key is located in the loaded chunk. The key will likely be present in the predicted po-

[†]Sometimes, records $pos - \delta$ through $pos + \delta$ span multiple data blocks; in such cases, BOURBON consults the index block (which specifies the maximum key in each data block) to find the data block for pos .

Figure 6: **BOURBON Lookups.** (a) shows that lookups can take two different paths: when the model is available (shown at the top), and when the model is not learned yet and so lookups take the baseline path (bottom); some steps are common to both paths. (b) shows the detailed steps for a lookup via a model; we show the case where models are built for files.

sition (the midpoint of the loaded chunk); if not, BOURBON performs a binary search in the chunk. ⑦ *ReadValue*: The value is read from the value log using the pointer.

Possible improvements. Although BOURBON's implementation is highly-optimized and provides many features common to real systems, it lacks a few features. For example, in the current implementation, we do not support string keys and key compression (although we support value compression). For string keys, one approach we plan to explore is to treat strings as base-64 integers and convert them into 64-bit integers, which could then adopt the same learning approach described herein. While this approach may work well for small keys, large keys may require larger integers (with more than 64 bits) and thus efficient large-integer math is likely essential. Also, BOURBON does not support adaptive switching between level and file models; it is a static configuration. We leave supporting these features to future work.

5 Evaluation

To evaluate BOURBON, we ask the following questions:

- Which portions of lookup does BOURBON optimize? (§5.1)
- How does BOURBON perform with models available and no writes? How does performance change with datasets, load orders, and request distributions? (§5.2)
- How does BOURBON perform with range queries? (§5.3)

Figure 7: **Datasets.** The figure shows the cumulative distribution functions (CDF) of three synthetic datasets (linear, segmented-10%, and normal) and one real-world dataset (OpenStreetMaps). Each dataset is magnified around the 15% percentile to show a detailed view of its distribution.

- In the presence of writes, how does BOURBON’s cost-benefit analyzer perform compared to other approaches that always or never re-learn? (§5.4)
- Does BOURBON perform well on real benchmarks? (§5.5)
- Is BOURBON beneficial when data is on storage? (§5.6)
- Is BOURBON beneficial with limited memory? (§5.7)
- What are the error and space tradeoffs of BOURBON? (§5.8)

Setup. We run our experiments on a 20-core Intel Xeon CPU E5-2660 machine with 160-GB memory and a 480-GB SATA SSD. We use 16B integer keys and 64B values, and set the error bound of BOURBON’s PLR as 8. Unless specified, our workloads perform 10M operations. We use a variety of datasets. We construct four synthetic datasets: linear, segmented-1%, segmented-10%, and normal, each with 64M key-value pairs. In the linear dataset, keys are all consecutive. In the seg-1% dataset, there is a gap after a consecutive segment of 100 keys (i.e., every 1% causes a new segment). The segmented-10% dataset is similar, but there is a gap after 10 consecutive keys. We generate the normal dataset by sampling 64M unique values from the standard normal distribution $N(0, 1)$ and scale to integers. We also use two real-world datasets: Amazon reviews (AR) [5] and New York OpenStreetMaps (OSM) [2]. AR and OSM have 33.5M and 21.9M key-value pairs, respectively. These datasets vary widely in how the keys are distributed. Figure 7 shows the distribution for a few datasets. Most of our experiments focus on the case where the data resides in memory; however, we also analyze cases where data is present on storage.

5.1 Which Portions does BOURBON Optimize?

We first analyze which portions of the lookup BOURBON optimizes. We perform 10M random lookups on the AR and OSM datasets and show the latency breakdown in Figure 8. As expected, BOURBON reduces the time spent in indexing. The portion marked *Search* in the figure corresponds to *SearchIB* and *SearchDB* in the baseline, versus *ModelLookup* and *LocateKey* in BOURBON. The steps in BOURBON have lower latency than their baseline counterparts. Interestingly, BOURBON reduces data-access costs too, because BOURBON loads a smaller byte range than the entire block loaded by the baseline.

Figure 8: **Latency Breakdown.** The figure shows latency breakdown for WiscKey and BOURBON. Search denotes *SearchIB* and *SearchDB* in WiscKey; the same denotes *ModelLookup* and *LocateKey* in BOURBON. LoadData denotes *LoadDB* in WiscKey; the same denotes *LoadChunk* in BOURBON. These two steps are optimized by BOURBON and are shown in solid colors; the number next to a step shows the factor by which it is made faster in BOURBON.

Figure 9: **Datasets.** (a) compares the average lookup latencies of BOURBON, BOURBON-level, and WiscKey for different datasets; the numbers on the top show the improvements of BOURBON over WiscKey. (b) shows the number of segments for different datasets in BOURBON.

5.2 Performance under No Writes

We next analyze BOURBON’s performance when the models are already built and there are no updates. For each experiment, we load a dataset and allow the system to build the models; during the workload, we issue only lookups.

5.2.1 Datasets

To analyze how the performance is influenced by the dataset, we run the workload on all six datasets and compare BOURBON’s lookup performance against WiscKey. Figure 9 show the results. As shown in 9(a), BOURBON is faster than WiscKey for all datasets; depending upon the dataset, the improvements vary ($1.23\times$ to $1.78\times$). BOURBON provides the most benefit for the linear dataset because it has the smallest number of segments (one per model); with fewer segments, fewer searches are needed to find the target line segment. From 9(b), we observe that latencies increase with the number of segments (e.g., latency of seg-1% is greater than that of linear). We cannot compare the number of segments in AR and OSM with others because the size of these datasets is significantly different.

Level learning. Given that level learning is suitable for read-only scenarios, we configure BOURBON to use level learn-

Figure 10: **Load Orders.** (a) shows the performance for AR and OSM datasets for sequential (seq) and random (rand) load orders. (b) compares the speedup of positive and negative internal lookups.

ing and analyze its performance. As shown in Figure 9(a), BOURBON-level is $1.33\times - 1.92\times$ faster than the baseline. BOURBON-level offers more benefits than BOURBON because a level-model lookup is faster than finding the candidate sstables and then doing a file-model lookup. This confirms that BOURBON-level is an attractive option for read-only scenarios. However, since level models only provide benefits for read-only workloads and give at most 10% improvement compared to file models, we focus on BOURBON with file learning for our remaining experiments.

5.2.2 Load Orders

We now explore how the order in which the data is loaded affects performance. For this experiment, we use the AR and OSM datasets and load them in two ways: sequential (keys are inserted in ascending order) and random (keys are inserted in an uniformly random order). With sequential loading, sstables do not have overlapping key ranges even across levels; whereas, with random loading, sstables at one level can overlap with sstables at other levels.

Figure 10 shows the result. First, regardless of the load order, BOURBON offers significant benefit over baseline ($1.47\times - 1.61\times$). Second, the average lookup latencies increase in the randomly-loaded case compared to the sequential case (e.g., $6\mu s$ vs. $4\mu s$ in WiscKey for the AR dataset). This is because while there are no negative internal lookups in the sequential case, there are many (23M) negative lookups in the random case (as shown in 10(b)). Thus, with random load, the total number of internal lookups increases by $3\times$, increasing lookup latencies.

Next, we note that the speedup over baseline in the random case is less than that of the sequential case (e.g., $1.47\times$ vs. $1.61\times$ for AR). Although BOURBON optimizes both positive and negative internal lookups, the gain for negative lookups is smaller (as shown in 10(b)). This is because most negative lookups in the baseline and BOURBON end just after the filter is queried (filter indicates absence); the data block is not loaded or searched. Given there are more negative than positive lookups, BOURBON offers less speedup than the sequential case. However, this speedup is still significant ($1.47\times$).

5.2.3 Request Distributions

Next, we analyze how request distributions affect BOURBON's performance. We measure the lookup la-

Figure 11: **Request Distributions.** The figure shows the average lookup latencies of different request distributions from AR and OSM datasets.

Figure 12: **Range Queries.** The figure shows the normalized throughput of range queries with different range lengths from AR and OSM datasets.

tencies under six request distributions: sequential, zipfian, hotspot, exponential, uniform, and latest. We first randomly load the AR and OSM datasets and then run the workloads; thus, the data can be segmented and there can be many negative internal lookups. As shown in Figure 11, BOURBON makes lookups faster by $1.54\times - 1.76\times$ than the baseline. Overall, BOURBON reduces latencies regardless of request distributions.

Read-only performance summary. When the models are already built and when there are no writes, BOURBON provides significant speedup over baseline for a variety of datasets, load orders, and request distributions.

5.3 Range Queries

We next analyze how BOURBON performs on range queries. We perform 1M range queries on the AR and OSM datasets with various range lengths. Figure 12 shows the throughput of BOURBON normalized to that of WiscKey. With short ranges, where the indexing cost (i.e., the cost to locate the first key of the range) is dominant, BOURBON offers the most benefit. For example, with a range length of 1 on the AR dataset, BOURBON is $1.90\times$ faster than WiscKey. The gains drop as the range length increases; for example, BOURBON is only $1.15\times$ faster with queries that return 100 items. This is because, while BOURBON can accelerate the indexing portion, it follows a similar path as WiscKey to scan subsequent keys. Thus, with large range lengths, indexing accounts for less of the total performance, resulting in lower gains.

5.4 Efficacy of Cost-benefit Analyzer with Writes

We next analyze how BOURBON performs in the presence of writes. Writes modify the data and so the models must be re-learned. In such cases, the efficacy of BOURBON's cost-benefit analyzer (cba) is critical. We thus compare

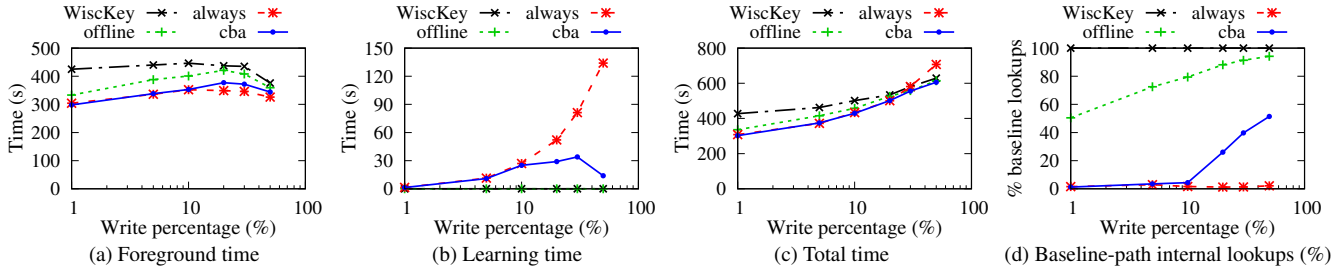

Figure 13: **Mixed Workloads.** (a) compares the foreground times of WiscKey, BOURBON-offline (offline), BOURBON-always (always), and BOURBON-cba (cba); (b) and (c) compare the learning time and total time, respectively; (d) shows the fraction of internal lookups that take the baseline path.

Figure 14: **Macrobenchmark-YCSB.** The figure compares the throughput of BOURBON against WiscKey for six YCSB workloads across three datasets.

BOURBON’s cba against two strategies: BOURBON-offline and BOURBON-always. BOURBON-offline performs no learning as writes happen; models exist only for the initially loaded data. BOURBON-always re-learns the data as writes happen; it always decides to learn a file without considering cost. BOURBON-cba re-learns as well, but it uses the cost-benefit analysis to decide whether or not to learn a file.

We run a workload that issues 50M operations with varying percentages of writes on the AR dataset. To calculate the total amount of work performed for each workload, we sum together the time spent on the foreground lookups and inserts (Figure 13(a)), the time spent learning (13(b)), and the time spent on compaction (not shown); the total amount of work is shown in Figure 13(c). The figure also shows the fraction of internal lookups that take the baseline path (13(d)).

First, as shown in 13(a), all BOURBON variants reduce the workload time compared to WiscKey. The gains are lower with more writes because BOURBON has fewer lookups to optimize. Next, BOURBON-offline performs worse than BOURBON-always and BOURBON-cba. Even with just 1% writes, a significant fraction of internal lookups take the baseline path in BOURBON-offline as shown in 13(d); this shows re-learning as data changes is crucial.

BOURBON-always learns aggressively and thus almost no lookups take the baseline path even for 50% writes. As a result, BOURBON-always has the lowest foreground time. However, this comes at the cost of increased learning time; for example, with 50% writes, BOURBON-always spends about 134 seconds learning. Thus, the total time spent increases with more writes for BOURBON-always and is even higher than baseline WiscKey as shown in 13(c). Thus, ag-

gressively learning is not ideal.

Given a low percentage of writes, BOURBON-cba decides to learn almost all the files, and thus matches the characteristics of BOURBON-always: both have a similar fraction of lookups taking the baseline path, both require the same time learning, and both perform the same amount of work. With a high percentage of writes, BOURBON-cba chooses not to learn many files, reducing learning time; for example, with 50% writes, BOURBON-cba spends only 13.9 seconds in learning (10× lower than BOURBON-always). Consequently, many lookups take the baseline path. BOURBON-cba takes this action because there is less benefit to learning as the data is changing rapidly and there are fewer lookups. Thus, it almost matches the foreground time of BOURBON-always. But, by avoiding learning, the total work done by BOURBON-cba is significantly lower.

Summary. Aggressive learning offers fast lookups but with high costs; no re-learning provides little speedup. Neither is ideal. In contrast, BOURBON provides high benefits similar to aggressive learning while lowering total cost significantly.

5.5 Real Macrobenchmarks

We next analyze how BOURBON performs under two real benchmarks: YCSB [10] and SOSP [28].

5.5.1 YCSB

We use six workloads that have different read-write ratios and access patterns: A (w:50%, r:50%), B (w:5%, r:95%), C (read-only), D (read latest, w:5%, r:95%), E (range-heavy, w:5%, range:95%), F (read-modify-write:50%, r:50%). We use three datasets: YCSB’s default dataset (created using

Figure 15: **Macrobenchmark-SOSD.** The figure compares lookup latencies from the SOSD benchmark. The numbers on the top show BOURBON’s improvements over the baseline.

Dataset	WiscKey latency (μs)	BOURBON	
		Latency(μs)	Speedup
Amazon Reviews (AR)	3.53	2.75	1.28×
NewYork OpenStreetMaps (OSM)	3.14	2.51	1.25×

Table 2: **Performance on Fast Storage.** The table shows BOURBON’s lookup latencies when the data is stored on an Optane SSD.

ycsb-load [3]), AR, and OSM, and load them in a random order. Figure 14 shows the results.

For the read-only workload (YCSB-C), all operations benefit and BOURBON offers the most gains (about 1.6×). For read-heavy workloads (YCSB-B and D), most operations benefit, while writes are not improved and thus BOURBON is 1.24× – 1.44× faster than the baseline. For write-heavy workloads (YCSB-A and F), BOURBON improves performance only a little (1.06× – 1.18×). First, a large fraction of operations are writes; second, the number of the internal lookups taking the model path decreases (by about 30% compared to the read-heavy workload because BOURBON chooses not to learn some files). YCSB-E consists of range queries (range lengths varying from 1 to 100) and 5% writes. BOURBON reaches 1.16× – 1.19× gain. In summary, as expected, BOURBON improves the performance of read operations; at the same time, BOURBON does not affect the performance of writes.

5.5.2 SOSD

We next measure BOURBON’s performance on the SOSD benchmark designed for learned indexes [28]. We use the following six datasets: book sale popularity (amzn32), Facebook user ids (face32), lognormally (logn32) and normally (norm32) distributed datasets, uniformly distributed dense (uden32) and sparse (uspr32) integers. Figure 15 shows the average lookup latency. As shown, BOURBON is about 1.48× – 1.74× faster than the baseline for all datasets.

5.6 Performance on Fast Storage

Our analyses so far focused on the case where the data resides in memory. We now analyze if BOURBON will offer benefit when the data resides on a fast storage device. We run a read-only workload on sequentially loaded AR and OSM datasets on an Intel Optane SSD. Table 2 shows the result. Even when the data is present on a storage device, BOURBON offers benefit (1.25× – 1.28× faster lookups than WiscKey).

Figure 16: **Mixed Workloads on Fast Storage.** The figure compares the throughput of BOURBON against WiscKey for four read-write mixed YCSB workloads. We use the YCSB default dataset for this experiment.

Workload	WiscKey latency (μs)	BOURBON	
		Latency(μs)	Speedup
Uniform	98.6	94.4	1.04×
Zipfian	18.8	15.1	1.25×

Table 3: **Performance with Limited Memory.** The table shows BOURBON’s average lookup latencies from the AR dataset on a machine with a SATA SSD and limited memory.

Figure 16 shows the result for read-write mixed YCSB workloads on the same device with the default YCSB dataset. As expected, while BOURBON’s benefits are marginal for write-heavy workloads (YCSB-A and YCSB-F), it offers considerable speedup (1.16× – 1.19×) for read-heavy workloads (YCSB-B and YCSB-D). With the emerging storage technologies (e.g., 3D XPoint memory), BOURBON will offer even more benefits.

5.7 Performance with Limited Memory

We further show that, even with no fast storage and limited available memory, BOURBON can still offer benefit with skewed workloads, such as zipfian. We experiment on a machine with a SATA SSD and memory that only holds about 25% of the database. We run a uniform random workload, and a zipfian workload with consecutive hotspots where 80% of the requests access about 25% of the database. Table 3 shows the result. With the uniform workload, BOURBON is only 1.04× faster because most of the time is spent loading the data into the memory. With the zipfian workload, in contrast, indexing time instead of data-access time dominates because a large number of requests access the small portion of data that is already cached in memory. BOURBON is able to reduce this significant indexing time and thus offers 1.25× lower latencies.

5.8 Error Bound and Space Overheads

We finally discuss the characteristics of BOURBON’s ML model, specifically its error bound (δ) and space overheads. Figure 17(a) plots the error bound (δ) against the average lookup latency (left y-axis) for AR dataset. As δ increases, fewer line segments are created, leading to fewer searches, thus reducing latency. However, beyond $\delta = 8$, although the time to find the segment reduces, the time to search within a segment increases, thus increasing latency. We find that BOURBON’s choice of $\delta = 8$ is optimal for other datasets too.

Figure 17: **Error-bound Tradeoffs and Space Overheads.** (a) shows how the PLR error bound affects lookup latency and memory overheads; (b) shows the space overheads for different datasets.

Figure 17(a) also shows how space overheads (right y-axis) vary with δ . As δ increases, fewer line segments are created, leading to low space overheads. Table 17(b) shows the space overheads for different datasets. As shown, for a variety of datasets, the overhead compared to the total dataset size is little (0% – 2%).

6 Related Work

Learned indexes. The core idea of our work, replacing indexing structures with ML models, is inspired from the pioneering work on learned indexes [31]. However, learned indexes do not support updates, an essential operation that an storage-system index must support. Recent research tries to address this limitation. For instance, XIndex [45], FITing-Tree [20], and AIDEL [35] support writes using an additional array (delta index) and with periodic re-training, whereas Alex [13] uses gapped array at the leaf nodes of a B-tree to support writes.

Most prior efforts optimize B- tree variants, while our work is the first to deeply focus on LSMs. Further, while most prior efforts implement learned indexes to stand-alone data structures, our work is the first to show how learning can be integrated and implemented into an existing, optimized, production-quality system. While SageDB [30] is a full database system that uses learned components, it is built from scratch with learning in mind. Our work, in contrast, shows how learning can be integrated into an existing, practical system. Finally, instead of “fixing” new read-optimized learned index structures to handle writes (like previous work), we incorporate learning into an already write-optimized, production-quality LSM.

LSM optimizations. Prior work has built many LSM optimizations. Monkey [11] carefully adjusts the bloom filter allocations for better filter hit rates and memory utilization. Dostoevsky [12], HyperLevelDB [16], and bLSM [42] develop optimized compaction policies to achieve lower write amplification and latency. cLSM [23] and RocksDB [18] use non-blocking synchronization to increase parallelism. We take a different yet complimentary approach to LSM opti-

mization by incorporating models as auxiliary index structures to improve lookup latency, but each of the others are orthogonal and compatible to our core design.

Model choices. Duvignau et al. [14] compare a variety of piecewise linear regression algorithms. Greedy-PLR, which we utilize, is a good choice to realize fast lookups, low learning time, and small memory overheads. Neural networks are also widely used to approximate data distributions, especially datasets with complex non-linear structures [34]. However, theoretical analysis [36] and experiments [43] show that training a complex neural network can be prohibitively expensive. Similar to Greedy-PLR, recent work proposes a one-pass learning algorithm based on splines [29] and identifies that such an algorithm could be useful for learning sorted data in LSMs; we leave their exploration within LSMs for future work.

7 Conclusion

In this paper, we examine if learned indexes are suitable for write-optimized log-structured merge (LSM) trees. Through in-depth measurements and analysis, we derive a set of guidelines to integrate learned indexes into LSMs. Using these guidelines, we design and build BOURBON, a learned-index implementation for a highly-optimized LSM system. We experimentally demonstrate that BOURBON offers significantly faster lookups for a range of workloads and datasets.

BOURBON is an initial work on integrating learned indexes into an LSM-based storage system. More detailed studies, such as more sophisticated cost-benefit analysis, general string support, and different model choices, could be promising for future work. In addition, we believe that BOURBON’s learning approach may work well in other write-optimized data structures such as the B^E -tree [6] and could be an interesting avenue for future work. While our work takes initial steps towards integrating learning into production-quality systems, more studies and experience are needed to understand the true utility of learning approaches.

LinnOS: Predictability on Unpredictable Flash Storage with a Light Neural Network

Henry Hoffmann, and Haryadi S. Gunawi

University of Chicago [†]Surya University

Abstract

This paper presents LinnOS, an operating system that leverages a light neural network for inferring SSD performance at a very fine—per-IO—granularity and helps parallel storage applications achieve performance predictability. LinnOS supports black-box devices and real production traces without requiring any extra input from users, while outperforming industrial mechanisms and other approaches. Our evaluation shows that, compared to hedging and heuristic-based methods, LinnOS improves the average I/O latencies by 9.6-79.6% with 87-97% inference accuracy and 4-6 μ s inference overhead for each I/O, demonstrating that it is possible to incorporate machine learning inside operating systems for real-time decision-making.

1 Introduction

Predictable performance is an important requirement for today's and future systems [19, 51, 55, 65]. For data-center systems serving web search, email, and many other types of interactive services, predictable latency is even more important. On the bright side, faster and faster SSDs are available and becoming a dominant factor in the storage market [10]. On the negative side, SSD internal complexity continues to grow, and achieving highly predictable latency on modern flash devices remains an open challenging problem.

Due to the intrinsic NAND idiosyncrasies, modern flash devices behave like an “operating system,” managing all of its internal resources with background operations such as garbage collection, buffer flushing, wear leveling, and read repairs. While important, these are the kinds of operations that pose a threat to latency predictability [15, 25, 27, 30, 49, 53, 71, 76], which is still a fresh problem faced by many storage industries in recent years [4, 31, 50, 57]. Furthermore, with a report that flash devices contribute to more than 19% of the total response time for some online applications [76], more solutions should be explored.

Because the device itself cannot mask the unpredictable latency, a vast amount of research has been devoted to this space. “White-box” approaches—that re-architect device internals [17, 33, 34, 36, 47, 61, 68, 71]—are powerful, but face a high barrier to adoption unless SSD vendors imple-

ment the recommendations. In the middle ground, “gray-box” methods suggest partial device-level modification combined with OS or application-level changes working together in taming the latency unpredictability [38, 39, 40, 58, 76, 77]. However, they also depend on the vendors' willingness to modify the device interface. Finally, more adoptable “black-box” techniques attempt to mask the unpredictability without modifying the underlying hardware and its level of abstraction. Some of them optimize the file systems or storage applications specifically for SSD usage [18, 37, 41, 42, 43, 54, 59, 69, 70], while some others simply use speculative execution [1, 5] but pay the cost of extra I/Os due to being oblivious to storage behaviors. Among all the approaches above, arguably, the most popular solution is speculative execution given its simplicity and capability to mitigate every slow I/O. For example, “hedged requests” [21], a form of speculative execution, is supported in many widely-used key-value stores today [1, 5, 8].

We take a new approach: let the device be the device (black-box) and do not redesign the file systems or applications, but *learn* the device behavior (*i.e.*, not be storage oblivious). The key to our approach is learning. Can we learn the behavior of the underlying device in a black-box way and use the results of the learning to increase predictability, so applications can know in advance whether their performance expectations can be fulfilled? This is a domain that machine learning can likely help. We introduce LinnOS, an operating system that has the capability of learning and inferring *per-I/O* speed with high accuracy and minimal overhead using a lightweight neural network. We show how LinnOS helps storage applications, in particular storage arrays/clusters with built-in failover logic (*e.g.*, flash RAID, Cassandra, MongoDB), achieve extreme latency predictability on unpredictable flash storage.

The biggest challenge for LinnOS is to be as effective and fine-grained as the popular approach, speculative execution, which can mitigate every slow I/O by sending a duplicate I/O to another node or device. Speculative execution's success in increasing predictability comes at the cost of poor resource utilization. The key to avoiding this cost is to know the current activities going on inside the devices and always schedule I/Os to those devices that will provide faster responses.

However, because keeping the abstraction barrier is a fundamental constraint, we need to learn to infer latency and make the inference highly usable. Achieving this requires *learning and inferring on a very fine, per-I/O scale* in a live fashion. To the best of our knowledge, there is no existing learning approach for I/O scheduling that supports such fine-grained learning due to the challenges of achieving per-I/O accuracy and fast online inference. To address this, LinnOS introduces three technical contributions.

First, LinnOS converts the hard latency inference problem into a simple *binary* inference (“fast” or “slow” speed). We take advantage of the typical latency distributions in system deployments, specifically, a behavior that forms a Pareto distribution with a high alpha number. In other words, most of the time (*e.g.*, >90%), the latency is very stable, but occasionally (*e.g.*, <10% of the time), the latency exhibits a long-tail behavior [16, 21, 45, 53]. The behavior of flash storage reflects the same distribution [15, 26]. In this simple view where users only want “slow” I/Os to become “fast,” inferring the exact latencies is overkill. With this intuition, LinnOS comes with an algorithm that monitors the latency distribution of the current workload running on the flash device and computes a roughly optimal threshold that separates the slow and fast speed ranges.

Second, with the binary model, LinnOS employs a simple admission control for clustered storage applications. LinnOS makes a binary inference on every incoming I/O using a light neural network model that infers the I/O speed in advance in a black-box manner without any guide from the device nor application. If the I/O is inferred to be fast, LinnOS will submit it to the flash device; otherwise it will revoke the I/O and inform the application. With this timely and straightforward binary information, the storage application can quickly failover the I/O to another node or device that holds the same replica. Furthermore, resources are efficiently utilized because the original slow I/O has been revoked.

Third, LinnOS balances the accuracy and performance of the neural network. High accuracy but high inference time will lead to a significant per-I/O overhead, especially for modern SSDs. On the other hand, lowering inference time by lowering accuracy will lead to many false inferences that make storage performance hard to reason about.

For high accuracy, LinnOS profiles the latency of millions of I/Os submitted to the device (a natural “data lake”), which will be used to train the neural network. Furthermore, as we convert regression to a simple binary classification, the output accuracy is significantly improved (akin to the simplicity of “cat or dog” image classification). The next challenge is to decide the input features that matter most to improving accuracy. We will present our surprising findings. For example, “important-looking” features such as block offsets, read/write flags, or long history of writes do not play a significant role. In the end, the input features become tractable with only two types of information: the latencies of a few re-

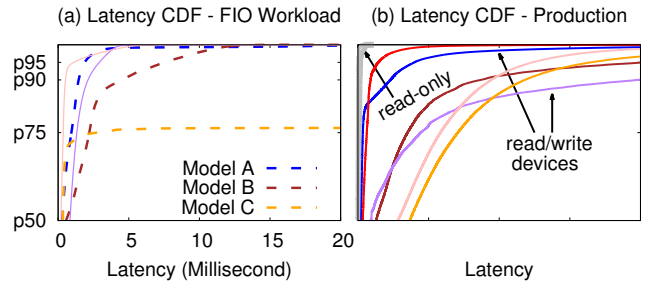

Figure 1: Latency distribution. The figures show CDFs of block-level read latencies, as discussed in Section 2. For the left figure, we ran one FIO workload on five different SSD models (the five CDF lines). For the right figure, we plot the latencies of seven block-level traces obtained from four read-write servers (colored lines) and two read-only servers (bold gray lines) in Azure, Bing, and Cosmos clusters. The x-axis is anonymized for proprietary reasons. The traces are available from Microsoft with NDA.

cently completed I/Os and the number of pending I/Os when those I/Os and the current, to-be-inferred I/O arrived.

For performance, the challenge is to make an inference (admission decision) in sub-10 μ s, which is crucial as we target fine-grained live inference for fast storage devices. While using deeper models with more features can improve accuracy, it will hurt inference latency and would be too expensive for usage in the I/O layer. Through several design iterations, we cut the inference time to 4-6 μ s with minor accuracy loss, achieved with several methods: a 3-layer light neural network, weight quantization, and (optional) 2-threaded/2-core matrix multiplication.

Our evaluation shows that LinnOS supports a wide variety of black-box devices (10 device models tested) and works on real production traces without requiring any extra input from users (*e.g.*, hints about traces/devices or latency deadlines etc.), outperforms industrial approaches such as pure hedging, and beats simple and “advanced” heuristics that we design. Compared to these methods, LinnOS, complemented by hedging based on the learning outcome, further improves the average I/O latencies by 9.6-79.6% with 87-97% accuracy and only 4-6 μ s inference overhead for every I/O.

Overall, we show that it is plausible to adopt machine learning methods for operating systems to learn black-box devices. We conclude with many interesting discussions to explore in the future. LinnOS code is made public.

2 Background

Unpredictability. To motivate the problem, the colored lines in Figure 1a show read latency distribution in a read-write workload running on five different SSD models ranging from consumer SATA and NVMe SSDs to new data-center ones. Model A delivers fast and stable latencies up to about “p98” (the 98th percentile), but models B and C exhibit larger la-

tency tails starting at p90 and p75, respectively. However, when the write operations are converted into read I/Os, the performance becomes highly stable without much latency tail (not shown in the figure). Figure 1b also confirms this in real production scenarios in Microsoft SSD-backed servers. The colored lines show block-level read latencies of read-write servers (more variability), and the gray lines for read-only servers (more predictability). All of these confirm how write-triggered garbage collection (GC), buffer flushing, and other internal operations are contending with user read I/Os. We only address read performance unpredictability because we found write latencies to be (surprisingly) stable as they are absorbed by the internal memory buffer on the device, hence not affected by internal contentions. Write latency spikes only happen when the buffer is full (rarely happened due to internal periodic flush).

Internal complexities. Inferring when a flash drive is exhibiting tail latency is hard given the internal complexities that factor into latency behavior. As a couple of examples, I/Os contend with each other if they fall into the same chip or channel, which depends on the hidden striping and partitioning logic; two user I/Os that go to separate channels might have different fates when one channel is occupied by GC data transfers between the chips in the channel. Our internal findings show that SSDs can have wide layouts (*e.g.*, 32 channels with four chips per channel) or deep layouts (*e.g.*, four channels with 16 chips per channel), where the latter will cause more channel contention. Some SSDs employ large write buffers from 256MB to as small as 12 MB and can periodically flush from every 3ms to as high as one second. As shown in Figure 1, this internal contention can affect from 1% to 25% of all read requests.

In this context, modern storage applications usually apply a “wait-then-speculate” approach that is agnostic about the device’s internal complexities. For example, with hedging, applications wait for a timeout (*e.g.*, the p95 latency), then issue extra speculative I/Os, and use whichever is the faster response. Speculative execution works well for coarse-grained tasks (tens to hundreds of seconds), but is ineffective for flash storage since the waiting is costly when the expected response time is less than a few milliseconds (§5.3).

Machine learning. Before we tried machine learning techniques such as neural networks, we asked whether simple heuristics would be accurate enough in inferring per-I/O speed. For example, one might assume that a long I/O queue length implies longer latencies—a heuristic that works well for spinning disks [13, 62, 64]. However, for SSDs, due to the internal complexities, queue length is not highly correlated with delay (we did not find a high Pearson’s correlation or Spearman’s correlation between queue length and I/O latency). We also created a more “advanced” heuristic, but it did not yield a satisfying result (more in the evaluation section). While it is possible to keep crafting the right

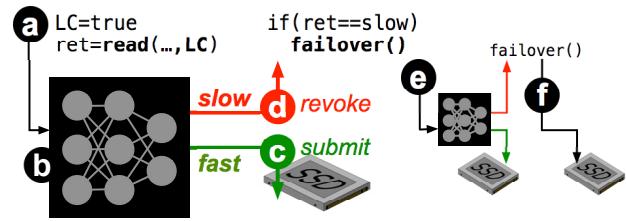

Figure 2: **Usage scenario.** This usage scenario is explained in Section 3.1. “LC” implies latency critical.

heuristic that can adapt to different workloads and device models, we decided to resort to machine learning. Recent operating and distributed systems research successfully employed machine learning for resource allocation and scheduling [22, 23, 24, 28, 48, 51, 52, 60]. A similar exploration targeting the I/O layer can lead to a powerful result, as we show in this paper.

3 Overview

We now give the overview of LinnOS, its usage scenario, architecture, and challenges, followed by its design (§4).

3.1 Usage Scenario

LinnOS is beneficial for parallel, redundant storage such as flash arrays (cluster-based or RAID) that maintain multiple replicas of the same block, as illustrated in Figure 2. (a) With LinnOS, when a storage application performs an I/O via OS system calls, it can add a one-bit flag, hinting to LinnOS that the I/O is latency-critical ($LC=true$), *e.g.*, for interactive services. Such tagging of critical operations has been proposed many times [73, 76], but in our case, the bit is used to trigger LinnOS to infer the I/O latency. (b) Before submitting the I/O to the underlying SSD, LinnOS inputs the I/O information to the neural network model that it has trained, which will make a binary inference: fast or slow. (c) If the output is “fast,” LinnOS *submits* the I/O down to the device. (d) Otherwise, if it is “slow,” LinnOS *revokes* the I/O (not entered to the device queue) and returns a “slow” error code. (e) Upon receiving the error code, the storage application can failover the same I/O to another replica. (f) In the worst case where the application must failover to the last replica, this last retry will not be tagged as latency-critical so that the I/O will complete and not be revoked.

3.2 Overall Architecture

Figure 3 shows LinnOS’s overall architecture, which consists of five main components.

(a) **The model.** At the center of LinnOS is the speedy inference model (Section 4.3) with a light neural network. The model’s input features are information about the current outstanding I/Os and recently completed ones. The model infers

Figure 3: **LinnOS architecture.** The figure displays LinnOS architecture including LinnApp, as summarized in Section 3.2. The two SSD pictures represent the same SSD instance; the left one depicts tracing/training and the right one live inference on the SSD.

the speed of every incoming I/O individually. The model’s output is the binary inference about the I/O (fast/slow).

(b) **Tracing.** To train the model, LinnOS uses the current live workload that the SSD is serving. To have a rich representative dataset, this can be done during normal busy hours. The I/O metadata (block offset, size, read/write) and their resulting latencies are recorded using blktrace. With millions of I/Os collected, this naturally forms the “data lake” of our model. The training data (the collected trace) is expected to be different than the “test data” (the I/Os that will be inferred when the model is activated).

(c) **Labeling with inflection point analysis.** The collected trace is then supplied to LinnApp, a supporting user-level application. LinnApp has three main jobs: labeling, training, and uploading trained weights to LinnOS. Because the model is designed to produce a binary output, the model must be trained with two labels, “fast” and “slow.” Hence, given a latency distribution in the trace, LinnApp runs an algorithm (§4.2.1) that finds the “inflection point,” a latency value that divides the fast and slow latency ranges.

(d) **Training.** With this inflection point, LinnApp labels the traced I/Os with “fast” and “slow” labels and proceeds with the training phase (using TensorFlow). We emphasize the labeling is done automatically *without* human input. This training phase can be run anywhere, on GPU or CPU nodes.

(e) **Uploading weights.** The training phase generates the weights for the neurons in the model that will be uploaded to LinnOS. Because using floating points is not well supported in OS kernel, the weights are converted to integers by quantization. The model is then activated, and LinnOS is ready to make inferences and revoke “slow” I/Os.

3.3 Challenges

Using a machine learning approach for making online, fine-grained inferences on I/O speed requires us to solve the following fundamental challenges.

Figure 4: **Anticipating heterogeneity.** The figure shows heterogeneous trained models, as mentioned in Section 3.3.

High accuracy. The inference must be accurate. We should not revoke I/Os that can be served fast (“false revoke”) or submit those that will be slow (“false submit”). Accuracy depends on careful output labeling and input features selection. If the label classification is too complicated, high accuracy is hard to achieve, e.g., we find that classification by linear bucketing (0-10, 10-20 μ s, etc.) or exponential bucketing (0-1, 2-4 μ s, etc.) is hard to make accurate and should remain as a future work. However, the simple two-class approach (fast or slow) simplifies the output into a binary format, which helps the model achieve high accuracy.

Fast inference. For modern SSDs, while the raw NAND read latency is advertised to be below 100 μ s, we see that for typical production workload on data-center SSDs (Section 5), the actual user-perceived latency is above 200 μ s more than 50% of the time. Given this observation, we believe the challenge is to do decision-making in around 5 μ s, a <3% overhead per I/O. Fast inference depends on input preprocessing, the depth of the layers, neuron complexity, and feature representation. Using deep layers that tend to improve accuracy is not attractive in our problem domain. The input features must be minimized to include only the features that matter. Hence, we must balance accuracy and performance. Moreover, considering that operating systems run on CPUs, the models must be CPU-friendly [67].

Anticipating heterogeneity. In flash arrays (RAID or cluster-based), the user load is not always balanced, and all the flash hardware might not be homogeneous. Because this heterogeneity can lead to different latency distributions observed on different devices, we should not use one global latency value (e.g., 1ms inflection point) to differentiate fast and slow speed for all the devices. For example, 3ms perhaps could be considered fast enough on slower SSDs or the ones with heavier user load. While we do not expect that the heterogeneity will be extreme (e.g., a good storage system typically balances the load very well), heterogeneity is still important to address. For this reason, LinnApp collects per-device traces and trains the model for *every* load-device pair in the array (Figure 4). After the training phase completes, LinnApp supplies the model weights to all instances of LinnOS in a cluster-based array or to one instance of LinnOS in a RAID-based array. In the latter, LinnOS carries N trained

models for the N drives in the RAID. Furthermore, to anticipate workload changes over time, LinnApp occasionally recollects traces (*e.g.*, every few hours) to check if the inflection point has shifted significantly such that the model must be retrained.

4 LinnOS Design

In this section, we describe our solution to the challenges mentioned above. To the best of our knowledge, LinnOS is the first operating system that successfully infers I/O speed in a *fast, accurate, live, fine-grained, and general* fashion. The key to this is the “lightness” of the neural network model that LinnOS employs. This section presents the final design and the principal intuitions about how we get there. We will explain LinnOS design chronologically, from data collection (§4.1), labeling via inflection point analysis (§4.2), the model design (§4.3), and how to improve its accuracy (§4.4) and performance (§4.5), and summarize its advantages (§4.6).

4.1 Training Data Collection

This project started with a simple question: can we infer the performance of every I/O accurately? Since we use machine learning, accuracy depends on the amount of true-signal data available, the more, the better. Fortunately, I/O systems inherently can collect a large amount of data. Given low-overhead tracing tools and hundreds of KIOPS of workload that modern SSDs can serve, collecting a large amount of data for training is not an issue (a large “I/O data lake”).

For every load-SSD pair to model, LinnApp collects traces of the real workload running on the drive. For example, for inferring a production workload performance on a particular SSD in deployment, an online trace will be collected. For every I/O, we collect five raw fields, the submission time, block offset, block size, read/write, and most importantly, the I/O completion time. Because the model input (Section 4.3) does not necessarily take the same raw fields, in this phase, we also convert the fields to the input feature format.

The main challenge here is to decide how long the trace should be. If the behavior of the training data (the latency distribution) is very different from that of the “test” data (the to-be-inferred I/Os), the inference accuracy will drop. In this work, we take a simple approach where we use a busy-hour trace (*e.g.*, midday). In the evaluation (§5.2), we show that for production workloads, a busy-hour trace well represents the other hours, *i.e.*, the inflection point does not deviate much. As mentioned above, to anticipate a dramatic shift in workload behavior, retracing and retraining can be done.

4.2 Labeling (with Inflection Point)

As we employ a supervised classification approach, the model must be trained with labels. If we label every I/O

Figure 5: **Inflection point (fast/slow threshold).** The figures show the results of using a higher, lower, or semi-optimum inflection point (IP) for the fast/slow threshold as explained in Section 4.2. The figure format is latency CDF, as in Figure 1.

with the actual μ s-level latency, there will be too many labels for our problem domain; a user might not care if the I/O is delayed by 1μ s. Another option is to use a linear (0-10 μ s, 10-20 μ s, and so on) or exponential labeling (2-4 μ s, 4-8 μ s, and so on). While these fit better, the model is still hard to make accurate and fast after many design iterations. The accuracy only reached 60-70% because many times, an I/O that should fall into a specific group (*e.g.*, 128-256 μ s) is often mis-inferred to the neighbor groups (*e.g.*, 256-512 μ s)—“a Lhasa Apso dog can easily be misidentified as a Shih Tzu dog.” This is perhaps why prior successes in auto-learning storage performance were only done at a coarse-grained level such as average latency or throughput aggregated for many requests [29, 66, 74].

With all this mind and an understanding of how performance variance behaves in the field [15, 21, 26, 45, 49], we observe that latencies often form a Pareto distribution with a high alpha number [7]. As an example shown in Figure 5a, 90% of the time, the latency is likely stable, but in the other 10% of the time, it starts forming a long tail. Such a Pareto distribution clearly contrasts the fast and slow regions. Hence, a simple conjecture can be made that users only worry about the tail behavior, not the precise latency.

To separate the two regions, we need to find the “best” inflection point (marked with “IP=?” in Figure 5a) for maximizing the latency reduction. Setting the inflection point too relaxed (*e.g.*, the p95 latency in Figure 5b) will make LinnOS treat the relatively slow I/Os between p90 and p95 as “fast” (no failover), reducing the scope for effective retries, hence failing to cut many tail latencies, as highlighted by the small shaded area between the original and projected distributions (more in §4.2.1) in Figure 5b. On the other hand, setting the inflection point too low (*e.g.*, the p80 latency in Figure 5c) will make LinnOS revoke too many I/Os, including those that are supposed to be fast, which will induce unnecessary retry overhead as shown in Figure 5c.

An optimum inflection point implies that for every slow I/O that will be revoked, it is likely that the other replicas can serve it fast within the same time frame. Likewise, for every fast I/O, it should not be failed over. Finding this optimum point will deliver the maximum gap between the original tail-heavy and tail-free distributions, as shown by the large shaded area in Figure 5d. Finding an optimum value how-

Figure 6: **Light neural network.** The figure depicts LinnOS 3-layer neural network explained in Section 4.3.

ever is hard in practice, fundamentally because of the many unknowns: we do not know which replica the request will be failed over to (application dependent); the training data is only an approximation of the future unknown test data; other variability such as CPU or network contention can factor into unknown retry overhead. The next section describes our best-effort algorithm in finding a semi-optimum inflection point for every workload-device pair.

4.2.1 Inflection Point Algorithm

First, during data collection, we collect t workload traces (T_1 to T_t) running on d devices (D_1 to D_d), respectively, where $t=d$. Every trace T_i gives us the latency distribution of the workload running on the device (as in Figure 5a). To find the unique inflection point (IP) value for every T_i-D_i pair, we run a user-space simulation based on random replica selection, with the assumption that latency delay is independent across the SSDs. For illustrative purposes, we use specific device numbers (e.g., D_1) in our explanation below.

(1) For every T_i-D_i pair, we pick a starting IP value where the slope of the CDF is one (likely entering the tail area). For example, if for D_1 , T_1 's 45-degree slope is at $y=p90.5$ and $x=1ms$, then the IP value is initially set to 1ms. (2) For the currently simulated device, D_1 , we run a simulation of one million I/Os, ($r_i=0..1000000$) where each I/O request r_i takes a random latency value from T_1 's real latency distribution. We then simulate LinnOS admission control: if the chosen latency is smaller than 1ms (the current IP), the r_i 's new latency is set to be the same; else, if it is larger than 1ms, it will be revoked and failed over to another randomly selected node (e.g., D_4) where a new random latency is picked from its trace, T_4 , and the admission control is repeated (submit or revoke). We assume three replicas (configurable), hence a request can only be revoked a maximum of two times. (3) The simulation produces the new, optimized latencies for all the r_i in workload trace T_1 that previously went to only one device, D_1 , but now can be redirected as if LinnOS admission control is activated. These optimized r_i latencies form the new CDF (as in the bold blue line in Figure 5d). Using the original and new CDFs, we can calculate the *area difference* (the shaded "boost area" in Figure 5d), which represents the latency gain if 1ms (p90.5)

is used as the IP value. (4) Still, for D_1 , we repeat all the steps above by moving ± 0.1 percentile within the ± 10 percentile ranges from the initial IP value. For every new IP value, the simulation gives a new boost area. We now can pick the IP^{max} , the IP value that gives us the *largest (positive) boost area*, which will be used as the fast-slow threshold in training the model for device D_1 . (5) We repeat all the steps for other devices (D_2 , D_3 , etc.). At the end, for every T_i-D_i pair, our algorithm generates a unique IP_i^{max} value. All these steps are repeated upon recalibration (§4.4).

4.3 Light Neural Network Model

Before we decided to build a light neural network model, we explored various learning methods such as logistic regression, decision trees, and random forests. We found that the accuracy only ranges from 17-84%, while a basic neural network can reach a better accuracy. Although it is possible to continue optimizing each of these methods to its full potential, we decided to start from an acceptable baseline that our initial neural model delivered. Below, we describe our final model (Figure 6), from input features, their representation, to the neural layers. We will emphasize how we use storage intuitions to design the model, as opposed to brute-force.

Input features. To infer the speed of every I/O, our model takes three inputs: (a) the number of pending I/Os when an incoming I/O arrives (in the number of 4KB pages, including the incoming I/O), (b) the latency of the R most-recently completed I/Os, where we set R as 4, and (c) the number of pending I/Os at the time when each of the R completed I/Os arrived. We now reason about these necessary inputs.

Deciding the first feature is straightforward—an I/O latency typically correlates with how many I/Os are currently pending. The unit we use here is the number of 4KB pending pages, and the reason is that the lowest granularity of striping inside SSDs is typically at the page level and the main contention is at channel and chip level.

While for disks, the first feature might be sufficient for inferring single-spindle performance, for SSDs, the other two features are required. In essence, to speculate whether the SSD is currently busy internally, we need to record a small piece of historical information, the latencies of the last four I/Os, as well as how many pending I/Os existed when those I/Os arrived. Put simply, if recent I/Os experienced a long delay without many pending I/Os, then the model could learn that there is likely an internal contention due to device-level activities such as GC, internal flushing, or wear leveling. In this case, the model will suggest revoking incoming I/Os until the number of pending I/Os drops substantially so that the device can provide fast responses despite heavy internal activity. Once the device resumes serving I/Os, the model can tell whether the device-level contention is over from the returned latency values.

Our features above look simple because we have removed

unnecessary features after many design iterations. For example, we surprisingly found that important-looking features such as block offsets, read/write flags, or long history of writes do not significantly improve accuracy. We make several conjectures. First, on read/write flags, although NAND-level read/write latencies differ, almost all medium/high-end SSDs employ write buffering. Thus, the problem of read-behind-write is no longer observable. More likely observable is read-behind-buffer-flush delays, which can be learned from our input features. Second, on block offsets, because we target production workloads and the fact that SSDs typically stripe incoming I/Os uniformly across all channels and chips (or with some bounded partitioning), the workload is likely to be evenly scattered, hence block offsets do not really matter for learning. In other words, scenarios where a batch of incoming I/Os with block offsets that simultaneously hit only one chip rarely happen in the field. Third, on history of writes, internal activities such as GC and buffer flush often happen in a short burst, hence they can be sensed by just observing the speed of the last four I/Os. These are surprising but fortunate findings because using just a small set of features will reduce the model's overhead.

Input format. The next challenge is to choose the right input format to be fed to the neurons. First, for the R value, if accuracy is the only important metric, we should record more completed I/Os (the higher R , the better), but it would prolong inference time as the number of neurons would increase. We found that $R=4$ suffices for balancing performance and accuracy.

In another simplification, we format the number of pending I/Os into three decimal digits. For example, the format for 15 pending I/Os is three integers $\{0,1,5\}$. Three digits suffice as device queue length of over 1,000 is rarely heard of. Similarly, for the latencies of the recent completed I/Os, we break the μs latency value into four digits. For example, a latency of a recent I/O that completed in $240\mu\text{s}$ will be formatted as four features $\{0,2,4,0\}$. Latencies larger than $9,999\mu\text{s}$ will be capped to $\{9,9,9,9\}$. In total, our model takes 31 input features, each a one-digit decimal number.

Reformatting the original integers into decimal digits is an effective trade-off. If we use bits and supply every bit to every neuron, there will be too many neurons that increase the model size and hurt inference time. On the other extreme, if every neuron takes a raw integer value, the neurons need to learn over a wide input range, which makes learning/training harder (e.g., latency value can range from $1\mu\text{s}$ to over $9,999\mu\text{s}$). With decimal digits, we make the neuron learning bounded within a small range of 0 to 9.

The network. The final model is a fully-connected neural network with only three layers ("light"), including one input/preprocess layer, one hidden layer, and one output layer, as shown in Figure 6. All the neurons are regular linear neurons ($y=wx+b$).

The input layer is supplied with the 31 features described above. The raw information from the block layer is converted to the feature format, in an offline way for training and an online way for live inference. For the latter, with some programming optimization, we can achieve $O(1)$ pre-processing overhead. Next, the hidden layer consists of 256 regular neurons. This layer uses RELU activation functions for its low computation cost and ability to support non-linear modeling. More neurons will cause longer inference time and fewer neurons less accuracy. Lastly, the output layer has two neurons with linear activation functions. We use an `argmax` operator to convert the output to a binary decision (e.g., $\{0.4,0.6\}$ to $\{0,1\}$). Overall, this design makes the network lightweight and easy to integrate into the OS, while balancing inference accuracy and performance.

Preceding design iterations. Here we briefly describe how we reach the current design. We started by using the I/O offsets in binary format (32-bit) as the input features since the device FTL mapping basically uses I/O offsets to decide where the I/Os go, which defines the resource contention. This setting allows the learning models to achieve higher accuracies (up to 99% for some traces), however it has a heavy model and high inference overhead, which is impractical for real-time usage. We further trimmed the heavy model but could not find a reasonable tradeoff between generality and inference overhead. As a result, we took a step back from the fine-grained features and switched to more aggregate ones, and finally reached the current design.

4.4 Improving Accuracy

To further improve the model accuracy, we perform false-submit reduction via biased training, model recalibration via retracing/retraining, and inaccuracy masking with high-percentile hedging.

Reducing false submits. An accurate inference means LinnOS submits I/Os that will be fast (true negative) and revokes those that will be slow (true positive). Reversely, inaccurate cases can be categorized into (a) "false submit" (false negative) wherein the model believes the request will be served fast, making LinnOS submit the request to the device, but the request will take longer than the fast-slow threshold, or (b) "false revoke" (false positive) where the I/O is revoked, but in fact, it can be served fast by the device.

Using the same system intuition on typical latency distributions in the field (Section 4.2), we found that *reducing false submits* is far more important, while false revokes are more tolerable. When the storage devices of a cluster exhibit similar tail behavior (high-alpha Pareto), the *probability* that peer devices are simultaneously busy is relatively *small*. For example, with three replicas and $P\%$ busyness, the probability that all the replicas are busy around the same time is $(P/100)^3$ (e.g., 0.000125 with 5% busyness). Another factor is that, with faster networks, a failover cost can be as low

as 1-6 μ s for flash arrays across PCIe or Fiber Channel or 5-40 μ s across Ethernet [3] (plus some negligible software overhead).

To summarize, the wrong inference penalty is small for false revokes but high for false submits. In the latter, the I/O will be “stuck” in the device and cannot be revoked. This motivates us to use *biased training* for reducing false submits by allowing more false revokes. We do this by customizing the categorical hinge loss function with a multiplier that puts more penalty weights for false submits, which makes the trained models favor false revokes.

Recalibrating. Another source of inaccuracy happens when the inflection point computed over the training data does not represent the same threshold of the “test” data (the workload during live inference). This can happen under significant workload changes that cause shifts in the latency distributions of the nodes in the cluster. Fortunately, our evaluation of production traces shows that latency distributions do not widely shift across hours (§5.2). However, to anticipate this scenario, re-tracing and re-computation of inflection point analysis can be done periodically every few hours. If in the new workload-device pair, the inflection point has shifted by five percentiles, LinnApp will retrain the model using the newly collected trace and re-upload the new trained weights to the device. Running `blktrace` during the busiest hour in the production workloads we use only generates 300 MB of data (85 KB/s of trace writes) and increases CPU overhead by 0.5% (only relevant parameters are traced).

Masking small inaccuracy. Our methods above managed to increase accuracy up to 98%. Just like other neural networks, achieving 100% accuracy is fundamentally hard and usually implies a lack of generality. Within the small inaccuracy, the long latency tail due to false submits still needs to be circumvented. This is where we marry learning and hedging [21]. When the false submit rate¹ (Section 5.4) is significant (e.g., >5%), we use the rate as an indicator for the hedging percentile value. For example, if 6% of the inferences produce false submits, then p94 hedging will be applied. When the false submit rate is lower, we round up to conventional p95 hedging. Though sometimes this design issues extra I/Os, we show that it can further improve the performance (§5.3).

4.5 Improving Inference Time

A large part of deep neural network (DNN) research mainly focuses on how to structure even larger networks to achieve the highest possible accuracy [11]. Strict latency is often not a constraint. However, putting a neural network into the storage layer poses a unique challenge. Our goal is to reach

¹To clarify, different from conventional way of calculating false positive/negative, in this paper, the false submit rate is based on the submit decision and the actual resulting latency.

around 5 μ s of inference time (as discussed in §3.3), and although the 3-layer design is fundamental to reach the goal, we made further optimizations.

Quantization. First, neuron weights are by default in floating points for improving accuracy, but it is an overkill for our purpose. Some of the major storage functionalities that define contention are striping and partitioning using mod operations over integers, which does not require ultra-high precision. Besides, floating point calculations are expensive and hard to manage inside the OS. Hence, we adopt DNN quantization by maintaining precision of three decimal points; the trained floating-point weights are converted to integers with precision of three decimal points. DNN quantization is a popular technique to reduce the space, power, and computation cost of DNN on mobile-platform and IoT devices, albeit some loss on accuracy [20, 32, 72]. In our case, the accuracy loss from quantization is less than 0.1%.

Co-processors. Second, using additional accelerators such as GPUs and TPUs may be possible in the future, but currently, they are optimized towards throughput and do not easily interact with host kernel code. If we move the inference to GPUs, the cross-communication would add more overhead. Furthermore, technology trends suggest that 100-200x improvement on inference latency can be foreseen in the near future with more advanced hardware [6]. This may make LinnOS faster in the future, especially as storage devices are also getting faster. However, until this technology arrives, we show that LinnOS can opportunistically use co-processors (if available) to reduce the average inference time from 6 to 4 μ s with 2-threaded optimized matrix multiplication using one additional CPU core.

4.6 Summary of Advantages

With all of the techniques, LinnOS delivers advantages in various dimensions, which we show in the evaluation.

- *Performance predictability.* The most important advantage is that LinnOS helps storage applications achieve predictable performance on flash arrays, outperforming other popular methods.
- *Automation.* LinnOS infers I/O operation latency by learning from millions of I/Os and automatically trains and produces neuron weights for different workloads and devices. Storage developers do not have to tweak and configure heuristics manually.
- *Generality.* To achieve predictability, LinnOS does not require device-level modification nor a heavy redesign of file systems or applications. Storage applications simply need to tag latency-critical I/Os. Failover/retry logic is already standard in many storage applications with data replicas.
- *Timeliness.* With fast inference, the application can failover as soon as the `slow` error code is returned, without the need to wait for a timeout.

- *Efficiency.* With auto-revocation, LinnOS eliminates duplicate I/Os suffered in hedging. Some production systems do not use hedging for the same reason and instead use a more efficient method such as “tied requests,” where clones are sent but when one of them is served, the duplicate is canceled [21]. Similar to this “clone-then-cancel” method, our “revoke-then-failover” also avoids duplicates. Furthermore, while some implementation of tied requests burdens the application layer [21], LinnOS supports I/O revocation inside the kernel.
- *Simplicity.* We do not require applications to supply an SLO value such as a deadline [14, 25, 63, 75]. I/O system calls today do not accept SLO info, arguably because setting the proper SLO is not easy [35, 46]. LinnOS simplifies this with an auto-tuned fast/slow binary classification.

4.7 Implementation Complexity

LinnOS extends Linux v5.4.8 in 2170 LOC within the block layer, mostly for the neural network model (written in C) and the simple revocation mechanism. The memory space needed for one neural network model (in total 8706 weights and biases) is 68 KB of kernel memory. LinnApp is written in 3820 LOC including data collection, analysis, labeling, training (using TensorFlow), and quantization. We make the source code public (Section A).

5 Evaluation

In this section, we first describe our evaluation setup (Section 5.1) and then present the results that answer the following important questions:

- *Stability* (Section 5.2): Is our inflection point algorithm stable enough for production workloads?
- *Latency predictability* (Section 5.3): Does LinnOS successfully deliver more predictable latencies compared to other methods?
- *Model accuracy* (Section 5.4): How accurate is the LinnOS neural network in inferring per-I/O speed?
- *Trade-offs* (Section 5.5): What are the performance and accuracy trade-offs in LinnOS?
- *Others* (Section 5.6): How does LinnOS work on other public traces? Can LinnOS support full-stack storage applications? What is the CPU overhead?

5.1 Setup

We present the evaluation workloads, devices, experiments, and methods to which we compare.

Workloads. Our ultimate goal is to evaluate whether LinnOS can help real production scenarios. We use SSD-level traces from Microsoft Azure (AZ), Bing Index (BingI/BI), Bing Select (BingS/BS), and Cosmos (CO) servers. Each server type contains I/O traces for six devices. The average

trace contains 36 hours of I/O operations.² For training data, from each of the four server types, we pick the three busiest device traces and then pick the busiest hour (same three hours); we limit to three due to the number of (expensive) enterprise SSDs that we have (more below). For the “test data” that is dedicated for live experiments, we pick a random time slice from other busy hours, hence training and test data do *not* overlap. Overall, the training and test data do not occupy the entire available traces.

SSD devices. For performance evaluation, we show how much LinnOS helps flash arrays deliver predictable latencies. We prepared two flash arrays with consumer (“C”) and enterprise (“E”) configurations. The former connects an array of three homogeneous SM951 consumer-level SSDs, and the latter forms three *heterogeneous* enterprise-level SSDs, Intel P4600, Samsung PM1725a, and WD Ultrastar DC SN200. We assume every block is replicated three times across the devices, a typical setup for consumer-facing storage servers. For both configurations, the machine has a 2.6GHz 18-core (36-thread) Intel i9-7980XE CPU with 128GB DRAM. Unless otherwise stated, we do not use accelerators (§4.5). The overhead for failing over revoked I/Os is 15μs. For accuracy evaluation, beyond these four flash models, we also use Intel SSDSC1BG40, Intel SSDSC2BX01, Intel P3700, Intel P4510, Intel S3700, and Samsung 960 EVO, for a total of 10 models. Prior to this evaluation, all devices have been used for months with many workloads that reach the devices’ full capacities, hence mimicking devices in the field.

The experiments. For performance evaluation, the experiments are performed with a storage application that executes the traces on the flash arrays, where all the devices serve read/write workloads. For example, in one experiment, the application simultaneously executes three different Azure traces on three separate SM951 devices in the consumer flash array and records the latencies of completed read I/Os. The application has a failover capability to complete revoked I/Os at other devices (as shown earlier in Figure 2). All read I/Os are marked as latency-critical.³ We are also aware that the traces were collected on medium-end devices at Microsoft (in 2016). Hence, for our high-end flash array configuration, we have to mimic a heavier workload by re-rating the traces to be more intensive. Our methodology is that for each re-rated trace, the resulting baseline latency distribution (after running it on the high-end device) should be similar to the latency distribution in the original trace.

Table 1 shows the I/O characteristics of the re-rated traces. Typically, running these re-rated traces on our drives shows a low slack (<5% of all I/Os), where SSDs see no pend-

²The traces are available from Microsoft to the academic community with NDA.

³We assume that no write I/Os are latency critical as they are usually absorbed by write buffers. However, if needed, our techniques can be easily integrated with kernels/applications that support write re-routing (e.g., AutoRAID, RAID+).

Test Trace	Avg IOPS	Max IOPS	R:W Ratio	Avg I/O Size Read/Write	Max I/O Size Read/Write

Table 1: **I/O characteristics of re-rated traces (§5.1).** The upper part (first four rows) is for the consumer-level flash array and the lower is for the enterprise-level one. Every max-IOPS value is measured within a 10-second window.

ing I/Os for a few milliseconds, and noticeable burstiness (5-30%), where I/Os need to wait in the OS as the SSD queues are full. We believe this accurately emulates the slack and tail behaviors seen in real deployments. Also, the workload bursts across devices are highly correlated, which, in some cases, can cause inevitable long-tail behaviors that no failover can handle. However, in real runs we find that the internal busyness of the devices is not necessarily correlated due to device-level complexities, as LinnOS shows great improvement by evading the underlying device idiosyncrasies (§5.3). All the experiments are repeated three times, and no significant variance was observed.

Methods compared. We perform an extensive evaluation that compares eight methods: baseline, cloning, constant-percentile hedging (e.g., at p95 latency), inflection-point hedging (with our algorithm), simple heuristic, advanced heuristic, LinnOS (by itself), and LinnOS with high-percentile hedging. Comparing LinnOS with white-box approaches [25, 30, 44, 56] is out of the scope of the paper because LinnOS targets black-box devices and we do not have access to an array of programmable devices.

5.2 Inflection Point (IP) Stability

One of the contributions in this paper is finding the semi-optimal fast/slow inflection point (IP) that brings a balance between timeliness and overhead (Figure 5 in Section 4.2). Table 2 shows the IP values our algorithm computed for every workload-device pair. The three numbers in every cell represent three different traces (from the same server type), each running on one of the SSDs in the flash array. As shown, the IP values widely range from p72 to p98, which highlights why a constant timeout value is not optimal and hurts performance. These IP values will be used for fast/slow labeling and training, which then generates a

	Consumer	Enterprise
Azure	p73.3, p77.0, p91.4	p91.0, p93.2, p97.8
BingIndex	p80.0, p94.5, p98.5	p80.1, p83.3, p97.0
BingSelect	p72.0, p76.9, p87.2	p75.3, p83.7, p86.8
Cosmos	p73.4, p82.5, p84.1	p83.2, p84.8, p95.1

Table 2: **Inflection point (IP) settings.** This table, as explained in Section 5.2, shows the IP values that our algorithm in Section 4.2.1 computed for every workload-device pair.

unique set of weights for each device.

We chose a busy hour ($T=1\text{hr}$ window) to collect the training data and calculate the IP values in that time slice. Figure 7 shows the stability of our methodology by plotting the max IP deviations in percentile (y -axis) within the next 20 hours (x -axis) for various T window values. For example, if the chosen hour exhibits p85 IP, but a subsequent hour exhibits p75 or p95 IP, then the deviation is 10 percentiles ($y=10$). The graph shows that if $T=1\text{hr}$ window, the deviation is bounded within five percentiles in the next 15 hours, indicating that frequent retraining is unnecessary. If T is shorter (e.g., 15min window), the deviation is more apparent (needs frequent retraining, which typically converges within 15-20 minutes on CPUs, due to LinnOS’s light model). If T is larger (2hr window), the gain is not significant. For generality, the figure is the result of our algorithm simulation on all the datasets (36 hours per trace, 24 traces, four server types).

The cost of delayed retraining depends on the deviation. Let us take an example of a model trained for p95 (5ms), but then the workload deviates such that the real IP is at p90 (10ms) because the workload becomes more write-intense. In this case, LinnOS (still using 5ms) will over-revoke many I/Os that could have finished before 10ms (more false revokes). If the failover overhead is negligible, this will not cause much harm. Another scenario is when the workload deviates such that the IP moves up to p99 (3ms). Here, LinnOS would over-accept (more false submits) because 3-5ms latency is inaccurately considered “fast,” but actually can be made faster. This is where LinnOS without retraining hurts.

5.3 Latency Predictability

We now evaluate LinnOS’s success in achieving extreme latency predictability. Figure 8 shows the average I/O latencies (user-perceived) on the two flash arrays (consumer and enterprise) across the eight methods. In more detail, Figure 9 shows the latencies at specific percentiles (p80 to p99.99 in the x -axis). Below we dissect the strengths and weaknesses of every method. We start from the baseline, then we jump to “LinnOS+HL” (the best outcome), followed by the others.

Baseline. The Base lines in Figure 9 confirm unpredictability of flash storage with latencies that spike almost exponentially in between p95 to p99.99, increasing the average latencies to 1.3–6.5 times compared to our best cases

Figure 7: **IP stability.**

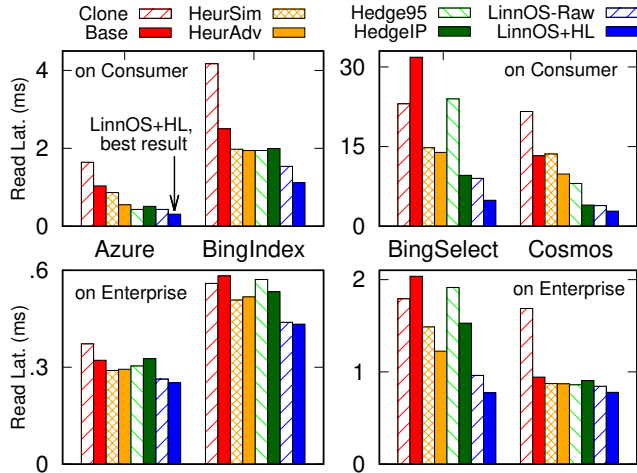

Figure 8: **Average latencies.** The figures show that LinnOS consistently outperforms all other methods, as explained in Section 5.3. The top and bottom graphs represent experiments on the consumer and enterprise arrays, respectively.

(Figure 8). Clearly, flash arrays with data redundancy should adopt tail-cutting methods to achieve higher predictability.

LinnOS+HL. This label represents the LinnOS method combined with high-percentile hedging for masking the small inaccuracy that is intrinsically hard to eliminate in a neural network (Section 4.4). That is, to compensate for the inaccuracies that cause false submits, our application sends a duplicate I/O after pX latency time has elapsed, where X is the smaller of 95 and $(1 - \text{false submit rate}) \times 100$. We use the false submit rates from the training process (Figure 10 in Section 5.4).

[Key outcome] \rightarrow The average latencies in Figure 8 show that LinnOS+HL consistently outperforms all other methods across different workloads and platforms. On average, LinnOS+HL reduces latency by 9.6-79.6% compared to p95 hedging (Hedge95), 14.2-49.5% to hedging with our IP algorithm (HedgeIP), and 10.7-71.2% to an advanced heuristic (HeurAdv). These speed-ups are a product of the stable latencies; in Figure 9, LinnOS+HL lines exhibit stable latencies even at extremely high percentiles, p99 to 99.99. These results bring a positive conclusion that the downsides of LinnOS (a $15\mu s$ failover overhead including a $6\mu s$ per-I/O inference cost and the inaccuracies) are outweighed by its effectiveness in delivering predictable latencies.

LinnOS (Raw). Here we show LinnOS efficiency even without hedging (*i.e.*, revoke+failover without I/O duplication). The LinnOS-Raw bars in Figure 8 shows that LinnOS by itself is effective enough, only 1.3-45.7% worse than LinnOS+HL, and compared to p95 hedging, LinnOS-Raw reduces latency by 0.3-62.3%, and to an advanced heuristic, by 3.0-60.7%. Figure 9 details why adding hedging is useful. At high percentiles, above p99, LinnOS-Raw starts ex-

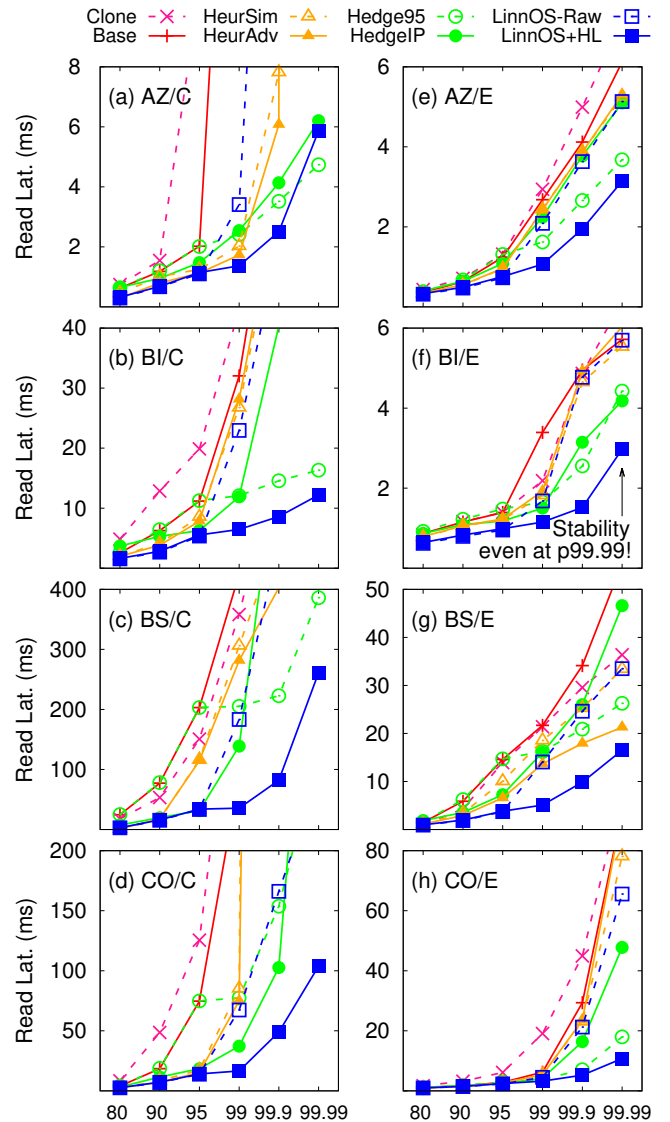

Figure 9: **Percentile latencies.** Explained in Section 5.3, the figures show that LinnOS +HL delivers the most predictable latencies (y-axis) across all percentiles (x-axis), even at p99.99. In Figure (a), “AZ/C” means Azure running on consumer array.

hibiting high latencies (due to false submits). Learning from the “small-tail” behavior of hedging (*e.g.*, the Hedge95 lines), we combined the best of the two in LinnOS+HL.

Hedging at p95. Sending a duplicate I/O after a p95-latency timeout has elapsed is a popular method used in the field [12, 21]. Figure 9 shows that, in general, this method is effective in cutting latency tail but generally incurs *higher* latencies than LinnOS+HL. This is because Hedge95 needs to *wait* for the timeout to happen before sending the duplicate I/Os, while LinnOS returns a timely revocation that allows the application to failover quickly. As the implication, Hedge95, on average, is slower than LinnOS+HL or even

LinnOS-Raw (Figure 8).

Hedging at IP. Many of the IP values shown in Table 2 are below p95, which raises the question of whether hedging at IP would be better than at p95. The average values in Figure 8 show a mixed result. On the consumer devices, HedgeIP improves upon Hedge95 by 2x for heavy workloads BingS and Cosmos, but loses by up to 15% in light workloads Azure and BingI. Similarly, on enterprise devices, HedgeIP wins in BingS while slightly losing in the others. Upon further investigation, we see that, for example, in consumer devices, Azure and BingI latencies are generally fast (<2 and 10ms respectively, as shown by the y -axis in Figure 9a-b), hence are *sensitive* to the extra load from duplicate I/Os; HedgeIP in our experiments are sending more duplicates than Hedge95. Nevertheless, our experiments show that for most of the workloads, HedgeIP is more effective than Hedge95, hence systems with hedging can adopt our IP algorithm.

Simple heuristic. The first heuristic we wrote, “HeurSim,” is based on a popular heuristic for spinning disks: if the device queue length (the number of outstanding I/Os) is larger than a threshold, the incoming I/O should be retried elsewhere [13, 62, 64]. For the threshold, we use a similar method as HedgeIP, but instead of using IP latency value, we use IP queue length. That is, we first profile the queue length distribution during tracing and then select the queue length at the IP percentile as the threshold for revoking. Figure 8 shows that HeurSim only gives a small improvement over the baseline and is far from the best case. In short, it is not smart enough to infer device-internal disruptions.

Advanced heuristic. We extend HeurSim to a more “advanced” heuristic, HeurAdv. For comparison fairness, we reuse the same intuition we had in building LinnOS and apply it to HeurAdv. An additional task that HeurAdv performs is scanning the last N completed I/Os ($N=4$, same as in LinnOS) and if this history shows a slow I/O (“slow” as defined in §4.2) but with a low queue length (less than the median), it will mark the drive as “internally busy.” In this state, incoming I/Os will not be admitted unless the queue length drops to a low value (less than the lower-quartile queue length). The state will not be changed from “busy” to “normal” until it sees recent I/Os become fast (“fast” as defined in §4.2).

[2nd key outcome] → Figure 8 shows that HeurAdv improves upon HeurSim in most cases, but still loses from other methods. We would like to note that we spent several weeks tuning the heuristic to the “best” outcome we can achieve. Continued expansion and tuning of the heuristic is possible. However, the main difficulty that will arise is the *large design space* of parameters (normal/busy states, median and lower-quartile queue lengths, etc.) that must be optimally and *manually configured* for different workloads and devices. This is where we show that machine learning helps. The use of a lightweight neural network allows us to focus on deciding what features matter, but at the same time letting the model

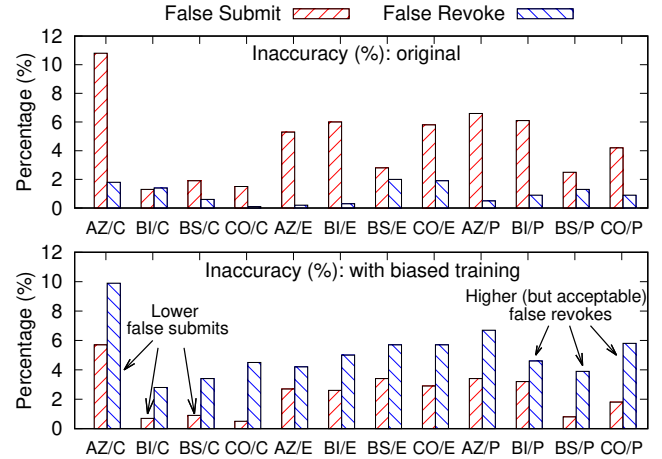

Figure 10: Low inaccuracy. The figure shows the percentage of false submits and false revokes. Note that only false submits really matter (see Section 5.4). Additionally, “P” represents other device models that we can access from a public cloud. For graph readability, here for “P” we only show the results for one device model, while the observations stand across the rest. In total, the accuracy evaluation covers 10 device models (1C+3E+6P).

learn and reverse-engineer SSD behaviors. In our case, LinnOS neural network *auto-trains all the 8706 weights* for different devices and workloads.

Cloning. This method is essentially p00 hedging, sending a duplicate I/O for every I/O on the outset. Although SSDs are fast and have internal parallelism, Figure 8 shows that Clone is mostly worse than the baseline due to the 2x load.

5.4 (Low) Inaccuracy

We now measure LinnOS inaccuracy by counting the number of false submits and false revokes (Section 4.4). The live experiments can only measure the former but not the latter. This is because revoked I/Os are never submitted to the device, hence we never know whether the revoke is accurate or not. Thus, for this evaluation, we measure inaccuracy in an offline way using TensorFlow, just like the training phase. However, note that both the training and test data were collected from running the workloads on real flash arrays (*i.e.*, not simulated data). Just like before, we use 1-hour data sets for training and then pick three different 1-hour data sets for testing accuracy, and measure the average inaccuracy.

Figure 10 shows the inaccuracies before and after we use biased training. To recap Section 4.4, false submits are more dangerous than false revokes. Without bias, the top graph shows that the false submit rates (red bars) are high, between 1.3% to 10.8%. With biased training, as shown in the bottom graph, we successfully lower the false submit rates to 0.7-5.7%, by *shifting* the inaccuracies to false revokes, which are more tolerable as explained in Section 4.4. For example, let us assume an inferior scenario of p80 inflection point (*i.e.*,

Model:	A	B	C	D	E
Acc. (%)	-(3-12)	-(1-4)	+(1-2)	+(4-5)	+(8-12)
Perf. (μs)	-4	-1	+40	+94	+1670

Table 3: **Trade-offs balance.** This table is explained Section 5.5. All the $+/-$ of accuracy and performance values are compared to our final neural network model described in §4.

20% slowness), which means the probability that all three replicas are slow is $0.008 ((^{20}/_{100})^3)$. Thus, although we have spiked up the false revokes to 2.8-9.7% in Figure 10b, only 0.008 of these false revokes probabilistically will result in slow I/Os. Finally, as mentioned before, for masking the dangerous low inaccuracy (the 0.7-5.7% false submits), combining LinnOS with high-percentile hedging (LinnOS+HL) led to a powerful result.

5.5 Trade-offs

Table 3 shows some possible trade-offs between inference overhead and accuracy (models A-E, with accuracy involving both false submits and false revokes). On one hand, if lower overhead is preferred and some accuracy loss is acceptable, then one option is to trim the input features and the model. For example, in model B with $R=3$ (i.e., including fewer history I/Os instead of $R=4$) can reduce the number of input features from 31 to 24 and lower inference overhead, $-1\mu s$, but it will bring some accuracy loss, $-(1-4\%)$, due to fewer inputs. Or, if even lower overhead is favorable, then in model A we can further cut the input features ($R=2$, 17 features) and use a slimmer hidden layer (from 256 neurons to 128), resulting in a lower inference time, $-4\mu s$, while bringing larger accuracy loss, $-(3-12\%)$.

If higher accuracy is needed, then we can bring in more features and heavier models. For example, in model C, by adding one more hidden layer to the model, we can gain $+(1-2\%)$ higher accuracy, while the inference overhead rises by $+40\mu s$. Taking a step further, we can involve more features (up to $R=10$ and 73 features) and more hidden layers (three layers with 256-512-256 neurons) to push the accuracy gain by $+(4-5\%)$, but an increased overhead, $+94\mu s$. The extreme model E includes block offsets in the input features (2048 features in total) and applies a model with five hidden layers (with 512 neurons each). For some traces, this model improves the accuracy by $+(8-12\%)$, but its inference overhead, $+1670\mu s$, is extremely high for live inference.

5.6 Other Evaluations

5.6.1 Additional Performance Evaluations

Other possible manually-tuned heuristics. To get a sense of how much performance a heuristic can ultimately reach, we pick several 10-min slices from the traces and manually tweak the adjustable parameters of *HeurSim* and *HeurAdv* with various thresholds until an optimal outcome is achieved.

In a nutshell, we start with the generic *HeurSim* and *HeurAdv*, evaluate them with the sliced traces, track the high-latency I/Os that are not revoked, update the thresholds to catch these I/Os without causing too many false revokes (e.g., $>15\%$), re-evaluate and repeat the entire process until an approximate optimum is observed. This approach is indeed capable of granting heuristics a further stretch. For example, we see a few cases where tweaked heuristics can outperform LinnOS-Raw by up to 20% at p95. However, this tuning procedure is onerous and impractical in real runs as the repeated manual tweaking is too slow to catch up with the fluctuation of incoming workloads.

LinnOS+H99. We also try LinnOS+H99, which employs p99 hedging that only generates 1% extra I/Os. Figure 11a shows one of its comparisons with LinnOS+HL. Generally, LinnOS+H99 encounters a larger tail area due to longer waiting, but responds faster at lower percentiles due to less extra I/Os. With that, sometimes LinnOS+HL can show slightly worse average latencies (up to 3%) than LinnOS+H99 (Figure 11b). However, in a large majority of our benchmarks, LinnOS+HL achieves 1.7-39.2% better average latencies than LinnOS+H99.

Figure 11: **LinnOS+H99.** 1.7-39.2% better average latencies than LinnOS+H99.

5.6.2 On Public Traces

Beyond our evaluation with Microsoft traces, Figure 12 shows a quick evaluation with the latest SSD traces published on the SNIA website [9] run on our consumer flash array. The result confirms that LinnOS also exhibits low inaccuracy (Figure 12a) and substantial latency improvement (Figure 12b).

5.6.3 MongoDB on Different Filesystems

To see how data applications can benefit from LinnOS, we set up a local MongoDB replica set on top of our three enterprise drives with homogeneous filesystem settings. For each type of filesystem, MongoDB receives 120K random read requests, and all drives run Microsoft traces as background noise when serving MongoDB requests as latency-critical I/Os. Here, we focus on high-percentile latency (e.g., p99 latency) since the average latency is largely impacted by filesystem buffering, while the tail latency reflects the raw performance from the devices.

Figure 13 shows that with LinnOS, MongoDB achieves

Figure 12: **On public traces.** As explained in §5.6.2.

much more predictable performance. For example, with all underlying devices formatted with f2fs, LinnOS reduces the p99 latency by 76.7%. Moreover, LinnOS only requires minor changes to MongoDB and filesystems: 50 additional LOC. For example, the filesystems should directly return LinnOS’s error code to the applications instead of conducting unnecessary self-checking, and MongoDB needs to be slightly modified to reuse its built-in failover logic.

5.6.4 Computation Overhead/Optimization

CPU overhead. A reasonable concern is that if the entire OS has many neural networks, then it will be CPU-intensive. Across all the benchmarks and SSDs, paired with a lightweight neural network, each device only costs 0.3–0.7% of the host CPU resource, making LinnOS practical for large-scale deployments.

Co-processors for acceleration. As mentioned in Section 4.5, additional processors can be utilized to speed up the inference. By utilizing one more CPU core, LinnOS can reduce the inference overhead by 36% (to 4μs), with the maximal CPU usage increased up to 1.4% per device.

6 Conclusion and Discussion

We have presented LinnOS, to the best of our knowledge, the first operating system capable of inferring the speed of every I/O to flash storage. We have shown the feasibility of using a light neural network in the operating system for making frequent, fine-grained, black-box live inferences. LinnOS outperforms many other methods and successfully brings predictability on unpredictable flash storage. We also believe that LinnOS’s success leads to exciting discussions and questions that can spur future work:

On performance. Though LinnOS inference overhead (4–6μs) is less noticeable compared with the access latency of current SSDs (e.g., 80μs), it could become problematic as SSDs march to 10μs latency range. Also, the consumption of computation resources can increase substantially as the IOPS grow. How to further lower the inference cost (e.g., to 1μs) to support faster devices and higher throughput? Can advanced accelerators help accelerate OS kernel operations? Can near-storage/data processing help? Can we skip the inference when the outcome is highly assured (e.g., the queue length is very low)? Can we cache the approximation results for popular predictions?

Figure 13: **MongoDB on different filesystems.** This figure shows that LinnOS can easily help data applications achieve more predictable latency (§5.6.3).

On masking the inaccuracy of machine learning. As machine learning (e.g., LinnOS) can never achieve 100% accuracy, how should “ML-for-system” solutions mask the cases that machine learning fails to catch, while still benefiting from its generality? Is marrying learning and heuristic (e.g., as in LinnOS+HL) a powerful option that exploits the advantages of both worlds?

On other integrations and extensions. One interesting question raised by LinnOS is why the latency behavior of SSDs—devices with complex idiosyncrasies—can be learned by the block layer with a few observable features. Understanding this can help other higher layers such as RAID, direct device access (SPDK), user/device-level filesystems, or distributed storage adopt our concept. Likewise, in lower layers, it is also a possibility in the future to have SSDs with latency inference capability built in. Although, arguably, one can say that the device already has full knowledge of its internals and does not need a black-box prediction, an argument can be made that SSD vendors can use the same machine learning method across different internal architectures. Hence, they do not need to re-develop the inference logic every time they modify the internal hardware, logic, and policies. Alternatively, SSD vendors can employ “gray-box” learning that incorporates some of the internal knowledge.

On precision. Can fast/slow inference be converted to a more precise latency inference, such as latency ranges (e.g., 2–4μs, 4–8μs, ...), percentile buckets (e.g., p0–p10, ..., p90–p100), or precise latency with high accuracy? Can model permutation or other machine learning techniques help?

7 Acknowledgments

We thank Tom Anderson, our shepherd, and the anonymous reviewers for their tremendous feedback and helpful comments. We also thank the Azure CSI group for providing the traces. A Artifact Appendix

A.1 Abstract

We assemble an executable LinnOS workflow that runs on Chameleon Cloud Research Platform [2]. This self-contained artifact contains the major components and step-by-step instructions.

A.2 Artifact check-list

- **Program:** LinnOS with preprocess scripts⁴.
- **Data set:** Example I/O traces.
- **Run-time environment:** Chameleon’s shared Jupyter experiment environment.
- **Hardware:** A flash array with at least three SSDs.
- **Output:** Trained models for I/O prediction and latency CDF lines.
- **Experiments:** LinnOS workflow.
- **Expected experiment run time:** Several hours.
- **Public link:** <https://www.chameleoncloud.org/experiment/share/15?s=409ab137f20e4cd38ae3dd4e0d4bfa7c>

A.3 Description

A.3.1 How to access

Access the public link provided above and click the “Launch on Chameleon” button (account required to access Chameleon resources), then see Readme.txt for a high-level description and LinnOS.ipynb for step-to-step instructions.

A.3.2 Hardware dependencies

Evaluating LinnOS requires a flash array with at least three SSDs, which are provided by the storage-hierarchy instances from Chameleon Testbed.

A.3.3 Data sets

The artifact contains some example I/O traces, which are used in the workflow for testing purposes.

A.4 Installation

Step-by-step installation instructions are available in the artifact.

A.5 Evaluation and expected result

Upon successful running, the workflow should produce a trained model, the accuracy outcome, and the I/O latency distribution of LinnOS and baseline. Please see readme.txt in the artifact for further details.

⁴Excluding the data collection and analysis code that may reveal sensitive information in Microsoft traces

A large scale analysis of hundreds of in-memory cache clusters at Twitter

Juncheng Yang

Carnegie Mellon University

Abstract

Modern web services use in-memory caching extensively to increase throughput and reduce latency. There have been several workload analyses of production systems that have fueled research in improving the effectiveness of in-memory caching systems. However, the coverage is still sparse considering the wide spectrum of industrial cache use cases. In this work, we significantly further the understanding of real-world cache workloads by collecting production traces from 153 in-memory cache clusters at Twitter, sifting through over 80 TB of data, and sometimes interpreting the workloads in the context of the business logic behind them. We perform a comprehensive analysis to characterize cache workloads based on traffic pattern, time-to-live (TTL), popularity distribution, and size distribution. A fine-grained view of different workloads uncover the diversity of use cases: many are far more write-heavy or more skewed than previously shown and some display unique temporal patterns. We also observe that TTL is an important and sometimes defining parameter of cache working sets. Our simulations show that ideal replacement strategy in production caches can be surprising, for example, FIFO works the best for a large number of workloads.

1 Introduction

In-memory caching systems such as Memcached [14] and Redis [16] are heavily used by modern web applications to reduce accesses to storage and avoid repeated computations. Their popularity has sparked a lot of research, such as reducing miss ratio [26, 28, 36, 37], or increasing throughput and reducing latency [43, 52, 53, 56]. On the other hand, the effectiveness and performance of in-memory caching can be workload dependent. And several important workload analyses against production systems [24, 59] have guided the explorations of performance improvements with the right context and tradeoffs in the past decade [43, 56].

Nonetheless, there remains a significant gap in the understanding of current in-memory caching workloads. Firstly, there has been a lack of comprehensive studies covering the wide range of use cases in today's production systems. Secondly, there have been new trends in in-memory caching usage since the publication of previous work [24]. Thirdly, some aspects of in-memory caching received little attention in the existing studies, but are known as critical to practition-

ers. For example, TTL is an important aspect of configuring in-memory caching, but it has largely been overlooked in research. Last but not least, unlike other areas where open-source traces [62, 63, 68, 70] or benchmarks [38] are available, there has been a lack of open-source in-memory caching traces. Researchers have to rely on storage caching traces [26], key-value database benchmarks [43, 56] or synthetic workloads [39, 57] to evaluate in-memory caching systems. Such sources either have different characteristics or do not capture all the characteristics of production in-memory caching workloads. For example, key-value database benchmarks and synthetic workloads don't consider how object size distribution changes over time, which impacts both miss ratio and throughput of in-memory caching systems.

In this work, we bridge this gap by collecting and analyzing workload traces from 153 Twemcache [6] clusters at Twitter, one of the most influential social media companies known for its real-time content. Our analysis sheds light on several vital aspects of in-memory caching overlooked in existing studies and identifies areas that need further innovations. The traces used in this paper are made available to the research community [1]. To the best of our knowledge, this is the first work that studied over 100 different cache workloads covering a wide range of use cases. We believe these workloads are representative of cache usage at social media companies and beyond, and hopefully provide a foundation for future caching system designs. Here's a summary of our discoveries:

1. In-memory caching does not always serve read-heavy workloads, write-heavy (defined as write ratio > 30%) workloads are very common, occurring in more than 35% of the 153 cache clusters we studied.
2. TTL must be considered in in-memory caching because it limits the effective (unexpired) working set size. Efficiently removing expired objects from cache needs to be prioritized over cache eviction.
3. In-memory caching workloads follow approximate Zipfian popularity distribution, sometimes with very high skew. The workloads that show the most deviations tend to be write-heavy workloads.
4. The object size distribution is not static over time. Some workloads show both diurnal patterns and experience sudden, short-lived changes, which pose challenges for slab-based caching systems such as Memcached.

- Under reasonable cache sizes, FIFO often shows similar performance as LRU, and LRU often exhibits advantages only when the cache size is severely limited.

These findings provide a detailed new look into production in-memory caching systems, while unearthing some surprising aspects not conforming to the folklore and to the commonly used assumptions.

2 In-memory Caching at Twitter

2.1 Service Architecture and Caching

Twitter started its migration to a service-oriented architecture, also known as microservices, in 2011 [8]. Around the same time, Twitter started developing its container solution [2, 3] to support the impending wave of services. Fast forward to 2020, the real-time serving stack is mostly service-oriented, with hundreds of services running inside containers in production. As a core component of Twitter’s infrastructure, in-memory caching has grown alongside this transition. Petabytes of DRAM and hundreds of thousands of cores are provisioned for caching clusters, which are containerized.

At Twitter, in-memory caching is a managed service, and new clusters are provisioned semi-automatically to be used as look-aside cache [59] upon request. There are two in-memory caching solutions deployed in production, Twemcache, a fork of Memcached [14], is a key-value cache providing high throughput and low latency. The other solution, named Nighthawk, is Redis-based and supports rich data structures and replication for data availability. In this work, we focus on Twemcache because it serves the majority of cache traffic.

Cache clusters at Twitter are considered *single-tenant*¹ based on the service team requesting them. This setup is very beneficial to workload analysis, because it allows us to tag use cases, collect traces, and study the properties of workloads individually. A multi-tenant setup will make similar study extremely difficult, as researchers have to tease out individual workloads from the mixture, and somehow connect them to their use cases. In addition, smaller but distinct workloads can easily be overlooked or mis-characterized due to low traffic.

Unlike other cache cluster deployments, such as social graph caching [19, 30] or CDN caching [47, 69], Twemcache is mostly deployed as a single-layer cache, which allows us to analyze the requests directly from clients without being filtered by other caches. Previous work [47] has shown that layering has an impact on properties of caching workloads, such as popularity distribution. This single-tenant, single-layer design provides us the perfect opportunity to study the properties of the workloads.

2.2 Twemcache Provisioning

There are close to 200 Twemcache clusters in each data center as of writing. Twemcache containers are highly homogeneous and typically small, and a single host can run many

¹Although each cluster is single-tenant, each tenant might cache multiple types of objects of different characteristics.

Figure 1: Slab-based memory management for bounded memory fragmentation. While Memcached uses object eviction, Twemcache uses slab eviction, which evicts all objects in one slab and returns the slab to global pool.

of them. The number of instances provisioned for each cache cluster is computed from user inputs including throughput, estimated dataset sizes, and fault tolerance. The number of instances of each cluster is automatically calculated first by identifying the correct bottleneck and then applying other constraints, such as number of connections to support. Size of production cache clusters ranges from 20 to thousands of instances.

2.3 Overview of Twemcache

Twemcache forked an earlier version of Memcached with some customized features. In this section, we briefly describe some of the key aspects of its designs.

Slab-based memory management Twemcache often stores small and variable-sized objects in the range of a few bytes to 10s of KB. On-demand heap memory allocators such as ptmalloc [45], jemalloc [13] can cause large and unbounded external memory fragmentation in such a scenario, which is highly undesirable in production environment, especially when using smaller containers. To avoid this, Twemcache inherits the slab-based memory management from Memcached (Figure 1). Memory is allocated as fixed size chunks called *slabs*, which default to 1 MB. Each slab is then evenly divided into smaller chunks called *items*. The *class* of each slab decides the size of its items. By default, Twemcache grows item size from a configurable minimum (default to 88 bytes) to just under a whole slab. The growth is typically exponential, controlled by a floating point number called growth factor (default to 1.25), though Twemcache also allows precise configuration of specific item sizes. Higher slab classes correspond to larger items. An object is mapped to the slab class that best fits it, including metadata. In Twemcache, this per-object metadata is 49 bytes. By default, a slab of class 12 has 891 items of 1176 bytes each, and each item stores up to 1127 bytes of key plus value. Slab-based allocator eliminates external memory fragmentation at the cost of bounded internal memory fragmentation.

Eviction in slab-based cache To store a new object, Twemcache first computes the slab class by object size. If there is a slab with at least one free item in this slab class, Twemcache uses the free item. Otherwise, Twemcache tries to allocate a new slab into this class. When memory is full,

Figure 2: Resources consumed for the three cache use cases.

slab eviction is needed for allocation.

Some caching systems such as Memcached primarily performs item-level eviction, which happens in the same slab class as the new object. Memcached uses an approximate LRU queue per slab class to track and evict the least recently used item. This works well as long as object size distribution remains static. However, this is often not true in reality. For example, if all keys start with small values that grow over time, new writes will eventually require objects to be stored in a higher slab class. However, if all memory has been allocated when this happens, there will be effectively no memory to give out. This problem is called *slab calcification* and is further explored in Section 4.6.2. Memcached developed a series of heuristics to move memory between slab classes, and yet they have been shown as non-optimal [10, 11, 17, 46] and error prone [9].

To avoid slab calcification, Twemcache uses slab eviction only (Figure 1). This allows the evicted slab to transition into any other slab class. There are three approaches to choose the slab to evict: choosing a slab randomly (random slab), choosing the least recently used slab (slabLRU), and choosing the least recently created slab (slabLRC). In addition to avoiding slab calcification, slab-only eviction removes two pointers from object metadata compared to Memcached. We further compare object eviction and slab eviction in Section 6.

2.4 Cache Use Cases

At Twitter, it is generally recognized that there are three main use cases of Twemcache: caching for storage, caching for computation, and caching for transient data. We remark that there is no strict boundary between the three categories, and production clusters are not explicitly labeled. Thus the percentages given below are rough estimates based on our understanding of each cache cluster and their corresponding application.

2.4.1 Caching for Storage

Using cache to facilitate reading from storage is the most common use case. Backend storage such as databases usually has a longer latency and a lower bandwidth than in-memory cache. Therefore, caching these objects reduce access latency, increases throughput, and shelters the backend from excessive read traffic. This use case has received the most attention in research. Several efforts have been devoted to reducing

miss ratio [26–28, 36, 37, 41, 47, 72], redesigning for a denser storage device to fit larger working sets [19, 42, 65], improving load balancing [33, 34, 39] and increasing throughput [43, 56].

As shown in Figure 2, although only 30% of the clusters fall into this category, they account for 65% of the requests served by Twemcache, 60% of the total DRAM used, and 50% of all CPU cores provisioned.

2.4.2 Caching for Computation

Caching for computation is not new — using DRAM to cache query results has been studied and used since more than two decades ago [20, 58]. As real-time stream processing and machine learning (ML) become increasingly popular, an increasing number of cache clusters are devoted to caching computation related data, such as features, intermediate and final results of ML prediction, and so-called object hydration, — populating objects with additional data, which often combines storage access and computation.

Overall, caching for computation accounts for 50% of all Twemcache clusters in cluster count, 26%, 31% and 40% of request rate, cache sizes and CPU cores.

2.4.3 Transient data with no backing store

The third typical cache usage evolves around objects that only live in cache, often for short periods of time. It is not caching in the strict sense, and therefore has received little attention. Nonetheless, in-memory caching is often the only production solution that meets both the performance and scalability requirements of such use cases. While data loss is still undesirable, these use cases really prize speed, and tolerate occasional data loss well enough to work without a fallback.

Some notable examples are rate limiters, deduplication caches, and negative result caches. Rate limiters are counters associated with user activities. They track and cap user requests in a given time window and prevent denial-of-service attacks. Deduplication caches are a special case of rate limiters, where the cap is 1. Negative result caches store keys from a larger database that are known to be misses against a smaller, sparsely populated database. These caches short-circuit most queries with negative results, and drastically reduce the traffic targeting the smaller database.

In our measurements, 20% of Twemcache clusters are under this category. Their request rates and cache sizes account for 9% and 8% of all Twemcache request rates and cache sizes, meanwhile, they account for 10% of all CPU cores of Twemcache clusters.

3 Methodology

3.1 Log Collection

Twemcache has a built-in non-blocking request logging utility called `klog` that can keep up with designed throughput in production. While it logs one out of every 100 requests by default, we dynamically changed the sampling ratio to 100% and collected week-long *unsampled* traces from two instances of each Twemcache cluster. Collecting unsampled

Figure 3: a) Production miss ratio of the top ten Twemcache clusters ranked by request rates, the bar shows the max and min miss ratio across one week. Note that the Y-axis is in log scale. b) The ratio between max and min miss ratio is small for most caches.

traces allows us to avoid drawing potentially biased conclusions caused by sampling. Moreover, we chose to collect traces from two instances instead of one to prevent possible cache failure during log collection and to compare results between instances for higher fidelity. Barring cache failures, the two instances have no overlapping keys.

3.2 Log Overview

We collected around 700 billion requests (80 TB in raw file size) from 306 instances of 153 Twemcache clusters, which include all clusters with per-instance request rate more than 1000 queries-per-sec (QPS) at the time of collection. To simplify our analysis and presentation, we focused on the 54 largest caches, which account for 90% of aggregated QPS and 76% of allocated memory. In the following sections, we use Twemcache workloads to refer to the workloads from these 54 Twemcache clusters. Although we only present the results of these 54 caches, we did perform the same analysis on the smaller caches, and they don't change our conclusions.

4 Production Stats and Workload Analysis

In this section, we start by describing some common production metrics to provide a foundation for our discussion, and then move on to workload analyses that can only be performed with detailed traces.

4.1 Miss Ratio

Miss ratio is one of the key metrics that indicate the effectiveness of a cache. Production in-memory caches usually operate at a low miss ratio with small miss ratio variation.

We present the miss ratios of the top ten Twemcache clusters ranked by request rates in Figure 3a where the dot shows the mean miss ratio over a week, and the error bars show the minimum and maximum miss ratio. Eight out of the ten Twemcache clusters have a miss ratio lower than 5%, and six of them have a miss ratio close to or lower than 1%. The only exception is a write-heavy cache cluster, which has a miss ratio of around 70% (see Section 4.3.2 for details about write-heavy workloads). Compared to CDN caching [47], in-memory caching usually has a lower miss ratio.

Besides a low miss ratio, miss ratio stability is also very important. In production, it is the highest miss ratio (and

Figure 4: The number of requests and objects being accessed every second for two cache nodes.

request rate) that decides the QPS requirement of the backend. Therefore, a cache with a low miss ratio most of the time, but sometimes a high miss ratio is less useful than a cache with a slightly higher but stable miss ratio. Figure 3b shows the ratios of $\frac{mr_{max}}{mr_{min}}$ over the course of a week for different caches, where mr stands for miss ratio. We observe that most caches have this ratio lower than 1.5. In addition, the caches that have larger ratios usually have a very low miss ratio.

Low miss ratios and high stability in general illustrate the effectiveness of production caches. However, extremely low miss ratios tend to be less robust, which means the corresponding backends have to be provisioned with more margins. Moreover, cache maintenance and failures become a major source of disruption for caches with extremely low miss ratios. The combination of these factors indicate there's typically a limit to how much cache can reduce read traffic or how little traffic backends need to provision for.

4.2 Request Rate and Hot Keys

Similar to previously observed [24], request rates show diurnal patterns (Figure 4). Besides, spikes in request rate are also very common because cache is the first responder to any change from the frontend services and end users.

When a request rate spike happens, a common belief is that hot keys cause the spikes [33, 48]. Indeed, load spikes often are the results of hot keys. However, we notice it is not always true. As shown in Figure 4, at times, when the request rate (top blue curve) spikes, the number of objects accessed in the same time interval (bottom red curve) also has a spike, indicating that the spikes are triggered by factors other than hot keys. Such factors include client retry requests, external traffic surges, scan-like accesses, and periodic tasks.

In addition to request rate spikes, caches often show other irregularities. For example, in Section 4.6.2, we show that it is common to see sudden changes in object size distribution. These irregularities can happen for various reasons. For instance, users change their behavior due to a social event, the frontend service adds a new feature (or bug), or an internal load test is started.

As a critical component in the infrastructure, caches stop most of the requests from hitting the backend, and they should be designed to tolerate these workload changes to absorb the impact.

Figure 5: a) Ratio of operation in each Twemcache cluster, box shows the 25th and 75th percentile, red bar inside the box shows the mean ratio, and whiskers are 10th and 90th percentile. b) write ratio distribution CDF across Twemcache clusters.

4.3 Types of Operations

Twemcache supports eleven different operations, of which `get` and `set` are the most heavily used by far. In addition, write-heavy cache workloads are very common at Twitter.

4.3.1 Relative usage comparison

We begin from the operations used by Twemcache workloads. Twemcache supports eleven operations `get`, `gets`, `set`, `add`, `cas` (check-and-set), `replace`, `append`, `prepend`, `delete`, `incr` and `decr`². As shown in Figure 5a, `get` and `set` are the two most common operations, and average `get` ratio is close to 90% indicating most of the caches are serving read-heavy workloads. Apart from `get` and `set`, operations `gets`, `add`, `cas`, `delete`, `incr` are also frequently used in Twemcache clusters. However, compared to `get` and `set`, these operations usually account for a smaller percentage of all requests. Nonetheless, these operations serve important roles in in-memory caching. Therefore, as suggested by the author of Memcached, they should not be ignored [15].

4.3.2 Write ratio

Although most caches are read dominant, Figure 5a shows that both `get` and `set` ratios have a large range across caches. We define a workload as write-heavy if the percentage sum of `set`, `add`, `cas`, `replace`, `append`, `prepend`, `incr` and `decr` operations exceeds 30%. Figure 5b shows the distribution of write ratio across caches. More than 35% of all Twemcache clusters are write-heavy, and more than 20% have a write ratio higher than 50%. In other words, in addition to the well-known use case of serving read-heavy workloads, a substantial number of Twemcache clusters are used to serve write-heavy workloads. We identify the main use cases of write-heavy caches below.

Frequently updated data Caches under this category mostly belong to cache for computation or transient data (Section 2.4.2 & 2.4.3). Updates are accumulated in cache before they get persisted, or the keys eventually expire.

²See <https://github.com/memcached/memcached/wiki/Commands> for details about each command.

Opportunistic pre-computation Some services continuously generate data for potential consumption by itself or other services. One example is the caches storing recent user activities, and the cached data are read when a query asks for recent events from a particular user. Many services choose not to fetch relevant data on demand, but instead opportunistically pre-compute them for a much larger set of users. This is feasible because pre-computation often has a bounded cost, and in exchange read queries can be quickly fulfilled by pre-computed results partially or completely. Since this is a trade-off mainly for user experience, the caches under this category see objects with fewer reuse. Therefore, the write ratio is often higher (>80%), and object access (read+write) frequency is often lower. In one case, we saw one cluster with a mean object frequency close to 1.

4.4 TTL

Two important features that distinguish in-memory caching from a persistent key-value store are TTL and cache eviction. While evictions have been widely studied [26, 28], TTL is often overlooked. Nonetheless, TTL has been routinely used in production. Moreover, as a response to GDPR [5], the usage of caching TTL has become mandatory at Twitter to enforce data retention policies. TTL is set when an object is first created in Twemcache, and decides its expiration time. Request attempts to access an expired object will be treated as misses, so keeping expired objects in the cache is not useful.

We observe that in-memory caching workloads often use short TTLs. This usage comes from the dynamic nature of cached objects and the usage for implicit deletion. Under this condition, effectively and efficiently removing expired objects from the cache becomes necessary and important, which provides an alternative to eviction in achieving low miss ratios.

4.4.1 TTL Usages

We measure the mean TTLs used in each Twemcache cluster and show the TTL distribution in Figure 6a. The figure shows that TTL ranges from minutes to days. More than 25% of the workloads use a mean TTL shorter than twenty minutes, and less than 25% of the workloads have a mean TTL longer than two days. Such a TTL range is longer than DNS caching (minutes) [51], but shorter than common CDN object caching (days to weeks). If we divide caches into *short-TTL caches* (TTL ≤ 12 hours) and *long-TTL caches* (TTL > 12 hours). Figure 6a shows 66% of all Twemcache clusters have a short mean TTL.

In addition to mean TTL distribution, we have also measured the number of TTL used in each cache. Figure 6b shows that only 20% of the Twemcache workloads use a single TTL, while the rest majority use more than one TTL. In addition, we observe that over 30% of the workloads use more than ten TTLs and there are a few workloads using more than 1000 TTLs. In the last case, some clients intentionally scatter TTLs over a pre-defined time range to avoid objects expiring at the

Figure 6: a) More than half of caches have mean TTL shorter than one day. b) Only 20% of caches use single TTL. c) The smallest TTL in each cache can be very long. d) TTLs ranges in workloads are often large.

same time. This technique is called *TTL jitter*. In another case, the clients seek the opposite effect — computing TTLs so that a group of objects will expire at the same, predetermined time.

Besides the number of TTLs used, the smallest TTL and the TTL range, defined as the ratio between TTL_{max} and TTL_{min} , are also important for designing algorithms that remove expired objects (see Section 7). Figure 6c shows that the smallest TTL in each cache varies from 10s of seconds to more than half day. In detail, around 30 to 35% of the caches have their smallest TTL shorter than 300 seconds, and over 25% of caches have the smallest TTL longer than 6 hours. Figure 6d shows the CDF of each workload’s TTL range. We observe that fewer than 40% of the workloads have a relatively small TTL range ($< 2 \times$ difference), while almost 25% of the caches have $\frac{TTL_{max}}{TTL_{min}}$ over 100.

Below we present the three main purposes of TTL to better explain how TTL settings relate to the usages of the caches.

Bounding inconsistency Objects stored in Twemcache can be highly dynamic. Because cache updates are best-effort, and failed cache writes are not always retried, it is possible that objects stored in in-memory cache are stale. Therefore, applications often use TTL to bound inconsistency, which is also suggested in the AWS Redis documentation [7]. TTLs for this purpose usually have relative large values, in the range of days. Some Twitter services further developed *soft TTL* to achieve a better tradeoff between data consistency

and availability. The main idea of soft TTL is to store an additional, often shorter TTL as part of the object value. When application decodes the value of a cached object and notices that the soft TTL has expired, it will refresh the cached value from its corresponding source of truth in the background. Meanwhile, the application continues to use the older value to fulfill current requests without waiting. Soft TTL is typically designed to increase with each background refresh, based on the assumption that newly created objects are more likely to see high volume of updates and therefore inconsistency.

Implicit deletion In some caches, TTL reflects the intrinsic life span of stored objects. One example is the counters used for API rate limiting, which are declared as maximum number of requests allowed in a time window. These counters are typically stored in cache only, and their TTLs match the time windows declared in the API specification. In addition to rate limiters, GDPR required TTL would also fall into this category, so no data would live in cache beyond the duration permitted under the law.

Periodic refresh TTL is also used to promote data freshness. For example, a service that calculates how much a user’s interest matches a cluster/community using ML models can make "who-to-follow" type of recommendations with the results. The results are cached for a while because user characteristics tend to be stable in the very short term, and the calculation is relatively expensive. Nonetheless, as users engage with the site, their portraits can change over time. Therefore such a service tends to recompute the results for each user periodically, using or adding the latest data since last update. In this case, TTL is used to pace a relatively expensive operation that should only be performed infrequently. The exact value of the TTL is the result of a balance between computational resources and data freshness, and can often be dynamically updated based on circumstances.

4.4.2 Working Set Size and TTL

Having the majority of caches use short TTLs indicate that the *effective working set size* (WSS_E) — the size of all unexpired objects should be loosely bounded. In contrast, the *total working set size* (WSS_T), the size of all active objects regardless of TTL, can be unbounded.

In our measurements, we identify two types of workloads

Figure 7: The working set size grows over time when TTL is not considered. However, when TTL is considered, the working set size is capped.

shown in Figure 7. The first type (Figure 7a) has a continuously growing WSS_T , and it is usually related to user-generated content. With new content being generated every second, the total working set size keeps growing. The second type of workload has a large growth rate in WSS_T at first, and then the growth rate decreases after this initial fast-growing period, as shown in Figure 7b. This type of workloads can be users related, the first quick increase corresponds to the most active users, the slow down corresponds to less active users. Although the two workloads show different growth patterns in total working set size, the effective working set size of both arrive at a plateau after reaching its TTL. Although the WSS_E may fluctuate and grow in the long term, the growth rate is much slower compared to WSS_T .

Bounded WSS_E means that, for many caches, there exists a cache size that the cache can achieve compulsory miss ratio, if an in-memory caching system can remove expired objects in time. This suggest the importance of quickly removing expired object from cache, especially for workloads using short TTLs. Unfortunately, while eviction has been widely studied [26, 28, 54], expiration has received little attention. And we will show in Section 7.2, existing solutions fall short on expiration.

4.5 Popularity Distribution

Object popularity is another important characteristic of a caching workload. Popularity distribution is often used to describe the cacheability of a workload. A popular assumption is that cache workloads follow Zipfian distribution [29], and the frequency-rank curve plotted in log-log scale is linear. A large body of work optimizes system performance under this assumption [33, 39, 44, 50, 57, 61]. However, a recent work from Facebook [19] suggested that in-memory caching workloads may not follow Zipfian distribution. Here we present the popularity of the caching workloads at Twitter.

Measuring all Twemcache workloads, we observe majority of the cache workloads still follow Zipfian distribution. However, some workloads show deviations in two ways. First, unpopular objects appear significantly less than expected (Figure 8a) or the most popular objects are less popular than expected (Figure 8b). The first deviation happens when objects

Figure 8: Some workloads showing small deviations from Zipfian popularity. a) The least popular objects are less popular than expected. b) The most popular objects are less popular than expected.

Figure 9: a) Most of workloads follow Zipfian popularity distribution with large confidence R^2 . b) The parameter α in Zipfian distribution is large, and the popularity of most workloads are highly skewed ($\alpha > 1$).

are always accessed multiple times so that there are few objects with frequency smaller than some value. The second deviation happens when the client has an aggressive client-side caching strategy so that the most popular objects are often cached at client. In this case, the cache is no longer single-layer.

Although these deviations happen, they are rare, and we believe it is still reasonable to assume in-memory caching workloads follow Zipfian distribution. Since most part of the frequency-rank curves are linear in the log-log scale, we use linear fitting³ confidence R^2 [12] as the metric for measuring the goodness of fit. Figure 9a shows the results of fitting. 80% of all workloads have R^2 larger than 0.8, and more than 50% of workloads have R^2 larger than 0.9. These results indicate that the popularity of most in-memory caching workloads at Twitter follows Zipfian distribution. We further measure the parameter α of the Zipfian distribution shown in Figure 9b. The figure shows that most of the α values are in the range from 1 to 2.5, indicating the workloads are highly skewed.

4.6 Object Size

One feature that distinguishes in-memory caching from other types of caching is the object size distribution. We observe that similar to previous observations [24], the majority of objects stored in Twemcache are small. In addition, size distribution is not static over time, and both periodic distribution shifts and sudden changes are observed in multiple workloads.

4.6.1 Size Distribution

We measure the mean key size and value size in each Twemcache cluster, and present the CDF of the distributions in Figure 10. Figure 10a shows that around 85% of Twemcache clusters have a mean key size smaller than 50 bytes, with a median smaller than 38 bytes. Figure 10b shows that the mean value size falls in the range from 10 bytes to 10 KB, and 25% of workloads show value size smaller than 100 bytes, and median is around 230 bytes. Figure 10c shows that CDF

³We remark that linear regression is not the correct way to modelling Zipf distribution from the view of statistics, we perform this to align with existing works [29].

Figure 10: Mean key, value, object size distribution and mean $\frac{\text{value}}{\text{key}}$ size ratio across all caches.

Figure 11: Heatmap showing request size distribution over time for four typical caches. X-axis is time, Y-axis is the object size using slab class size as bins, and the color shows the fraction of requests that fall into a slab class in that time window.

distribution of the mean object size (key+value), which is very close to the value size distribution except at small sizes. Value size distribution starts at size 1, while object size distribution starts from size 16. This indicates that for some of the caches, value size is dramatically smaller than the key size. Figure 10d shows the ratio of mean value and key sizes. We observe that 15% of workloads have the mean value size smaller than or equal to the mean key size, and 50% of workloads have value size smaller than $5\times$ key size.

4.6.2 Size Distribution Over Time

In the previous section, we investigated the static size distribution of all objects accessed in the one week’s time of each Twemcache cluster. However, the object size distribution of workloads are usually not static over time. In Figure 11, we show how the size distribution changes over time. The X-axis shows the time, and the Y-axis shows the size of objects (using slab class size as bins), the color shows how much of the objects in one time window fall into each slab class. We observe that some of the workloads show diurnal patterns (Figure 11a, 11b), while others show changes without strict patterns.

Periodic/diurnal object size shifts can come from the following sources, a) value for the same key grows over time. and b) size distribution correlates with temporal aspects of key access. For example, text content generated by users in Japan are shorter/smaller than those by users in Germany. In this case, it is the geographical locality that drives the temporal pattern. On the other hand, we do not yet have a good understanding of how most sudden, non-recurring changes happen. Current guesses include user behavior changes during events,

Table 1: Correlation between write ratio and other properties

Property	Pearson coefficient with write ratio
$\log(\text{TTL})$	-0.6336
$\log(\text{Frequency})$	-0.7414
Zipf fitting R^2	-0.7690
Zipf alpha	-0.7329

and a temporary change in production settings.

Both short-term and long-term size distribution shifts pose additional challenges to memory management in caching systems. They make it hard to control or predict external fragmentation in caches that use heap memory allocators directly, such as Redis. For slab-based caching systems, they can cause slab calcification. In Section 7.5, we discuss why existing techniques do not completely address the problem.

5 Further Analysis of Workload Properties

We have shown the properties of the in-memory caching workloads at Twitter. In this section, we show the relationship between the properties, and how they relate to major caching use cases.

5.1 Correlations between Properties

Throughout the analysis in previous sections, we observe some workload characteristics have strong correlations with the write ratio. For example, write-heavy workloads usually use short TTLs. Presented in Figure 12a, the dashed red curve shows the mean TTL distribution of write-heavy workloads, and the solid blue curve shows the mean TTL distribution

Figure 12: Write-heavy workloads tend to show short TTL, small object access frequency, relatively large deviations from Zipfian popularity distribution and are usually less skewed (small α).

of read-heavy workloads. Around 50% of the write-heavy workloads have mean TTL shorter than 10 minutes, while for read-heavy workloads, this is 15 hours. Further, the Pearson coefficient between write ratio and \log^4 of mean TTL (Table. 1) is -0.63 indicating a negative correlation, confirming that large write ratio workloads usually have short TTLs.

Besides TTL, write-heavy workloads also show low object frequencies. We present the mean object frequency (in terms of the number of accesses in the traces) of read-heavy and write-heavy workloads in Figure 12b. It shows that read-heavy workloads have a mean frequency mostly in the range from 6 to 1000, with 75% percentile above 200. Meanwhile, write-heavy workloads have a mean frequency mostly between 1 and 100, with 75% percentile below 10. We further confirm this relationship with the Pearson coefficient between write ratio and log of frequency, which is -0.7414 (Table. 1), suggesting the low object access frequency in write-heavy caches.

In addition, the popularity of write-heavy workloads has relatively larger deviations from Zipfian distribution, and the fitting confidence R^2 is usually much smaller than that of read-heavy workloads (Figure 12c). Moreover, the α parameter of Zipfian distribution in write-heavy workloads is usually small, as shown in Figure 12d. It shows the write-heavy workloads have a median α around 0.9, and the median of read-heavy workloads have an α around 1.4. This correlation is also backed up by the Pearson coefficient (Table 1).

5.2 Properties of Different Cache Use Cases

Here we further explore common properties exhibited by each of the three major caching use cases as described in Section 2.4.

5.2.1 Caching for Storage

Caches for storage usually serve read-heavy workloads, and their popularity distributions typically follow Zipfian distribution with a large parameter α in the range of 1.2 to 2.2. While this type of workload is highly skewed, they are easier to cache, and in production, 95% of these clusters have miss ratios of around or less than 1%. Being more cacheable and having smaller miss ratios do not indicate they have small

working set sizes. In our observation, 7 of the top 10 caches (ranked by cache size) belong to this category.

Because these caches store objects persisted in the backend storage, any modifications to the objects are explicitly written to both the backend and the cache. Therefore the TTLs used in these caches are usually large, in the range of days. There is no specific pattern about object size in this type of caches, and the value can be as large as tens of KB, or as small as a few bytes. For example, the number of favorites a tweet received is persisted in the backend database and sometimes cached.

5.2.2 Caching for Computation

Caches under this category serve both read-heavy and write-heavy traffic depending on the workloads. For example, machine learning feature workloads are usually read-heavy showing a good fit of Zipfian popularity distribution. While intermediate computation workloads are normally write-heavy and show deviations from Zipfian. Compared to caching for storage, workloads under this category use shorter TTLs, usually determined by the application requirement. For example, caches storing intermediate computation data usually have TTLs no more than minutes because other services will consume the data in a short time. For features and prediction results, the TTLs are usually in the range of minutes to hours (some up to days) depending on how fast the underlying data change and how expensive the computation is. The mean TTLs we observe for caches under this category is 9.6 hours. There are no particular patterns about object sizes in these caches.

Since objects stored in these caches are indirectly related to users and contents, the workloads usually have large key spaces and total working set sizes. For example, a cache storing the distance between two users will require a N^2 cache size where N denotes the number of users. However, because these caches have short TTLs, the effective working set sizes are usually much smaller. Thus removing expired objects can be more important than eviction for these caches.

As real-time stream processing becomes more popular, we envision there will be more caches being provisioned for caching computation results. Because the characteristics are different from caching for storage, they may not benefit equally from optimizations that only aim to make the

⁴We choose to use log of TTL and frequency because of their wide ranges in different workloads.

read path fast and scalable, such as optimistic cuckoo hashing [43]. Therefore, including evaluation against caching-for-computation workloads that are write-heavy and more ephemeral will paint a more complete picture of the capabilities of any caching system.

5.2.3 Transient Data with No Backing Store

There are two characteristics associated with this type of caches: Caches under this category usually have short TTLs, and the TTLs are often used to enforce implicit object deletion (Section 4.4). In addition, objects in these caches are usually tiny and we observe an average object size of 54 bytes. Although caches of this type only contribute 9% of total Twemcache cluster request rate and 8% of total cache sizes, they currently play an irreplaceable role in site operations.

6 Eviction Algorithms

We have shown the characteristics of in-memory cache workloads in the previous sections. In this section, we use the same cache traces to investigate the impact of eviction algorithms. This evaluation considers production algorithms offered by Twemcache and other production systems.

6.1 Eviction algorithm candidates

Object LRU and object FIFO LRU and FIFO are the most common algorithms used in production caching systems [4, 18]. However, they cannot be applied to systems using slab-based memory management such as Twemcache without modification. Therefore, we evaluate LRU and FIFO assuming the workloads are served using a non-slab based caching system, while ignoring memory inefficiency caused by external fragmentation. As a result, we expect that the results to have a bias toward the effectiveness of LRU and FIFO compared to the three slab-based algorithms. Production results for these two algorithms might be worse than what is suggested in this section, depending on the workloads.

slabLRU and slabLRC These two algorithms are part of eviction algorithms offered in Twemcache. slabLRU and slabLRC are equivalent to LRU and FIFO but executed at a level much coarser granularity of slabs rather than a single object. Twitter employs these algorithms to alleviate the effect of slab calcification and also to reduce the size of per-object metadata.

Random slab eviction Besides slabLRU and slabLRC, Twemcache also offers Random slab eviction, which globally picks a random slab to evict. This algorithm is workload-agnostic with robust behavior, and therefore used as the default policy in production. However, it is rarely the best of all algorithms and are non-deterministic, therefore we do not include it in comparison.

Memcached-LRU Memcached adapted LRU by creating one LRU queue per slab class. We call the resulted eviction algorithm Memcached-LRU, which does not enable Memcached's slab auto-move functionality. We did, however, evaluate Memcached-LRU with slab auto-move turned on, and

most of the results are somewhere between LRU and slabLRU. The rest of the paper omits this combination.

6.2 Simulation Setup

We built an open-source simulator called libCacheSim [71] to study the steady-state miss ratio of the different eviction algorithms. Specifically, we use five-day traces to warm up the caches, then use one-day traces to evaluate cache miss ratios. Each algorithm is applied against all traces, and then grouped by results.

In terms of cache sizes, our simulation always starts with 64MB of DRAM, and chooses the maximum as $2\times$ their current memory in production. We stop increasing the size for a particular workload when all algorithms have reached the compulsory miss ratio. Note that when plotting, the size range is truncated to better present the trend.

6.3 Miss Ratio Comparison

The outcome of our comparison can be grouped into four types, and representatives of each are shown in Figure 13.

The first group shows comparable miss ratios for all algorithms in the cache sizes we evaluated. For this type of workload, the choice of eviction algorithms has a limited impact on the miss ratio. Production deployments may very well favor simplicity or decide based on other operational considerations such as memory fragmentation. Twemcache uses random slab eviction by default because random eviction is simple and requires less metadata.

The second type of result shows that for some workloads LRU works better than others. Such a result is often expected because LRU protects recently accessed objects and is well-known for its miss ratio performance in workloads with strong temporal locality.

The third type of result shows that FIFO is the best eviction algorithm (Figure 13c). This result is somewhat surprising since it does not conform to what is typically observed in caching of other scenarios such as CDN caching. We give our suspected reasons below. Figure 14 shows the inter-arrival time distribution of the two workloads in Figure 13b and Figure 13c respectively. The inter-arrival time is the number of requests between two accesses to the same object. Figure 14a shows a smooth inter-arrival time curve, while Figure 14b shows a curve with multiple segments. For workloads with inter-arrival time like Figure 14a, LRU can work better than FIFO because it promotes recently accessed objects, which have a higher chance of being reused soon. This promotion protects the recently accessed objects but demotes other objects that are not reused recently. Demoting non-recently used objects can be an unwise decision if some of the demoted objects will be reused after 10^6 requests, such as the ones shown in Figure 14b. In contrast, FIFO treats each stored object equally; in other words, it protects the objects with a large inter-arrival gap. Therefore, for workloads similar to the one in Figure 14b, FIFO can perform better than LRU. Such

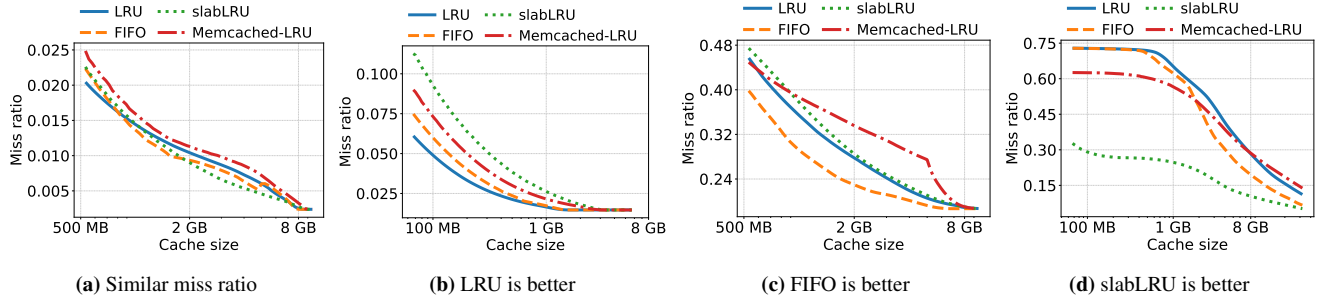

Figure 13: Four typical miss ratio results: a) all algorithms have similar performance, b) LRU is slightly better than others, c) FIFO is better than others, d) slabLRU is much better than others.

Figure 14: The inter-arrival gap distribution corresponding to the workloads in Figure 13b and Figure 13c respectively.

workloads may include scan type of requests such as a service that periodically sends emails.

The last type of result show that in some workloads, slabLRU performs much better than any other algorithms. The main reason is that the workloads showing this type of result have periodic/diurnal changes. Figure 11b shows the object size distribution over time of the workload corresponding to Figure 13d. We suspect this is due to the following reason, but we leave the verification as future work. Although LRU and FIFO are not affected by any change in object size distribution, they cannot respond to workload change instantly. In contrast, slabLRU can quickly adapt to a new workload when the new workload uses a different slab class because it prioritizes the slabs that have more recent access. From another view, slabLRU gives a larger usable cache size for the new workloads (slab class). Figure 13d shows that the difference between algorithms reduces at larger cache sizes, this is because the benefit of having a large usable cache size diminishes as cache size increases. Moreover, in these workloads, Memcached-LRU sometimes has better performance than LRU, but for most of the workloads, Memcached-LRU is worse (not shown in the figure) because of the missing capability of moving slabs. Thus it has a smaller usable cache size. When Memcached-LRU has better performance at small cache sizes, we suspect that the changing workloads cause thrashing for LRU and FIFO [27]. Since Memcached-LRU can only evict objects within from the same slab class as the new object, it protects the objects in other slab classes from thrashing, thus showing better performance.

Figure 15: a) The best eviction algorithms under different sizes. b) The relative miss ratio difference between FIFO and LRU under different sizes. Positive region shows FIFO is worse.

In most cases, both miss ratio and the difference between algorithms decrease as cache capacity increases. We observe that within our simulation configuration, which stops at or before $2\times$ current size, the difference between algorithms eventually disappears. This suggests that to achieve low miss ratio in real life, it can be quite effective to create implementations that increase the effective cache capacity, such as through metadata reduction, adopting higher capacity media, or data compression.

Given there are more than a couple of workloads showing each of the four result types, we would like to explore whether there is one algorithm that is often the best or close to the best most of the time.

In the next section, we explore how often each algorithm is the best with a special focus on LRU and FIFO.

6.4 Aggregated Statistics

In this section, we evaluate the same set of algorithms as in Section 6.3, focusing on four distinct cache sizes and present the aggregated statistics. Because different workloads have different working set sizes and compulsory miss ratios, we choose the four cache sizes in the following way. We define the *ultimate cache size* s_u to be the size where LRU achieves compulsory miss ratio for a workload. However, if LRU can not achieve compulsory miss ratio at $2\times$ production cache size, we use $2\times$ production cache size as s_u . We choose *large* cache size to be 90% of s_u , and *medium*, *small* and *very small*

cache sizes to be 60%, 20% and 5% of s_u respectively. We remark that, at Twitter, 76% of the caches have cache sizes larger than the *large* cache size category, and 34% of the rest have cache sizes within 10% of the *large* cache size.

We show the miss ratio comparison in Figure 15a, where each bar shows the fraction of workloads for which a particular algorithm is the best. We see that at the *large* cache size slabLRU is the best for around 10% of workloads, and this fraction gradually increases as we reduce cache size. This increase is because for smaller cache sizes, quickly adapting to workload change is more valuable. Besides this, FIFO has similar performance compared to LRU at *small*, *medium* and *large* size categories. And only at *very small* cache sizes, LRU becomes significantly better than FIFO. This is because at relatively large cache sizes, promoting recently accessed objects is less crucial. Instead, not demoting other objects is more helpful in improving the miss ratio, especially for workloads having multiple segments in inter-arrival time like the one shown in Figure 14b.

Figure 15a suggests that for close to half of the workloads, FIFO is as good as LRU at reasonably large cache sizes. Now we explore the magnitude by which FIFO is better or worse compared to LRU on each workload. Figure 15b shows the relative miss ratio difference between FIFO and LRU: $\left(\frac{mr_{FIFO} - mr_{LRU}}{mr_{LRU}}\right)$, where mr stands for miss ratio, for each workload at different cache sizes. When the value on X-axis is positive, it indicates that FIFO has a higher miss ratio, and LRU has better performance, while a negative value indicates the opposite. We observe that all the curves except the one for very small cache size are all close to being symmetric around x-axis value 0. This indicates that across workloads, FIFO and LRU have similar performance for small, medium and large cache sizes. For the very small size category, we observe LRU being significantly better than FIFO, this is because for workloads with temporal locality, promoting recently accessed objects becomes crucial at very small cache sizes. In production, most of the caches are running at cache sizes larger than or close to the *large* category. We believe that for most in-memory caching workloads, FIFO and LRU have a similar performance at reasonably large cache sizes.

The fact that FIFO and LRU often exhibit similar performance in production-like settings is important because using LRU usually incurs extra computational and memory overhead compared to FIFO [55, 56]. For example, implementing LRU in Memcached requires extra metadata and locks, some of which can be removed if FIFO is used.

7 Implications

In this section, we show how our observations differ from previous work, and what the takeaways are for informing future in-memory caching research.

7.1 Write-heavy Caches

Although 70% of the top twenty Twemcache clusters serve read-heavy workloads (Section 4.3.2), write-heavy workloads

are also common for in-memory caching. This is not unique to Twitter. Previous work [24] from Facebook also pointed out the existence of write-heavy workloads, although the prevalence of them were not discussed due to the limited number of workloads. Furthermore, write-heavy workloads are expected to increase in prominence as the use case of caching for computation increases (Section 2.4.2). However, most of the existing systems, optimizations and research assume a read-heavy workload.

Write-heavy workloads in caching systems usually have lower throughput and higher latency, because the write path usually involves more work and can trigger more expensive events such as eviction. In Twitter’s production, we observe that serving write-heavy workloads tend to have higher tail latencies. Scaling writes with many threads tends to be more challenging as well. In addition, as discussed in Section 5, write-heavy workloads have shorter TTLs with less skewed popularity, which are in sharp contrast to read-heavy workloads. This calls for future research on designing systems and solutions that consider performance on write-heavy workloads.

7.2 Short TTLs

In Section 4.4.1, we show that in-memory caching workloads frequently use short TTLs, and the usage of short TTLs reduces the effective working set size. Therefore, removing expired objects from the cache is far more important than evictions in some cases. In this section, we show that existing techniques for proactively removing expired objects (termed proactive expiration) are not sufficient. This calls for future work on better proactive expiration designs for in-memory caching systems.

Transient object cache An approach employed for proactive expiration (especially for handling short TTLs), proposed in the context of in-memory caches at Facebook [59], is to use a separate memory pool (called transient object pool) to store short-lived objects. The transient object cache consists of a circular buffer of size t with the element at index i being a linked list storing objects expiring after i seconds. Every second, all objects in the first linked list expire and are removed from the cache, then all other linked lists advance by one.

This approach is effective only when the cache user uses a mix of very short and long TTLs with the short TTL usually in the range of seconds. Since objects in the transient pool are never evicted before expiration, the size of transient pool can grow unbounded and cause objects in the normal pool to be evicted. In addition, the TTL threshold of admitting into transient object pool is non-trivial to optimize.

As we show in Figure 6b, 20% of the Twemcache workloads use a single TTL. For these workloads, transient object pool does not apply. For the workloads using multiple TTLs, we observe that fewer than 35% have their smallest TTL shorter than 300 seconds, and over 25% of caches have the smallest TTL longer than 6 hours (Figure 6c). This indicates

that the idea of transient object cache is not applicable to a large fraction of Twemcache clusters.

Background crawler Another approach for proactive expiration, which is employed in Memcached, is to use a background crawler that proactively removes expired objects by scanning all stored objects.

Using a background crawler is effective when TTLs used in the cache do not have a broad range. While scanning is effective, it is not efficient. If the cache scans all the objects every T_{pass} , an object of TTL t can be scanned up to $1 + \lceil \frac{t}{T_{pass}} \rceil$ times before removal, and can overstay in the system by up to T_{pass} . The cache operator therefore has to make a tradeoff between wasted space and the additional CPU cycles and memory bandwidth needed for scanning. This tradeoff gets harder if a cache has a wide TTL range, which is common as observed in Section 4.4. While the Twemcache workloads are single tenant, wide TTL range issue would be further exacerbated for multi-tenant caches.

Figure 6d shows that TTLs used within each workload have a wide range. Close to 60% of workloads have the maximum TTL more than twice as long as the minimum, and 25% of workloads show a ratio at or above 100. This indicates that for the 25% of caches, if we want to ensure all objects are removed within $2\times$ their TTLs, objects with the longest TTL will be scanned 100 times before expiration.

The combination of transient object cache with background crawler could extend the coverage of workloads that can be efficiently expired. However, the tradeoff between wasted space and the additional CPU cycles and memory bandwidth consumed for scanning would still remain. Hence, future innovation is necessary to fundamentally address use cases where TTLs exhibit a broad range.

7.3 Highly Skewed Object Popularity

Our work shows that the object popularity of in-memory caching can be far more skewed than previously shown [19], or compared to studies on web proxy workloads [29] and CDN workloads [47]. We suspect this has a lot to do with the nature of Twitter’s product, which puts great emphasis on the timeliness of its content. It remains to be seen whether this is a widespread pattern or trend. Cache workloads are also more skewed compared to NoSQL database such as RocksDB [38], which is not surprising because database traffic is often already filtered by caches, and has the most skewed portion removed via cache hits. In other words, in-memory caching and NoSQL database often observe different traffic even for the same application. Besides these two reasons, sampling sometimes results in bias in the popularity modelling, and we avoid this by collecting unsampled traces. Our observation that the workloads still follow Zipfian distribution with large alpha value emphasizes the importance of addressing load imbalance [44, 57, 61].

7.4 Object Size

Similar to previously reported [24], we observe that objects cached in in-memory caching are often tiny (Section 4.6). As a result, in-memory caches are not always bound by memory size; instead, close to 20% of the Twemcache clusters are CPU-bound.

On the other hand, small objects signifies the relative large overhead of metadata. Memcached stores 56-byte with each object, and Twitter’s current production cache uses 38-byte metadata with each object. Reducing object metadata further can yield substantial benefits for caching tiny objects.

In addition, we observe that compared to value size, the key size can be large in some workloads. For 60% of the workloads, the mean key size and mean value size are in the same order of magnitude. This indicates that reducing key size can be very important for these workloads. Many workloads we observed have namespaces as part of the object keys, such as `NS1:NS2:...:id`. This format is commonly used to mirror the naming in a multi-tenant database, which is also observed at Facebook [32]. Namespaces thus can occupy large fractions of precious cache space while being highly repetitive within a single cache cluster. However, there is no known techniques to “compress” the keys. To encourage and facilitate future research on this, we keep the original but anonymized namespace in our open sourced traces.

Several recent works [26, 28] on reducing miss ratio (improving memory efficiency) focused on improving eviction algorithms and often add more metadata. Given our observations here, we would like to call more attention to the optimization of cache metadata and object keys.

7.5 Dynamic Object Size Distribution

In Section 4.6.2, we show that the object size distribution is not static, and the distribution shifts over time can cause out-of-memory (OOM) exceptions for caching systems using external allocators, or slab calcification for those using slab-based memory management. In order to solve this problem, one solution, employed by Facebook, is to migrate slabs between slab classes by balancing the age of the oldest items in each class [59]. Earlier versions of Memcached approached this problem by balancing the eviction rate of each slab class. Since version 1.6.6, Memcached has also moved to using the solution of balancing the age as mentioned above.

Besides efforts in production systems, slab assignment and migration has also been a hot topic in recent research [31, 35, 36, 46]. However, to the best of our knowledge, the problem has only been studied under a “semi-static” request sequence. Specifically, the research so far assumes that the miss ratio curve or some other properties of each slab class hold steady for =certain amount of time, which often precludes periodic and sudden changes in object size distribution.

In general, the temporal properties of object sizes in cache are not well understood or quantified. As presented in Figure 11c and Figure 11d, it is not rare to see unexpected

changes in size distribution only lasting for a few hours. Sometimes it is hard to pinpoint the root cause of such changes. Nonetheless, we believe that temporal changes related to object size, whether recurring or as a one-off, usually have drivers with roots beyond the time dimension. For example, the tweet size drift throughout the day may very well depend on the locales or geo-location of active users. Some caches may be shared by datasets which differ in size distribution and access cycles, resulting in different distributions dominating the access pattern at different instants of the day. In this sense, studying the object size distribution over time could very well provide deeper insights into characteristics of the datasets being cached. Considering the increasing interest in using machine learning and other statistical tools to study and predict caching behavior, we think object size dynamics might provide a good proxy to evaluate the relationship between basic dataset attributes and their behavior in cache, allowing caching systems to make smarter decisions over time.

8 Related Work

Due to the nature of this work, we have discussed related works in detail throughout the paper.

Multiple caching and storage system traces were collected and analyzed in the past [24, 25, 32, 47, 48, 59]; however, only a limited number of reports focus on in-memory caching workloads [24, 48, 59]. The closest work to our analysis is Facebook’s Memcached workload analysis [24], which examined five Memcached pools at Facebook. Similar to the observations in this work [24], we observe the sizes of objects stored in Twemcache are small, and diurnal patterns are common in multiple characteristics. After analyzing 153 Twemcache clusters at Twitter, in addition to previous observations [24], we show that write-heavy workloads are popular. Moreover, we focus on several aspects of in-memory caching which have not been studied to the best of our knowledge, including TTL and cache dynamics. Although previous work [24] proposed analytical models on the key size, value size, and inter-arrival gap distribution, the models do not fully capture all the dimensions of production caching workloads such as changing working set and dynamic object size distribution. Compared to synthetic workload models, the collection of real-world traces that we collected and open sourced provide a detailed picture of various aspects of the workloads of production in-memory caches.

Besides workload analysis on Memcached, there have been several workload analysis on web proxy [21–23, 49, 64] and CDN caching [47, 67]. The photo caching and serving infrastructure at Facebook has been studied [47], with a focus on the effect of layering in caching along with the relationship between content popularity, age, and social-networking metrics.

In addition to caching in web proxies and CDNs, the effectiveness of caching is often discussed in workload studies [25, 60, 66] of file systems. However, these works primarily

studied the cache to the extent that of its effectiveness in reducing traffic to the storage system rather than on aspects that affect the design of the cache itself. Besides, file system caching is different from distributed in-memory caches due to a variety of reasons. For example, file system caches usually store objects of fixed-sized chunks (512 bytes, 4 KB or larger), while in-memory caches store objects of a much wider range (Section 4.6), and scan is common in file systems, while rare in in-memory caches.

Because of the similarities in the interface, in-memory caching is sometimes discussed together with key-value databases. Three different RocksDB workloads [32] at Facebook has been studied in depth, with a focus on the distribution of key and value sizes, locality, and diurnal patterns in different metrics. Although Twemcache and RocksDB have a similar key-value interface, they are fundamentally different because of their design and usage. RocksDB stores data for persistence, while Twemcache stores data to provide low latency and high throughput without persistence. In addition, compared to RocksDB, TTL and evictions are unique to in-memory caching.

9 Conclusion

We studied the workloads of 153 in-memory cache clusters at Twitter and discovered five important facts about in-memory caching. First, although read-heavy workloads account for more than half of the resource usages, write-heavy workloads are also common. Second, in-memory caching clients often use short TTLs, which limits the effective working set size. Thus, removing expired objects needs to be prioritized before evictions. Third, read-heavy in-memory caching workloads follow Zipfian popularity distribution with a large skew. Fourth, the object size distributions of most workloads are not static. Instead, it changes over time with both diurnal patterns and sudden changes, highlighting the importance of slab migration for slab-based in-memory caching systems. Last, for a significant number of workloads, FIFO has similar or lower miss ratio performance as LRU for in-memory caching workloads. We have open sourced the traces collected at <https://github.com/twitter/cache-trace>.

Acknowledgements We thank our shepherd Andrea Arpaci-Dusseau and the anonymous reviewers for their valuable feedback. We thank our colleagues Jack Kosaian and Rebecca Isaacs for their extensive reviews and comments that improved this work. We also want to thank the Cache team and IOP team at Twitter for their support in collecting and analyzing the traces, and Daniel Berger for his comments in the early stage of the project. Moreover, we thank CloudLab [40] in helping us process the open-sourced traces, and Geoff Kuenning from SNIA in helping hosting and sharing the traces. This work was supported in part by NSF grants CNS 1901410 and CNS 1956271.

Abstract

SQL is the de-facto language for big-data analytics. Despite the cost of distributed SQL execution being dominated by disk and network I/O, we find that state-of-the-art optimizers produce plans that are not I/O optimal. For a significant fraction of queries (25% of popular benchmarks like TPCDS), a large amount of data is shuffled redundantly between different pairs of stages. The fundamental reason for this limitation is that optimizers do not have the right set of primitives to perform reasoning at the map-reduce level that can potentially identify and eliminate the redundant I/O.

This paper proposes RESIN, an optimizer extension that adds first-class support for map-reduce reasoning. RESIN uses a novel technique called *Generalized Sub-Query Fusion* that identifies sub-queries computing on overlapping data, and *fuses* them into the same map-reduce stages. The analysis is general; it does not require that the sub-queries be syntactically the same, nor are they required to produce the same output. Sub-query fusion allows RESIN to sometimes also eliminate expensive binary operations like *Joins* and *Unions* altogether for further gains.

We have integrated RESIN into SPARKSQL and evaluated it on TPCDS, a standard analytics benchmark suite. Our results demonstrate that the proposed optimizations apply to 40% of the queries and speed up a large fraction of them by 1.1 – 6 \times , reducing the overall execution time of the benchmark suite by 12%.

1 Introduction

SQL is the de-facto language for performing big-data analytics. As there are many alternative ways to express the same query in SQL, query optimizers employ SQL-to-SQL rewrite rules to find equivalent queries that are likely to run faster. The rewritten query is compiled down to an executable plan that consists of many map or reduce stages. Each stage in the plan then runs in a data-parallel manner on many machines.

Data is materialized to disk at the end of each stage and transferred between stages using an all-to-all network *shuffle* (also referred to as an *exchange*). In practice, shuffles that involve very large amount of data require multiple rounds of I/O in order to incrementally aggregate data [15, 27]. It is not surprising therefore, that the cost of running a query is dominated by disk and network I/O [15].

Despite the bottleneck on I/O, we find that state-of-the-art query optimizers [4, 5, 18, 21, 22] produce execution plans that read or shuffle the same data redundantly multiple times. In fact, on a standard benchmark like TPCDS, the SPARK query optimizer produces plans where 40% of queries incur redundant I/O (Section 6). A large fraction of these spend at-least half their time in stages with redundant I/O.

A standard big-data query optimizer (Figure 1) performs query optimization using a sequence of tree-rewrite rules. It applies *logical* rules to substitute operator trees with equivalent trees. Then it uses implementation strategies (also called *physical* rules) to transform an optimized operator tree into a tree of physical operators. Each physical operator has a pre-defined map-reduce implementation. As shown in the figure, a standard optimizer only performs SQL-to-SQL rewrite rules at the logical level and the physical operators just provide data-parallel implementations of SQL operators.

Performing optimization at the SQL level is not optimal for a runtime that can execute arbitrary data-parallel operators. A previous system called BLITZ [10, 19] shows evidence of this opportunity for further optimization. BLITZ [19] uses program synthesis to identify single-input single-output sub-queries that can be implemented by a single imperative map-reduce program. Through program synthesis, it finds map-reduce implementations of queries where a query optimizer produces inefficient execution plans. Subsequent work [10] added some of the newly discovered operators (referred to as *super-operators*) back into the optimizer along with rewrite-rules that target them. They showed that queries that use a super-operator can run up to 2 \times faster.

A key limitation of BLITZ, however, is that it only optimizes single-input sub-queries, and further it only targets optimiza-

*Work was done while the author was at Microsoft

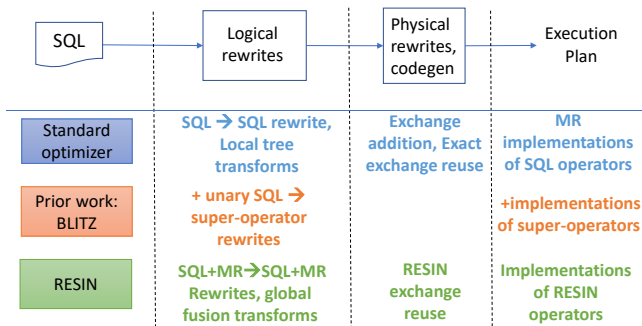

Figure 1: Key components of a big-data query optimizer. RESIN performs map-reduce reasoning starting at the logical level, when prior work only considers it late in the process.

tions that produce a single map-reduce program. The logical rewrite rules in BLITZ (as in a standard optimizer) only make local transformations. They substitute a connected set of operators with a single super-operator. As a result, BLITZ can only eliminate redundant I/O from specific types of sub-queries with *self-joins* or *self-unions*. This turned out to be insufficient on a standard benchmark suite like TPCDS where BLITZ only applies to a small fraction (2%) of queries.

This paper introduces RESIN, an optimizer extension that eliminates redundant I/O from complex multi-stage multi-input queries. This fundamentally requires new techniques. As shown in Figure 1, RESIN performs map-reduce reasoning right from the beginning. It introduces two generic logical operators, a parameterized *mapper* (RESINMAP) and a parameterized *reducer* (RESINREDUCE) that are each capable of implementing complex sub-queries. RESIN introduces new rules that *fuse* operators from different parts of the query tree that are processing overlapping sets of data. The fusion relies on the additional expressiveness of RESINMAP and RESINREDUCE. The fusion further enables the elimination of binary operators from the query. Binary operators are particularly expensive as they typically induce multiple shuffles [10]. Compared to BLITZ, we significantly broaden the optimization opportunities: RESIN applies to 38% of TPCDS.

We integrated RESIN with SPARK [5, 26], a popular open-source big-data system, and evaluated on the entire TPCDS suite. Our results demonstrate that RESIN optimizations apply to 40 of the 104 queries in the suite, and speed up 25% of the queries by a significant fraction (average 1.4 \times). RESIN brings down the cumulative execution time for the entire benchmark suite by 12%.

The rest of the paper is organized as follows. Section 2 gives an overview of optimizations performed by RESIN. Section 3 formally defines the query language and introduces RESIN operators. Section 4 describes the core optimizations, sub-query fusion and binary operator elimination. Section 5 presents some key features of our implementation. Section 6 reports our evaluation and Section 7 discusses related work.

2 Overview

This section provides an overview of RESIN. Consider a (fictitious) IoT application that collects readings from multiple sensors deployed all over the world and derives intelligence from it through SQL queries. Each device emits a single message every few hours with two readings corresponding to two different times. The message has the following fields, $\langle id, hr_1, signal_1, hr_2, signal_2 \rangle$ where *id* is the device identifier, *hr₁* is the hour at which the first reading was taken, *signal₁* is the value of the first reading. Similarly, *hr₂* and *signal₂* are the hour and value of the second reading. The collective log, which can reach Billions of entries across all devices, is processed once a month using SQL queries. We describe RESIN optimizations on two example queries.

Example 1 The query is shown in Figure 2(a)¹. The query separates the subset of columns $\langle id, hr_1, signal_1 \rangle$ and $\langle id, hr_2, signal_2 \rangle$ of each row of the *rawLogs* table to get intermediate tables *V1* and *V2*, and then performs a *Union* to put them together. The *Union* operator performs a multi-set union, i.e., it does not remove duplicate rows from the output. (In general, all our queries operate with multi-set semantics.) Each of *V1* and *V2* additionally requires a filter to check for the validity of the input (*hr* fields are in the expected ranges and the *signal* fields are valid). Figure 2(b) shows a small input table with 5 rows and the result of executing the query on that input. Each of *V1* and *V2* will contain 4 rows each and the final output *signals* has 8 rows. For a production-sized execution, imagine scaling each table by a factor of a Billion.

Figure 2(c) shows the execution plan for this query generated by SPARK. The plan employs duplicate scan operators, thus, it reads the same input twice. Even if there is an index on the input (in fact, we are going to assume a perfect index that can filter out irrelevant rows), many rows (*R₂*, *R₃*, *R₅*) would still be read twice (because they are needed for both *V1* and *V2*) and processed independently. Unfortunately, SQL’s relational operators provide no better way of expressing the query because there is no way to produce multiple output rows for each input row, other than by using a *Union* operator as in this example. When the inputs to the *Union* have a common source, the binary operator induces redundant I/O. This example shows a case where input data is read redundantly, however in general a *Union* could induce redundant shuffles as well.

There is a better way to implement the query directly using map-reduce operators. Consider the mapper shown in Figure 3. It reads and processes each input row once, producing up to two output rows per input row. The mapper applies the filters (Line 4 and Line 7) one after the other and outputs the relevant columns. (We operate in the standard *multi-set*

¹We show queries as a sequence of statements for the ease of illustration. They could have instead been written as a single nested query; our optimizations still apply in the same manner.

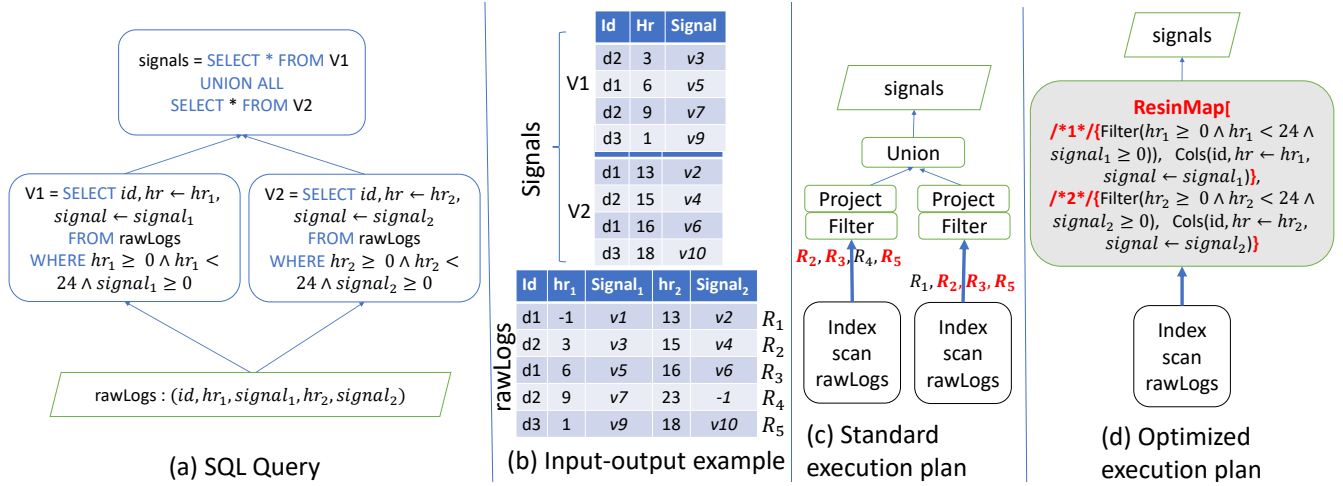

Figure 2: A SQL query, example input-outputs, execution plan showing redundant I/O and an optimized plan produced by RESIN.

```

1 //Mapper m processes a partition rawlogs[m]
2 method exampleResinMap(m){
3   foreach (id,hr1,signal1,hr2,signal2) ∈ rawLogs[m] {
4     if (hr1 ≥ 0 ∧ hr1 < 24 ∧ signal1 ≥ 0) {
5       hr = hr1; signal = signal1; output (id,hr,signal);
6     }
7     if (hr2 ≥ 0 ∧ hr2 < 24 ∧ signal2 ≥ 0) {
8       hr = hr2; signal = signal2; output (id,hr,signal);
9     } } }

```

Figure 3: A mapper that implements the query Figure 2.

semantics of SQL, so the order of rows in an output table is immaterial.) The mapper is sufficient to implement our example query. The reason current optimizers do not consider this option is that they do not reason at the level of mappers (or reducers) during optimization. They only reason about SQL operators and perform SQL-to-SQL query rewrites.

RESIN extends the optimizer with a generic map operator RESINMAP and a generic reduce operator RESINREDUCE (used in the next example). RESINMAP is a row-wise operator that may produce zero or more output rows for each input row. The generated plan with RESIN for our example query is shown in Figure 2(d). The plan uses a RESINMAP operator. (The code generated for this operator is essentially the one in Figure 3.) RESINMAP consists of multiple entries (two in the example, marked 1 and 2 in the Figure), each with a filter and associated expressions to produce output. The RESINMAP operator is quite powerful. It can implement any single-input single-output sub-query containing arbitrary combinations of *Select*, *Project* and *Union* operators.

Example 2 As a second example, consider the more complex query shown in Figure 4. The query has two inputs, the *signals* table, which comes from the output of the previous example, and another table called *dInfo* that has device-specific

Figure 4: A SQL query with an input-output example.

information. Each row of *dInfo* contains a device identifier d_{id} , the *city* of deployment of the device, and the height *ht* at which the device is installed. The query works as follows. Its result is the *Join* of two intermediate tables *Agg1* and *Agg2*. The table *Agg1* contains the maximum day-time reading ($5 \leq hr \leq 19$) per city among all devices deployed at ground level ($ht \leq 2$). This itself requires a join on the *signals* and *dInfo* tables. The table *Agg2* similarly is the maximum night-time ($hr \geq 17 \vee hr \leq 7$) reading for devices deployed at a height above the ground level ($ht \geq 11$).

A *Join* operator is parameterized by a predicate in the *ON* clause. It takes all combinations of pairs of rows from its input tables, concatenates them and filters according to the *ON* condition. A common usage of *Join* is an *Equi-Join*, where the *ON* clause equates the values of one (or more) columns in the first argument table with one (or more) columns in the second argument table. The query contains three equi-joins, two on the device identifier (for *J1* and *J2*) and one on the

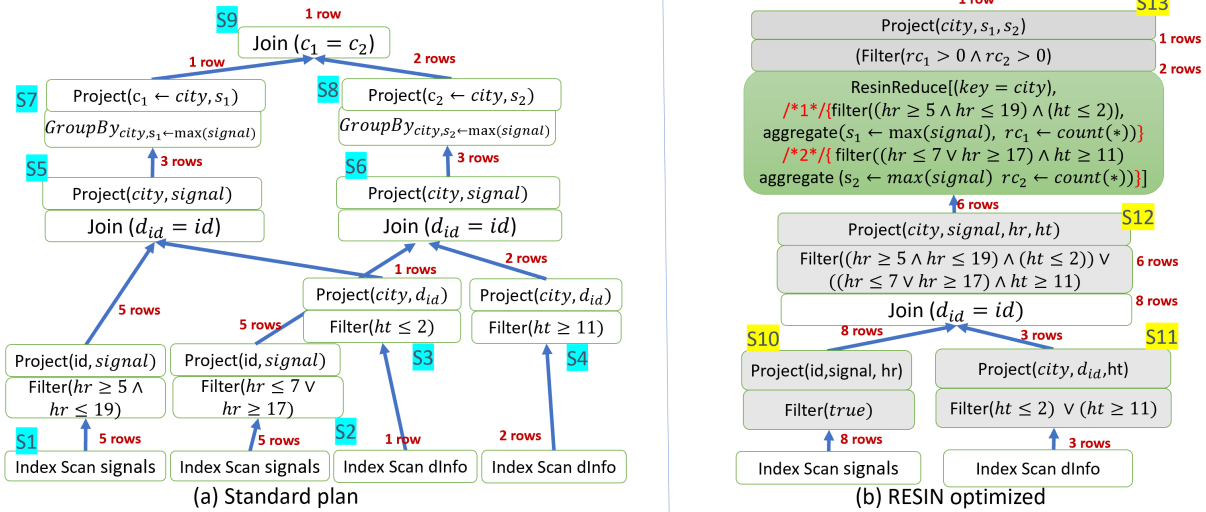

Figure 5: Query execution plans before and after RESIN optimization.

city (for the final output *summary*).

Aggregation happens via the *GroupBy* operator; it partitions its input table on unique values of the grouping key and performs an aggregation on each partition. It necessarily produces only one output row per partition. For instance, the computation of *Agg1* partitions the table *J1* on *city*, and for each partition it computes the maximum *signal* value using the aggregation *max*.

Figure 5 shows the execution plan generated by SPARK for this query (solid lines indicate I/O). As before, there is an index scan used each time the query references an input table. The implementation of an equi-join requires its inputs to be partitioned on equated columns, so shuffles are introduced along both arguments for all of the joins. Standard predicate push-down rules in a query optimizer will push the filters on *hr* and *ht* below join and into the respective scans in order to reduce the amount of data shuffled. Similarly, a *GroupBy* requires that its inputs be partitioned by the grouping key. So a shuffle is introduced before each *GroupBy*. In total, the plan has 9 stages; four for scanning input tables (*S1*, *S2*, *S3*, *S4*), three for the *Join* operators (*S5*, *S6*, *S9*), and a further two for the *GroupBy* operators (*S7*, *S8*).

This plan has many sources of redundant I/O. First, some rows of the *signals* table (e.g., with signal values *v5* and *v10*) are redundantly scanned. Note that the redundant scan happens despite having the best possible indices because some rows can satisfy both the filters on *hr*. The scanned tables are then partitioned on the same column (*id*) and shuffled to the respective join operators (*J1* and *J2*). A shuffle is a partitioning operator, it takes as input a partitioning key and a partition count, and partitions the input rows according to the key. We say two shuffle operators redundantly shuffle a row if (a) the key column for the two shuffles has the same value, and (b) all the columns of the row are derived from a common set

of source tables. For our example, the two rows corresponding to *v5* and *v10*, are redundantly shuffled before the join because they come from the same input row in *signals* table. Furthermore, as the left and right aggregates are computed separately, the aggregated results for the same city (city *a* for our example) are computed and shuffled redundantly.

Figure 5(b) is the optimized plan generated by RESIN. It has only 4 stages, each table is scanned once and no redundant shuffles. On a real dataset, a query with this structure (TPCDS *Q90* for example) would speedup by $2\times$.

RESIN eliminates redundant I/O through two key techniques: *sub-query fusion* and *binary operator elimination*. Sub-query fusion merges operators from different parts of the query if they process the same data. More formally, given two sub-queries *Q1* and *Q2*, the fusion rule attempts to construct a triple $\langle Q, ResinMap_1, ResinMap_2 \rangle$ such that $Q_1 = ResinMap_1(Q)$ and $Q_2 = ResinMap_2(Q)$.

For our example query, RESIN first merges the filters and projects applied on each of the input tables. *S1* and *S2* is merged into a single RESINMAP operator to obtain *S11*². Similarly, *S3* and *S4* are merged into a single RESINMAP operator *S12*. Notice that the filters are combined with a disjunction and projected columns are unioned, so that all of the data required by the query is read in one go.

The fusion process then recursively moves up the tree and the two joins (*J1* and *J2*) are merged together into a single join (*J*) that computes both the results. An additional RESINMAP is added right after to ensure that only rows required by either *J1* or *J2* are retained. A salient feature of the fusions rules is that they ensure that the computation of the fused query *Q* does not shuffle more rows than the individual queries.

²All the light shaded *Filter*, *Project* chains in Figure 5 actually represent RESINMAP. We do not show the RESINMAP explicitly, as we did in Figure 2(d), for ease of exposition.

```

1  // ps ∈ partition(J, [city, signal, ht, hr]);
2  max1 = max2 = ∞;
3  rc1 = rc2 = 0;
4  foreach ((city, signal, ht) in ps.group) {
5      if (hr ≤ 19 ∧ hr ≥ 5 ∧ ht ≤ 2) {
6          max1 = max(max1, signal); rc1 = rc1 + 1;
7      }
8      if ((hr ≥ 17 ∨ hr ≤ 7) ∧ ht ≥ 11) {
9          max2 = max(max2, signal); rc2 = rc2 + 1;
10     }
11 }
12 output (city, max1, max2, rc1, rc2);

```

Figure 6: A reducer for the query plan in Figure 5.

Note once again that the output of the individual joins $J1$ and $J2$ can be separated out by applying appropriate filters on J . The reader can verify that $J1 = \text{Select}(hr \leq 19 \wedge hr \geq 5 \wedge ht \leq 2) \text{ from } J$ and $J2 = \text{Select}((hr \geq 17 \vee hr \leq 7) \wedge ht \geq 11) \text{ from } J$.

Finally, the two aggregations are fused together. Note that the aggregates need to be applied on different filtered subsets of J . It turns out that fusion of aggregation operations cannot be done with standard SQL operators, neither with RESINMAP alone. RESIN introduces a generic reduce operator RESINREDUCE that makes the optimization process much more expressive by directly considering map-reduce plans. As seen in Figure 5, the two GroupBy are fused into a RESINREDUCE operator. The RESINREDUCE operator is parameterized by a (partition) key (in this case, *city*) and a list with two entries. Each entry contains the filter that determines a subset of rows to be aggregated as well as the aggregation function. In addition, each entry has a *count*(*) aggregation for reasons described below.

Figure 6 shows the code that implements the reducer, applied to each partition of J (partitioned on *city*) independently. The reducer maintains variables $max1, max2, rc1, rc2$ for computing four aggregations. It then iterates over the partition, and for each row, it updates the aggregation variable if the row satisfies the corresponding predicate. The reducer outputs one row per partition, with five columns: the grouping key *city* and the four aggregated values.

The variables $rc1$ and $rc2$ are used to check if an aggregation was even applied for a partition. This is necessary to obtain back the output of the original GroupBys. For our example, the output of the reducer³ will contain 2 rows corresponding to cities a and b , however for $city = b$, $rc1 = 0$, indicating that Agg1 has no output for $city = b$.

Once the aggregations are fused, RESIN performs *binary operator elimination* to get rid of the final Join ($S7$) altogether. RESIN figures out that the join was doing nothing more than putting together the aggregates from the two sub-queries, which is already done in the output of the RESINREDUCE

³We have not shown the output of the fused query; its output is the union of the original fused queries (with extra columns).

operator. RESIN replaces the *Join* with a simple filter that ensures that a row is output only if both aggregates produce an output, as is dictated by the semantics of a join.

In summary, RESIN introduces a class of optimizations that target map-reduce operators to eliminate redundant I/O.

3 Preliminaries

We use a query language based on SPARKSQL [5] to present our analysis formally. We define a table as a multi-set of rows that each follow the same *schema*. A schema S is a set of pairs of column name and data type: $\{\langle a_1, t_1 \rangle \langle a_2, t_2 \rangle \cdots \langle a_n, t_n \rangle\}$. A row r that follows schema S is a tuple of form $\{a_1 : v_1, \dots, a_n : v_n\}$ that assigns a value v_i of type t_i to column a_i of the schema. In this case, we say $r.a_i = v_i$. We will not explicitly refer to the data-types of columns in the rest of this paper because it is not relevant to our analysis.

3.1 SQL Operators

This section defines the core SQL operators of our query language. We assume a generic syntax for *expressions* that can be evaluated over a row to produce a scalar data value. A *predicate* is simply an expression that evaluates to a Boolean value. Our implementation supports all SPARKSQL expressions and predicates.

Select $T_2 = \sigma[\phi](T_1)$

A *Select* operator discards rows of T_1 that do not satisfy the filter predicate ϕ .

Project $T_2 = \pi[\text{map}(c_i \leftarrow e_i)](T_1)$

A *Project* is parameterized by a map of $\langle c_i, e_i \rangle$ pairs, where c_i is a column name and e_i are expressions. *Project* is a row-wise operator. It iterates over all the rows of the input table T_1 and for each row, it applies the expressions e_i to compute data values of output columns c_i . Note that *Project* can be used to create *aliases* of existing columns. For instance, the operator $\pi[c_{\text{new}} \leftarrow c_{\text{old}}]$ renames input column c_{old} to the output column c_{new} . We sometimes write this operator as $\pi[C \leftarrow E]$ where C is a list of column names and E is a list of expressions and $\|C\| = \|E\|$.

GroupBy $T_2 = \gamma[K, \text{map}(c_i \leftarrow \text{agg}_i(\text{col}_i))](T_1)$

A *GroupBy* partitions the input table T_1 by unique values of columns K and applies aggregations agg_i over each partition. A partition is also referred to as a *group*. Each aggregation agg_i applies a commutative and associative function (e.g., sum, min, max, etc.) over a single column col_i of T_1 . Each column of the output table is either the result of an aggregation or a key column. We sometimes write a *GroupBy* as $\gamma[K, C \leftarrow A(\text{Col})]$ where C and Col are lists of column names, A is a list of aggregations, and $\|C\| = \|A\| = \|\text{Col}\|$.

```

1 method ResinMapOperator(T,  $\mu[L]$ ) {
2   foreach(row in T) {
3     foreach( $\langle \phi, C \leftarrow E \rangle$  in L) {
4       if( $\phi(\text{row})$ ) {
5         for(i in 1..|E|) out.C[i]  $\leftarrow E[i](\text{row})$ 
6         output(out)
7       }
8     }
9   }
10 }

```

Figure 7: RESINMAP Operator

Join (equi-join) $T_2 = \bowtie[\psi, jt](T_{\text{left}}, T_{\text{right}})$

A *Join* is a binary operator that matches rows from T_{left} with rows from T_{right} on a conjunction of equality predicates ψ of the form $(a_1 = b_1 \wedge a_2 = b_2 \dots \wedge a_n = b_n)$, where a_i are columns of T_{left} and b_i are columns of T_{right} . The operator requires that the columns names of the two input arguments be distinct. Parameter *jt* is a *join type* and can be any of *inner* (i), *leftOuter* (lo), *rightOuter* (ro), *leftSemi* (ls), or *rightSemi* (rs) with the standard semantics [5]. For simplicity we only define rules for inner joins in this paper. Our implementation handles other types as well.

Union $T_2 = \uplus(T_{\text{left}}, T_{\text{right}})$

A *Union* is a binary operator that unions the rows of T_{left} and T_{right} . It performs a multi-set union, i.e., it does not remove duplicate rows from the output. The two tables need to have the same number of columns and their types must match. The output table T_2 retains the schema from the left input. We note that different SQL dialects tend to pick different ways of assigning the output schema of a *Union*. We choose one particular style that is closest to SPARKSQL.

A *query* is a sequence of assignments that each produce a new table from existing ones using one the operators described above. Formally, let T_0, T_1, \dots, T_n be a sequence of input tables. A query is a sequence of assignments of the form $T_i = \text{uop}(T_j)$ (for unary operators *uop*) or $T_i = \text{bop}(T_j, T_k)$ (for binary operators *bop*) such that $i > n, j < i, k < i$. We sometimes refer to a table T_i by the query that computes it.

3.2 RESIN operators

RESIN introduces two operators, RESINMAP and RESINREDUCE that are used during the optimization process.

RESINMAP $T_2 = \mu[\text{List}(\phi, C \leftarrow E)](T_1)$

A RESINMAP is a row-wise unary operator. It is parameterized by a list L of pairs $\langle \phi, C \leftarrow E \rangle$. Its semantics is defined by the imperative code shown in Figure 7. For each input row, the operator can produce up to $\|L\|$ output rows. The operator iterates over L (Line 3), and if the predicate

```

1 method ResinReduceOperator(G,  $\rho[K, L]$ ) {
2   foreach( $\langle \phi_i, c_i, \text{agg}_i(\text{col}_i) \rangle$  in L)
3     out.ci  $\leftarrow \text{init}(\text{agg}_i)$ 
4   foreach(row in G.rows) {
5     foreach( $\langle \phi_i, c_i, \text{agg}_i(\text{col}_i) \rangle$  in L)
6       if( $\phi_i$ ) out.ci =  $\text{agg}(\text{out.c}_i, \text{row.col}_i)$ 
7   }
8   output(G.keys, out)
9 }

```

Figure 8: RESINREDUCE Operator

ϕ is satisfied (Line 4) then it applies expressions in E to compute data values of output columns C (Line 5). In other words, RESINMAP applies different chains of *Select* ($\sigma[\phi]$) followed by *Project* [$C \leftarrow E$] operators, to produce multiple output rows for each input row. This operator requires that for each map $C \leftarrow E$ in its list, the set of output columns C be the same (which is also the schema of the output table). The expressions in E can, however, be different. For example, $\mu[(\phi_1, a \leftarrow e_1, b \leftarrow e_2), (\phi_2, a \leftarrow e_3, b \leftarrow e_4)]$ is a valid operator, whereas the following is not: $\mu[(\phi_1, a \leftarrow e_1), (\phi_2, c \leftarrow e_3)]$.

RESINREDUCE $T_2 = \rho[K, \text{List}(\phi, c \leftarrow \text{agg}(\text{col}))](T_1)$

A RESINREDUCE operator first partitions the input into groups on input columns K , and processes each group independently in a streaming manner. The operator is parameterized by a list L of triples $\langle \phi, c, \text{agg}(\text{col}) \rangle$. Figure 8 describes the per-group computation. It takes a single group G as input, represented as the partition key $G.\text{key}$ and a multi-set of rows $G.\text{rows}$. It first initializes all the aggregations (Line 3) and then iterates over the rows in G (Line 4). For each row, it applies the filter ϕ_i (Line 6) and then updates the corresponding aggregate agg_i (Line 6). Once the entire group is processed, we get a single row containing the keys and the computed aggregates. As notational convenience, we use $\text{init}(\text{agg})$ to denote the identity value for an aggregation *agg*. For instance, $\text{init}(\text{sum})$ would be 0, $\text{init}(\text{max})$ would be $-\infty$ and $\text{init}(\text{min})$ would be ∞ .

RESINSIMPLEMAP $T_2 = \lambda[\phi, C \leftarrow E](T_1)$

RESINSIMPLEMAP is a simplified version of RESINMAP that produces at-most one output row per input row. It applies a single predicate ϕ and if a row satisfies the predicate, it computes output columns C by applying expressions E . Its semantics is as in Figure 7 with L having a single element. It represents the most basic form of a mapper that still subsumes a *Select* and a *Project*.

4 RESIN optimizations

RESIN integrates new rules into an existing query optimizer. It leverages the existing rules to perform certain normalizations

that increase the scope of the newly introduced rules. We begin this section by stating rule ordering assumptions and then describe the two core optimizations of RESIN, namely sub-query fusion and binary operator elimination.

4.1 Assumptions

RESIN assumes that the following two rules are applied before further optimizations are attempted. These assumptions are not fundamental to the analysis, they are only required to simplify the presentation.

Column name normalization The query language allows the reuse of column names within a query. For example, $T' = \gamma[a, b \leftarrow \text{sum}(b)](T)$ assigns the column name b to the result of an aggregation in T' , even though b is already a column in T . We assume that a normalization pre-pass assigns unique names to new columns produced in the query. For example, the above would be rewritten to $T' = \gamma[a, b\#1 \leftarrow \text{sum}(b)](T)$. Such a pre-pass is commonly applied by all query optimizers. In addition to aggregations, a *Project* operator can also produce new columns. We require that for any projection map $\text{map}(c_i \leftarrow e_i)$, either e_i is just c_i or c_i is a fresh column name. In other words, either a column is just passed through or the output table must use a fresh column name.

Predicate pushdown The optimizer pushes *Select* operators to apply before *Project* operators. Such a rewriting is always possible, and in fact, standard optimizers have many rules that ensure *Select* operators apply on the input data as soon as possible. In particular, RESIN assumes that a *Select* operator is never a parent of a *Project*.

We also define some standard functions. The function $\text{cols}(e)$ takes as input an expression e and returns the set of column names used in the expression. For example, $\text{cols}(b_1 + b_3 > 0)$ is $\{b_1, b_3\}$. We also define a function $\text{fresh}()$ that returns a fresh (globally unique) column name each time. Finally, as the output of a *Union* operator inherits column names from the left argument, we assume the availability of an expression-renaming function $\alpha(\uplus(T_{\text{left}}, T_{\text{right}}), e)$ that given an expression e over columns of T_{right} , returns an expression over the corresponding columns of T_{left} . For example, if T_{left} has columns (a_1, a_2, a_3) and T_{right} has columns (b_1, b_2, b_3) , then $\alpha(\uplus(T_{\text{left}}, T_{\text{right}}), b_1 + b_3 > 0)$ is $a_1 + a_3 > 0$. We drop the first argument of α when it is clear from the context.

4.2 Generalized sub-query fusion

The goal of sub-query fusion is to combine two queries Q_1 and Q_2 that operate on the same set of input tables, but may produce different outputs. Fusion produces a common query Q and two *residual* RESINSIMPLEMAP operators λ_{r1} and λ_{r2} such that $Q_1 = \lambda_{r1}(Q)$ and $Q_2 = \lambda_{r2}(Q)$. This ensures that the any redundant computation across Q_1 and Q_2 is captured

Figure 9: Basic query fusion.

in one single query Q , and only simple map operators (via the residual operators) are needed to get back the original outputs. Furthermore, as would be evident from the way we fuse operators, we ensure that the computation of Q itself does not require more stages than what is required for computing just one of the sub-queries. Finally, we ensure that Q does not output any row that is not needed by either Q_1 or Q_2 . This kind of fusion is, of course, not always possible. The rules below define the conditions under which it is possible and how to combine the queries when possible.

Identity Invariant. Given a RESINSIMPLEMAP operator $\lambda[\phi, \text{map}(c_i \leftarrow e_i)]$, we say that it satisfies the *identity invariant* if e_i is simply c_i for all indices i . This means that the operator carries a subset of the input columns unmodified to the output table. For a set of columns C , we use the shorthand $\lambda[\phi, I(C)]$ to represent such operators, where $I(C)$ is the identity function on C : $\{c \leftarrow c \mid c \in C\}$. We will ensure that all residual operators produced as a result of fusion satisfy the identity invariant.

4.2.1 Base rule

The rule for fusing two RESINSIMPLEMAP operators applied on the same table is shown in Figure 9. The RESINSIMPLEMAP operators λ_1 and λ_2 apply different filters and projections to the same input table. Fusing these operators is simple, except that we must take care to establish the identity invariant for the residual operators. This is important for recursively fusing more operators up the query tree. The fusion first applies a disjunction of the filters and a union of the projections (λ_{common}). This ensures that the necessary rows and columns are carried forward. Next, all the residual operators λ_1 and λ_2 need to do is to apply the specific filters for Q_1 and Q_2 , respectively.

Note that column-name normalization (Section 4.1) guarantees that for any column c , if $c \in C_1$ and $c \in C_2$ then the column must be passed through from T , i.e., both λ_1 and λ_2 apply the projection $c \leftarrow c$. This ensures that the projection map of λ_{common} is well-defined, i.e., it does not include two different mappings for the same output column.

$$FUSE(op_1(Q_1), op_2(Q_2)) := \langle op'(Q), \lambda'_{r1}, \lambda'_{r2} \rangle$$

$$\text{Given } FUSE(Q_1, Q_2) := \langle Q, \lambda_{r1}, \lambda_{r2} \rangle$$

Figure 10: Recursive fusion of unary operators. Given two fusible queries Q_1 and Q_2 , shown in dotted circles, the figure shows how to fuse $op_1(Q_1)$ and $op_2(Q_2)$. The shaded circles depict the output of the fusion.

Figure 11: RESINSIMPLEMAP query fusion.

4.2.2 Recursive fusion of unary operators

Fusion proceeds recursively. For this section, fix the fact that $FUSE(Q_1, Q_2) := \langle Q, \lambda_{r1}, \lambda_{r2} \rangle$. As described in Figure 10, our goal is to construct $FUSE(op_1(Q_1), op_2(Q_2))$, where op_1 and op_2 are one of RESINSIMPLEMAP (λ), GROUPBY (γ) or RESINREDUCE (ρ). For ease of notation, an operator λ_x always expands to $\lambda[\phi_x, C_x \leftarrow E_x]$.

Recursive fusion of two RESINSIMPLEMAP operators, which subsumes the fusion of *Select* and *Project* operators, is shown in Figure 11. Observe that predicates ϕ_{r1} and ϕ_{r2} are applied on the output of Q . Further, as the residual operators satisfy the identity invariant, the columns referred in the predicates ϕ_1 and ϕ_2 also come from the result of Q . Therefore, the identity projections in λ_{r1} and λ_{r2} can be dropped and the filters ϕ_1 and ϕ_{r1} can be conjoined together, and so can ϕ_2 and ϕ_{r2} . Fusion then follows by applying the rule in Figure 9.

The rule for fusing two GROUPBY operators is shown in Figure 12. The figure shows two aggregations on the same table, which is the output of Q , except that they first apply their own filter $s\lambda_{r1}$ and λ_{r2} , respectively. (For simplicity, we have shown a single aggregation in each of the GROUPBY operators. The case for multiple aggregations extends easily.) The GROUPBY operators are on the same key, so we can fuse them into a single RESINREDUCE operator that does the aggregations conditionally as shown in the figure. In addition, the

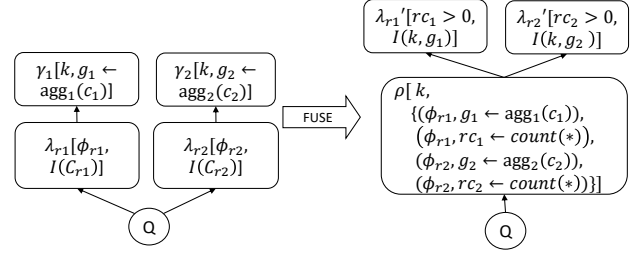

Figure 12: GROUPBY query fusion. Both rc_1 and rc_2 are fresh column names.

$$FUSE(op_1(Q_1, Q_3), op_2(Q_2, Q_4)) := \langle op'(Q_{lt}, Q_{rt}), \lambda'_{r1}, \lambda'_{r2} \rangle$$

$$\text{given } FUSE(Q_1, Q_2) := \langle Q_{lt}, \lambda_{r1}, \lambda_{r2} \rangle$$

$$\text{and } FUSE(Q_3, Q_4) := \langle Q_{rt}, \lambda_{r3}, \lambda_{r4} \rangle$$

Figure 13: Recursive fusion of binary operators. The figure shows how to extend fusion of two pairs of fusible queries Q_1, Q_3 and Q_2, Q_4 (shown in dotted circles), by additional binary operators op_1 and op_2 . The shaded circles depict the output of such recursive fusion.

fusion requires two new aggregations rc_1 and rc_2 that count how often the predicates are satisfied. For the left (respectively, right) group-by to produce any output for a grouping key, at least some rows in the group should satisfy the filter of λ_{r1} (respectively, λ_{r2}). Thus, we need to guard the left (right) output of the fused query with a predicate that ensures that at least one row in the group satisfied the predicate. The new residual operators λ'_{r1} and λ'_{r2} apply the filters $rc_1 > 0$ and $rc_2 > 0$ to only output groups that have at least some rows that satisfy the predicates. The rule extends directly to the fusion of two RESINREDUCE operators as well.

Column Aliasing Our implementation relaxes the rule's precondition that grouping keys be exactly the same; even *aliasing* columns are allowed. That is, columns can be renamed versions of the *same* column in an earlier table. The same relaxation also applies to the join rule that follows later.

Figure 14: Join query fusion

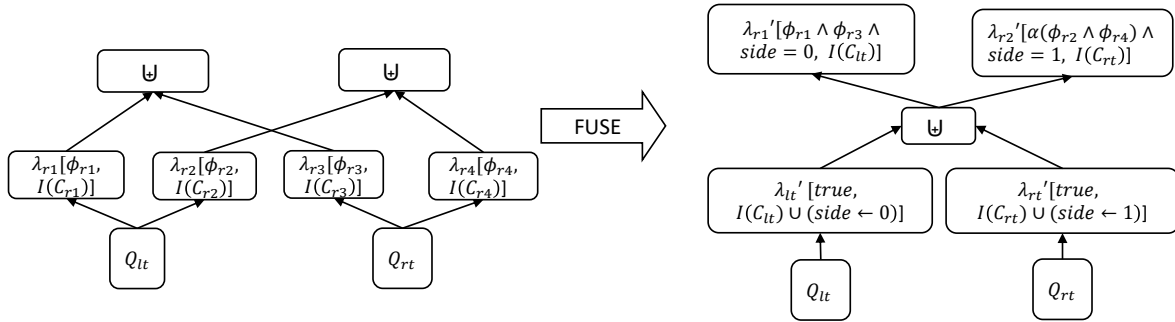

Figure 15: Union query fusion. The column *side* is a fresh name.

4.2.3 Binary operator fusion

Binary operator fusion is depicted in Figure 13. It defines $FUSE(op_1(Q_1, Q_3), op_2(Q_2, Q_4))$ using $FUSE(Q_1, Q_2)$ and $FUSE(Q_3, Q_4)$.

Figure 14 shows the rule for fusing two *Join* operators. The rule simply pulls up the residual predicates from before the join to after. Next, it conjoins the residual predicates that are relevant to $(Q_1 \bowtie Q_3)$, namely ϕ_{r1} and ϕ_{r3} , to obtain λ'_{r1} . Similarly, $\phi'_{r2} = \phi_{r2} \wedge \phi_{r4}$. The residual predicates satisfy the identity invariant. However, we still apply the base fusion rule (Figure 9) to push down the common predicate $(\phi_{r1} \wedge \phi_{r3}) \vee (\phi_{r2} \wedge \phi_{r4})$. This would eliminate rows that are not needed by either $Q_1 \bowtie Q_3$ or $Q_2 \bowtie Q_4$, potentially before a shuffle.

Figure 15 shows the rule for fusing two *Union* operators. We only describe a simplified version of the rule where we assume that Q_{lt} and Q_{rt} are union-compatible, i.e., they have the same number of columns and their types match. This version is enough to cover the core ideas.

In order to fuse two unions, we need to be able to pull up filters above a union. This poses a challenge as the output has rows from both sides and we want to apply different predicates to the rows from each side. To enable this pull up, we add an additional (fresh) column *side* that tags rows with the side that generated them. This additional column is added by applying λ'_{lt} and λ'_{rt} to Q_{lt} and Q_{rt} , respectively. The new residual predicates do an additional check to match rows from the appropriate sides. As the union result renames the columns from the right input, λ'_{rt} additionally applies the

renaming function α (defined in Section 4.1).

4.2.4 Operator alignment and exact fusion

The fusion rules described so far only fuse operators of the same type. RESIN also has an auxiliary rule that enables fusion of operators that are preceded by a RESINSIMPLEMAP on one side but not on the other. Given Q_1 and Q_2 are fusible, we enable the fusion of $op_1(\lambda(Q_1))$ and $op_2(Q_2)$, where op_1 and op_2 are fusible according to rules 1-6 above. We do so by adding an empty lambda $\lambda_e = \lambda[true, I(*)]$ as a child of op_2 .

We have described the fusion of core SQL operators. Our implementation handles all SPARKSQL operators, but fusion of other operators is only possible if they have the exact same parameters and apply on the exact same query. We define this *exact* fusion rule as $FUSE(op_1(Q_1), op_2(Q_2)) = op_1(Q_1)$ only if $op_1 = op_2$ and $Q_1 = Q_2$. Finally, note that the rules above define the fusion of two sub-queries. Through repeated application of the rules we can fuse any number of sub-queries (say, n) into a single query with n residual operators.

4.3 Binary operator elimination

When the two arguments of a binary operators can be fused, RESIN can sometimes eliminate the binary operator altogether. The two elimination rules are defined below.

UNION ELIMINATION RULE

Given a *Union* query $\uplus(Q_1, Q_2)$ where Q_1 and Q_2 can be fused such that $FUSE(Q_1, Q_2) := \langle Q, \lambda_{r1}, \lambda_{r2} \rangle$ then we

Figure 16: Union elimination rule.

Figure 17: Join elimination rule. The rule requires that each of K_1 and K_2 alias with K .

can eliminate the *Union* altogether using the rule shown in Figure 16. The rule follows directly from the definition of RESINMAP. Recall that a RESINMAP operator $\mu[List(\phi, C \leftarrow E)]$ can produce multiple outputs per input row. This is sufficient to implement the *Union* operator of the form above. The resulting RESINMAP operator has one entry for each input that applies the filter ϕ_{r_i} . The right expressions are renamed using α and assigned to the column names from the left (C_1) to conform to the semantics of a *Union*. Figure 2 is an example application of this rule.

RESIN rules show that any single-input query consisting of *Select*, *Project* and *Union* operators can be implemented by a single RESINMAP operator.

JOIN ELIMINATION RULE The goal of this rule is to substitute a binary join operator with a mapper, which is a row-wise unary operator. This is only possible if the output of the join has already been computed in the fused query. This holds when the join combines the results of a RESINREDUCE query $\rho[K, L]$ and is equi-join on K (modulo aliasing). The rule is shown in Figure 17. Figure 5 shows an example application of this rule.

5 Implementation

We integrated RESIN into a popular state-of-the-art big-data system SPARK [26]. Our optimizations are general and can be applied to other big-data systems [22, 30] as well. We chose SPARK because it is easier to extend [5], has rich code-

gen support as well as competitive performance. Moreover, SPARK already performs some low-level I/O optimizations. For instance, it implements exchange reuse [1, 2] that determines if two exchanges are exactly equivalent and skips the duplicate computation. It also implements store-predicate pushdown that pushes down filters and projections to the storage layer [3].

SPARK makes use of the Catalyst query optimizer [5]. Optimization rules in Catalyst are organized into batches. As is standard, logical rules are applied before physical rules. Each physical operator has a pre-defined map-reduce implementation based on a low-level *resilient distributed dataset* (RDD) API [25]. SPARK uses a whole-stage code generator [23] to efficiently compile all operators in a single stage. We describe key details of our implementation.

Initiation and termination of RESIN rules We added all RESIN rules in a batch that executes after the standard optimizations are applied. These rules apply in a single (pre-order) traversal of the query tree. RESIN initiates fusion starting from input table scans. It then moves up the tree fusing operators recursively. The fusion process terminates when none of the fusion rules apply. At this point, RESIN applies the operator elimination rules in cases where the consumers of a fused query share a common parent. After elimination, the resulting query could have zero or more fused sub-queries whose output is consumed more than once, requiring the use of *exchange* operators, as described next.

RESIN exchange reuse The only operator in SPARK whose output can be consumed more than once is an *exchange* operator. Thus, RESIN introduces an exchange at the reuse points. An exchange is parameterized by a partitioning column. To decide on the partition column, RESIN traverses up along each of the consumers C_i until it hits an operator that requires partitioning (RESINREDUCE, *Join*, *GroupBy*), and identifies a partitioning column p_i for each consumer. Next, it picks the column p_i that is required by most consumers (we use random choice to break ties).

RESIN operators We added three new logical operators with the structure defined in Section 3. We also add their corresponding physical operators. The physical operator for RESINSIMPLEMAP is just a combination of *Select* and *Project*. We added a new physical operator that implements RESINMAP with appropriate whole-stage code-generation support. The physical operator for RESINREDUCE is implemented by carefully extending existing aggregation iterators in SPARK. This allowed us to delegate the handling of different column types and the various associated subtleties in the application of aggregation functions (e.g., *null* values, type-casting, overflow/underflow, etc.) to routines already present in SPARK. Finally, we added implementation strategies for our opera-

Figure 18: Fraction of time spent in stages with redundant I/O.

tors. The strategies analyze the logical operators, construct partial aggregates and introduce partitioning operators (for RESINREDUCE), and substitute the logical operators with corresponding physical operators.

6 Evaluation

We evaluated RESIN using the TPCDS benchmark suite, consisting of 104 queries, at scale factors of 1TB and 10TB. The evaluation was done on two different SPARK clusters. We used a cluster with 120 cores and roughly 480GB memory, spread over 10 nodes for evaluating at 1TB scale. For evaluating at 10TB we used a cluster with 480 cores and 1.6TB memory, spread over 34 nodes. The input tables were stored in parquet format. We ran each query 5 times, discarded the first run and took average of the rest. Among the 104 queries, we found that 40 queries have redundant I/O. As mentioned before, the baseline already has basic I/O optimizations. It pushes predicates and projects to the store for all these queries. And it is able to reuse exchanges (usually right after a map stage) even without RESIN optimizations in about half of these queries. In the rest of this section, we focus on these queries alone. We begin by presenting detailed results at 1TB scale and present summary results at 10TB scale in Section 6.4.

6.1 Optimization opportunity

For each query, we identified stages that perform redundant I/O. This was done post-facto by comparing baseline and optimized plans, and determining the baseline stages that were fused together by RESIN. Figure 18 shows the fraction of time spent in these stages relative to the total execution time of the query. The larger the fraction, the greater the optimization opportunity. We find that 40% of the queries spend at least 50% of the time in stages with redundant I/O. We mark these queries as *high-impact* queries as they have significant potential for improvement. Another 25% spend at least 10% of their time in stages with redundant I/O, and we mark them as *medium-impact* queries. The remaining (*low-*

impact) queries may have some redundant I/O but eliminating it is unlikely to affect the overall query execution time.

TPCDS queries are over multiple (*fact* and *dimension*) input tables. There are 6 large fact tables and several small dimension tables. A deeper inspection of our results revealed that the fraction of time spent in redundant sub-queries is significantly influenced by whether one of these large tables was redundantly processed or not. All queries that have medium or high impact were processing at least one such table multiple times (sometimes even after joining with few other tables).

6.2 Speedup from RESIN optimizations

Figure 19 reports the performance improvements from RESIN on high and medium impact queries. These cover 25% of the entire benchmark suite. As can be seen, RESIN improves the execution time of most of the queries. It achieves an average (geomean) speedup of $1.4\times$ across these queries. RESIN performs particularly well on *high-impact* queries where it achieves a geomean speedup of $1.6\times$ with some queries speeding up by $6\times$.

The queries that benefit most (Q9, Q28, Q88, Q75, Q31, Q90) are also ones where RESIN was able to apply *binary operator elimination*. All the other queries benefit only from *generalized sub-query fusion*. Some of these (Q65, Q61, Q81, Q1, Q30, Q59) had multiple exchanges after fusion on the *reuse exchange column* and they see moderate gain. A few queries (Q92, Q32, Q16, Q41) had reuses close to input scans. These are the queries that see the least benefit because the baseline already performs some basic I/O optimizations (exchange reuse and store-predicate pushdown; see Section 5).

In two queries (Q74, Q41) the data overlap between the sub-queries that were fused was very low. However, fusion still helps produce execution plans with fewer stages, and does so while guaranteeing that the number of rows shuffled after fusion is no more than the baseline. We find that, in Q74, simplifying the plan has some second order system effects (see Section 6.3), and fusion improves performance. In Q41,

Figure 19: Overall execution time speedup for high and medium impact queries. Each bar is labeled with the execution time of the baseline query (in seconds).

Figure 20: For low impact queries we plot the speedup in sub-query with redundant I/O alone. Along the x-axis we report the execution time of the entire query (in seconds) with and without RESIN.

the reuse is close to the input and hence fusion only eliminates one map stage. As a result, we see a small 3% degradation.

Comparison with BLITZ We evaluated BLITZ on these queries and found that it only optimizes two of the queries: *Q9* and *Q28*. Both these queries perform a chain of joins at the end. BLITZ was only able to eliminate the first of these joins and therefore was only able to get speedups of $1.6\times$ and $1.9\times$, respectively. This limitation has also been acknowledged in prior work [10]. RESIN eliminates multiple joins and achieves a speedup of $2.4\times$ and $3.3\times$, respectively, on these queries.

Speedup on low impact queries Figure 20 reports speedups for low impact queries. We report the execution time of the entire query along the x-axis. As can be seen RESIN optimizations have no significant gains or degradation on any of these queries. To isolate the effects of RESIN optimizations, we plot the speedup for the sub-query that was optimized. RESIN achieves a moderate speedup on several of these sub-queries. RESIN optimizations show a small degradation in a few of these sub-queries (*Q2*, *Q5*, *Q95*). In *Q5* the amount of redundant I/O is too small to matter. In *Q2*, *Q95*, the baseline already performs an exchange reuse. RESIN fuses one additional operator, but once again the additional I/O is too small to matter.

Overall, RESIN reduces the total time to run all the 104 queries by 12%. Note that RESIN has a negligible impact on query optimization time; the overall compilation time for the entire benchmark increased from 42 to 45 seconds.

6.3 Impact of RESIN optimizations on systems resources

Figure 21 - Figure 24 plot the impact of RESIN optimizations on disk, network, memory and CPU for medium and high impact queries (we see no discernible impact on low impact queries). For disk, we report the cumulative bytes of data accessed from disk. For network, we report the cumulative number of packet transfers performed. Note that data sizes transferred over the network follow the same trend as disk I/O, as most I/O in a big-data setting is over the network. For memory, we plot the cumulative memory footprint. For CPU, we plot the total CPU time spent by all tasks on all machines. This is a measure of the total CPU work done to evaluate a set of queries and is largely independent of cluster size [19]. We infer the following conclusions from these plots.

First RESIN reduces the cumulative CPU, network and disk footprint, consuming 24%, 25% and 19% fewer resources respectively. The savings in-terms of CPU are slightly higher than disk because RESIN not only saves on I/O but also on I/O induced processing (compression, serialization etc) which have a significant compute cost [14].

Second, RESIN achieves these benefits while incurring the same overall memory cost (Figure 23) as the baseline. A few queries (*Q64*, *Q31*, *Q61*) see a slight increase in memory requirement, while a few others (*Q4*, *Q75*, *Q88*) need lesser memory. However, all these queries see significant reduction in execution time. Overall even if fusion increases the amount of data processed by each operator, it does not impact the overall memory footprint of the workload (see Figure 19).

Third, the gap between RESIN and the baseline widens as we move to the right. Queries on the right usually have deeper operator trees and this graph demonstrates that RESIN is able to fuse deep and complex queries.

Finally, the plots indicate that RESIN optimizations

Figure 21: Cumulative disk I/O

Figure 22: Cumulative network packets

Figure 23: Cumulative memory footprint

Figure 24: Cumulative CPU time of tasks

Figure 25: Speedup for 10TB TPCDS. Each bar is labeled with the execution time of the baseline query (in seconds).

are fairly robust, even the worst performing queries ($Q92, Q32, Q41$) do not show any discernible degradation on any of the system metrics. In $Q74$ RESIN fusion does not reduce the amount of disk I/O, but it still reduces the CPU and network load, and hence sees an execution time benefit.

6.4 Impact on larger scale data

We report the impact of RESIN on TPCDS at 10TB scale. Figure 25 shows the speedup's obtained for the 40 affected queries. We see that RESIN does somewhat better at larger

scale. It obtains higher speedup on a few medium and high impact queries ($Q64, Q39a, Q39b, Q28$) while achieving similar speedups for the other queries (except $Q59$). We find that the average (geomean) speedup for high and medium impact queries goes up to $1.5\times$ (was $1.4\times$ at 1TB). Once again, the optimizations have no significant improvement or degradation on the low-impact queries. Figure 26 reports the I/O savings. The total disk I/O saved went up to 31% (was 19% at 1TB). Overall, RESIN reduces the execution time of the entire workload (104 queries) by 17%.

Figure 26: Cumulative disk I/O for 10TB TPCDS.

7 Related Work

We discuss three broad lines of work related to this paper.

Advances in big-data query optimization Big-data query optimizers borrow and build upon rewrite rules from the database literature. Several big-data-specific optimizations have also been used [8, 9, 15, 16, 28–30]. However, none of these logically fuse multiple operators or eliminate binary operators. The work that is most closely related to RESIN is BLITZ [10], which presented an extension to the query optimizer to find and substitute sub-queries that can be implemented by a streaming operator. BLITZ added new rules that optimize three specific query patterns. Two of these patterns were self-joins and self-unions that followed a *GroupBy* on the same input table. The third pattern was a specialized implementation of a *min* aggregation followed by a *Join*. The BLITZ rules can perform some of the operator eliminations that RESIN can perform. However, we find that BLITZ patterns cover a very small fraction of queries in standard benchmarks. Only one of the patterns applies to TPCDS queries and that too only on two queries. Furthermore, BLITZ operators do not compose with each other and therefore do not even eliminate redundant shuffles from multi-way self-joins and self-unions. RESIN introduces the ability to fuse multi-input sub-queries and eliminate unnecessary shuffles. This fusion facilitates more join and union elimination.

Multi-query optimization Multi-query optimization (MQO) is a well studied problem in classical database literature [11, 17, 20, 31]. The goal of MQO is to optimize many concurrently submitted queries together, and is typically done by reusing results of common sub-queries. Such optimizations are typically performed in a single scale-up database setting and trade-off latency for throughput. The goal of RESIN is very different. RESIN looks for intra-query redundancy in the big-data setting, and eliminates it while ensuring no additional rows are shuffled. Thus, it simultaneously improves both latency and throughput.

The fusion techniques proposed here are also significantly different than MQO. MQO is typically limited to Select-Project-Join (SPJ) queries, whereas RESIN supports com-

possible fusion for all SparkSQL operators. Such support is necessary to eliminate redundancy from deep queries. Our evaluation reveals that optimization of the high and medium impact queries in TPCDS requires fusion of a large number of operators: 21 of 25 queries have 10 to 30 operators. We show that fusion and elimination are not always possible without having new operators and propose RESINMAP and RESINREDUCE operators to enable this. For example, *Union* elimination is only possible with RESINMAP and *GroupBy* fusion is only possible with RESINREDUCE. Finally, our binary operator elimination rules are not part of any multi-query or database optimizer.

Code generation techniques for query processing.

There is a long line of work on compilation techniques to generate efficient single-machine code for a chain of SQL operators [6, 12, 13, 23]. Such compilers target low level inefficiencies such as virtual call overheads and computation of common sub-expressions across operators. This is an active area of research, and includes recent efforts like FLARE [6] that target the compilation of SPARK to single machine systems. Such compilers have limited scope in the big-data setting because they only optimize the code within a single stage [6]; determining what operators constitute a stage is still decided by the query optimizer. SPARK makes use of one such code-generation engine [23] that builds upon HyPer [13]. The physical operators that we add are whole-stage code-gen enabled and benefit directly from such techniques.

Recent literature has seen advance techniques that optimize mixed-mode queries: queries that embed non-SQL functions and expressions into SQL [7, 16, 24]. This line of work is orthogonal to RESIN.

8 Conclusions

The cost of running big-data queries is dominated by I/O. This paper proposes RESIN, a system that helps identify and eliminate redundant I/O. The system proposes extensions to big-data query optimizers that enable first class map-reduce reasoning during query compilation. We show how these can be used to fuse operators processing overlapping data into a single stage of computation, and sometimes eliminate expensive binary operators altogether. We demonstrate that the optimizations are useful for 40% of queries in TPCDS, and bring significant gains (average $1.4\times$) to a quarter of the benchmark queries.

A Simpler and Faster NIC Driver Model for Network Functions

Solal Pirelli and George Candea, EPFL

Abstract

The advent of software network functions calls for stronger correctness guarantees and higher performance at every level of the stack. Current network stacks trade simplicity for performance and flexibility, especially in their driver model. We show that performance and simplicity can co-exist, at the cost of some flexibility, with a new NIC driver model tailored to network functions. The key idea behind our model is that the driver can efficiently reuse packet buffers because buffers follow a single logical path.

We implement a driver for the Intel 82599 network card in 550 lines of code. By merely replacing the state-of-the-art driver with our driver, formal verification of the entire software stack completes in 7x less time, while the verified functions' throughput improves by 160%. Our driver also beats, on realistic workloads, the throughput of drivers that cannot yet be formally verified, thanks to its low variability and resource use.

Our code is available at github.com/dslab-epfl/tinyntf.

1. Introduction

The networking world is moving from hardware network functions to software ones to gain flexibility. This brings new problems to light in the network stacks of mainstream operating systems, which were not designed for this use case. In response to this move, the kernel-bypass model for software networking appeared, designed for low latency and high throughput. However, one area of the stack that remains under-explored is network drivers. We present the state of network functions, stacks and drivers in Section 2.

Modern network cards contain powerful and complex hardware offloads, but their core features are conceptually simple. Network cards fetch requests and return responses to software using data structures named descriptors. The main complexity for packet reception and transmission is the descriptor ownership mechanism. We present the basics of modern network cards in Section 3.

The current network driver model is too flexible for the needs of common network functions, which must pay the complexity costs of modern drivers without reaping their benefits. This is mainly because the current driver model allows network functions to process packets out of order, a powerful feature that is not needed in many of the core functions making up the Internet's backbone. We formalize the current driver model for network cards and propose our conceptually simplified version in Section 4.

We implement our new driver model for the Intel 82599, a modern 10 Gb/s Ethernet controller. Our implementation uses the model's insights and stays as simple as possible: it is only 550 lines of C code. Its key features are a minimal number of operations thanks to the driver design and to modern network card features, as well as some simple but powerful scheduling algorithms. We present our driver, which we call "TinyNF", in Section 5.

This paper's core hypotheses are that our simpler model (1) makes network functions easier to formally verify, (2) is faster than the current most complex driver model that can be formally verified, (3) provides competitive performance against the fastest state-of-the-art drivers regardless of complexity, and (4) is applicable to most network functions that are deployed today.

We show that hypotheses (1) and (2) hold in Section 6. Our driver has exponentially fewer code paths than current drivers and can thus be used to formally verify network functions in 7x less time than with a state-of-the-art driver while offering 2.5x the throughput, as well as lower median and tail latency.

We show that hypothesis (3) holds in Section 7, with the surprising observation that our driver outperforms the state of the art using real network functions even though it loses on a synthetic "no-op" function. This is because our driver slows down less when running real functions due to having room to grow in instruction-level parallelism and cache use.

We provide evidence for hypothesis (4) in Section 8, showing that our model is applicable to most of the low-level network infrastructure, either running on bare metal or as virtualized network functions.

We believe that the separation in common use between "drivers" and other software is blurry, and we argue that it hinders progress. This situation is worse in networking due to the lack of good baselines for benchmarks, leading to driver optimizations that increase complexity but may not increase performance in the real world. Our minimal driver also highlights opportunities in hardware documentation. We discuss these issues in Section 9.

In summary, we make the following contributions: (1) a simplified driver model for network functions that process packets in order, (2) a formally verified driver based on our model that is easier to reason about and faster on realistic workloads than existing drivers, and (3) evidence that the current standard of benchmarking for network drivers leads to suboptimal performance in the real world.

2. Background on network functions

In this section, we introduce network functions: packet-processing appliances performing tasks such as routing, rate limiting, access control or caching.

Hardware network functions are the traditional way to implement network functions for high-traffic networks. They are physical boxes with custom hardware that are part of the network, distinct from standard computers.

They are typically robust because fixing hardware bugs after deployment is not possible, thus engineers must test them extensively before deployment. However, they are not flexible because they cannot be modified after deployment. Changing a network's policies can require replacing the hardware entirely.

Software network functions run on general-purpose hardware such as x86 and mainstream operating systems such as Linux, communicating with network cards through a software stack that includes drivers and implementations of protocols such as IP and TCP.

The networking world is moving to software network functions to increase flexibility. Software network functions are flexible since they have low deployment costs. This means correctness guarantees, while important, are not a hard requirement for deployment.

Verifying the correctness of software network functions is an open problem, with recent work showing it is easier than the intractable problem of general software verification. The Vigor [33] project verifies network functions without human interaction, but cannot deal with common optimizations such as parallelism or batch processing.

The other key concern of software network function is performance. This includes variability, since worst-case performance determines the guarantees network operators can offer. These guarantees turn into business concerns such as Service Level Agreements.

To illustrate how crucial performance is, consider the time budget for processing a 64-byte packet and its 20-byte Ethernet header at 10 Gb/s: $(64+20) * 8 / (10*10^9) = 67.2\text{ns}$. This is the same order of magnitude as a memory read; a network function will exceed its time budget if it needs data outside the CPU cache.

Figure 1. Number of lines of C code in the network drivers included with DPDK 20.02.

Software network stacks in modern operating systems are not adapted to network functions for three reasons.

First, traditional stacks use a push model: hardware uses interrupts to notify software of packet reception. If packets are infrequent, this is efficient. But in network functions, packets are frequent thus interrupt overheads dominate. The pull model, in which software continuously polls for packets, better fits network functions because it is efficient if most polls succeed, as is the case under high load.

Second, traditional stacks only access hardware through the operating system to provide isolation. Going through the operating system is an expensive operation, especially given the low time budget for each packet. But network functions typically run alone, paying the performance cost of isolation without the associated benefits. Systems such as netmap [28] have shown this cost can be amortized by processing packets in batches.

Third, traditional stacks allow to manage packet buffers with complete flexibility. This is convenient for general-purpose programs but hinders optimizations in the network stack. Network functions have restricted and well-defined behavior, yet they pay the performance cost of flexibility. Systems such as Windows Registered I/O [24] have shown that decreasing flexibility can increase performance.

Kernel-bypass stacks, which allow programs to access hardware directly instead of going through the operating system, arose from the need for different tradeoffs. These stacks also focus on polling instead of interrupts, on tighter control of packet buffers, and on processing packets in batches. The de facto standard kernel-bypass stack is DPDK, the Data Plane Development Kit [5].

Drivers, network or otherwise, have a poor reputation among software developers because of the challenges of hardware interactions and the lack of documentation.

Developers can only rely on specifications released by manufacturers to know how hardware behaves, and these specifications are not always public. Reverse-engineering hardware is infeasible without special equipment, unlike software. Since drivers are often exclusively maintained by hardware manufacturers, driver developers do not need to publicly document their code. Bug-finding efforts have shown that driver code is far from bug-free [21, 25].

These problems lead developers to think of drivers as mystical black boxes. But drivers are a fundamental part of the network stack; their correctness and performance are upper bounds on the entire stack.

As an example of driver complexity, the network drivers in DPDK, which supports many different types of hardware, all have at least 1,000 lines of code, as we show in Figure 1, with the largest one being over 66,000 lines of code.

Emmerich et al. [10] showed that network drivers can fit in under 1,000 lines of code, though their driver focuses on educational value and not performance or correctness.

3. Background on network cards

In this section, we summarize the architecture of modern Network Interface Controllers, or “NICs” for short, which is necessary to understand network driver design.

While NICs are diverse, the core concepts are similar. We estimate that, out of the 44 families of physical or virtual NICs supported by DPDK 20.02, this section applies to 40 of them. The remaining ones are three FPGA-based cards and one proprietary virtual NIC.

Communication between CPU and NIC uses three channels: PCI registers, NIC registers, and RAM.

PCI registers are stored on the NIC and accessed by the CPU using port-mapped I/O. The CPU only uses them for the first stage of NIC initialization.

NIC registers are stored on the NIC and accessed by the CPU using memory-mapped I/O. Their latency is an order of magnitude higher than RAM [19], making them a performance bottleneck.

RAM is the main shared storage. The CPU accesses it as usual, and the NIC uses Direct Memory Access, or “DMA” for short, to transfer data into it. RAM holds packet buffers and metadata. The CPU and the NIC are not notified when the other has modified RAM; if they want to be aware of changes, they must poll RAM or use a side channel.

The packet descriptor is the main NIC data structure, containing a pointer to a data buffer and some metadata. The metadata typically contains required fields such as the packet length, and optional fields such as whether to use advanced hardware offloading features.

Software chooses the total number of descriptors when initializing hardware. Descriptors are given from the CPU to the NIC to issue commands, such as packet transmission, and given by the NIC back to the CPU when the associated command has finished. Different NICs have different ways to manage descriptor ownership, such as flags in metadata.

Software can change the buffer pointer before giving a descriptor to the NIC. This lets developers implement buffer pools, to reuse descriptors without losing received data. This is useful for cases such as TCP, where packets must be kept until an entire message has arrived.

Reception and transmission are the core operations of network cards, and work in symmetric ways.

To receive packets, the CPU gives descriptors to the NIC indicating where to deposit packets in memory. The NIC gives descriptors back when it has received packets. The NIC sets descriptor metadata to indicate the packet length and other such information.

To transmit packets, the CPU gives descriptors to the NIC indicating where packets are in memory, and the NIC gives descriptors back once it has transmitted packets. The metadata is set by the CPU, to inform the NIC of the packet length and other such information.

Figure 2. A descriptor ring with 8 elements; the head is 1 and the tail is 5, thus hardware owns elements 1, 2, 3 and 4.

Descriptor rings are the main mechanism for descriptor ownership in modern cards. We present here their inner workings in Intel’s 82599 NIC as a concrete example.

A descriptor ring is composed of a region of memory, a head pointer, and a tail pointer. The memory is in RAM, while the pointers are NIC registers. Descriptors between the head, inclusive, and the tail, exclusive, belong to the NIC. Other descriptors belong to the CPU. If the head and tail are equal, the CPU owns all descriptors. We present an example ring in Figure 2.

Since descriptors start in an unknown state, descriptor metadata has a “Descriptor Done” flag to let the CPU know whether a descriptor has been processed by the NIC or was just never initialized.

The CPU gives descriptors to the NIC by clearing their “Descriptor Done” flag and incrementing the tail pointer. Since the tail pointer is a NIC register, the NIC immediately notices the change. The NIC gives descriptors back to the CPU by setting the “Descriptor Done” flag in metadata and incrementing the head pointer. To know when a descriptor has been given back, the CPU polls the metadata.

The head and tail can only be incremented, though they can be incremented by more than 1 to give descriptors in batches. Decrementing is forbidden since it would logically be an attempt to steal descriptors.

NIC queues are a hardware mechanism to allow for parallel packet processing. A queue consists of a descriptor ring and some configuration. The NIC places all received packets in the first reception queue by default; developers can configure the NIC to route packets to a queue based on packet headers, such that packets belonging to the same logical flow are routed to the same queue.

For transmission, all queues behave in the same way, without flow tracking: packets added to any transmission queue are sent to the wire regardless of which queue it is.

Queues allow multiple CPU cores to handle packets without having to synchronize NIC accesses, increasing software scalability.

4. Simplifying the driver model

In this section, we present the existing kernel-bypass driver model, and our proposed simplification of it for common network functions.

The driver model in modern frameworks such as DPDK is based around reusing a fixed set of packet buffers, in order to avoid the overheads of memory allocation. We formalize this model as a diagram in Figure 3, where the overall system is a set of first-in-first-out buffer queues. Each conceptual “step” of the system is performed by one of three actors: the NIC, the driver, or the network function. In the initial state, all buffers are in the “Free” state, which represents unused buffers in the buffer pool.

The driver typically takes the first steps, by “allocating” buffers from the pool and giving them to the NIC for reception. This “allocation” refers to taking buffers from the pool, not creating new ones. If there are buffers in the “receiving” state, the NIC can transition them to the “received” state once it gets data from the network. The network function typically runs a polling loop to move buffers into the “processing” step. From there, the network function can choose to transmit the buffer, possibly after modifying it. The NIC will then send out the buffer contents to the network and move the buffer to the “transmitted” state. The driver moves transmitted buffers back to the “free” state at well-defined points, for instance when there are too few free buffers left. The network function can also choose to keep the buffer for later, or to “drop” it and return it to the pool. The network function can also allocate buffers from the pool and process them like received buffers.

Unlike classical driver models found in mainstream operating systems and exposed to programmers in libraries such as BSD sockets [29], the system is closed: none of the actors can insert buffers into the system from the outside, such as by asking the operating system for memory. Actors cannot remove buffers either, though the network function is allowed to keep buffers indefinitely by using its “keep” transition to reorder buffers in the “processing” state.

The reason for a closed system is performance: buffer allocation and deallocation are expensive. This is not only due to general software issues such as the overheads of keeping a “free list” of memory blocks, or the cost of asking the operating system for more memory, but also to an issue specific to drivers: memory pinning. The driver gives physical memory addresses to the network card when specifying buffer addresses. If the operating system were to change which physical page backs a virtual page used by the driver, the network card would not see the change and write to the wrong page. Thus, the operating system has to be informed of which memory is used for buffers and give it special treatment. While modern hardware can use I/O memory management units to allow devices to address virtual memory, there is a cost to changing I/O memory mappings.

Figure 3. Diagram of the kernel-bypass driver model. Each box is a queue, each arrow is a step moving one packet from one queue to another. Steps are annotated with their actor and their name. “RX” is reception, “TX” is transmission, “Proc” is processing, and “NF” is network function.

This model provides flexibility to network functions: they can keep buffers aside to reassemble messages from high-level protocols such as TCP, and can allocate buffers from the pool in response to non-network events such as timers indicating a request needs to be retried.

The model also lends itself well to concurrency: the “free” queue is the central element shared by any number of reception, transmission or processing queues. A network function can receive and transmit packets from multiple NICs, and it can use multiple processing queues that each communicate with different reception and transmission queues on the same NIC to process packets concurrently and increase overall throughput.

But this flexibility comes at a cost: the steps that the network function can perform besides transmission introduce forks in the path of packet buffers. This requires buffer management within the “free” queue, including support for concurrent accesses. It also requires the driver to implement a policy for buffer freeing and allocation, adding complexity to the overall system.

The model additionally introduces a failure case that is not fundamental to the concept of a network function. If there is a state within the processing logic in which any buffer is kept, and the only way to get out of that state is to receive new data, the system will only make progress if there are buffers outside of the processing queue, which is not guaranteed. Reasoning about the existence of such a state requires reasoning about the invariants that hold in the network function code across packets.

This flexibility is not always needed: some of the network functions that power the backbone of the Internet, such as IP routers or Ethernet bridges, process packets one by one, never keep buffers aside, and never allocate buffers. Overall, they are conceptually simpler than the general case of a network function, yet they must currently pay the price of driver flexibility they do not use.

We propose a new driver model designed for common network functions that do not need the flexibility provided by existing models. It is based on two key insights: we can remove the buffer pool altogether, and we can implement buffer drops on modern NICs without the theoretical branch they introduce, minimizing the amount of state that the driver must keep track of.

Our model is designed to be as simple as possible, thus improving correctness and performance. Its simplicity makes it easier to formally or informally reason about and requires less code and simpler code to implement.

Our model is a subset of the existing model: as shown in Figure 4: the core differences are that it has no pool of free buffers, and does not allow network functions to keep buffers. The driver moves transmitted buffers directly to the reception queue, and the network function must choose to either transmit or drop received packets. This simplifies the driver by giving it only one choice when transmitting a packet: recycling transmitted buffers to the receiving queue now or later. Removing the buffer pool also makes progress easier to reason about: the software can only halt if the driver does not recycle buffers when the receiving queue is empty, or if the network function halts. While termination is impossible to prove in the general case due to the halting problem [31], network functions have strict performance requirements, thus their code is unlikely to have loops whose termination is not obvious because such loops could be performance bugs.

Our model minimizes state by combining reception, processing, and transmission into a single logical descriptor ring containing all buffers, without the need for any other data structure. While it is implemented using one reception ring and one transmission ring, the driver mirrors the head of the transmission ring to the tail of the reception ring, thus ensuring that buffers that have finished transmitting are reused for reception without any intermediate steps.

The key hardware feature that allows this is called “null transmit descriptors”: as its name implies, it allows some descriptors in a transmission ring to have no effect. Packet drop is thus a special case of packet transmission, which removes the fork in buffers’ paths and allows for a regular buffer flow. For instance, a network card can implement this by dropping packets whose length in metadata is zero.

The driver’s job consists of three tasks: move buffers from the “received” queue to the “processing” queue when the network function asks for a packet, move buffers from the “processing” queue to the “transmitting” queue when the network function asks to transmit or drop its current packet, and recycle buffers from the “transmitted” queue to the “receiving” queue to ensure the “receiving” queue is never empty. Since this last operation is not a response to a specific input, the driver must choose when to perform it, for instance once every few transmitted packets.

Figure 4. Diagram of our proposed driver model. Semantics are the same as in Figure 3.

Our model supports multiple outputs by using multiple transmission rings and making the driver synchronize their state. That is, the driver must set the tails of all transmission rings at the same time and use the earliest head in all rings as the head to mirror to the reception tail. Transmitting a packet when the driver has multiple outputs conceptually maps to transmitting it on some outputs and dropping it on all others; all rings still have a descriptor pointing to the buffer, but that descriptor is null in some of the rings. This may cause packet drops if an output link is too slow, in which case the entire ring will be used for transmission with no space left for reception. The same could happen in a traditional model if all buffers in the pool were used for transmission due to a slow output.

Multiple inputs can be handled concurrently: while the same processing queue cannot have multiple inputs, since it is not possible to synchronize the state of reception rings, the entire system can be duplicated so that there is one reception queue per input, one associated processing queue, and any number of synchronized transmission queues. Modern NICs have hundreds of queues, thus it is not a problem to use one transmission queue per input.

This does not mean our model requires parallelism: a single thread of execution can implement many instances, which are thus concurrent but not parallel.

Our model is amenable to parallelism: multiple threads of execution can run in parallel, each implementing any number of instances, without having to synchronize any state. Only the state of the rings within an instance needs to be kept in sync. This is similar to existing models.

The key limitation of our model is the flip side of its strength: since network functions must process buffers one by one without keep any aside, they cannot reconstruct multi-packet messages without copying buffers that arrive out of order. Thus, while core functions such as routing and network address translation can be implemented with our model, one cannot terminate TCP connections or otherwise reassemble fragments without copying buffers, which is an expensive operation given modern network speeds.

5. Implementing our new model

In this section, we describe an implementation of our driver model for the Intel 82599 NIC [12] which we call “TinyNF”, short for “Tiny Network Function”.

TinyNF’s goals are to be easy to reason about and fast. The former is different from “correct” because it is hard to tell whether a driver operates as expected without hardware schematics, since the data sheet may be incorrect. However, we want to make it simple enough that it is not a bottleneck in network function verification efforts.

For simplicity, TinyNF processes buffers one at a time: there is always at most one buffer in the processing queue. One key hypothesis in this project was that TinyNF could be fast without explicitly processing packets in batches.

The keys to TinyNF’s performance the avoidance of any operation that is not absolutely required, and the use of a few small but surprisingly effective scheduling algorithms for synchronizing queue state.

TinyNF avoids unneeded work, even metadata copy. Because each buffer always belongs to exactly one queue, and because queues are ordered, it is enough to set the buffer pointers at initialization time and never change them afterwards. Moving a buffer from one queue to another only requires writing to the source head and destination tail.

There are fewer delimiters in practice than in theory since some of them are implicit, as shown in Figure 5. The “transmitted” head and tail are the “receiving” tail and “transmitting” head, respectively. Similarly, the “received” head and tail are the “processing” tail and “receiving” head. While there is technically a “processed” queue that does not exist in the conceptual model, its head and tail are the “transmitting” tail and “processing” head respectively. The “processing” tail does not need explicit tracking, because it is always either one buffer ahead of the head or equal to it, due to the one-packet-at-a-time constraint.

TinyNF avoids reading from NIC registers entirely after initialization. To check for received buffers, the “descriptor done” metadata flag of the descriptor at the processing tail is enough. To check for transmitted buffers, the 82599 NIC provides a “transmit head write-back” feature: software can request hardware to write the transmit head to RAM after hardware has finished transmitting a buffer.

TinyNF cannot avoid updating the receive and transmit tails, which are NIC registers and thus slower than RAM, but it can avoid doing so after every packet. Updating the receive tail, which moves buffers to the “receiving” queue, is only necessary once every few transmitted buffers since reception continues working as long as there are buffers in the queue, even if there are less than there theoretically could be. Updating the transmit tail is necessary for buffers to be transmitted to the network, but this can be done once every few transmissions, or when there are no packets to receive and thus no other work to do.

Figure 5. Logical ring composed of reception, processing and transmission queues. “In progress” queues are light, “done” ones are dark and shaded. Heads and tails refer to “in progress” queues, but implicitly delimit the others.

TinyNF carefully schedules operations to minimize the amount of communication between software and hardware. This improves overall latency and reduces the fraction of PCIe throughput used for metadata.

Two operations can be scheduled together: asking the NIC to update the transmission tail and checking for such updates to recycle buffers. The request is made with a bit in transmission metadata, and the check is made by reading the value that the NIC wrote to RAM via DMA. TinyNF schedules both operations once every 64 packets. The check will thus see the update that was requested 64 packets ago.

The most important scheduling decision is updating the transmission tail: frequent updates decrease latency by making the NIC aware of packets sooner, but they increase throughput by performing less book-keeping. Networking stacks such as DPDK solve this with adaptive batching: they check for multiple received buffers at a time up to a limit, let the network function process them all, then update the transmission tail. This theoretically allows drivers to make better scheduling decisions because they have more data: they know how many packets have arrived, rather than whether there is at least one packet.

TinyNF’s one-packet-at-a-time model is incompatible with batching, thus we chose an algorithm based on past data instead. TinyNF updates the transmission tail either once every few transmitted packets, or as soon as there are no packets to receive since this likely indicates there is time to perform this expensive operation. This keeps the period short under low load, avoiding latency spikes, but allows for longer periods under high load, avoiding throughput drops, without looking at packets beyond the current one.

Overall, TinyNF is around 550 lines of C code, and its only dependency is a 300-line environment abstraction. It runs entirely in user mode, without kernel dependencies.

6. Evaluation: TinyNF for verification

In this section, we evaluate two hypotheses about TinyNF: its simplicity should (1) make it easier to reason about and (2) make it faster than other verified drivers.

We evaluate TinyNF by using it in the formally verified network functions of the Vigor [33] project. Vigor verifies the entire software stack, including the network function code and the network card driver.

Vigor does not need DPDK’s flexibility: it is focused on network functions that form the Internet’s backbone, such as Ethernet bridges and IP load balancers. This makes Vigor network functions good candidates to evaluate TinyNF.

Vigor uses DPDK for performance, but it cannot take full advantage of DPDK’s optimizations either. Vigor’s use of DPDK allows its network functions to outperform those written using traditional networking APIs that go through the kernel to receive and transmit packets. However, some DPDK optimizations such as batching and vectorization are currently out of the reach of automated formal verification. Thus, the driver formally verified by Vigor is the subset of the DPDK driver that can be automatically verified, not all of the driver.

TinyNF makes Vigor network functions 8x faster to verify, as we show in Table 1. We ran verification on two Intel Xeon E5-2690 CPUs at 2.90 GHz, totaling 32 cores.

Vigor verification has two steps: first Vigor symbolically executes the network function code to find all paths, then it validates each path using a theorem prover, which can be done in parallel. Both parts of Vigor verification are faster with TinyNF for the same main reason: symbolic execution does not need to explore DPDK’s complex stack, thus it takes 1/5th the time and yields 1/7th the number of paths. Individual paths are also faster to validate since they have less code, though this is less pronounced since validation focuses on network function code, not driver code.

The most drastic change is in the load-balancer, due to its more complex paths that involve more data structures: its total verification time on our machine goes down from ~1h45min to ~14min. This allows full-stack verification to be used as part of development, such as verifying every code change, as opposed to being for special occasions.

	DPDK		TinyNF	
	Sym. ex.	Validation	Sym. ex.	Validation
NAT	337s	149 × 83s	63s	20 × 73s
Bridge	527s	312 × 89s	104s	39 × 77s
LB	731s	297 × 620s	161s	51 × 425s
Policer	392s	190 × 90s	75s	25 × 76s
FW	323s	140 × 83s	61s	20 × 68s

Table 1. Verification time statistics for the Vigor network functions using DPDK and TinyNF.

TinyNF is 1/11th the code of the DPDK driver and has exponentially fewer paths, as we show in Table 2, which explains why the improvements in verification time are so drastic. We measured the code complexity of TinyNF and of the verified subset of DPDK’s driver. We manually counted paths, so that we could define them in terms of the public parameters: the arguments passed in the code, and the choices made at DPDK build time when picking a data structure implementation. Automating this using symbolic execution would have only found the number of paths given a concrete configuration. When counting paths, we assume that NIC hardware behaves as per its data sheet.

To show the effect of a change in driver model and not only in implementation, we also included the “Ixy” driver by Emmerich et al. [10], a simplified implementation of DPDK’s design for educational purposes that does not aim for comparable performance. As expected, TinyNF and Ixy use similar amounts of code to initialize, since they both use a limited set of NIC hardware features. However, TinyNF has less code and exponentially fewer paths than Ixy in the reception and transmission functions that form the core of the driver, providing more evidence in favor of our model.

We note that the number of paths can change based on programmer decisions: using Boolean expressions rather than conditionally executed code can lower the number of paths, such as writing $x = c ? y : x$; instead of $\text{if}(c) \{ x = y; \}$ in C. We could have used this to bring down the number of paths in TinyNF’s transmission function to 4, without any exponent regardless of the number of output links, but chose not to as such code is compiled to conditional move instructions which have poor tail latency on our machines.

	Init.		Reception			Transmission		
	#funs	#LoCs	#funs	#LoCs	#paths	#funs	#LoCs	#paths
DPDK	115	3204	5	136	$1 + A_F + 288A_S$	5	122	$(8 + 14(F_F^T + P((F_S + F_F)^T - F_F^T)))^O$
Ixy	14	279	1	63	$1 + A_F + A_S$	1	53	14^O
TinyNF	4	245	1	17	3	1	29	$2 + 2^O$

A_S , A_F and F_S , F_F : Number of success and failure paths in packet allocation and freeing respectively; Ixy’s freeing cannot fail

P : Number of paths in the “put buffers back” operation of the DPDK memory pool in use

T : DPDK parameter for the transmit descriptors write-back threshold, must be >0

O : Number of output links

Table 2. Number of functions, lines of code and paths in DPDK, Ixy and TinyNF drivers for the Intel 82599.

TinyNF makes fewer assumptions on its environment than DPDK. Vigor makes assumptions about the behavior of two components: DPDK data structures and operating system functions.

One fundamental issue with DPDK’s driver, even in the verified version, is its need for a data structure to hold free packet buffers. This leaves two options for verification: use a simpler but slower data structure that can be verified or assume that a faster but unverified data structure is correct. Unlike DPDK and TinyNF, there is no evidence that simpler data structures can match their more complex counterparts in performance. In fact, the opposite is true: data structure contracts are already simple yet popular implementations become more complex with time, such as a 2500-line change in Java 8 to make the hash map more resilient to collisions [15]. By comparison, Vigor’s verified map has less than 300 lines of code in its entirety.

Another issue with DPDK’s driver is in the amount of assumptions it makes about operating system functions. When verifying network functions running on Linux, Vigor replaces these functions during symbolic execution with custom models. This ensures DPDK calls operating system functions correctly according to Linux’s documentation, such as by validating the order and arguments of function calls. The models then return symbolic values that cover the range of documented behaviors. But there is no formal specification for these functions, much less a formal proof that the Linux implementation is correct. Thus, Vigor needs to assume the correctness of dozens of models for its proof on Linux. This can be avoided by using a custom operating system, at the cost of losing Linux tools and features such as multitenancy and scheduling. TinyNF needs much less from its environment, drastically reducing the number of assumptions even on Linux.

TinyNF is easier to analyze than DPDK, since it only needs standard C. DPDK uses non-standard extensions to give hints to the CPU and compiler, such as prefetching memory and vectorizing loops. TinyNF does not need any such hints; the driver does not even use the standard library directly, going through a small environment abstraction layer instead.

This standards compliance makes TinyNF analyzable “out of the box” with most tools and allows future tools to support TinyNF without special treatment. This includes symbolic execution engines such as KLEE [4], which Vigor uses and extended to support DPDK code, and manual provers such as VeriFast [14], also used by Vigor. We think this will accelerate networking research in drivers and functions by making it easier to develop new techniques and tools. For instance, TinyNF’s simplicity and small size makes it amenable to a proof of functional correctness given a hardware specification, which would improve upon Vigor’s proof of memory safety through hardware models.

	DPDK			TinyNF		
	Tput	Latency (μ s)		Tput	Latency (μ s)	
	(Gb/s)	50%	99%	(Gb/s)	50%	99%

FW	2.65	3.97	4.49	8.14	3.88	4.24

Table 3. Single-link throughput and latency with 1 Gb/s background load of Vigor functions on DPDK and TinyNF.

TinyNF improves the throughput of Vigor network functions by 160%, with 2% less median latency, as we show in Table 3. 99th percentile latency decreases by 7%.

To measure performance, we used two machines in a setup based on RFC 2544 [26], with a “device under test” running a network function and a “tester” running the MoonGen packet generator [9], which can measure latency using NIC timestamps. Both machines run Ubuntu 18.04 on two Intel Xeon E5-2667 v2 CPUs at 3.60GHz with power-saving features disabled and have two Intel 82599ES NICs, using only one port per card to ensure PCIe bandwidth is not a bottleneck. We measure throughput using minimally sized packets. Our workload fills the internal flow table of the network functions to 90% of their capacity. Measuring latency with MoonGen instead of on the device under test allows us to capture the latency of NIC register writes as well as the effects of drivers’ NIC configuration. This setup is similar to the one used to originally evaluate Vigor, and can replicate Intel’s DPDK performance numbers [7].

We replicate Vigor’s benchmark setting: measuring the max throughput that a Vigor network function can achieve with less than 0.1% loss, in a single direction, as well as the latency with 1 Gb/s of background load.

Vigor’s NAT gets the lowest throughput improvement; this is because its bottleneck is not the driver but computing packet checksums since it has to modify packet headers. To confirm this, we tried modifying the DPDK version of the NAT to use batching: this results in the same throughput as the TinyNF version of the NAT, confirming that the driver is unlikely to be the bottleneck.

In summary, both of our hypotheses are validated:

TinyNF is easier to reason about in terms of code quantity and code complexity, and network functions using TinyNF are faster than the same functions using DPDK’s verified subset. Thus, TinyNF allows developers to formally verify their network functions in less time, get more correctness guarantees, more than double the functions’ throughput, and lower the functions’ median and tail latency.

7. Evaluation: TinyNF in general

In this section, we compare the performance of TinyNF and DPDK for general purpose network functions, regardless of verifiability.

We use the same benchmark setup as in the previous section, but this time use both directions for throughput, for a maximum of 20 Gb/s. We keep throughput symmetric during the benchmarks, i.e., if a function cannot handle a given load, we reduce the load of both directions by the same amount and retry. We then measure the latency at load increments of 1 Gb/s to paint a clear picture of the function’s overall performance profile.

TinyNF can outperform a fully optimized DPDK setup, as we show in Figures 6 and 7 using a traffic policer as an example. We compare the Vigor policer using TinyNF as its driver to the same code using either “unbatched” DPDK, which is the simpler version used by Vigor, or “batched” DPDK, which is the standard way to use DPDK that enables optimizations such as adaptive batching and vectorization. We also implemented a 2-core parallelization of the policer for all three variants. We chose the policer because, by design, traffic in one direction is independent of traffic in the other, which means it admits a trivial 2-core parallelization for our experiments. We are not proposing a new way to parallelize network functions, but merely showing that TinyNF can be parallelized in a similar way to existing drivers. This also shows how much improvement parallelization can bring compared to batching.

Using TinyNF, the policer achieves better throughput than using batched DPDK, with an even starker difference when using two cores. The bottleneck that prevents the dual-core TinyNF version of the policer from reaching line rate is the frequent reads from the CPU time, which it needs for flow expiration.

TinyNF leads to better latency at low and high loads but worse latency in the middle, especially the 99th percentile latency. Looking at individual data points, which we show in Figure 8, the TinyNF-based policer has lower latency in some cases, but this advantage is lost in the tail latency. We believe this is a case where DPDK’s batching shines: it can detect “gaps” between packets, in which updates to the transmission tail do not compete with packet processing, by looking at how many packets there are in the queue.

Finally, since we had to modify the policer code to use TinyNF, we wanted to see whether the same performance benefits could be obtained without code changes. We wrote a compatibility layer that implements some of the DPDK API on top of TinyNF. The layer cannot implement all of the DPDK API, by design, but can replace DPDK for functions that fit the TinyNF model by changing an environment variable at compile time. The compatibility layer allows for 1% more maximum throughput than batched DPDK, at the cost of increased latency.

Figure 6. Throughput and median latency of a traffic policer using DPDK with and without batching, TinyNF, and 2-core versions of all three.

Figure 7. 99th percentile latency version of Figure 6.

Figure 8. Complementary cumulative latency distributions of a traffic policer using the same alternatives as Figure 6, with 1 Gb/s background load.

A no-op function can handle more throughput with DPDK than with TinyNF, even though the opposite holds with real functions. We reached this surprising conclusion by benchmarking DPDK’s “testpmd” built-in application, which DPDK developers use in performance reports [7] to benchmark driver speed. We configured testpmd to update packets’ MAC address to provide some realism. Using our setup, both TinyNF and DPDK in its batched mode could saturate two 10 Gb/s links, as we show in Figure 9. We also included the Ixy driver [10], which performed admirably given its educational purpose but could not sustain line rate even with batching.

Since our setup was bottlenecked by link capacity, we chose to lower the CPU frequency to 2 GHz and re-run the benchmark. In this setup, DPDK can reach 97.5% of line rate while TinyNF peaks at around 92.5% of line rate, as we show in Figure 10, though its latency is lower.

We believe the bump around 11 Gb/s is due to hardware issues, since it appears in three independently written drivers and in both a no-op and a nontrivial function.

This result is interesting, since the no-op benchmark is the one used by DPDK developers to measure their progress when optimizing DPDK’s performance. If this benchmark does not accurately represent driver performance on real network functions, the DPDK developers may believe they are improving DPDK’s performance but do the opposite.

To explain this finding, we started by plotting the no-op function’s latency in more detail. We did this because of an observation we made while running the other benchmarks: TinyNF’s performance appeared more stable than DPDK’s, yielding more consistent results across runs, such as never dropping packets under high loads whereas DPDK would sometimes drop a few packets per million.

As expected, TinyNF has a more stable latency profile than DPDK: without background load, TinyNF’s latency remains low up until the 99.9th percentile, whereas DPDK’s latency starts jittering before this, as show in Figure 11. We stop at the 99.99th percentile because Primorac et al. showed that NIC timestamping is not accurate after that point [23].

This measurement highlights a key issue with DPDK’s driver model: the driver has to manage buffers explicitly instead of merely moving them from one queue to the next, which leads to a distinct bump in latency before the 99th percentile. The same holds for Ixy, since it uses the same driver model as DPDK.

We used the toplev microarchitectural measurement tool [22] to investigate bottlenecks in DPDK’s driver when running the Vigor policer. While the tool indicates that the policer is bottlenecked on memory writes, there is no single write that dominates. Some of the memory writes that take the most time are fundamental to DPDK’s design, such as moving buffer pointers to and from the buffer pool, while others could be removed at the cost of some functionality, such as writes to packet buffer metadata.

Figure 9. Throughput and median latency of DPDK’s no-op function with and without batching, a port of it on TinyNF, and a port of it on Ixy with and without batching.

Figure 10. Same benchmark as Figure 9 but with the CPU capped to 2 GHz. We do not show Ixy since it could not sustain line rate even at full CPU speed.

Figure 11. Complementary cumulative latency distributions of the no-ops from Figure 9 without background load.

TinyNF slows down less when running real functions because its instruction-level parallelism has room to grow and it interferes less with the CPU's caches. We reached this conclusion after measuring low-level CPU counters using libPAPI [30], in particular the number of cycles, instructions, and cache hits per packet at 20 Gb/s.

Before going further, we must caution against over-interpreting our results, in particular absolute numbers of cycles. To measure low-level CPU metrics, we instrumented network functions with code that copies counter values for later processing. This has overhead: reading performance counters uses cycles, and copying their values touches the CPU caches. Furthermore, due to the out-of-order nature of modern CPUs, accurately measuring cycle counts requires inserting serializing instructions to ensure past instructions have completed. Thus, measuring the cycle count increases it as it prevents the CPU from reordering some instructions. The measurement overhead is stable, so we measure it and subtract it from the measurements, but we cannot fully account for cache changes due to storing counter values, or for the effects of serialization. Because of this, cycle counts can only be compared to other functions on the same driver. Instruction counts and cache use can be compared globally.

We collected data by running network functions ten times collecting ten million packets each time. We intended to collect data in a single run, but noticed that some runs have a lower cache miss rate than others, despite using the same executable run in the same way on a CPU not otherwise used by the operating system.

We used four functions: a no-op function that does not even touch packets, one that writes a constant to the destination MAC address, one that sets the destination MAC address using a lookup table based on the source MAC address, and the Vigor policer. In our setup, the write function is faster on DPDK but the lookup one is faster on TinyNF. We report the measured cycles, instructions and cache hits in Table 4. We do not report main memory hits as they are negligible, around one in a million packets.

Two results stand out: the increase in instructions per cycle for TinyNF when running more realistic functions, and TinyNF's low cache use compared to DPDK.

TinyNF has low instruction-level parallelism in a no-op because the CPU is waiting for operations on descriptors and NIC registers, which cannot be executed out of order. On a more realistic function, the CPU executes the function instructions out of order, increasing efficiency, thus the slowdown is not linear. This is consistent with TinyNF's low latency in the reduced frequency benchmark: the frequency makes little difference when waiting for the NIC.

Batched DPDK, on the other hand, can execute multiple instructions per cycle even in no-ops, due to instructions for metadata and buffer management. Its use of vector instructions also helps keep a high instruction count per cycle by waiting for multiple descriptors in parallel without reordering. The slowdown when executing a real function is thus linear in the number of instructions, unlike TinyNF.

TinyNF also has a lower memory footprint than DPDK, thus realistic functions have fewer cache misses, an effect that cannot be observed in no-ops.

	IPC	Cycles		Instrs		L1d hits		L2 hits		L3 hits	
	50%	50%	99%	50%	99%	50%	99%	50%	99%	50%	99%

Table 4. Low-level metrics. IPC is Instructions Per Cycle. Cycles and IPC are only comparable within the same driver, as explained in the main text. DPDK batched uses batches of size 32. Main memory hits are negligible and not shown.

8. Applicability

In this section, we evaluate the applicability of our model to real-world network function deployment. Did we strike a good tradeoff choosing not to support some functions to simplify the model? And is our model useful in the context of network function virtualization?

As previously explained, the core limitation of our driver model is that network functions cannot keep buffers aside for later use. For instance, they cannot reconstruct messages in TCP or other higher-level protocols. Our model targets network functions that do not need to do so because they logically handle packets one at a time.

Our model supports many well-known functions, though there is no standard list of network functions. Despite their increased importance in modern networking, there is no consensus on what is a “network function” and what is not. There have been attempts such as RFC 3234 [27] to classify “middleboxes”, which are functions that are not crucial to the network, but to the best of our knowledge there is no commonly accepted list of network functions. We chose to use the list of functions from the ClickOS [18] paper, which were also used by the authors of Vigor [33] to estimate the applicability of their verification technique. We complement this list with our own knowledge, for lack of a more standard source.

Our driver model supports 13 of the 14 types of network functions listed in ClickOS: load balancing, DPI, NAT, firewalls, tunnel, multicast, BRAS, monitoring, DDoS prevention, IP proxies, congestion control, IDS, and IPS. The only one that our model cannot support without compromises is a traffic shaper, because shaping requires keeping packets to send them later in the desired traffic shape. Among the network functions not mentioned by ClickOS, our model can be used for Ethernet bridges, ARP clients and servers, DNS proxies, statistics collectors, traffic policers, and Google’s Maglev [8] load-balancer.

However, our driver model cannot efficiently support functions based on entire TCP messages, since this requires keeping IP packets around to reorder and merge them into logical messages. Such functions include proxies and HTTP servers. While one could implement reordering by copying buffers before giving descriptors back to the hardware, this would hinder performance.

We believe our model is a good fit for network functions that form the backbone of networks, such as routing, load-balancing, NAT and DNS, access control and statistics. However, it is not suited to high-level functions that deal with entire connections or protocols that fragment packets.

Some requirements are orthogonal to our model. For instance, offloading checksums to hardware would remove the main bottleneck in the NAT we benchmarked. Any such feature that can be used by providing metadata to the NIC can be implemented in a driver using our model.

TinyNF can be used for virtualization, which is a key tool for the practical deployment of network functions [35]. Virtualization allows operators to deploy multiple network functions on the same physical machine, instead of having to dedicate an entire machine to a single function. They also provide an easier way to manage network functions, in the same way virtual machines ease software management.

We experimented with virtualization using Single-Root I/O Virtualization, or “SR-IOV” for short, a PCIe standard with which network cards can expose virtual network cards with the same packet-processing features as the physical card. The virtual machine monitor can let virtual machines access virtual devices directly, without surrendering control over the physical card. The physical card includes hardware to route packets to virtual cards based on packet headers, for instance by Ethernet address. The physical card can limit the rate at which each virtual card transmits packets and can prevent virtual cards from transmitting packets with a different source address than their own. Virtual machines thus gain the benefits of direct access without the ability to monopolize the link or lie about their network identity.

The Intel 82599’s virtual cards do not support some of the physical features. Notably, using transmit head write-back causes virtual cards to hang, a problem not mentioned in the card’s data sheet but already reported by the authors of Arrakis [20]. Another missing feature is legacy packet descriptors, which are simpler to use, though the data sheet calls this out. We wrote a version of TinyNF that does not use these features, making it slightly slower. The Arrakis authors estimated that the lack of transmit head write-back causes a 5% performance penalty.

We used the same physical setup as before, but with 16 virtual functions on each of the two network cards, for a total of 32 virtual cards. Each virtual card has an Ethernet address, and physical cards route packets to virtual cards based on these addresses. The only code changes are due to the missing features mentioned above, as well as a few dozen lines of configuration. The functions forward each packet using a virtual card on the physical card opposite the one whose virtual card received the packet.

The Vigor policer handles 12.2 Gb/s of minimally-sized packets without loss when using TinyNF in this setup. A no-op function reaches 14 Gb/s. Both are bottlenecked by reading packet descriptors for packet fetches, as the data from packets and descriptors no longer fits in the L2 cache.

This experiment is only intended to show that our driver model is applicable to virtualized environments. With this number of devices, other concerns arise such as load skew across devices and non-uniform memory accesses, which we do not capture here. We believe TinyNF is as sensitive to these concerns as other stacks. In particular, the order in which the function checks virtual cards for packets matters. For instance, if packets mostly arrive on one card, checking the other cards for packets will limit performance.

9. Discussion

In this section, we present our main takeaways from this project, in the form of actionable recommendations for both researchers and practitioners.

Drivers are not a special category of software, and the line currently drawn between drivers and other kinds of software is neither well-defined nor helpful. Drivers should be considered just another kind of software system, one that is more focused on hardware than usual. The same techniques used in systems that handle requests can and should be scaled down to “drivers”, instead of creating new vocabulary for one kind of software.

The common meaning of “driver” is a piece of code that has exclusive access to hardware and exposes a software API to programs who want to use it. However, software that does this is not always called a driver. Operating systems allows programs to access CPUs, including isolation and high-level APIs to access features such as clocks, but they are not commonly referred to as “CPU drivers”, with the notable exception of Barrelfish [1]. The same can be said of higher-level frameworks such as Java or .NET, which offer an abstraction over low-level CPU details yet are not called drivers. This applies to other kinds of devices as well: code that lets programs run GPU shaders is called a driver, but code that lets programs to draw windows and buttons on the screen is not, even though it is also a way for programs to draw. The internal architecture of some systems does rely on “drivers” as an indirection to access hardware, but this is not relevant from users’ point of view.

An example of overly specific vocabulary is “batching” in network drivers: a feature that improves performance by amortizing costs. It is really composed of three independent features: (1) getting multiple packets at a time from the NIC, gaining information about network load, (2) processing multiple packets at a time, allowing for vectorized code, and (3) giving multiple packets at a time to the NIC, amortizing the cost of NIC register writes. TinyNF shows that only (3) is required for high throughput, though (1) may be required to get consistently low latency. In fact, any developer that uses batching but does not explicitly keep track of network load or use vector operations is already implicitly aware of this. Amortizing NIC writes is similar to existing techniques such as buffering reads and coalescing writes in disk I/O.

The idea that drivers are a special kind of software is hindering research. Most systems for fast networking, such as ClickOS [18], DPDK [5], netmap [28], SoftNIC [11], and IX [2], reuse existing drivers, which are bottlenecks on their performance. Arrakis [20] uses custom drivers but focuses on interrupt-driven I/O, which strikes a different tradeoff. Ixy [10], is the only research driver we know of besides ours. It is odd to have more research operating systems than drivers: the former are by definition more complex as they contain at least one driver.

Isolation is required for low-level performance, just as modularity is required for high-level correctness. The best-effort approach of shared caches is no longer enough when interferences that cause even a low number of cache misses cause a noticeable performance difference, as is the case with fast networking.

One way to provide performance modularity is to run each part of a system on physically separate hardware, as in TAS [16]. This eliminates interference in per-core caches, at the cost of increasing resource use. It also increases the cost of communication between modules, in the same way protection rings eliminate functional interference between user and kernel mode at the cost of an expensive boundary between the two modes.

However, the current way to measure low-level metrics through special CPU registers cannot be isolated from the code under measurement. This is not an issue for most code, because the overhead of measurement is low, but it becomes an issue with nanosecond-scale code such as TinyNF.

One way to avoid measurement overhead is to use static instead of dynamic analysis, but this requires a hardware model. TiML [32] includes performance reasoning in a type system, and Bolt [13] infers performance metrics from the source code of network functions written in C. However, predicting cycle counts requires accurate hardware models. For instance, Bolt predicts instruction counts within a few percent of ground truth but is 300% off the true cycle count for typical workloads. Since hardware optimizations are considered a competitive advantage, perfectly accurate hardware models are unlikely to be made publicly available.

Standard benchmarks would improve the state of network function research. Other areas of research use benchmarks such as SPEC [3] to measure improvements on a widely-accepted scale. There is no equivalent for network functions, not even non-standard ones.

We chose to explore a new point in the design space of networking code based on our experience with networking research, but the main threat to this paper’s validity is that we have no way to validate the usefulness of this design. It may be that real-world traffic looks more like the one used to benchmark Arrakis [20], for instance, in which Peter et al. came to the conclusion that handling operations in user mode entirely eliminates the need for even transmission tail update coalescing.

Unlike other domains in which one can substitute benchmarks with well-known publicly available targets, such as compiling the compiler itself to show optimization improvements, network functions are generally not public.

This problem is getting worse as hardware gets faster. With 100 Gb/s Ethernet becoming more popular, should we focus on handling minimally sized packets, with a budget of 6ns per packet, or should we assume that traffic is made up of packets in the hundreds of bytes, as Pigasus [34] does? We do not know.

Any benchmark, even if unrealistic, would improve the situation, which is that both industry and academia use no-op functions as a de facto standard. DPDK's performance reports [6] from Intel, Mellanox, and Broadcom all exclusively use no-ops, and research such as netmap [28] or SoftNIC [11] mostly use no-ops. But no-ops are not representative of either general or specific cases. Even overly specific benchmark suite would at least result in systems optimized for a real use case, instead of systems optimized for no-ops which are not useful to anyone.

Since the performance of infrastructure code interferes with the performance of application code in non-obvious ways, extrapolations from no-ops are not representative of actual performance. We believe that using any real network function as a standard benchmark would provide a data point from which one can extrapolate more credibly to other real functions. The chosen function would be closer to any other function than a no-op is in terms of how the infrastructure code influences its performance, regardless of how close it is in terms of functionality.

We started this project with the goal to close the gap between unverified and verified performance using the Vigor network functions as benchmarks. Had we measured no-op performance for TinyNF first, under the belief that it was representative, we would have come to the conclusion that it was worse than DPDK. This could have led us to make TinyNF more complex to “fix” its no-op performance, accidentally lowering performance for real functions in the process.

More formal hardware data sheets could speed up software development and reduce bugs, without the need to change the hardware. TinyNF's complexity mainly comes from the number of assumptions it makes about hardware. These are due to missing or incorrect data, which is a natural consequence of free-form data sheets.

Most of the data sheet errors could be avoided using the same kind of analysis performed by compilers today. For instance, the Intel 82599 NIC's data sheet [12] has typos in register names and even in the size of some register fields; these could be caught by consistency checks ensuring all referenced names are declared and all registers contain the right number of bits. Some registers are only documented within the list of registers and not in the explanations of the operations they are used for, requiring developers to read the entire data sheet to learn about them; these could be caught by a check for unused declarations.

It would be unreasonable to expect hardware engineers to always provide perfect data sheets or design bug-free hardware, in the same way that it would be unreasonable to expect software engineers to always write bug-free code. However, our experience is that most current bugs are low-hanging fruit that could be caught without inventing new analysis techniques, if data sheets written in a machine-readable format first.

Using the basic features of a modern NIC does not have to be complicated, despite the belief that hardware has become inherently harder to deal with than in the past. We examined the oldest driver we could find for a NIC of the Intel 8259x family, which is the so-called “apricot” driver [17] for the Intel 82596, released with Linux 1.1 in 1994. It contains 450 lines of code not including debug code, which is close to TinyNF's 550.

Most lines of code in TinyNF come from unused features that must be initialized anyway. For instance, software must clear packet filters and virtualization-related registers after resetting the hardware, unlike some other features that are left in a clean state by the hardware reset. This kind of issues is not a fundamental source of complexity but a hardware implementation detail. If the hardware could be fully reset in a single operation, TinyNF would have fewer lines of code than the old “apricot” driver. This overhead is not as visible in a driver such as DPDK's, whose complexity comes from the amount of features it supports.

We hope this paper serves as evidence that developing code that interacts with network cards is both interesting and rewarding, and that it is not as complex or difficult as is often believed. On the contrary, we found that developing our own driver made the development and verification of network functions easier, by removing all dependencies on complex external stacks and kernel-mode drivers.

Acknowledgements

We thank our shepherd Simon Peter for his useful feedback and guidance; the anonymous reviewers for their useful and detailed reviews; the anonymous artifact evaluators for their useful feedback on the code and experiments; Arseniy Zaostrovnykh, Akvilė Valentukonytė, Blagovesta Kostova, Katerina Argyraki, Lei Yan, Rishabh Iyer, Samuel Chassot, and Yassmine Abdrabo, for providing feedback on the ideas, paper, and code.

Availability

Our code is available at github.com/dslab-epfl/tinynf, and described further in the Artifact Appendix below. The code obtained the “Artifact Available”, “Artifact Functional” and “Results Reproduced” badge from artifact evaluation and can thus be reused by others with confidence.

In particular, the TinyNF code can be used as a simpler and faster base for any network function that fits its model, or as a baseline to evaluate low-level networking code. The benchmarking scripts are independent of TinyNF and can be reused to measure the performance of network functions that use any framework or driver.

Artifact Appendix

Abstract

The artifact of this paper contains the code of the “TinyNF” prototype, as well as scripts to run the various experiments used in this paper. The benchmarking scripts can be used for any network function, not only TinyNF.

Checklist

Program: driver and network functions

Metrics: throughput, latency, code complexity

Output: compiled network function including the driver

Experiments: as described in Sections 6, 7, and 8

Required disk space: 80 GB for low-level metrics, a few MBs for everything else

Expected run time: around half a day to run all available experiments, almost all of which is spent waiting

Public link: github.com/dslab-epfl/tinynf

Code license: MIT

Description

How to access: Use the link above.

Hardware dependencies: Two machines with Intel 82599 NICs, as mentioned in *experiments/ReadMe.md*.

Software dependencies: TinyNF currently supports Linux only. A few standard packages are required to compile and run experiments, as described in *experiments/ReadMe.md*.

Installation

There is no explicit installation step, cloning the repository is enough. The artifact is fully self-contained and does not install files to the rest of the machine, except for benchmark scripts copied to a configurable directory on the machine that runs them.

Experiment workflow

All experiments are run using scripts. Manual work is not needed beyond executing the scripts with some parameters and setting up a configuration file once.

Evaluation and expected result

The scripts produce tables and figures that correspond to those in this paper. Tables are produced as tab-separated output on the command line, while figures are produced as vector images.

Experiment customization

The benchmarking scripts are reusable for any experiment even not including TinyNF. They are designed to measure the throughput and latency of any network function, with special treatment for ones that require DPDK-compatible kernel drivers.

Notes

We elaborate here on the environment abstraction library mentioned in Section 5, which is the only dependency of the TinyNF driver. The driver itself does not depend on any kernel-mode driver and only needs “freestanding” features of the C library, i.e., it only uses a few headers and types but no C functions from the standard library.

The abstraction contains 5 groups of functions: memory allocation and deallocation, translation between virtual and physical addresses, PCI register reads and writes, endianness conversion, and sleep.

We believe these 5 groups are all necessary to write NIC drivers without compromises, though some of these could be modified or removed under certain conditions. Sleeping could be replaced by a clock function combined with busy-waiting in the driver, but this would be less efficient and no less complex. Memory deallocation could be omitted if the software uses a crash-only failure mode. Translating virtual to physical addresses may not be necessary in the presence of an IOMMU, if memory allocation also configured the IOMMU. In systems that use the Enhanced Configuration Access Mechanism for PCI registers, or “ECAM” for short, the functions to read and write PCI registers could instead be a single function providing the memory address at which this space is accessible for a given device.

Notably, the abstraction does not expose non-uniform memory access: implementations are expected to provide sane defaults. The current Linux implementation allocates memory on the same node as the current CPU and does not allow for PCI operations on devices on other nodes. This would need to change in a more production-ready version, in which various strategies can be used when dealing with devices on multiple nodes, but those strategies are beyond the scope of this paper.

Abstract

Programmable NICs have diverse uses, and there is a need for a NIC platform that can offload computation from multiple co-resident applications to many different types of substrates, including hardware accelerators, embedded FPGAs, and embedded processor cores. Unfortunately, there is no existing NIC design that can simultaneously support a large number of diverse offloads while ensuring high throughput/low latency, multi-tenant isolation, flexible offload chaining, and support for offloads with variable performance.

This paper presents PANIC, a new programmable NIC. There are two new key components of the PANIC design that enable it to overcome the limitations of existing NICs: 1) A high-performance switching interconnect that scalably connects independent engines into offload chains, and 2) A new hybrid push/pull packet scheduler that provides cross-tenant performance isolation and low-latency load-balancing across parallel offload engines. From experiments performed on an 100 Gbps FPGA-based prototype, we find that this design overcomes the limitations of state-of-the-art programmable NICs.

1 Introduction

The gap between network line-rates and the rate at which a CPU can produce and consume data is widening rapidly [71, 66]. Emerging *programmable* (“*smart*”) NICs can help overcome this problem [32]. There are many different types of offloads that can be implemented on a programmable NIC. These offloads, which accelerate computation across all of the different layers of the network stack, can reduce load on the general purpose CPU, reduce latency, and increase throughput [32, 48, 59, 69, 13].

Many different cloud and datacenter applications and use cases have been shown to benefit from offloading computation to programmable NICs [13, 48, 59, 42, 32, 37, 49, 46, 62, 47, 30, 36, 70, 69, 35, 55, 45]. However, there is no single “silver bullet” offload that can improve performance in all cases. Instead, we anticipate that different applications will specify their own chains of offloads, and that the operator will then merge these chains with infrastructure-related offloads and run them on her programmable NICs. To realize this vision, this paper presents PANIC, a new scalable and high-performance programmable NIC for multi-tenant networks

that supports a wide variety of different types of offloads and composes them into isolated offload chains.

To enable cloud operators to provide NIC offload chains as a service to tenants, a programmable NIC must support: 1) Offload variety: some offloads like cryptography are best suited for hardware implementations, while an offload providing a low-latency bypass for RPCs in an application is better suited for an embedded core [51]; 2) Offload chaining: to minimize wasted chip area on redundant functions, the NIC should facilitate composing independent hardware offload units into a chain as needed, with commonly-needed offloads shared across tenants; 3) Multi-tenant isolation: tenants should not be able to consume more than their allocation of a shared offload; 4) Variable-performance offloads: there are useful offloads that are not guaranteed to run at line-rate, as well as important offloads that run with low latency and at line-rate.

There exist many different programmable NICs [32, 12, 75, 31, 58, 72, 23, 24, 11, 57, 53, 54, 52, 76], but, there is no programmable NIC that is currently able to provide all of the above properties. Existing NIC designs can be categorized as follows, with each category imposing key limitations:

- **Pipeline-of-Offloads** NICs place multiple offloads in a pipeline to enable packets to be processed by a chain of functions [52, 32]. Chaining can be modified in these NICs today but requires a significant amount of time and developer effort for FPGA synthesis, and slow offloads cause packet loss or head-of-line (HOL) blocking.
- **Manycore** NICs load balance packets across many embedded CPU cores, with the CPU core then controlling the processing of packets as needed for different offloads [23, 24, 53, 54, 57, 72, 58]. These designs suffer from performance issues because embedded CPU cores add tens of microseconds of additional latency [32]. Also, no existing manycore NICs provide performant mechanisms to isolate competing tenants. Further, performance on manycore NICs can degrade significantly if the working set does not fit within the core’s cache.
- **RMT** NICs use on-NIC reconfigurable match+action (RMT) pipeline to implement NIC offloads. The types of offloads that can be supported by RMT pipelines are limited because each pipeline stage must be able to handle processing a new packet every single clock cycle.

This paper presents the design, implementation and evaluation of PANIC, a new NIC that overcomes the key limitations of existing NIC designs. PANIC draws inspiration from recent work on reconfigurable (RMT) switches [21, 67, 68, 27, 16]. PANIC’s design leverages three key principles:

1. *Offloads should be self-contained.* The set of potentially useful offloads is diverse and vast, spanning all of the layers of the network stack. As such, a programmable NIC should be able to support both hardware IP cores and embedded CPUs as offloads.
2. *Packet scheduling, buffering, and load-balancing should be centralized* for the best performance and efficiency because decentralized decisions and per-offload queuing can lead to poor tail response latencies and poor buffer utilization due to load imbalances.
3. Because the cost of small/medium-sized non-blocking fabrics is small relative to the NIC overall, *the offloads should be connected by a non-blocking/low-oversubscribed switching fabric* to enable flexible chaining of offloads.

Following these design principles, this paper makes three key contributions: 1) A novel programmable NIC design where diverse offloads are connected to a non-blocking switching fabric, with chains orchestrated by a programmable RMT pipeline, 2) A new hybrid push/pull scheduler-and-load balancer with priority-aware packet dropping, and 3) An analysis of the costs of on-NIC programmable switching and scheduling that finds them to be low relative to the NIC as a whole.

The PANIC NIC has four components: 1) an RMT switch pipeline, 2) a switching fabric, 3) a central scheduler, and 4) self-contained compute units. The RMT pipeline provides programmable chain orchestration. A high performance interconnect enables programmable chaining at line-rate. The central scheduler provides isolation, buffer management, and load-balancing. Self-contained compute units may be either hardware accelerators or embedded cores and are not required to run at line-rate.

To evaluate the feasibility of PANIC, we have performed both ASIC analysis and experiments with an FPGA prototype. Our ASIC analysis demonstrates the feasibility of the PANIC architecture and shows that the crossbar interconnect topology scales well up to 32 total attached compute units. Our FPGA prototype can perform dynamic offload chaining at 100 Gbps, and achieves nanosecond-level ($<0.8 \mu s$) packet scheduling and load-balancing under a variety of chaining configurations. We empirically show that PANIC can handle multi-tenant isolation and below line-rate offloads better than a state-of-the-art pipeline-based design. Our end-to-end experiments in a small scale testbed demonstrate that PANIC can achieve dynamic bandwidth allocation and prioritized packet scheduling at 100 Gbps. In total, the components of PANIC, which includes an $8 * 8$ crossbar, only consume a total of 11.27% of the total logic area (LUTs) available on the

Offload	Config	Tput (Gbps)	Delay

2 Motivation

We discuss in detail the requirements that we envision programmable NICs in multi-tenant networks ought to meet. We then explain why existing NICs designs fail to meet them.

2.1 Requirements

1. Offload Variety: There are a large variety of network offloads, and different types of offloads have different needs. Not all offloads are best implemented on the same type of underlying engine. For example, a cryptography offload can provide much better performance if implemented with a hardware accelerator built from a custom IP core instead of an embedded processor core. To shed light on this, we experimented with a few different types of offloads using an Alpha Data ADM-PCIE-9V3 Programmable NIC [12] to evaluate the behavior of different hardware IP cores that could be used as on-NIC accelerators, and the Rocket Chip Generator [14] to perform cycle-accurate performance measurements of a RISC V CPU to understand the costs of running these offload with an on-NIC embedded processor. Our results in Table 1 indeed show that offloads for encryption/decryption and authentication are a poor fit for embedded CPU designs and should be implemented in hardware.

In contrast, an application-specific offload to walk a hash table that is resident in main memory is better suited for an embedded processor core because a hardware offload may not provide enough flexibility [51]. Thus, a programmable NIC should ideally provide support for both hardware and software offloads.

2. Dynamic Offload Chaining: In the case of hardware accelerators, it is important to be able to compose independent offload functionality into a chain/pipeline to avoid wasted area on redundant functionality. For example, using a programmable NIC to implement a secure remote memory access for a tenant may require the tenant to compose cryptography, congestion control, and RDMA offload engines.

¹PANIC artifact: https://bitbucket.org/uw-madison-networking-research/panic_osdi20_artifact

Further, as tenants come and go, and as a given application’s traffic patterns change, the on-NIC offload chains will also need to be dynamically updated. This is because different network transfers benefit from different sets of offloads. Further, not every application packet needs every offload. For example, for a key-value store that serves requests from both within-DC and WAN-distributed clients, IPSec and/or compression could be offloaded, but only the packets sent over the WAN may need IPSec authentication and/or compression.

Thus, an ideal programmable NIC should not restrict the type of offloads that may be simultaneously used, and should instead support dynamic offload chaining, i.e., switching and scheduling packets as needed between independent offloads.

3. Dynamic Isolation: Today’s data center servers colocate applications from different competing tenants [50, 39, 15, 61, 32]. Each tenant may have its own offload chains that may need to run on a programmable NIC, so it is necessary for a programmable NIC to provide performant low-level isolation mechanisms. For example, consider the case that two tenants A and B are running offload chains where packets are first uncompressed and then sent to an embedded CPU for further processing, and packet contents are such that the workload for tenant B runs at half the rate of that of tenant A. To support this, the NIC’s mechanisms must ensure fair packet scheduling at the shared compression offload and that the slow chain does not cause head-of-line (HOL) blocking for the other chain. Further, if a third tenant C were to start, packet processing load across chains may shift. To handle this, the scheduling policy may need to be reprogrammed.

4. Support for offloads with variable and below line-rate performance: Some offloads may not run at line-rate. Of the compression, cryptography, authentication, and inference offloads that we ran on hardware, only inference was able to run at 100 Gbps (Table 1), and others ran well below line-rate. Also, offload performance is variable and sometimes workload-dependent, incurring significant delay for certain requests; see, for example, compression and authentication, whose performance depends on packet size.

These results also show the need for an approach to load-balancing that can accommodate offloads with variable performance. Slow offloads can be duplicated across multiple engines (e.g., 3 AES-256 engines) for line-rate operation.

5. High-Performance Interconnect: It is important for a programmable NIC to be able to provide high throughput for line-rate offloads. In the case where no offloads or only low-latency offloads are used, a programmable NIC should not incur any additional latency. Achieving high performance is complicated by bidirectional communication, multi-port NICs, and chaining. An offload that is used for TX and RX on a dual port NIC needs to operate at four times line-rate to prevent becoming a bottleneck. When offloads are chained, a single packet may traverse the on-NIC network multiple times. Effectively, the NIC must be able to emulate creating a line-rate connection between each hop in an offload chain.

NIC Design	Offload Chaining	Multi-Tenant Isolation	Variable Perf	High Perf	Offload Variety
Pipeline	✗	✗	✗	✓	✗
Manycore	✓	✗	✓	✗	✓
RMT	✗	✓	✗	✓	✗

Table 2: **Programmable NIC designs compared w.r.t. the requirements in Section 2.1.**

2.2 Limitations of Existing Designs

We argue below that programmable NIC designs today (Figure 1) lag behind these requirements (Table 2).

2.2.1 Pipeline Designs

Figure 1a illustrates the pipelined programmable NIC design. In this design, the offloads are arranged in a linear sequence, i.e., a pipeline. Effectively, each offload looks as though it is an independent device attached in the middle of the wire connecting the NIC to a TOR switch. Most existing NICs with on-board FPGAs located as a “bump-in-the-wire” use this design [52, 32, 31], and other NICs use this design for fixed function offloads for TCP checksums and IPSec [6, 38].

Chaining: Chaining offloads is difficult in pipelined designs because of their static offload topology; the offloads are arranged in a line. Although packets can be *recirculated* through the pipeline as needed, this wastes on-NIC bandwidth and hurts line-rate performance.

Variable Performance Offloads: A slow offload that does not run at line-rate can cause HOL blocking in the pipeline of offloads if the pipeline is stalled, and packet loss if the pipeline is not. This can be avoided with routing logic to bypass offloads, but this requires additional buffer memory at each offload: packet arrivals in Ethernet are bursty [41, 17], and it common for tens of packets to arrive back-to-back at line-rate. There would be significant packet loss if offloads that are not guaranteed to run at line-rate are not allocated buffer resources. For offloads where running at line-rate is workload or configuration dependent, the chip area allocated to per-offload buffers would be wasted under some traffic patterns.

Multi-tenant Isolation: In a pipeline, packets are forwarded through offloads that do not need to process the packet. Even if every offload runs at full line-rate, a high latency offload used by Tenant A but not by Tenant B will unnecessarily lead to increased latency for Tenant B. This can be avoided with routing logic to bypass offloads, but this also requires additional buffer memory at each offload to avoid pipeline stalls or packet drops. It is only possible to bypass an offload without stalling the pipeline if there is somewhere else to put the packets that it is currently processing.

Multi-tenant isolation is more problematic if not all offloads are guaranteed to run at line-rate. In this case, if tenant A has already consumed all of the packet buffers allocated for an offload, then tenant B will experience HOL-blocking and possibly packet loss. Although per-offload scheduling

Figure 1: Illustrations of existing programmable NIC architectures.

logic could be used to overcome this limitation, this has area overheads, and, as with per-offload packet buffers, this logic may be unutilized in some workloads.

Offload Variety: Pipeline-of-offloads designs are typically used for programmable NICs that only support hardware offloads. The limitations of pipeline designs are best avoided with low-latency offloads that run at line-rate. Because embedded CPU cores may not run at full line-rate and can incur high processing latency, this makes them a poor fit for pipeline designs. To overcome this limitation, the Azure SmartNIC [32] onloads computation from the programmable NIC to a core on the main CPU for certain tasks. This approach is costly, especially in cloud environments where servers are leased to customers on a per-core basis.

Some FPGA NICs implement all NIC functionality on an FPGA, including the Ethernet MAC and PCIe engines [12, 75, 76, 31]. Such NICs do not have many inherent limitations as a platform. With the right design, such NICs can meet all of our requirements, but no such design currently exists.

2.2.2 Manycore Designs

Figure 1b illustrates a manycore programmable NIC design [24, 53, 72, 73]. These designs implement network offloads by parallelizing flow processing across a large number of embedded processors that are arranged into a multi-hop on-chip tiled topology. Some manycore NICs additionally contain hardware engines for cryptography and compression [72, 58]. This supports chaining and a variety of different offloads, but performance and isolation are poor.

Performance: Manycore NICs use an embedded CPU core to orchestrate the processing of a packet across offloaded functions [34]. This is because the on-chip network cannot parse complex packet headers to determine the appropriate on-NIC addresses for the packet's destination. As a result of this design choice, manycore NICs have throughput and latency problems that prevent high-performance chaining. Further, manycore NICs even struggle to drive 100 Gbps and faster line-rates [32]. Because a single embedded processor is not enough to saturate line-rate, manycore NICs require packet load-balancing and buffering to scale performance.

Manycore NICs struggle to provide high-throughput chaining because manycore interconnects typically only provide enough throughput for a received packet to be sent to one embedded core before being sent via DMA to main memory. As applications become complex, state and caching limitations can require that different offloads be implemented

as microservices distributed across cores instead of parallel monoliths. Current manycore NIC designs are not able to provide high performance for such a usecase.

Similarly, involving a CPU in a manycore NIC adds significant packet processing latency that otherwise could be avoided for packets that only need to be processed by a hardware accelerator. For example, Firestone *et al.* [32] report that processing a packet in one of the cores on a manycore NIC adds a latency of 10 μ s or more.

Multi-Tenant Isolation: Because manycore NICs must buffer packets and load-balance them across parallel embedded cores [48], the extent to which tenants are isolated is determined by how buffer resources are managed, and how packets are load balanced. Unfortunately, existing manycore NIC designs do not provide explicit control over packet scheduling and buffering [48]. They use FIFO packet queuing and drop-tail buffer management; without any other isolation mechanisms, this can lead to HOL blocking, and drop-tail packet buffers can allow one tenant to unfairly consume buffers.

However, some level of isolation is possible in manycore NICs by (1) statically partitioning CPU resources across different tenants [48], which is inefficient, and (2) then using NIC-provided SDN mechanisms for steering tenants' flows to different cores. Additionally, some NICs such as the Broadcom Stingray allow running an OS to provide software-based isolation through a Linux operating system [22], but this can exacerbate the NICs' performance issues.

2.2.3 Reconfigurable Match+Action (P4) Designs

Figure 1c shows an RMT NIC design; these are built using an ASIC substrate with a programmable match+action (RMT) pipeline [42, 60]. In this model, incoming packets are first parsed by a programmable parser and then sent through a pipeline of M+A tables. Unfortunately, RMT NICs cannot support many interesting offloads (e.g., compression, encryption, or any offload that must wait on the completion of a DMA from main memory) because the actions that are possible at each stage of the pipeline are limited to relatively simple *atoms* that can execute within 1-2 clock cycles [67, 60, 21]. However, RMT NICs do not suffer from multi-tenant performance isolation problems because each offload runs at line-rate with extremely low latency.

3 PANIC Overview

PANIC is a new programmable NIC design that meets the aforementioned requirements (Section 2.1). The core idea be-

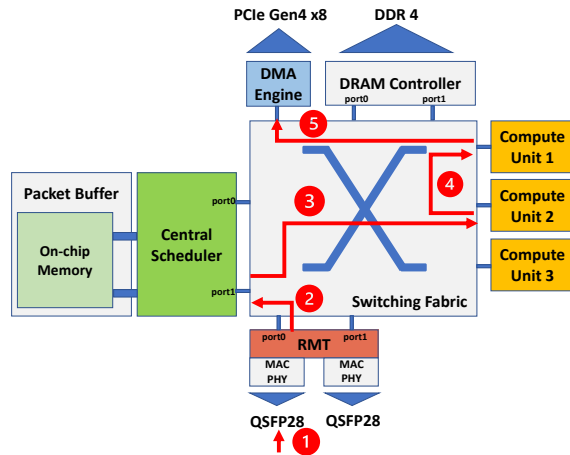

Figure 2: PANIC Architecture

hind the design of PANIC is that programmable NICs should be implemented as four logical components (Figure 2): 1) A programmable RMT pipeline, which provides programmable offload chaining on a per-packet basis; 2) A switching fabric, which interconnects all other components in PANIC and enables dynamic chaining at line-rate; 3) A central scheduler, which achieves high-performance packet scheduling, traffic prioritization and traffic isolation; 4) Compute units, each of them running a single offload. This system architecture is shown in Figure 2. We show that this design is suitable for both ASIC and FPGA implementations.

Operational overview: Figure 2 illustrates how PANIC operates when packets are received. In this example, there are three compute units 1, 2, and 3 running services A, B, and C respectively. When packets are received in PANIC in Step 1, they are first processed by the RMT pipeline. The RMT pipeline parses the packet headers and matches on them to identify the chain of offloads that the packet should be forwarded to, and then it generates a PANIC descriptor that contains this offload chain information. In this example, the offload chain that is found will first send the packet to service B and then to service A.

Next, the packet is injected into the switching fabric. If the packet does not need to be processed by any offloads, it will be forwarded straight to the DMA engine of the NIC, which is connected to the interconnect in the same manner as all of the compute units used to implement offloads. Otherwise, it is sent to the central packet scheduler (Step 2).

The scheduler then buffers the packet and orchestrates scheduling and load-balancing the request across its offload chain. When there is no load, packets are chained with a source route that takes them from offload to offload without stopping at the packet scheduler. In this example, the scheduler first buffers this packet until Unit 2 is idle. Then, in Step 3, it steers this packet to Unit 2, and, in Step 4, the packet is directly *pushed* to Unit 1. Finally, in Step 5, after Unit 1 finishes the computation of service A, the source route steers this packet to the DMA engine, which is responsible

for transferring packets over the PCIe bus into main memory on the host.

When load is high (not shown), the loaded unit (say Unit 1) detours a packet that was pushed to it (by Unit 2) off to the buffer in the central scheduler. From there, the packet can be *pulled* later for processing by either Unit 1 when it has finished processing a packet or by another parallel unit running the same logic as Unit 1 entirely.

Transmitting packets is similar to receiving packets in reverse, except that the main CPU can associate offload chains with transmit queues beforehand so that the RMT pipeline does not need to process packets before they can be sent to offloads. After the main CPU enqueues packet descriptors, they will be read by the DMA engine, forwarded through an offload chain and managed by the central packet buffer as needed, and then forwarded to the appropriate Ethernet MAC.

PANIC makes it possible to meet all of our requirements:

1. Offload Variety: Each offload in PANIC is an independent tile attached to the high-performance interconnect, and the RMT pipeline builds the packet headers necessary to enable hardware offloads to process packet streams without any additional routing or packet handling logic. This allows for a large variety of different types of computation to be performed by the offload engine, including hardware IP cores, embedded processors, and even embedded FPGAs [74].

2. Dynamic Offload Chaining: Installing a new chain in the RMT pipeline for received packets involves programming lookup tables, and installing a new chain for a transmit queue can be done by issuing MMIO writes from the main CPU.

3. Policies for Dynamic Multi-Tenant Isolation: Performance isolation is provided by the central packet scheduler, which performs packet scheduling across the packets buffered for groups of parallel offloads that provide the same service. The scheduling algorithm determines both how chains competing for a service are isolated and how chains share packet buffers. Similar to prior work [68, 70], packet scheduling policies in PANIC are programmable. Further, PANIC improves upon prior work by also providing policy-aware packet dropping to enable cross-tenant memory isolation.

PANIC supports any scheduling algorithm that can be implemented by assigning an integer priority to a packet, and this includes a wide range of different policies, including strict priority, weighted fair queuing (WFQ), least slack time first (LSTF), and leaky bucket rate limiting [56, 68]. Although strict priorities lead to starvation, this is intended—if there is enough mission-critical traffic to consume all available resources, then it is acceptable for competing best-effort traffic to starve. If starvation is undesirable, it can be avoided by using WFQ and rate-limiting.

PANIC can support a hierarchical composition of different scheduling algorithms, *e.g.*, fair sharing across tenants with prioritization of flows for each tenant, although this comes with additional hardware costs. More complex scheduling algorithms are also possible in PANIC because priorities for

Figure 3: PANIC Descriptor

later services in a chain can be dynamically computed by an earlier chain stage. Similarly, each group of offloads that form a service can have its own custom scheduling algorithm, which is useful when different chains start with different offloads and then converge and share the same service.

4. Support for offloads with variable and below line-rate performance: The central packet scheduler supports offloads that have variable performance. Packets for slow offloads will be buffered at the central scheduler. As loads shift, packet buffers can be dynamically allocated to different offload groups. PANIC’s hybrid push/pull load balancing scheme outlined in the example above load-balances packets across parallel offloads, ensuring precise load control, low tail latency, and minimal and efficient on-chip network use. Similar to the packet scheduler, the load balancer is also programmable.

5. High Performance: PANIC uses an on-chip network inspired by network routers to provide a high-performance interconnect between different offload tiles and the tiles for DMA and the Ethernet MACs. PANIC uses non-blocking high-bisection topologies like the crossbar making it possible to guarantee line-rate performance even if every offload in a chain sends/receives at line-rate over the on-chip network.

4 Design

This section discusses the design of the individual components of PANIC in more detail.

4.1 RMT Pipeline

The RMT pipeline in PANIC is used to provide programmable chaining and to look up scheduling metadata as part of providing programmable scheduling. The design of the RMT pipelines is borrowed from the design used in programmable switches [21, 67]. When a packet is received by the NIC, the RMT pipeline first parses incoming packets and then processes them with a sequence of match-action tables (MA tables). Each MA table matches specified packet header fields and then performs a sequence of actions to modify or forward the packet. Via these actions, the RMT pipeline 1) performs simple, line-rate packet processing (*e.g.*, IP checksum calculation) and 2) generates a PANIC descriptor for each packet that contains the appropriate chaining and scheduling metadata given the configuration that was programmed by the operator/user. Additionally, the RMT pipeline can maintain state on a per-traffic-class or per-flow basis if needed to support programmable scheduling or flow affinity.

Figure 3 shows the PANIC descriptor added by the RMT pipeline. It includes the packet length, the allocated buffer address, and the service chain for this packet, which is a list of services to send the packet to along with per-service metadata from the RMT. Because multiple compute units

Figure 4: Architecture of the multi-ported central scheduler

may implement the same service (offload), this means that the RMT pipeline does not specify the exact unit a packet will be sent to in advance. This enables the scheduler to perform dynamic load balancing across multiple computation units implementing the same service in parallel.

In addition to specifying a list of services, the offload chain also contains metadata. For example, per-hop scheduling metadata like traffic class and priority allows a chain to have different priorities and weights across different services. Similarly, the descriptor may also contain service-specific metadata to allow the RMT pipeline to perform pre-processing to speed-up or simplify different compute units. Examples of this type of metadata include pointers to fields in a parsed packet and a pre-computed hash of an IP address.

The RMT pipeline directly connects to the switching fabric. To ensure low latency, the pipeline directly steers packets that are not processed by any service to the DMA engine.

4.2 High Performance Interconnect

To enable dynamic service chaining, PANIC use an on-chip interconnect network to switch packets, providing high-speed communication between the scheduler and on-NIC units.

Because it is necessary to forward packets between offloads at line-rate, it is important to build a high-performance network. PANIC utilizes a non-blocking, low latency, and high throughput crossbar interconnect network, which, for the scale of our design, still has a low area and power overhead. The crossbar can be configured to connect any input node to any output node with no intermediate stages, and each port runs at line-rate. As a result, every offload can simultaneously send and receive at line-rate, which enables line-rate dynamic chaining regardless of which offloads a chain uses.

Although economical in small configurations, crossbar interconnects unfortunately do not scale well with an increase in the number of cores. Most of these problems arise from the delay and area cost associated with long interior wires because the number of these wires increases significantly with the number of cores. Fortunately, with PANIC, we are able to choose between different interconnect topologies without having to change other parts of the design. If there is

a need to scale beyond the limits of a single crossbar, we can switch to a more scalable (but higher-latency) flattened butterfly topology [43].

4.3 Centralized Scheduler

The centralized scheduler buffers packets, schedules the order in which competing packets are processed by a service, and load-balances packets across the different compute units in a service. The scheduler architecture is shown in Figure 4. The scheduler uses a new hybrid scheduling algorithm to support low-latency chaining while avoiding load imbalance, and it uses a new hardware-based priority queue (*i.e.*, PIFO [68]) to schedule and drop packets according to a programmable inter-tenant isolation policy.

An overview of the operation of the central scheduler is as follows: When a packet and its descriptor arrive, the scheduler writes the packet data into high-speed on-chip memory and stores the packet descriptor into the appropriate logical PIFO queue given the next destination service of this packet. Each logical PIFO queue corresponds to a service and sorts buffered descriptors by rank, which enables the scheduler to drop packets according to the same policy as they are scheduled by dropping the lowest-rank packet currently enqueued for the service if needed. Then, whenever any of the parallel compute units for a service have available “credits” at the scheduler, the credit manager (Figure 4) chooses the compute unit with most credits, dequeues the head element of the corresponding logical PIFO queue, and sends the packet data and descriptor along with the packet data across the on-chip interconnect to the chosen unit.

4.3.1 Hybrid Push/Pull Scheduling and Load Balancing

When one service cannot achieve line-rate with a single unit, PANIC uses multiple parallel units to improve bandwidth. To support load-balancing across variable performance offloads, PANIC provides *load-aware* steering. Specifically, PANIC introduces a new hybrid pull/push scheduler and load balancer that overcomes the limitations of either push or pull scheduling to provide both precise request scheduling and high utilization.

Pull-based scheduling provides the most precise control over scheduling because decisions are delayed until each unit is able to perform work. However, pull-based scheduling can lead to utilization inefficiencies because each unit must wait for a pull to complete before it can start work on a new packet, and busy-polling can lead to increased interconnect load. In contrast, push-based scheduling can lead to load-imbalance and increased tail latencies when packets have variable processing times. In this scenario, it is not possible to know how much work is enqueued at each unit at the time that load-balancing decisions must be made.

The hybrid scheduler used in PANIC provides the best properties of both pull and push scheduling. In this scheduler,

during periods of *high* load, the central scheduler uses *pull*-based load balancing to provide effective load balancing and packet scheduling. During *low* load, the scheduler *pushes* packets to all of the units in a service chain with low latency. To accomplish this, the scheduler uses credits to monitor the load at different units. Next, we describe the two modes of operation, pull and push, and the use of credits.

Credit Management: The credit manager tracks credits to measure load and dynamically switch between push-based and pull-based scheduling. The credit manager initially stores C credits for each compute unit. After sending a packet out, it decreases the credit number for that unit by one. When a compute unit is done processing a packet, it returns credit back to the credit manager.

The central scheduler operates in push mode as long as any of the parallel compute units in a service have credits available. If flow affinity is not needed, the scheduler steers packets to the unit which has the maximum number of pull credits to avoid load imbalance.

In contrast, if no unit has credit when a packet arrives, the scheduler buffers packets until credit is available. In this case, the central scheduler provides pull scheduling. Because the decision on which replica to use is made lazily, the number of packets queued at each unit will never exceed C .

By default, the number of initial credits C is set to two to avoid a stop-and-wait problem. However, it is possible to configure different credit numbers for each unit if needed. For example, ClickNP [47] uses a SHA1 engine that can process 64 packets in parallel, and PANIC can support this level of parallelism by giving 64 or more credits to the SHA1 engine.

Push-based Chaining: Push scheduling provides low-latency offload chaining. When a packet needs to traverse multiple offloads (*e.g.*, from A to B to C), the packet will be directly pushed to B when it finishes the computation in A rather than going back to the central scheduler. If B accepts the pushed packets, it will send a *cancel* message to the central scheduler to decrease its credit by one. In the case that there are multiple parallel units providing a service, the push destination is precalculated in the central scheduler. By pushing the packet directly to the next destination unit, PANIC reduces interconnect traversal latency and reduces on-chip network bandwidth demands. Furthermore, this reduces the load on the central scheduler as chain lengths grow.

Detour Routing: Push mode chaining may cause a packet to be pushed to a busy downstream unit that has no buffer space to accept packets. In this case, we use *detour* routing: when local buffer is occupied, the downstream unit redirects the packet back to the central scheduler, where it is buffered until it can be scheduled to another idle unit.

4.3.2 Packet Scheduling

To achieve priority scheduling and performance isolation, every packet stored in the packet buffer has its descriptor enqueued in a PIFO [68]. PANIC uses this PIFO-based priority

Figure 5: Accelerator-Based Compute Unit Design

Figure 6: Core-Based Compute Unit Design

scheduler to provide both performance and buffer isolation across tenants.

Isolation Policy and Rank Computation: When a packet arrives, the central scheduler uses stateful atoms (ALUs) [67] to take metadata about the packet, look it up in the RMT pipeline, and compute an integer priority that is used to enqueue a descriptor for the packet into a PIFO block. This enables PANIC to provide multi-tenant isolation, ensuring traffic from high-priority tenants has low latency. Additionally, if multiple PIFO blocks are used inside the scheduler, it is possible to support hierarchical policies. Because the on-chip network ports are bidirectional, there is enough network throughput to forward incoming packets back out regardless of which logical queue the packets use.

Prioritized Dropping: PANIC’s PIFO scheduler performs *prioritized packet dropping*. Specifically, PANIC ensures that when the NIC is overloaded, the lowest priority packets will be dropped. To achieve prioritized dropping, PANIC reuses the priority-sorted descriptor queue already used for scheduling in the PIFO. When the free space in the packet buffer for a logical PIFO is smaller than a threshold, the scheduler will remove the least-priority descriptor from the logical PIFO and drop this packet.

4.3.3 Performance Provisioning:

It is important to ensure that the central scheduler does not become a performance bottleneck and can forward packets across chains at full line-rate. To ensure that the scheduler has sufficient throughput, PANIC uses multiple ports to attach the scheduler to the on-chip network. Because the switching fabric is designed to forward between arbitrary ports at line-rate, increasing the number of ports used by the scheduler is sufficient to scale the network performance of the scheduler.

The speed of the PIFO block used to schedule packets can also become a performance bottleneck. The PIFO block that we use can schedule one packet per cycle, *e.g.*, 1000Mpps when operating at a 1GHz frequency when implemented in an ASIC design. Although this is sufficient to schedule packets in both transmit and receive directions in our current design, in the case that this number is greater than the performance of a single PIFO block, multiple parallel PIFO blocks need to be used to scale up performance.

Provisioning for Compute Unit Performance: The design

of the on-chip network and the scheduler can also ensure that offloads may be fully utilized despite complications from chaining. Specifically, when an offload O1 in a chain (Chain A=O1–O2–O3) runs at a slower rate than the rest of the offloads (O2–O3), it will become a bottleneck and cause O2–O3 to be not fully utilized. However, this does not lead to resource stranding. A second chain B that does not use O1 can still use O2–O3 and benefit from the remaining capacity of these offloads. The scheduler can ensure that the contending chains fairly share capacity.

4.4 Compute Unit

To support offload variety, PANIC utilizes compute units to attach offloads to the switching fabric. These compute units are self-contained, meaning that hardware offloads can be designed without needing to understand the packet switching fabric and without having to issue pull requests to the hybrid scheduler. The interfacing with the switching fabric is handled by the traffic manager (Figures 5 and 6). This both reduces offload complexity by avoiding duplicating packet processing functionality and reduces packet processing latency by avoiding incurring the overheads of processing a packet with a CPU.

An offload engine in PANIC can either be a hardware accelerator or a core, and Figure 5 and Figure 6 presents the design of an ASIC accelerator-based and CPU-based compute unit in PANIC, respectively. In both of these designs, the offload functionality is encapsulated as an offload engine. Both perform packet processing by reading a packet once it arrives from the network and has been placed in a local scratchpad buffer. The traffic manager is responsible for communicating with the switching fabric. This component includes logic for sending and receiving packets as well as logic for updating PANIC descriptors as needed for push-based chaining. The compute unit’s local credit manager interfaces with the central scheduler and is responsible for returning credits (when a packet’s processing is done) and sending cancel messages that decrement credits (when accepting a pushed packet).

The primary difference between an accelerator-based design and CPU-based design is that there is additional logic in the CPU-based design that is used to interface with the memory subsystem of the embedded CPU core. As Figure 6 shows, the compute unit utilizes memory-mapped I/O (MMIO) to connect an embedded CPU core as follows: 1) The traffic manager (TM) writes network data directly to a pinned region of the per-core memory. 2) Then the TM writes to an input doorbell register to notify the core that data is ready. 3) After the core finishes processing, it writes data back to the pinned memory region if needed and then writes to an output doorbell register that is used to notify the TM of a new outgoing packet. To make sure the packet data is written back to memory, the core needs to flush the cache lines for the pinned memory region. 4) The TM collects the output data and sends it back to the switching fabric.

5 ASIC Analysis

We expect an eventual implementation of PANIC to use an application-specific integrated circuit (ASIC), although we have also prototyped PANIC in the context of an FPGA platform for expediency. This is because relative to an FPGA, an ASIC provides higher performance, consumes less power and area, and is cheaper when produced in large volumes [44]. While an ASIC implementation is beyond the scope of this work, in this section we briefly discuss the feasibility of implementing different components of PANIC in an ASIC.

RMT: The implementation of an RMT pipeline in ASIC has already been proven feasible [21]. The Barefoot Tofino chip [16] is a concrete realization of the RMT architecture.

PIFO: PANIC uses a hardware priority queue to provide programmable scheduling. Our current design was borrowed from the ASIC-based flow scheduler design of the PIFO paper [68]. While this design is conceptually simple and easy to implement because it maintains a priority queue as a sorted array, it is less scalable relative to other priority queue designs, e.g., PIEO [64], which uses two levels of memory or pHeap [20], which uses a pipelined heap. For better scalability, we can replace our current design with such scalable hardware designs of priority queues at the expense of greater design and verification effort.

Interconnect: One of the biggest potential scalability limitations of a PANIC implementation is the on-chip switching fabric. While crossbar interconnects are conceptually simple, the sheer number of wires in a crossbar might become a physical design and routing bottleneck, causing both an increase in area as well as an inability to meet timing beyond a certain scale. Fortunately, prior work has already demonstrated that it is feasible to build crossbars on an ASIC that are larger than are needed in PANIC. Specifically, Chole *et al.* built a $32 * 32$ crossbar with a bit width of 640 bits [28, Appendix C] at a 1 GHz clock rate. As another data point, the Swizzle-Switch supports a $64 * 64$ crossbar with a bit width of 128 bits using specialized circuit design techniques at 559 MHz in a relatively old 45 nm technology node [63]. For comparison, to provide 32 compute units each a 128 Gbps connection to the switching interconnect, PANIC only needs a $32 * 32$ crossbar with a bit width of 128 bits and 256 bits at 1 GHz and 500 MHz clock frequencies, respectively.

At the same time, we anticipate a crossbar becoming no longer viable at some point as the number of offloads continues to increase. At this point, we anticipate switching to other more scalable topologies such as a flattened butterfly at the cost of increased latency and reduced bisection bandwidth.

Compute Units: The PANIC offload engine can be a hardware accelerator or a CPU core. There are several ASIC-based RISC-V implementations which can be used as a CPU core for the offload engine [25, 26, 8]. Several functions important to networking, such as compression, encryption, and checksums are available as hardware accelerators, which can be

reused for PANIC. Our own AES and SHA implementations (Section 6) are based on open-source hardware accelerator blocks [1, 7].

6 FPGA Prototype

We implement an FPGA prototype of PANIC in ~6K lines of Verilog code, including a single-stage RMT pipeline, the central scheduler, the crossbar, the packet buffer, and compute units. Also, we built a NIC driver, DMA Engine, Ethernet MAC, and physical layer (PHY) using Corundum [33]. Although the PANIC architecture supports both the sending path and receiving path, in our current implementation, we mainly focus on the receive path.

RMT pipeline: We implemented a single-stage RMT pipeline in our FPGA prototype. We configure the RMT pipeline in our prototype by programming the FPGA. The RMT pipeline maintains a flow table, in which each flow is assigned an offload chain and scheduling metadata. In the match stage, the RMT module matches the flow table with the IP address fields and port fields in the packet header. In the action stage, the RMT module calculates scheduling metadata and generates the PANIC descriptor (Figure 3). The frequency of the RMT pipeline is 250 MHz.

FPGA-based Crossbar: We have implemented an $8 * 8$ fully connected crossbar in our FPGA prototype. The frequency for this crossbar is 250 MHz, and the data width is 512 bits. This leads to a per-port throughput of 128 Gbps.

Central Scheduler and Packet Buffer: The architecture of the scheduler is shown in Figure 4. The scheduler is connected with two crossbar ports to ensure a sufficiently high throughput connection to the on-chip network. In our implementation, the PIFO block runs at 125 MHz frequency with a queue size of 256 packets; all other components in the scheduler run at 250 MHz, with a 512 bit data width, and we add a cross-domain clocking module between other components and the PIFO. We use lower frequency for the PIFO because it suffers from a scalability issue when implemented on the FPGA (we explain this further in Section 7.5). The packet buffer is implemented with dual-channel high-speed BRAM, where each BRAM channel supports concurrent reads and writes. The packet buffer size in our implementation is 256 KB with a 512 bit data width and a 250 MHz frequency. For ease of implementation, our current prototype uses a separate physical PIFO for each logical PIFO at the cost of increasing the relative resource consumption of PIFOs.

Compute Units: As Figure 5 shows, our implementation of a compute unit includes a traffic manager, a credit manager, and a scratchpad packet buffer. We choose the AXI4-Stream interface [2] as the common interface between the offload engine and scratchpad buffer. We have included two types of accelerator-based offload engines in our FPGA prototype. One is the AES-256-CTR encryption engine [1], and the other is the SHA-3-512 hash engine [7].

We have also implemented a RISC-V core engine based on the open-source CPU core generator [9]. Figure 6 shows how the RISC-V core is connected to PANIC’s traffic manager, credit manager, and per-core memory. The RV32I RISC-V core we use has a five-stage pipeline with a single level of cache. The data cache and instruction cache are 2 KB each, and the local memory size is 32 KB. The frequency for this CPU is 250 MHz, and the per-core memory data width is 512 bits.

7 Evaluation

This section evaluates our FPGA prototype to show that it meets the design requirements put forth in Section 2.1. In Section 7.2, we use microbenchmarks to show that PANIC achieves high throughput and low latency under different offload chaining models. In Section 7.3, we compare PANIC’s performance with a pipeline-of-offloads NIC. Section 7.4 measures the I/O performance of a RISC-V core in PANIC, and Section 7.5 measures the hardware resource usage of our FPGA prototype. Finally, in Section 7.6, we implement different offload engines, and test PANIC end-to-end; these results demonstrate that PANIC can isolate and prioritize traffic efficiently under multi-tenant settings.

7.1 Testbed and methodology

For our microbenchmarks, we implemented our FPGA prototype in the ADM-PCIE-9V3 network accelerator [12], which contains a Xilinx Virtex UltraScale Plus VU3P-2 FPGA. For this evaluation, we also implemented a delay unit, a packet generator, and a packet capture agent on the FPGA. The delay unit emulates various compute units by delaying packets in a programmable fashion, which allows us to flexibly control per-packet service time and chaining models. This enables us to run microbenchmarks that systematically study PANIC’s performance limits. The packet generator generates traffic of various packet sizes at different rates. The packet capture agent receives packets and calculates different flows’ throughput and latency. We calculate packet processing latency by embedding a send timestamp in every generated packet.

For our end-to-end experiments, we evaluate PANIC in a small testbed of 2 Dell PowerEdge R640 servers. One server is equipped with a Mellanox Connectx-5 NIC, and the other server is equipped with the ADM-PCIE-9V3 network accelerator carrying our PANIC prototype. The Mellanox NIC and ADM-PCIE-9V3 card are directly connected. We program the VU3P-2 FPGA on the network accelerator using our Verilog implementation of PANIC. We use DPDK to send customized network packets and use PANIC to receive packets and run offloads. Because of a performance bottleneck in the kernel-based FPGA NIC driver [33], we use the packet capture agent on the FPGA to report PANIC’s receive throughput instead of capturing packets on the host machine.

7.2 PANIC System Microbenchmarks

We microbenchmark PANIC’s performance using the different chaining models shown in Figure 7. Our results demonstrate that PANIC can both achieve high throughput and low latency for various common offload chaining models.

Model 1 (“Pipelined Chain”): In model 1 (Figure 7a), we attach N delay units in sequence. Each unit emulates a different service, and all of them process packets at X Gbps with fixed delay. We then configure a service chain that sends packets through all N units in numerical order.

First, we measure the throughput and latency overhead of PANIC when $N = 3$ and $X = 100$. Figure 8a shows the overall throughput under different packet sizes. With MTU-sized packets, PANIC can schedule packets at full line-rate. When the initial number of credits in PANIC is small, we see a nonlinear performance downgrade with small packets. This is because throughput for small packets is bounded by the scheduling round trip time in PANIC, which is 14 clock cycles. If we increase the initial credit number for each unit, we see a performance increase for small packets. When the credit number is greater than 8, the small packet performance is no longer bounded by the scheduling round trip, instead, it is bounded by the small packet performance of our delay unit. These results also demonstrate the benefits of PANIC’s flexibility in per-unit credit allocation. Setting different credit numbers for each unit can improve performance.

Next, Figure 8b shows the latency of different packet sizes in the same experiment. In this pipelined chain, packets can be scheduled through three units within 0.5 microseconds. This low latency performance also arises from PANIC’s push scheduling which helps PANIC avoid extra packet traversals between units and the scheduler.

Next, Figure 9 shows PANIC’s throughput as a function of the chain length when push scheduling is disabled. Without push scheduling, the packet needs to go back to the scheduler at every hop, and the total traffic that goes into the scheduler is the ingress traffic from the RMT pipeline plus the detoured traffic from units, which is: $T_{total} = T_{RMT} + T_{detour} = T_{RMT} + (N - 1) * X = N * X$. As Figure 9 shows, when T_{total} exceeds the dual-ported scheduler’s maximum bandwidth ($250 \text{ MHz} * 512 \text{ bits} * 2 \text{ ports} = 256 \text{ Gbps}$), the chaining throughput downgrades. For example, when $N = 3$, $X = 70$, $T_{total} = 210 \text{ Gbps} < 256 \text{ Gbps}$, thus PANIC can schedule this chain at full speed even when push scheduling is disabled. When $N = 3$, $X = 90$, $T_{total} = 270 \text{ Gbps} > 256 \text{ Gbps}$, the chaining throughput downgrades since the scheduler bandwidth becomes the bottleneck.

Model 2 (“Parallelized Chain”): In model 2 (Figure 7b), we attach three delay units running in parallel. These three units run the same service, and each unit has an average 34 Gbps throughput but *variable latency*. PANIC load-balances packets across these units. Figure 8c shows the throughput under different packet sizes and service time variance (the service time follows uniform distribution). We see that even when

Figure 7: The different chaining models used in experiments.

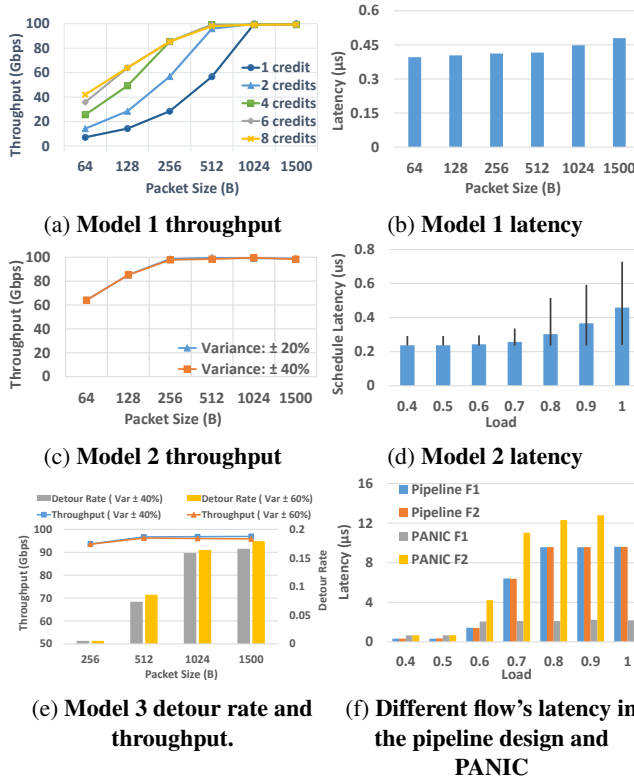

Figure 8: PANIC performance under different chaining models

the processing latency variance increases from 20% to 40%, PANIC can still efficiently load-balance packets between the parallel units without impacting throughput. In this experiment, small packet performance is better than model 1 because model 2 has multiple units running in parallel. Overall throughput is no longer bounded by the delay of a single unit.

Figure 8d shows PANIC scheduling latency under different loads with MTU sized packets and 40% service time variance. The error bars in this figure represent 5%-ile and 99%-ile latency. Scheduling latency reveals how long the incoming packets wait before being processed by an idle unit; we calculate it by subtracting the unit processing time from the total latency. When the NIC load is much smaller than 1, scheduling tail latency grows slowly, and is under $0.4 \mu s$. When the load approaches 1, queueing occurs in the packet buffer, which causes tail latency to grow, but it still stays $< 0.8 \mu s$. This shows that our credit-based scheme keeps latency low even at high load, and most latency is due to queueing.

Model 3 (“Hybrid Chain”): Model 3 (Figure 7c) is a hybrid chaining model where packets are not only load-balanced between parallel units but also go through multiple services.

Figure 9: Model 1 throughput when push is disabled.

Figure 10: Performance of a single RISC-V core with MTU-sized packets.

	Throughput	Total
Flow 1 (Pipeline Design)	18.7 Gbps	60.6 Gbps
Flow 2 (Pipeline Design)	41.9 Gbps	
Flow 1 (PANIC)	30.7 Gbps	59.8 Gbps
Flow 2 (PANIC)	29.1 Gbps	

Table 3: Throughput of the pipeline design and PANIC.

Packets need to be processed first by service A and then by service B, and both services have multiple parallel compute units. Each compute unit for service A has an average throughput of 52 Gbps, while each compute unit for service B has an average throughput of 50 Gbps. Compute units for both service A and B have variable latency.

Figure 8e shows the throughput and detour rate in this hybrid model. When the packet size is bigger than 256 bytes, the detour rate is high. This is because the downstream B units have lower throughput than the upstream A units. As a result, the B units are always busy because they are the throughput bottleneck in this system. Busy units are likely to have no space to accept pushed packets: if A unit tries to push packets to a busy downstream B unit, then the B units will more often than not detour the pushed packets back to the central scheduler.

Figure 8e also shows that detour routing does not degrade throughput. This is because the maximum bandwidth of our dual-ported scheduler is 256 Gbps, and in this hybrid model, the ingress traffic from the RMT pipeline will take up 100 Gbps bandwidth in the scheduler, thus there is more than 100 Gbps bandwidth left for the detoured traffic.

However, detour routing can increase packet latency. In order to mitigate this, the central scheduler increases the priority for each detoured packet, to help them get rescheduled first. Thus, the latency incurred by detoured packets is the RTT between the compute unit and the scheduler, which is $< 0.5 \mu s$.

7.3 Comparison with the Pipeline Design

To demonstrate that PANIC handles multi-tenant isolation and below line-rate offloads better than state-of-the-art, we build and compared against the pipeline-of-offloads NIC as our baseline. We choose model 4 (Figure 7c) as the offload chain for this comparison. The difference between model 4 and model 1 is that the delay unit emulates a below-line-rate offload in model 4. We assume two flows are competing: Flow 1 has a higher priority, and takes up 30% of the total traffic. Flow 2 has a lower priority, and takes up 70% of the total traffic.

We implemented a pipeline-of-offloads NIC in the ADM-PCIE-9V3 network accelerator. In this NIC, all incoming packets are first buffered in a FIFO (First-In-First-Out) queue before entering unit A. Unit A and unit B are directly connected using the AXI4-stream interface [2]. We configured the pipeline-of-offloads NIC and PANIC to have the same buffer size (64 KB), same frequency (250 MHz), and same bit-width (512 bits).

Figure 8f presents a comparison of the latency of both the pipeline design and PANIC in this experiment. When the NIC load is low, Unit A is not the bottleneck, and both NICs have low latency. The pipeline design has slightly better latency since units are directly connected in it, while scheduling packets in PANIC has some overhead. When load increases, Unit A becomes the bottleneck, and both NICs start to buffer and drop packets. With high load, Flows 1 and 2 have the same latency in the pipeline design, since packets are scheduled in First-Come-First-Served order and can experience HOL blocking. In PANIC, the high priority packets have fixed low latency due to the central scheduler sorting buffered packet descriptors and serving high priority packets first.

We compare the throughput between the pipeline design and PANIC in Table 3. The total throughput is bounded by Unit A (60 Gbps). In the pipeline design, the low priority flow 2 has a higher throughput than flow 1, because the high-volume flow 2 steals on-chip bandwidth by taking up most of the on-chip buffer. PANIC preferably allocates buffer to high priority packets and always drops the lowest priority ones. Thus flow 1 can always achieve full throughput in PANIC.

Overall, PANIC achieves good isolation: 1) PANIC achieves comparable throughput and latency with the pipeline design when there is no HOL blocking. 2) When HOL blocking occurs, PANIC ensures that the high priority flows have a fixed low latency. 3) PANIC allocates bandwidth according to a flow's priority.

7.4 RISC-V Core Performance

To investigate the I/O overhead of using an embedded NIC core to send/receive network packets from PANIC, we performed experiments with a single RISC-V CPU core as the only offload engine in a chain. We measure the system

throughput and per-packet latency using four example C programs:

No-Touch: After receiving the packet from PANIC, this program will send the packet back to PANIC immediately. This program does not make any changes to the packet data.

Memcpy: This program will copy the received packet to another memory address and then send the copied packet back to PANIC.

NAT: The Network Address Translation (NAT) program uses the embedded CPU core to lookup a <Translated IP, Port>pair for a given 5-tuple, and then replace the IP address and port header fields using the lookup results. The lookup table is stored in the local memory inside the offload engine. The RMT pipeline will pre-calculate the hash value for each packet, and the hash value is stored as per-service metadata in the PANIC descriptor. Thus the CPU core can directly read the pre-calculated hash value from the descriptor.

Swap OvS: This program swaps the Ethernet and IP source and destination addresses.

Figure 10 shows the RISC-V core throughput and per-packet latency with MTU sized packets. We breakdown the latency number into three different parts: 1) Network I/O: the time that is spent on pulling/writing the input/output doorbell register, 2) Flush Cache: the time spent on flushing the L1 cache, 3) Computation: the time spent on computation, including the data exchange time between the L1 cache and the per-core memory. The results of this experiment show that the overhead of the NIC to CPU core interface is low, and, for those low-throughput applications, the I/O time introduced by PANIC is negligible.

For example, the throughput of the No-Touch program is 61.4 Gbps, and all the time is spent in network I/O. The throughput of the NAT and Swap OvS programs is 21.3 Gbps and 20.2 Gbps, respectively. ~20% of the time is spent in flushing the cache, ~27% in network I/O, and ~50% in computation. Cache flushing is costly in our current prototype: to synchronize the data between the cache and memory, the whole L1 cache is flushed before processing the next packet. If needed, this performance could be improved by modifying the CPU to support an instruction that only flushes the cache lines for the pinned memory region used by the packet.

The throughput of Mемcpy is only 1.2 Gbps, and 97% of the time is spent in computation. This is due to the limitations of the performance of the FPGA based RISC-V core. With a faster core and a higher clock frequency, this performance can be improved.

7.5 Hardware Resource Usage

Our UltraScale VU3P-2 FPGA has 3 MB BRAM, and 394k LUTs in total. Table 4 shows different components' resource usage under different settings. In our end-to-end experiments (Section 7.6), the crossbar has 8 ports, total queue size in the PIFO array is 256 packets, and packet buffer size is 256 KB. Under this setting, we find that PANIC's design will only

Module	Setting	LUTs(%)	BRAM(%)
Crossbar	8 ports	5.5	0.00
	16 ports	13.64	0.00
Scheduler (PIFO)	PIFO = 256	5.18 (4.9)	0.07 (0.01)
	PIFO = 512	9.95 (9.42)	0.07 (0.01)
Packet Buffer	256 KB	0.16	8.94
Simple RMT	/	0.27	0.00

Table 4: **FPGA resource usage for different components.**

cost 11.27% logic area (LUTs) in our middle-end FPGA. Total BRAM usage is 8.94% due to the limited BRAM in our FPGA.

The crossbar and PIFO occupy most of the on-chip logic resources in PANIC. When the crossbar uses 8 ports, it costs around 5.5% logic area, and for 16 ports, the logic area cost is 13.64%. When the total PIFO size is 256, it will cost 4.9% logic area, and when the size is 512, it will cost 9.42%. PIFO suffers from high logic area cost because its hardware design does not access BRAM at all; it only uses the logic unit to compare and shift elements. This design causes PIFO to be less scalable in the FPGA since it cannot benefit from the FPGA’s memory hierarchy to efficiently distribute storage and processing across SRAM and LUTs. Recent advancements [64] can be used to address this (Section 5). Overall, we find that PANIC can easily fit on any middle-end FPGA without utilization or timing issues.

7.6 End-to-End Performance

In this section, we measure PANIC’s end-to-end performance in our cluster. Because of the performance bottleneck of the kernel-based FPGA NIC driver, we use hardware counters to measure PANIC’s receiving throughput. We implement two FPGA-based offload engines in PANIC: a SHA-3-512 engine and an AES-256 engine. Our end-to-end experiment demonstrates that: 1) PANIC can schedule network traffic at full line-rate, 2) PANIC can precisely prioritize traffic when different flows are competing for computation resources at the offloads, and 3) PANIC can support different isolation policies, including strict priority and weighted fair queueing.

The AES-256-CTR encryption engine [29] encrypts input plain text into ciphered text or decrypts ciphered text to yield plain text. The fully pipelined AES-256 engine can accept 128-bit input per cycle, and it can run at 250 MHz frequency with 32 Gbps throughput. The SHA-3-512 engine [19] performs SHA-3, a newest cryptographic hash which uses permutation as a building block [18]. The FPGA-based SHA-3-512 engine that we use runs at 150 MHz with 6 Gbps throughput.

Since the throughput of a single SHA engine is low, we put 4 SHA engines into a single hash unit, and set the initial credit number for the hash unit to 4. Thus, the hash unit can use 4 SHA engines to process these packets in parallel. We connect two decryption units and two hash units with PANIC. Thus, the bandwidth of hash computation is $(6 * 4) * 2 = 24 * 2 = 48$ Gbps, and that for decryption is $32 * 2 = 64$ Gbps.

In our experiment, we assume there are two types of traffic

Traffic	IPSec	Video	Background
Drop Rate	0%	33.1%	0%

Table 5: **Packet dropping rate in phase 1 in Figure 11a.**

competing for the computation resource in PANIC. One is high-volume multimedia traffic, which uses AES offload to decrypt video streams. Another is low-volume IPSec traffic, which first uses SHA to ensure the integrity of the data and then uses AES to decrypt IP payload. The IPSec traffic has higher priority than video stream traffic, and each of these traffic streams contains multiple flows. Also, we add background traffic that does not need to be processed by any compute unit. The offload chains are shown in Figure 12.

In the first experiment, we use the strict priority policy, which means all the IPSec packets have higher priority than the video packets. Figure 11a shows different traffic’s receiving throughput under different traffic patterns. In phase 1, the sending throughput is 30 Gbps for IPSec and is 50 Gbps for video. We can see the receiving throughput for IPSec is 30 Gbps, which is the same as the sending throughput. The receiving throughput for the video stream is only 34 Gbps. This is because IPSec and video stream share the AES offload. However, the available peak bandwidth for the AES offload is only 64 Gbps. Thus, PANIC will first satisfy the high priority IPSec traffic requirement, which only leaves 34 Gbps (64 - 30) of bandwidth for the video stream. Table 5 shows the dropping rate under phase 1. Due to prioritized packet dropping, PANIC only drops low priority video packets. Overall, when a below-line-rate offload becomes the bottleneck, PANIC always first satisfies high priority traffic’s bandwidth demands.

In phase 2, the DPDK sender switches to the next traffic pattern, in which the IPSec traffic sending rate drops to 10 Gbps, and video traffic sending rate grows to 50 Gbps. Since the IPSec sending rate drops, the video stream can get more bandwidth, but it will still lose some bandwidth and experience packet drops because of the AES bottleneck. In phase 3, the DPDK sender switches to the last pattern, in which the AES offload is no longer the bottleneck; no packet drops occur, and the total throughput can reach 100 Gbps. Another noteworthy aspect in Figure 11a is that no matter what computation happens, background traffic performance is unaffected.

In the second experiment, we use a weighted fair queueing (WFQ) scheduling policy where the AES offload’s capacity is divided across IPSec traffic and video traffic in 2 : 1 ratio. Figure 11b shows the throughput of the different traffic types under the WFQ policy for different traffic patterns. In phase 1, the sending throughput for IPSec is 70 Gbps, and for the video stream is 30 Gbps. We can see the receiving throughput for IPSec is exactly twice of the video stream, and the total throughput is 64 Gbps. If the IPSec sending rate drops to 50 Gbps (phase2), the receiving throughput remains unchanged. This result proves PANIC can shape the traffic

(a) Strict Priority Policy

(b) Weighted Fair Queueing Policy

Figure 11: Receiving throughput with different traffic patterns. Figure a uses strict priority policy: all the IPsec packets have higher priority than the video packets. Figure b uses WFQ policy: the offload capacity is divided across IPsec traffic and video traffic in the ratio 2:1. The table in Figure a and Figure b shows how the sending traffic pattern changes with time.

Figure 12: Offload chains; end-to-end experiment

precisely, regardless of the sending rate.

In phases 1 and 2, the scheduler switches to pull-based scheduling since the AES offload is always congested. As a result, the egress packet of the SHA offload goes directly back to the scheduler instead of the congested AES offload. The scheduler then shapes the video traffic and the detoured IPsec traffic into a desired rate using WFQ.

In phase 3, the AES offload is no longer the bottleneck. Thus, the central scheduler operates in push mode: the egress packet of the SHA offload can bypass the scheduler and be directly pushed to the AES offload. As shown in Figure 11b, both IPsec and video's receiving throughput can reach the sending rate, which is 30 Gbps. Overall, this shows that PANIC can shape the traffic precisely with the WFQ policy.

8 Related Work

Several projects introduce new offloads that utilize programmable NICs and new frameworks for deploying these offloads [13, 48, 59, 42, 32, 37, 49, 65, 46, 62, 47, 40, 30, 36, 70, 69, 35, 55, 45]. PANIC is orthogonal to these projects.

The Pensando DSC-100 NIC [58] is similar to PANIC in that it has an RMT pipeline and supports both hardware and software offloads. However, the DSC-100 requires cores to achieve offload chaining instead of a hardware scheduler.

The Fungible Data Processing Unit (DPU) is a NIC design that was recently announced in August 2020 [3]. Based on publicly available documents [4, 5], it has a hardware architecture that shares a few similarities with PANIC (e.g., processing cores, accelerators, a hardware work scheduler, and a customized on-chip network). A head-to-head compari-

son of PANIC to the Fungible DPU would be an interesting avenue for future work once the DPU is generally available.

PANIC is also similar to FairNIC [34], which improves fairness between competing applications running on a commodity manycore NIC. However, PANIC provides features not possible in FairNIC like chaining without involving a CPU. Further, FairNIC helps motivate the need for PANIC detailing the non-trivial costs of isolation on manycore NICs. Adopting PANIC's scheduler and non-blocking crossbar interconnect can solve these fundamental problems with manycore NICs.

9 Conclusions

Programmable NICs are an enticing option for bridging the widening gap between network speeds and CPU performance in multi-tenant datacenters. But, existing designs fall short of supporting the rich and high-performance offload needs of co-resident applications. To address this need, we presented the design, implementation, and evaluation of PANIC, a new programmable NIC. PANIC synthesizes a variety of high-performance hardware blocks and data structures within a simple architecture, and couples them with novel scheduling and load balancing algorithms. Our analysis shows that PANIC is amenable to an ASIC design. We also built a 100G PANIC prototype on an FPGA, and conducted detailed experiments that show that PANIC can isolate tenants effectively, ensure high throughput and low latency, and support flexible and dynamic chaining.

A Artifact Appendix

A.1 Abstract

This artifact contains the source code and test benches for PANIC’s 100Gbps FPGA-based prototype. Our FPGA prototype is implemented in pure Verilog. Features of the prototype include: the hybrid push/pull packet scheduler, the high-performance switching interconnect, self-contained compute units, and the lightweight RMT pipeline.

This artifact provides two test benches to reproduce the results in Figure 8c and Figure 11a in the Vivado HDL simulator.

A.2 Artifact check-list

- **Compilation:** Running this artifact requires Vivado Design Suite [10]. Vivado v2019.x and v2020.1 WebPack are verified.
- **Hardware:** This artifact does not requires any specific hardware.
- **Metrics:** This artifact measures PANIC’s receiving throughput under different chaining models and traffic patterns.
- **Output:** The result will be printed to the console and log files.
- **Experiments:** This artifact includes testbenches and running scripts to replay Figure 8c and Figure 11a.
- **Public link:** https://bitbucket.org/uw-madison-networking-research/panic_osdi20_artifact

A.3 Description

A.3.1 How to access

This artifact is publicly available at https://bitbucket.org/uw-madison-networking-research/panic_osdi20_artifact.

A.3.2 Software dependencies

Running this artifact requires Vivado [10]. Vivado WebPack version is license-free, and it has simulation capabilities to recreate our results. Since installing the Vivado WebPack requires plenty of disk space (>20GB), you can choose to instance an FPGA Developer AMI in AWS (<https://aws.amazon.com/marketplace/pp/B06VVYBLZZ>) to run this artifact. The FPGA Developer AMI has pre-installed the required Vivado toolchain.

A.4 Experiment workflow

1. Check Vivado is Installed Correctly

```
$ vivado -mode tcl
// Enter the Vivado Command Palette
Vivado% version
// v2019.x and v2020.1 is verified
Vivado% quit
```

2. Clone the Repo and Make Run

```
$ git clone [Artifact_Repo]
$ cd panic_osdi20_artifact
$ make test_parallel
$ make test_shaaes
```

The make command first compiles the source code, then runs the simulation tasks in Vivado. The *test_parallel* test replays Figure 8c and the *test_shaaes* test replays Figure 11a.

A.5 Evaluation and expected result

The result will be printed to the console. The output will also be logged in *./build/export_sim/xsim/simulate.log*. For the expected output and analysis please reference Figure 8c and Figure 11a.

A.6 Notes

For more details about the code structure, please reference https://bitbucket.org/uw-madison-networking-research/panic_osdi20_artifact/src/master/README.md

A.7 AE Methodology

Submission, reviewing and badging methodology:

Abstract

Resource-disaggregated architectures have risen in popularity for large datacenters. However, prior disaggregation systems are designed for native applications; in addition, all of them require applications to possess excellent locality to be efficiently executed. In contrast, programs written in managed languages are subject to periodic garbage collection (GC), which is a typical graph workload with poor locality. Although most datacenter applications are written in managed languages, current systems are far from delivering acceptable performance for these applications.

This paper presents *Semeru*, a distributed JVM that can dramatically improve the performance of managed cloud applications in a memory-disaggregated environment. Its design possesses three major innovations: (1) a universal Java heap, which provides a unified abstraction of virtual memory across CPU and memory servers and allows any legacy program to run *without modifications*; (2) a distributed GC, which offloads *object tracing* to memory servers so that tracing is performed *closer to data*; and (3) a swap system in the OS kernel that works with the runtime to swap page data efficiently. An evaluation of *Semeru* on a set of widely-deployed systems shows very promising results.

1 Introduction

The idea of *resource disaggregation* has recently attracted a great deal of attention in both academia [16, 45, 49, 87] and industry [3, 33, 39, 52, 65]. Unlike conventional datacenters that are built with *monolithic* servers, each of which tightly integrates a small amount of each type of resource (*e.g.*, CPU, memory, and storage), resource-disaggregated datacenters contain servers dedicated to individual resource types. Disaggregation is particularly appealing due to three major advantages it provides: (1) *improved resource utilization*: decoupling resources and making them accessible to remote processes make it much easier for a job scheduler to achieve full resource utilization; (2) *improved failure isolation*: any server failure only reduces the amount of resources of a particular type, without affecting the availability of other types of resources; and (3) *improved elasticity*: hardware-dedicated servers make it easy to adopt and add new hardware.

State of the Art. Architecture [10, 22, 23, 58] and networking [7, 30, 46, 55, 72, 83, 86, 88] technologies have matured to a point at which data transfer between servers is fast enough for them to execute programs collectively. LegoOS [87] pro-

vides a new OS model called *splitkernel*, which disseminates traditional OS components into loosely coupled monitors, each of which runs on a resource server. InfiniSwap [49] is a paging system that leverages RDMA to expose memory to applications running on remote machines. FaRM [37] is a distributed memory system that uses RDMA for both fast messaging and data access. There also exists a body of work [12, 28, 38, 60, 61, 64, 65, 73, 77, 94, 96, 97, 105] on storage disaggregation.

1.1 Problems

Although RDMA provides efficient data access among remote access techniques, fetching data from remote memory on a memory-disaggregated architecture, is time consuming, incurring microsecond-level latency that cannot be handled well by current system techniques [20]. While various optimizations [37, 38, 49, 84, 87, 105] have been proposed to reduce or hide fetching latency, such techniques focus on the low-level system stack and do *not* consider *run-time semantics* of a program, such as locality.

Improving performance for applications that exhibit *good locality* is straightforward: the CPU server runs the program, while data are located on memory servers; the CPU server has only a small amount of memory used as a *local cache*¹ that stores recently fetched pages. A cache miss triggers a page fault on the CPU server, making it fetch data from the memory server that hosts the requested page. Good locality reduces cache misses, leading to improved application performance. As a result, a program itself needs to possess *excellent spatial and/or temporal locality* to be executed efficiently under current memory-disaggregation systems [7, 8, 49, 87].

This high requirement of locality creates two practical challenges for cloud applications. First, typical cloud applications are written in managed languages that execute atop a managed runtime. The runtime performs automated memory management using *garbage collection (GC)*, which frequently traces the heap and reclaims unreachable objects. GC is a typical graph workload that performs reachability analysis over a huge graph of objects connected by references. Graph traversal often suffers from poor locality, so GC running on the CPU server potentially triggers a page fault as it follows each reference. As shown in §2, memory disaggregation can increase the duration of GC pauses by $>10\times$, significantly degrading application performance.

¹In this paper, “cache” refers to local memory on the CPU server.

Second, to make matters worse, unlike native programs whose data structures are primarily array-based, managed programs make heavy use of object-oriented data structures [74, 100, 101], such as maps and lists connected via pointers without good locality. To illustrate, consider a Spark RDD — it is essentially a large list that references a huge number of element objects, which can be distributed across memory servers. Even a sequential scan of the list needs to access arbitrarily located elements, incurring high performance penalties due to frequent remote fetches.

In essence, managed programs such as Spark, which are typical cloud workloads that resource disaggregation aims to benefit, have not yet received much support from existing resource-disaggregated systems.

1.2 Our Contributions

Goal and Insight. The goal of this project is to design a memory-disaggregation-friendly managed runtime that can provide superior efficiency to all managed cloud applications running in a memory-disaggregated datacenter. Our major drive is an observation that shifting our focus from low-level, semantics-agnostic optimizations (as done in prior work) to the *redesign of the runtime* that improves data placement, layout, and usage, can unlock massive opportunities.

To achieve this goal, our insights are as follows. To exploit *locality for GC*, most GC tasks can be *offloaded* to memory servers where data is located. As GC tasks are mostly memory intensive, this offloading fits well into a memory server’s resource profile: weak compute and abundant memory. Memory servers can perform some offloaded GC tasks — such as tracing objects — *concurrently* with application execution. Similarly, other GC tasks — such as evacuating objects and reclaiming memory — can be offloaded to memory servers, albeit while application execution is paused. Furthermore, evacuation can improve *application locality* by moving objects likely to be accessed together to contiguous memory.

Semeru. Following these insights, we develop *Semeru*,² a distributed Java Virtual Machine (JVM) that supports efficient execution of *unmodified* managed applications. As with prior work [49, 87], this paper assumes a setting where processes on each CPU server can use memory from multiple memory servers, but no single process spans multiple CPU servers. *Semeru*’s design sees three major challenges:

The first challenge is what memory abstraction to provide. A reachability analysis over objects on a memory server requires the server to run a user-space process (such as a JVM) that has its own address space. As such, the same object may have different virtual addresses between the CPU server (that runs the main process) and its hosting memory server (that runs the tracing process). Address translation for each object can incur large overheads.

To overcome this challenge, *Semeru* provides a memory abstraction called the *universal Java heap (UJH)* (§3.1). The

execution of the program has a main compute process running on the CPU server as well as a set of “assistant” processes, each running on a memory server. The main and assistant processes are all JVM instances, and servers are connected with RDMA over InfiniBand. The main process executes the program while each assistant process only runs offloaded memory management tasks. The heap of the main process sees a contiguous virtual address space partitioned across the participating memory servers, each of which sees and manages a disjoint range of the address space. *Semeru* enables an object to have the same virtual address on both the CPU server and its hosting memory server, making it easy to separate an application execution from the GC tasks.

The second challenge is what to offload. An ideal approach is to run the entire GC on memory servers while the CPU server executes the program, so that memory management tasks are performed (1) near data, providing locality benefits, and (2) concurrently without interrupting the main execution. However, this approach is problematic because some GC operations — notably evacuating (moving) and compacting objects into a new region — must coordinate extensively with application threads to preserve correctness. As a result, many GC algorithms — including the high-performance GC that our work extends — trace live objects concurrently with application execution, but move objects only while application execution is paused (*i.e.*, stop-the-world collection).

We develop a distributed GC (§4) that selectively offloads tasks and carefully coordinates them to maximize GC performance. Our idea is to offload *tracing* to memory servers concurrently with application execution. Tracing computes a transitive closure of live objects from a set of roots. It does nothing but pointer chasing, which would be a major bottleneck if performed at the CPU server. To avoid this bottleneck, *Semeru* lets each memory server trace its own objects, as opposed to bringing them into the CPU server for tracing.

Tracing is a memory-intensive task that does not need much compute [27] but benefits greatly from being close to data. To leverage memory servers’ weak compute, memory servers trace their local objects *continuously* while the CPU server executes the main threads. Tracing also fits well into various hardware accelerators [69, 85], which future memory servers may employ. The CPU server periodically stops the world for memory servers to *evacuate* live objects (*i.e.*, copy them from old to new memory regions) to reclaim memory. Object evacuation provides a unique opportunity for *Semeru* to relocate objects that may potentially be accessed together into a *contiguous* space, improving spatial locality.

The third challenge is how to efficiently swap data. Existing swap systems such as InfiniSwap [49] and FastSwap [11] cannot coordinate with the language runtime and have bugs when running distributed frameworks such as Spark (§2). Mellanox provides an NVMe-over-fabric (NVMe-oF) [1] driver that allows the CPU server to efficiently access remote storage using RDMA. A strawman approach here is to mount

²*Semeru* is the highest mountain on the island of East Java.

Figure 1: Slowdowns of two representative Spark applications under disaggregated memory; NVMe-oF was used for data swapping. Spark was executed over OpenJDK 12 with its default (Garbage First) GC. The four groups for each program report the slowdowns of the nursery (young) GC, full-heap GC, mutator, and end-to-end execution. Each group contains three bars, reporting the execution times under three cache configurations: 100%, 50%, and 25%. Each configuration represents a percentage of the application’s working set that can fit into the CPU server’s local DRAM. Execution times of the 50% and 25% configurations are normalized to that of 100%.

remote memory as RAMDisks and use NVMe-oF to swap data. However, this approach does not work in our setting where remote memory is subject to memory-server tracing and compaction, precluding it from being used as RAMDisks. To this end, we modify the NVMe-oF implementation (§5) to provide support for remote memory management. InfiniBand gather/scatter is used to efficiently transfer pages. We also develop new system calls that enable effective communications between the runtime and the swap system.

Results. We have evaluated *Semeru* using two widely-deployed systems – Spark and Flink – each with a representative set of programs. Our results demonstrate that *Semeru* improves the end-to-end performance of these systems by an average of $2.1\times$ and $3.7\times$ when the cache size is 50% and 25% of the heap size, application performance by an average of $1.9\times$ and $3.3\times$, and GC performance by $4.2\times$ and $5.6\times$, respectively, compared to running these systems directly on NVM-oF where remote accesses incur significant latency overheads. These promising results suggest that *Semeru* reduces the gap between memory disaggregation and managed cloud applications, taking a significant step toward efficiently running such applications on disaggregated datacenters.

Semeru is publicly available at <https://github.com/uclasytem/Semeru>.

2 Motivation

We conducted experiments to understand the latency penalties that managed programs incur on existing disaggregation systems. We first tried to use existing disaggregation systems including LegoOS [87], InfiniSwap [49], and FastSwap [11]. However, LegoOS does not yet support socket system calls and cannot run socket-based distributed systems such as Spark. Under InfiniSwap and FastSwap, the JVM was frequently stuck — certain remote fetches never returned.

Background of G1 GC. To collect preliminary data, we set up a small cluster with one CPU and two memory servers, using Mellanox’s NVMe-over-fabric (NVMe-oF) [1] protocol

for data swapping, mounting remote memory as a RAMDisk. On this cluster, we ran two representative Spark applications: Triangle Counting (TC) from GraphX and KMeans from MLib with the Twitter graph [63] as the input. We used OpenJDK 12 with its high-performance *Garbage First* (G1) GC, which is the default GC recommended for large-scale processing tasks, with a 32GB heap. G1 is a *region-based, generational* GC that most frequently traces the young generation (*i.e.*, nursery GC) and occasionally traces both young and old generations (*i.e.*, full-heap GC). This is based on the *generational hypothesis* that most objects die young and hence the young generation contains a larger fraction of garbage than the old generation [93].

Under G1, the memory for both the young and old generations is divided into *regions*, each being a contiguous range of address space. Objects are allocated into regions. Each nursery GC traces a small number of selected regions in the young generation. After tracing, live objects in these regions are evacuated (*i.e.*, moved) into new regions. Objects that have survived a number of nursery GCs will be *promoted* to the old generation and subject to less frequent tracing. Each full-heap GC traces the entire heap, and then evacuates and compacts a subset of regions.

Performance. The performance of these applications is reported in Figure 1. In particular, we measured time spent on nursery and full-heap collections, as well as end-to-end execution time. Three cache configurations (shown in three bars of each group) were considered, each representing a particular percentage of the application’s working set that can fit into the CPU server’s local DRAM.

Despite the many block-layer optimizations in the NVMe-oF swap system, performance penalties from remote fetching are still large. Under the 25% cache configuration, the average slowdown for these applications is $10.6\times$. Note that for a typical Big Data application with a large working set (*e.g.*, 80–100GB), 25% of the working set means that the CPU server

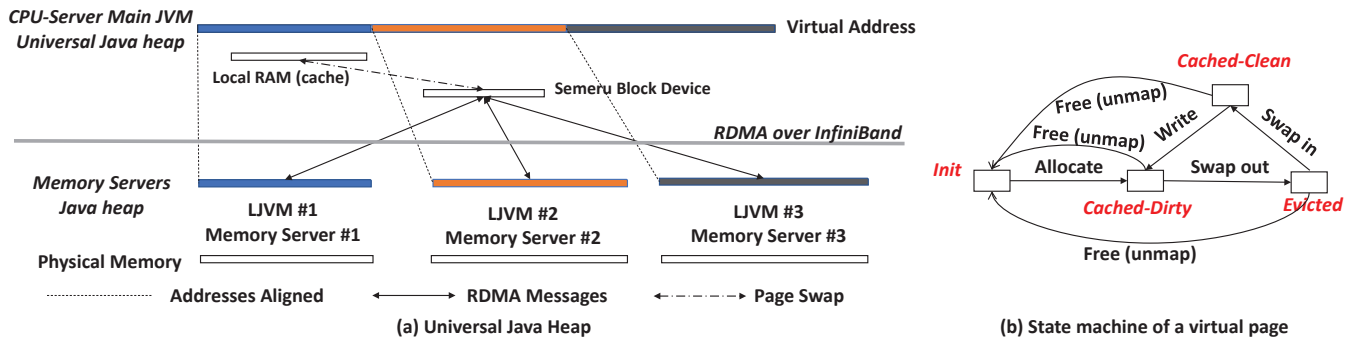

Figure 2: *Semeru*'s heap and virtual page management.

needs at least 20–25GB DRAM for a *single application* to have a $\sim 10\times$ slowdown. Considering a realistic setting where the CPU server runs multiple applications, there is a much higher DRAM requirement for the CPU server, posing a practical challenge for disaggregation.

Takeaway. Disaggregated memory incurs a higher slowdown for the GC than the main application threads (*i.e.*, *mutator* threads in GC literature terminology) — this is easy to understand because compared to the mutator (which, for example, manipulates large Spark RDD arrays), the GC has much worse locality. Moreover, KMeans suffers much more from remote memory than TC due to significantly increased full-heap GC time. This is because KMeans uses a number of persisted RDDs (that are held in memory indefinitely). Although TC also persists RDDs, those RDDs are too large to be held in memory; as such, Spark releases them and re-constructs them when they are needed. This increases the amount of computation but reduces the GC effort under disaggregation. However, since memoization is an important and widely used optimization, it is not uncommon for data processing applications to hold large amounts of data in memory. As a result, these applications are expected to suffer from large-working-set GC as well.

These results call for a new managed runtime that can deliver good performance under disaggregated memory without requiring developers to be aware of and reason about the effects of disaggregation during development.

3 *Semeru* Heap and Allocator

This section discusses the design of *Semeru*'s memory abstraction. In order to support legacy applications developed for monolithic servers and to hide the complexity of data movement, we propose the *universal Java heap* (UJH) memory abstraction. We first describe this abstraction, and then discuss object allocation and management.

3.1 Universal Java Heap

The main process (*i.e.*, a JVM instance) running on the CPU server sees a large contiguous virtual address space, which we refer to as the universal Java heap. The application can access any part of the heap regardless of the physical locations. This contiguous address space is *partitioned* across

memory servers, each of which provides physical memory that backs a disjoint region of the universal heap. The CPU server also has a small amount of memory, but this memory will serve as a software-managed, inclusive cache and hence not be dedicated to specific virtual addresses. Mutator (*i.e.*, application) threads run on the CPU server. When they access pages that are uncached on the CPU server, a page fault is triggered, and the paging system swaps pages that contain needed objects into the CPU server's local memory (cache). When the cache is full, selected pages are swapped out (evicted) to their corresponding memory servers, as determined by their virtual addresses.

Figure 2(a) provides an overview of the UJH. In addition to the main process running on the CPU server, *Semeru* also runs a *lightweight JVM* (LJVM) process on each participating memory server that performs tracing over local objects. This LJVM³ is specially crafted to contain only the modules of object tracing and memory compaction, with support for RDMA-enabled communication with the CPU server. Due to its simplicity (*i.e.*, the modules of compiler, class loader, and runtime as well as much of the GC are all eliminated), the LJVM has a very short initialization time (*e.g.*, milliseconds) and low memory footprint (*e.g.*, megabytes of memory for tracing metadata). Hence, a memory server can easily run many LJVMs despite its weak compute (*i.e.*, each for a different CPU-server process).

When the LJVM starts, it aligns the starting address of its local heap with that of its corresponding address range in the UJH. As a result, each object has the same virtual address on the CPU and memory servers, enabling memory servers to trace their local objects without address translation. All physical memory required at each memory server is allocated when the LJVM is launched and pinned down during the entire execution of the program.

Coherency. This memory abstraction is similar in spirit to distributed shared memory (DSM) [66], which has been studied for decades. However, different from DSM, which needs to provide strong coherency between servers, *Semeru*'s coherency protocol is much simpler because memory servers, which collectively manage the address space, do not execute

³It is technically no longer a JVM since it does not execute Java programs.

any mutator code. The CPU server has access to the entire UJH, but each memory server can only access data in the address range it manages. In *Semeru*, each non-empty virtual page is in one of two high-level states, *cached* (in the CPU server) or *evicted* (to a memory server). When the CPU server accesses an *evicted* virtual page, it swaps the page data into its cache and changes the page’s state to *cached*.

3.2 Allocation and Cache Management

Object allocation is performed at the CPU server. Allocation finds a virtual space that is large enough to accommodate the object being allocated. We adopt G1’s region-based heap design where the heap is divided into *regions*, which are contiguous segments of virtual memory. The region-based design enables *modular tracing and reclamation* — each memory server hosts a set of regions; a memory server can trace any region it hosts independently of other regions, thereby enabling memory servers to perform tracing in parallel (while the CPU server executes the program). Modular tracing is enabled by using *remembered sets*, discussed shortly in §4.

When an object in a region is requested by the CPU server, the page(s) containing the object are swapped in. At this point, the region is *partially cached* and registered at the CPU server into an *active region list*. *Semeru* uses a simple LRU-based cache management algorithm to evict pages. The region is removed from this list whenever all its pages are evicted.

Upon an allocation request, the *Semeru* allocator finds the first region from this list that has enough space for the new object. If none of these regions can satisfy the request, *Semeru* creates a new region and allocates the object there. Allocation is based upon an efficient *bump pointer* algorithm [57], which places allocated objects contiguously and in allocation order. Bump pointer allocation maintains a position pointer for each region, pointing to the starting address of the free space. Bump pointer allocation maintains a position pointer for each region that points to the starting address of the region’s free space. For each allocation, the pointer is simply “bumped up” by the size of the allocated object. Very large objects are allocated to a special heap area called the *humongous space*.

```

1 struct region {
2     uint64_t start;           // start address
3     uint64_t bp;             // bump pointer
4     uint64_t num_obj;         // total # objects
5     uint64_t cached_size;     // size of pages in CPU cache
6     uint16_t survivals;       // # evacuations survived
7     remset* rem_set;         // remembered set (Section 4)
8     ...
9 }
```

Figure 3: A simplified definition for a region descriptor in *Semeru*.

The CPU server maintains, for all regions, their state *descriptors*. Each region descriptor is a `struct`, illustrated in Figure 3. Descriptors are used in both allocation and garbage collection. For example, `start` and `bp` are used for allocation; they can also be used to calculate the size of allocated objects. `survivals` indicates the total number of evacuation phases that the regions’ objects have survived. It can be used,

together with `num_obj`, to compute an *age* measurement for the region. `rem_set` is used as the tracing roots, which will be discussed shortly in §4.2.

Cache Management. *Semeru* employs a lazy write-back technique for allocations. Each allocated object stays in the CPU server’s cache and *Semeru* does not write the object back to its corresponding memory server until the pages containing the object are evicted. For efficiency, only dirty pages are written back. Figure 2(b) shows the state machine of a virtual page. Each virtual page is initially in the `Init` state. Upon an object allocation on a page, the object is placed in the cache of the CPU server and its virtual page is marked as `Cached`, indicating that the object is currently being accessed by the CPU server. Evicted pages are swapped out to memory servers. Virtual pages freed by the GC are *unmapped* from their physical pages (their corresponding page table entries are *not* freed) and have their states reset to `Init`. This state machine is managed solely by the CPU server; memory servers do not run application code and hence do not need to know the state of each *page* (although they need to know the state of *regions* for tracing).

4 *Semeru* Distributed Garbage Collector

Semeru has a distributed GC that offloads tracing — the most memory-intensive operation in the GC (as it visits every live object) — to memory servers. Tracing is a task that fits well into the capabilities of a memory server with limited compute. That is, traversing an object graph by chasing pointers does not need strong compute, but benefits greatly from being close to data. In addition to memory-server tracing that runs continuously, *Semeru* periodically conducts a highly parallel stop-the-world (STW) collection phase to free cache space on the CPU server and reclaim memory on memory servers by evacuating live objects.

Design Overview. Although regions have been used in prior heap designs [36, 79], there are two unique challenges in using regions efficiently for disaggregated memory.

The first challenge is *how to enable modular tracing for regions*. Prior work such as Yak [79] builds a *remembered set* (remset) for each region that records references coming into objects in the region from other regions. These references, which are recorded into the set by instrumentation code called a *write barrier*, when the mutator executes each *object write of a non-null reference value*, can be used as additional *roots* to traverse the object graph for the region. However, none of the existing techniques consider a distributed scenario, where region tracing is done on memory servers, while their remsets are updated by mutator threads on the CPU server. We propose a new distributed design of the remset data structure to minimize the communication between the CPU and memory servers. Our remset design is discussed in §4.1.

The second challenge is *how to split the GC tasks between servers*. Our distributed GC has two types of collections:

Figure 4: *Semeru* GC overview: the MSCT (on memory servers) traces evicted regions; the CSSC (coordinated between CPU and memory servers) traces cached regions and reclaims all regions.

Memory Server Concurrent Tracing (MSCT, §4.2): Each memory server performs *intra-region* tracing over *regions for which most pages are evicted*, as a *continuous task*. Tracing runs *concurrently* on memory servers by leveraging their cheap but idle CPU resources. One can think of this as a background task that does not add any overhead to the application execution. The goal of MSCT is to compute a live object closure for each region at memory servers without interfering with the main execution at the CPU server. As a result, by the time a STW phase (*i.e.*, CSSC) runs, much of the tracing work is done, minimizing the STW pauses.

CPU Server Stop-The-World Collection (CSSC, §4.3): The CSSC is the main collection phase, coordinated between the CPU and memory servers to reclaim memory. During this phase, memory servers follow the per-region object closure computed during the MSCT to evacuate (*i.e.*, move out) live objects. Old regions are then reclaimed as a whole. Also during this phase, the CPU server traces and reclaims regions *for which most pages are cached*. Such regions are not traced by the MSCT. For evacuated objects, pointers pointing to them need to be updated in this phase as well.

Figure 4 shows an overview of these two types of collections. While the CPU server runs mutator threads, memory servers run the MSCT that continuously traces their hosted regions. When the CPU server stops the world and runs the CSSC, memory servers suspend the MSCT and coordinate with the CPU server to reclaim memory.

4.1 Design of the Remembered Set

The remset is a data structure that records, for each region, the references coming into the region. The design of the remset is much more complicated under a memory-disaggregated architecture due to the following two challenges. First, in a traditional setting, to represent an inter-region reference (*e.g.*, from field *o.f* to object *p*), we only need its *source* location — the address of *o.f*. This is because *p* can be easily obtained by following the reference in *o.f*. However, in our setting, both *o.f* and *p* need to be recorded for efficiency. This is because *o* and *p* can be on different servers and naïvely following the reference in *o.f* can trigger a remote access.

The second challenge is that the remset of each region is updated by the write barrier executed on the CPU server, while the region may be traced by a memory server. As a result, the CPU server has to periodically send the remsets to

Figure 5: *Semeru*'s remset design; the source and target queues are implemented as bitmaps for space efficiency.

memory servers for them to concurrently trace their regions. In addition, after memory servers evacuate objects, they need to send update addresses for the remsets back to the CPU server for it to update the sources of references (*e.g.*, *o.f* may point to a moved object *p*).

Figure 5 shows our remset. To represent the source of a reference, we leverage OpenJDK's *card table*, which groups objects into fixed-sized buckets (*i.e.*, cards) and tracks which buckets contain references. A card's ID can be easily computed (*i.e.*, via a bit shift) from a memory address and yet we can enjoy the many space optimizations already implemented in OpenJDK (*e.g.*, for references on *hot* cards that contain references going to the same region [36], their sources need to be recorded only once). As such, each incoming reference is represented as a pair $\langle \text{card}, \text{tgt} \rangle$ where *card* is the (8-byte) index of the card representing the source location of the reference, and *tgt* is the (8-byte) address of the target object.

Shown on the left side of Figure 5 are inter-region references recorded by the write barrier of each mutator thread. To reduce synchronization costs, each mutator thread maintains a thread-local queue storing its own inter-region references. The CPU-server JVM runs a daemon (transfer) thread that periodically moves these references into the remsets of their corresponding regions (*i.e.*, determined by the target addresses). For each region, a pointer to its remset is saved in the region's descriptor (Figure 3), which can be used to retrieve the remset by the CPU server. When a reference is recorded in a remset, its *card* and *tgt* are decoupled and placed separately into a source and a target queue.

Target queues are sent (together with stack references) — during each CSSC via RDMA — to their corresponding memory servers, which use them as roots to compute a closure over live objects. Source queues stay on the CPU server and are used during each CSST to update references if their target objects are moved during evacuation. The benefit of using a transfer thread is that mutator threads simply dump inter-region references, while the work of separating sources and targets and deduplicating queues (based on a simple hash-based data structure) is done by the transfer thread, which does not incur overhead on the main (application) execution.

4.2 Memory Server Concurrent Tracing (MSCT)

The MSCT brings significant efficiency benefits because (1) tracing computation runs where data is located, avoiding

high swapping costs, and (2) tracing regions *concurrently* on multiple memory servers has zero impact on the execution of the main application on the CPU server.

The MSCT *continuously* traces regions (until the CSSC starts) in the order of a region's age (*i.e.*, the smaller the value of *survivals*, the younger a region) and the percentage of evicted pages. That is, younger regions with more evicted pages are traced earlier. This is because (1) younger regions are likely to contain more garbage (according to the generational hypothesis), and (2) evicted pages are not touched by the CPU server. Regions with a low ratio of evicted pages are *not* traced since cached objects may be frequently updated by the CPU server. Tracing such regions would be less profitable because these updates can change pointer structures frequently, making the tracing results stale.

Identifying Roots. There are two types of roots for the MSCT to trace a region: (1) objects referenced by stack variables and (2) cross-region references recorded in the region's remset. Both types of information come from the CPU server — during each CSSC (§4.3), the CPU server scans its stacks, identifies objects referenced by stack variables, and sends this information, together with each region's remset, to its corresponding memory server via RDMA.

Live Object Marking. The MSCT computes a closure of reachable objects in each region by traversing the object sub-graph (within the region) from its roots. When live objects are traversed, we remember them in a per-region bitmap `live_bitmap` where each bit represents a contiguous range of 8 bytes (because the size of an object is always a multiple of 8 bytes), and the bit is set if these bytes host a live object. Furthermore, since live objects will be eventually evacuated, we compute a new address for a live object as soon as it is marked. The new address indicates where this object will be moved to during evacuation. New addresses are recorded in a *forward table* (*i.e.*, a key–value store) where keys are the indexes of the set bits in `live_bitmap` and values are the new addresses of the live objects represented by these bits.

Each new address is represented as an *offset*. At the start of the MSCT, it is unclear where these objects will be moved to (since evacuation will not be performed until a CSSC). As a result, rather than using absolute addresses, we use offsets to represent their relative locations. Their actual addresses can be easily computed using these offsets once the starting address of the destination space is determined.

Offset computation is in *traversal order*. For example, the first object reached in the graph traversal receives an offset 0; the offset for the second object is the size of the first object. This approach dictates that *objects that are contiguous in traversal will be relocated to contiguous space after evacuation*. Hence, the traversal order, which determines which objects will be *contiguously placed* after evacuation, is critical for improving data locality and prefetching effectiveness.

For instance, if the traversal algorithm uses DFS, *objects connected by pointers* will be relocated to contiguous memory

(based on an observation that such objects are likely in the same logical data structure and hence accessed contiguously). As another example, if we use BFS to traverse the graph, *objects at the same level of a data structure* (such as elements of an array) will be relocated to contiguous memory; this can be useful for streaming applications that may do a quick linear scan of all such element objects (*i.e.*, BFS) rather than fully exploring each element (*i.e.*, DFS). To support these different heuristics, *Semeru* allows the user to customize the traversal algorithm for different workloads.

Tracing Correctness. There are two potential concerns in tracing safety. First, if a region has a cached page, can the memory server safely trace the region (given that the CPU server may update the cached page)? For example, if an update happens after tracing completes, would the tracing results still be valid? Second, the root information may be out of date when a region is traced because the CPU server may have updated certain inter-region references or stack variables since the previous CSSC (where roots are computed and sent). Is it safe to trace with such out-of-date roots?

The answer to both questions is that it is still valid for a memory server to trace a region over an *out-of-date* object graph. An important safety property is that *objects unreachable in any snapshot of the object graph will remain unreachable in any future snapshots* (*i.e.*, “once garbage, always garbage”). Thus the transitive closure may include dead objects (due to pointer changes the memory server is not aware of), but objects *not* in the closure are guaranteed to be dead (except for newly allocated objects, discussed next).

However, tracing using an out-of-date object graph may lead to two issues. First, the CPU server may allocate new objects into a region *after* the region is traced on a memory server. These new objects are missed by the closure computation. To solve this problem, we identify *all* objects that have been allocated into the region *since the last CSSC*; such objects are all marked live at the time the region is reclaimed in the next CSSC so that no live object is missed. Newly allocated objects can be identified by remembering the value of the bump pointer (`bp` in Figure 3) at the the last CSSC and comparing it with the current value of `bp` — the difference between them captures objects allocated since the last CSSC. Such handling is *conservative*, because some of the objects may be dead already but are still included in the closure.

The second issue is that some objects in the region may lose their references and become unreachable after tracing is done. These dead objects are still in the closure. For this issue, we take a *passive* approach by not doing anything — we simply let these dead objects stay in the closure and be moved during evacuation. These dead objects will be identified in that next MSCT and collected during the next CSSC. Essentially, we delay the collection of these objects by one CSSC cycle. Note that datacenter applications are often not resource strapped; hence, delaying memory reclamation by one GC cycle is a better choice than an aggressive alternative that retraces the

region before reclamation (which can increase the length of each CSSC pause).

Handling CPU Evictions. A significant challenge is that concurrent tracing of a region can potentially *race* with the CPU server evicting a page into the region. To complicate matters, memory servers are not aware of remote reads/writes due to *Semeru*'s use of one-sided RDMA (for efficiency). Although recent RDMA libraries (such as LITE [91]) provide rich synchronization support, our use of RDMA at the block layer has many specific needs that are not met by these libraries, which were developed for user-space applications.

To overcome this challenge, we develop a simple workaround: each memory server reserves the *first 4 bytes of each region* to store two tags $\langle \text{dirty}, \text{ver} \rangle$. The first 2 bytes encode a boolean *dirty* tag and the second 2 bytes encode an integer *version* tag. These two tags are updated by the CPU server both before and after evicting pages into a region, and checked by the memory server both before and after the region is traced. Figure 6 shows this logic.

<pre> 1 atomic_write(<1, v1>; 2 evict_pages(); 3 atomic_write(<0, v2>; </pre> <p>(a) CPU server eviction</p>	<pre> 4 <dirty, ver> = atomic_read(); 5 if(!dirty) { 6 trace(); 7 <dirty, ver1> = atomic_read(); 8 if(ver != ver1) discard(); 9 } 10 else skip(); </pre> <p>(b) MSCT tracing</p>
--------------------------------------------------------------------------------------------------------------------------	----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------

Figure 6: Detection of evictions at a memory server.

Before evicting pages, the CPU server assigns 1 to the dirty tag and a new version number v_1 to the version tag (Line 1). This 4-byte information is written atomically by the RDMA network interface controller (RNIC) into the target region. After eviction, the CPU server clears the dirty tag and writes another version number v_2 (Line 3). The memory server reads these 4 bytes atomically and checks the dirty tag (Line 4). If it is set, this indicates a potential eviction; the memory server skips this region and moves on to tracing the next region (Line 10). Otherwise, the region is traced (Line 6). After tracing, this metadata is retrieved again and the new version tag is compared with the pre-tracing version tag. A difference means that an eviction may have occurred and the tracing results are discarded (Line 8).

The algorithm is sufficient to catch all concurrent evictions. The correctness can be easily seen by reasoning about the following three cases. (1) If Line 1 comes before Line 4 (which comes before Line 3), tracing will not be performed. (2) If Line 1 comes after Line 4 but before Line 8, the version check at Line 8 will fail. (3) If Line 1 comes after Line 7, the eviction has no overlap with the tracing and thus the tracing results are legitimate.

This algorithm introduces overheads due to extra write-backs. However, by batching pages from the same region and employing InfiniSwap's gather/scatter, we manage to reduce this overhead to about 5%, which can be easily offset by the

savings achieved by tracing objects on memory servers (see §6.4). Concurrent CPU-server reads are *allowed*. Similar to tracing out-of-date object graphs, fetching a page into the CPU server can potentially lead to new objects and pointer updates to the page. However, our aforementioned handling is sufficient to cope with such scenarios.

4.3 CPU Server Stop-The-World Collection (CSSC)

CSSC Overview. As the major collection effort, the CSSC runs when (1) the heap usage exceeds a threshold, *e.g.*, $N\%$ of the heap size, or (2) *Semeru* observes large amounts of swapping. The CPU server suspends all mutator threads and collaborates with memory servers to perform a collection. Our goal is to (1) reclaim cache memory at the CPU server and (2) provide a STW phase for memory servers to safely reclaim memory by evacuating live objects in the traced regions. Figure 7 overviews the CSSC protocol; edges represent communications of GC metadata between CPU and memory servers. The CSSC has four major tasks.

Task 1: The CPU server prepares information for memory servers to reclaim regions. Such information includes which regions to reclaim at each memory server (❶) and newly allocated objects for each region to be reclaimed (❷). As discussed in §4.2, newly allocated objects need to be marked live for safety and are identified by differencing the current value of *bp* and its old value (*old_bp*) captured in the last CSSC. This information is sent to memory servers (❷ → ❸) before they reclaim regions. Before evacuation happens, each memory server must ensure that regions to be evacuated have all their pages evicted, to avoid inconsistency. To this end, the CPU server evicts all pages for each selected region (❶).

Task 2: Memory servers reclaim selected regions by moving out their live objects (❸ – ❹). For these regions, their tracing (*i.e.*, closure computation) is already performed during the MSCT, and hence, reclamation simply follows the closure to copy out live objects (*i.e.*, object evacuation) from old regions into new ones. Object evacuation is done using a region's forward table, which is computed in traversal order to improve locality, as discussed earlier in §4.2. Live objects from multiple old regions can be compacted into a new region to reduce fragmentation. Moreover, each memory server attempts to coalesce regions connected by pointers, again, to improve locality — if region A has references from region B, *Semeru* attempts to copy live objects from A and B into the same (new) region. The new addresses of these objects can be computed easily by adding their offsets from the forward tables onto the base addresses of their target spaces (which may be brand-new or half-filled regions).

Since objects are moved, their addresses have changed and hence pointers (stack variables or fields of other objects) referencing the objects must be updated. Pointer updates, however, must be done through the CPU server, because pointers can be scattered across the cache and other memory servers. Thus after reclaiming regions, each memory server

Figure 7: *Semeru*'s CSSC protocol: edges represent communications in the RDMA control path; $bp - old_bp$ represents the difference between the current bp and the value of bp captured at the last CSSC.

sends the updated addresses of moved objects back to the CPU server (12). If a cached object references a moved object, the CPU server updates the pointer directly; the CPU server must also propagate these update requests to other memory servers (6 → 13), which may host objects referencing moved objects.

Task 3: While memory servers reclaim their regions, the CPU server reclaims regions where most objects are cached. Since these regions have not been traced during the MSCT, the CPU server has to trace them to build the closure and then reclaim them using the same object evacuation algorithm (3 and 4). Unlike memory-server region reclamation, the CPU server has to additionally write new regions back to their respective memory servers after object evacuation to ensure consistency (4). Next, the CPU server remembers the current value of bp into old_bp (5) for use in the next CSSC.

Task 4: Since most dead objects have already been reclaimed, the CPU server scans the remsets to remove *dead entries* (7). This is important since otherwise remsets can keep growing and dead entries would become memory leaks. Removing dead entries at the CPU server requires memory servers to provide information about which objects are dead (14 → 7) because most regions are traced and reclaimed at memory servers. The CPU server then scans each reference in each region's remset and removes those references with dead targets. Finally, the CPU server scans its stacks and the updated remset of each region to compute new roots, which are sent to memory servers for the next round of MSCT (8). Memory servers reset the metadata (e.g., *live_map* and forward table) so that the next round of MSCT can trace each region from scratch (15 and 16).

Since each CSSC only collects selected regions, it may not reclaim enough memory for the application to run. In such rare cases (e.g., one or two in our experiments with each Spark application), *Semeru* runs a full-heap scan (i.e., the same as a regular full-heap GC in G1), which brings all objects into the cache for tracing and collection. Since CSSC relies on remset-based modular tracing, it cannot reclaim dead objects

that are (1) in different regions and (2) form cycles. Such objects have to be reclaimed at a full-heap GC.

5 The *Semeru* Swap System

We build *Semeru*'s swap system by piggybacking on Melanox's NVMe-oF implementation [1]. This section briefly describes our modifications. During booting, the CPU server sends JVM metadata (such as metadata of loaded classes) in its *native heap* to memory servers, which use such information to launch LJVMs. On each memory server, the LJVM receives these native objects and reconstructs their virtual tables for function calls to execute correctly on these objects.

Block Layer. We modify NVMe-oF's block layer to add support for remote memory management. The remote physical memory that backs the Java heap on all memory servers is registered as a whole as an RDMA buffer and pinned down throughout the execution. As a simple optimization, we remove block-layer staging queues and merge several block I/O (BIO) requests into a single I/O request, turning them directly into RDMA messages.

Merging BIOs enables the use of InfiniBand's gather-scatter for data transfer. For each BIO request generated by the block layer, it often contains multiple physical pages to be transferred to a memory server. These physical pages are not necessarily contiguous. One optimization here is instead of generating multiple RDMA messages separately for these physical pages, we amortize per-message overhead by leveraging the scatter-gather technique so that these pages can be processed using a single RDMA message. We also develop thread-local RDMA message pools so that multiple threads can perform their own RDMA message creation and initialization without needing synchronization.

RDMA Management. All communications between the CPU and memory servers are through reliable one-sided RDMA. We distinguish these communications based on data types: (1) page fetching and evictions, which dominate the communications, go through a *data path* inside the kernel (to provide transparency to applications); (2) signals and GC information (e.g., all messages in Figure 7), are passed through a *control path* implemented as a user-space library for efficiency. A user-space implementation benefits from efficiency from raw RDMA (e.g., no overhead from system calls); since the control path does not overlap with the data path and transfers small amounts of information (i.e., only inside each CSSC), our implementation can deliver good performance for both control and data paths.

6 Evaluation

To implement *Semeru*, we wrote/modified 58,464 lines of (non-comment) C/C++ code, including 43,838 lines for the LJVM (based upon OpenJDK version 12.0.2) on memory servers, 7,406 lines for the CPU-server JVM, and 7,220 lines for the Linux kernel (4.11-rc8). Our kernel support contains 4,424 lines of C code for the paging system and RDMA

management (based upon NVMe-oF), and 2,796 lines for the modified block layer and memory management part as well as new system calls.

Setup and Methodology. We ran *Semeru* in a cluster with one CPU server and three memory servers. Each server has two Xeon(R) CPU E5-2640 v3 processors, 128GB memory, one 200GB SSD, and one 40 Gbps Mellanox ConnectX-3 InfiniBand network adapter. Servers are connected by one Mellanox 100 Gbps InfiniBand switch. To emulate the weak compute of memory servers, we let the LJVM on each memory server use only one core. All our experiments used a 32GB heap, 512MB regions, and 4K pages. The default swap prefetching mechanism in Linux was used.

Unfortunately, we were only able to gain exclusive use of a small cluster with four machines when evaluating *Semeru*. Despite running on this small cluster, our experiments used large-scale applications involving multiple memory servers, representing a real-world use of *Semeru*. Adding more memory servers would not change the results because (1) memory servers perform modular collection — they do not communicate with each other and hence not have scalability issues; and (2) the CPU server only communicates with memory servers during each CSSC — more memory servers would only increase the control-path communication, which is minimal. Adding CPU servers and running more processes would increase the amount of tracing work on each memory server. However, as shown in §6.3, tracing for a large Spark application can only utilize 13% of each memory server’s compute — one single core on each server can support simultaneous tracing for ~8 Spark applications.

Name	Dataset	Size

Table 2: Description of three Flink batch-processing programs.

We evaluated *Semeru* with two widely deployed data analytics systems: Apache Spark (3.0.0) and Apache Flink (1.10.1). Spark was executed under Hadoop 3.2.1 and Scala 2.12.11, using a set of five programs (listed in Table 1): PageRank (GPR) and ConnectedComponents (GCC) from the GraphX [48] libraries, as well as Bayes Classifier (MBC) from the MLlib libraries. We also included naïve PageRank (NPR) and naïve TriangleCounting (NTC), implemented directly atop Spark.

Flink also ran on top of Hadoop version 3.2.1. Flink has both streaming and batch-processing models. In this experi-

ment, we focused on the batch-processing model, in particular, Map/Reduce programs. The programs and their datasets are summarized in Table 2. These programs are selected based on their popularity and usefulness, covering a spectrum of text analytics, graph analytics, and machine learning tasks.

6.1 Overall Semeru Performance

We compared *Semeru* and the original OpenJDK 12 that runs the G1 GC — the default GC in the JVM since OpenJDK 9. G1 is a concurrent GC that runs concurrent tracing as the mutator thread executes and stops the world for memory reclamation. G1 is designed for short latency (*i.e.*, GC pauses) at the cost of reduced throughput (*i.e.*, concurrent tracing slows down the mutator as it competes resources with the mutator). We have tested other GCs as well and found that G1 consistently outperforms all others in latency.

We ran G1 with two swap mechanisms: a local RAMDisk and NVMe-oF, which connects the CPU server to remote memory on the three memory servers. To use NVMe-oF, we configured remote memory as remote RAMDisks, which host data objects without supporting memory management. *Semeru* ran on our own swap system built on top of NVMe-oF with added support for the remote heap and memory management. Each memory server hosts around one-third of the 32GB Java heap. There are three cache configurations: 100%, 50%, and 25%. The 100% configuration is our baseline, which represents the original OpenJDK’s performance without any swapping.

Running Time. Figure 8 shows performance comparison between these systems, for our eight programs, under the three cache configurations. There is only one bar under the 100% cache configuration, representing the original performance of G1 that does not perform swapping.

System	50% Cache			25% Cache		
	Mutator	GC	All	Mutator	GC	All
G1-RD	1.82×	2.79×	1.87×	3.16×	4.59×	3.23×
G1-NVMe	2.00×	4.44×	2.24×	3.85×	14.13×	4.58×
<i>Semeru</i>	1.06×	1.42×	1.08×	1.22×	2.67×	1.32×

Table 3: Overhead summary: overheads are calculated using the G1 performance under the 100% cache configuration as the baseline.

Table 3 summarizes the time overheads incurred by memory disaggregation on these systems. The baseline used to calculate these overheads is the G1 performance under the 100% cache ratio (without any kernel and JVM modification). On average, G1 has 1.87× and 2.24× end-to-end overhead under RAMDisk and NVMe-oF, respectively, for the 50% cache configuration. When the cache ratio reduces to 25%, these overheads increase to 3.23× and 4.58×, respectively. By offloading tracing and evacuation to memory servers and improving the locality for the mutator threads, *Semeru* reduces these overheads, by **3.23 times overall**, to **1.08×** and **1.32×** for the two cache ratios, respectively.

Our first observation here is that disaggregation incurs a much higher overhead on GC than the mutator for Spark

Figure 8: Performance comparisons between G1 under NVMe-oF (left bar of each group), G1 under RAMDisk (middle bar), and Semeru (right bar) for three cache configurations: 100%, 50%, and 25%; each bar is broken down into mutator (bottom) and GC (top) time (second).

applications, and it is consistent with our motivating data reported in §2. This is because GC algorithms inherently do not possess good locality and, as a result, pay a higher penalty for remote memory fetching than the mutator. This overhead grows significantly when the cache size decreases. It is also easy to see that accessing remote memory (via NVMe-oF) incurs a higher overhead than accessing the local RAMDisk.

The second observation is that for Flink, which has much less GC than Spark, *Semeru* can still considerably improve its performance. An inspection found that Flink stores data in the serialized form and implements operators that can process data without creating objects for them. Flink allocates long-lived data items directly in native memory and/or reserved space in the old generation. Nevertheless, *Semeru*'s optimizations are still effective. This is because the G1 GC uses a disaggregation-agnostic policy to dynamically tune the size of young generation. Since most objects in Flink die in the young generation, the pause time of each young GC is extremely short (*e.g.*, less than 10 ms) and always meets G1's pause-time target. As such, G1 keeps increasing the young generation size to reduce the GC frequency, making the young generation quickly reach the size of the CPU cache.

However, the problem here is the young generation contains large amounts of garbage, cached on the CPU server, leaving little cache space for long-lived data. This causes hot, long-lived data (*e.g.*, in native memory) to be frequently swapped in and out. In contrast, under *Semeru*'s region design, a CSSC is triggered when *Semeru* observes frequent swapping. The CSSC reclaims garbage and compacts regions, freeing up cache space for accommodating other hot data.

The third observation is that applications have different levels of tolerance to fetching latency. For example, GCC and GPR have an exceedingly high GC overhead because they create large RDDs and *persist* them in memory. These RDDs

System	50% Cache			25% Cache		
	Mutator	GC	All	Mutator	GC	All
G1-RD	1.73×	2.31×	1.75×	2.65×	2.35×	2.56×
G1-NVMe	1.91×	4.20×	2.10×	3.31×	5.61×	3.69×

Table 4: Summary of performance improvements achieved by *Semeru*: improvements are computed with $\frac{a}{b}$ where a is the (mutator, GC, or end-to-end) time under a system and cache configuration, and b is *Semeru*'s time under the same configuration.

and their elements quickly become old and get promoted to the *old generation*. G1 cannot reclaim much memory in nursery GCs and, as such, most GCs scan the entire heap, requiring many remote fetches. For other applications such as Spark NPR, their GC performance is not as significantly degraded because their executions generate many temporary objects that die young (rather than old objects) — when a nursery GC runs, most young objects are garbage cached locally on the CPU server, and hence, they can be easily reclaimed without triggering many remote fetches.

To make *Semeru*'s improvements clear, Table 4 reports detailed improvement ratios under each configuration. It is easy to see that *Semeru* improves the performance of both the mutator and GC. On the mutator side, *Semeru* eliminates G1's concurrent marking — which runs on the CPU server in parallel with application execution, competing for resources with mutator threads and polluting the cache — and dynamically improves locality (discussed in §4.3) by relocating objects likely to be accessed to contiguous memory. On the GC side, *Semeru* significantly reduces pause time by letting memory servers perform tracing and evacuation, all of which used to be done on the CPU server.

Memory. To understand *Semeru*'s ability to reclaim memory, we collected post-GC memory footprints for Spark NPR and Spark KMS under three GCs: *Semeru*, G1, and Parallel

Figure 9: Memory footprints under *Semeru*, G1, and Parallel Scavenge for NPR (a) and KMS (b); (c) shows the memory footprint and GC pause time with and without continuous tracing for NPR.

Scavenge (PS). PS is a non-concurrent GC designed for high throughput. We added PS because it often can reclaim more memory at each GC than G1 at the cost of higher latency. PS’s strong memory reclamation capabilities are clearly seen in Figure 9(a) where PS has the lowest memory footprint throughout the execution. *Semeru* outperforms G1 — G1 uses concurrent tracing to estimate a garbage ratio for each region; with this information, when each STW phase runs, the GC can selectively reclaim regions with the highest garbage ratios. Under memory disaggregation, however, concurrent tracing runs slowly due to frequent remote fetches. It cannot finish tracing the heap at the time a STW starts; as a result, garbage ratios are not available for most regions.

As a result, at each STW phase, there is not much information about which regions have the most garbage, and thus, the GC selects arbitrary regions to collect. Many such regions do not have much garbage, which explains why G1 reclaims less memory than *Semeru* and PS. Note that *Semeru* does not suffer from this problem because tracing is done locally on memory servers; hence, it runs efficiently and can trace many regions between two consecutive CSSCs.

Figure 9(b) shows the memory footprint for Spark KMS running under the 25% cache configuration. In this case, *Semeru*’s collection performance is close to that of PS — for both of them, the program’s memory consumption becomes stabilized after about 400 seconds. Under G1, however, the memory footprint fluctuates, again due to the (semi-random) selection of regions to collect. If regions with large garbage ratios happen to be in the cache, G1 is able to quickly identify them during concurrent marking and collect them in a subsequent STW phase. However, if they are remotely resident on memory servers, G1 would lack sufficient information in a STW phase to collect the right regions.

6.2 Effectiveness of Continuous Tracing

To understand the usefulness of continuous tracing on memory servers, we compared *Semeru* with a variant that does not perform continuous tracing but rather traces regions in each CSSC. In this variant, tracing is still done on memory servers but combined with other memory management tasks such as object evacuation in each STW phase. Without continuous tracing, which uses idle resources on memory servers to trace local regions, *Semeru* suffers from the same problem

as G1 — when a CSSC runs, *Semeru* does not know which regions have the most garbage and thus should be reclamation targets. To minimize the GC latency, each CSSC has to be extremely short, leaving memory servers insufficient time to trace many regions. As a result, memory servers can only trace and reclaim regions based on their age without the more useful information of their garbage ratio.

To illustrate this problem, Figure 9(c) shows the post-GC memory footprint (*i.e.*, y-axis on the left) and the pause time of each CSSC (*i.e.*, y-axis on the right). The two lines represent the memory footprints of *Semeru* with and without continuous tracing while the short bars report the GC pauses. We make two important observations here. First, *Semeru* with continuous tracing consistently reclaims more memory than the version without continuous tracing, because it knows the right regions to reclaim in each CSSC. Second, since the version without continuous tracing cannot reclaim enough memory, it triggers a full-heap scan at the 484th second, which is extremely time consuming (*i.e.*, 65 seconds).

A modern generational GC achieves its efficiency by scanning only the young nursery generation in most of its GC runs. As soon as it needs to scan the entire heap, its performance degrades significantly. This is especially the case with memory disaggregation where a full-heap scan fetches most objects from memory servers to the CPU server, incurring an extremely long pause, as shown in the figure. The full-heap GC reclaims much space and reduces memory consumption.

In contrast, with continuous tracing, *Semeru* does not encounter any full-heap GC throughout the execution. Although it does not reclaim as much memory as a full-heap GC, it avoids long pauses and yet is still able to give the application enough memory to run.

6.3 Tracing Performance

Memory servers are expected to possess weak compute power. To understand how tracing performs under different levels of compute, we used one single core on each memory and varied its frequency with DVFS. Table 5 summarizes the impact of each frequency on the tracing performance, GC and mutator performance, and end-to-end performance of NPR. We also obtained the same measurements when tracing is performed on the CPU server with a dedicated core. As shown, even with a single core at 1.2GHz, tracing on memory servers still yields

Configuration	Tracing Performance				Overall Performance		
	Thruput	CUtil	AT	AIT	GC	Mutator	Overall
(Memory Server) single core, 1.2 GHz	418.3 MB/s	29.0%	6.5 secs	4.6 secs	59.4 secs	180.2 secs	239.6 secs
(Memory Server) single core, 2.6 GHz	922.2 MB/s	12.4%	5.7 secs	5.0 secs	59.3 secs	173.9 secs	233.2 secs
(CPU Server) single core, 2.6 GHZ, dedicated to GC	93.9 MB/s	N/A	38.8 secs	N/A	126.0 secs	218.9 secs	344.9 secs

Table 5: Performance of NPR when tracing is performed under different core frequencies at memory servers: reported are the configurations (**Configuration**) of memory-server cores, tracing throughput (**Thruput**), memory-server CPU utilization (**CUtil**), average time between two consecutive CSSCs (**AT**), average idle CPU time between two consecutive CSSCs (**AIT**), total GC (**GC**) and mutator time (**Mutator**), and end-to-end run time (**Overall**).

Figure 10: Comparisons between *Semeru*'s swap system and local RAMDisk: (a) shows Spark running times when the size of the cache is 50% of the heap size; the first bar reports performance of the baseline (cache ratio = 100%); (b) shows normalized performance (i.e., slowdowns) for the two cache configurations (50% and 25%).

a throughput $4.5\times$ higher than doing so on the CPU server with a dedicated 2.6GHz core. This is easy to understand: the bottleneck of a memory-disaggregated system is at (1) the poor locality, which triggers many on-demand swaps, and (2) racing for network resource between the mutator and GC threads, *not* the lack of compute power.

Another important observation is on the low CPU utilization on memory servers. Even with a 1.2GHz core, continuous tracing between consecutive CSSCs has only 29% CPU utilization — this is because (1) tracing only follows pointers, (2) dead objects are not traced and hence, for each region, only a small fraction needs to be traced, and (3) not all regions need to be traced (i.e., those with a high rate of cached objects are not traced). These results demonstrate that supporting multiple processes, with weak compute on memory servers, should not be a concern.

6.4 Swap Performance

To evaluate our swap system's performance, we turned off the *Semeru* runtime (i.e., all memory management tasks on memory servers) and ran the original G1 GC on top of our swap system. We tried to run InfiniSwap [49], but its executions were frequently stuck, even on native programs. This subsection focuses on comparisons of swap performance between local RAMDisk and *Semeru*'s swap system (with and without using InfiniSwap's gather/scatter).

The results of Spark NPR are reported in Figure 10. We used two cache configurations: 50% and 25%. Figure 10(a) shows actual running times when the cache ratio is 50% between four versions of the system: in-memory (i.e., cache ratio is 100%), RAMDisk, *Semeru*-no-gs (i.e., gather/scatter

is not used), and *Semeru*-gs (which uses gather/scatter). For ease of comparison, Figure 10(b) shows normalized times.

Figure 11: A comparison of the combined swap read/write throughput between *Semeru*-gs, *Semeru*-no-gs, and RAMDisk.

Under the 50% cache configuration, using RAMDisk as the swap partition incurs a $1.5\times$ and $1.6\times$ overhead in the mutator and GC, respectively, compared with the in-memory baseline. *Semeru*-no-gs increases the overheads to $1.6\times$ and $2.2\times$. Merging BIO requests and using gather/scatter brings the overheads down to $1.5\times$ and $1.7\times$, which are on par with those of the RAMDisk. Similar observations can be made for the 25% cache rate. Across all programs, gather/scatter improves the swap performance overall by 14%.

Figure 11 compares the read/write throughput between *Semeru*-gs, *Semeru*-no-gs, and RAMDisk when Spark LRG is executed under the 25% cache configuration. As shown, gather/scatter helps *Semeru* achieve a higher peak read/write bandwidth than *Semeru*-no-gs (especially when pages contiguously swapped come from / go to the same region).

Figure 12: Average read/write throughput.

A comparison on the average read/write throughput between the three systems is shown in Figure 12. *Semeru*-gs's

Figure 13: Numbers of on-demand swap-ins between G1 and *Semeru* under the 25% cache configuration for Spark MBC.

overall read/write throughput is 13% higher than that of *Semeru-no-gs* and is on par with that of RAMDisk. Clearly, additional gains can be obtained by merging BIO requests and using gather-scatter.

6.5 Locality Improvement

To understand how *Semeru* improves locality for application execution, we measured the number of on-demand swap-ins performed by the swap system under G1 and *Semeru* when Spark MBC was executed with a 25% cache ratio. Figure 13 reports how such numbers change as the execution progresses for both the mutator and GC. Both *Semeru*-mutator and *Semeru*-GC need significantly fewer on-demand swap-ins due to improved locality. On average, *Semeru* reduces the number of on-demand swap-ins by **8.76×**. Note that both G1 and *Semeru* ran under the default swap prefetcher in Linux, which relies on the pages swapped in during the last two page faults: if they are contiguous, Linux continues to bring in several contiguous pages into the page cache; otherwise, it assumes that there are no patterns and reduces or stops prefetching. Despite the recent development of more advanced prefetchers (such as Leap [71]) for remote memory, *Semeru* already performs well under the default prefetcher in Linux. We expect it to continue to work well when other prefetchers are used. The average ratio between the sizes of data swapped in the data and control path is 29.8 across the programs.

7 Related Work

Resource Disaggregation. Due to rapid technological advances in network controllers, it has become practical to reorganize resources into disaggregated clusters [21, 29, 45, 51]. A disaggregated cluster can increase the hardware resource utilization and has the potential to overcome fundamental hardware limits, such as the critical “memory capacity wall” [9, 13, 17, 58, 67, 68, 95]. A good number of systems have been developed in the past to take advantage of this architecture [7, 35, 41, 42, 44, 54, 62]. However, almost all of them treat remote memory as fast storage. When the network connection only has microseconds of latency and hundreds of gigabits of bandwidth [55, 72], applications can suffer from significant delays in memory access. Despite many optimiza-

tions [7, 11, 49, 84, 87–89] developed to reduce this latency, they all focus on low-level system stacks and do not consider run-time characteristics of programs. They do not work well for managed cloud applications such as [6, 14, 15, 24–26, 31, 32, 50, 56, 75, 76, 81, 82, 92, 102–104, 106]. *Semeru* co-optimizes the runtime and the swap system, unlocking opportunities unseen by existing techniques.

Garbage Collection for Modern Systems. GC is a decades-old topic. In order to meet the requirements of low latency and high throughput, many concurrent GC algorithms have been proposed, including the Garbage-First (G1) GC [36], Compressor [59], ZGC [2], the Shenandoah GC [43], Azul’s pauseless GC [34], and C4 [90], as well as several real-time GCs [18, 19]. These GC algorithms can run in the background with short pauses for mutator threads. However, none of them can work directly in the resource-disaggregated environment, which has a unique resource profile — data are all located on memory servers, the CPU server has a small cache, and memory servers have weak compute.

Efficiently using memory is important especially for applications running on the cloud [40]. Yak [79] is a region-based GC developed for such applications. Taurus [70] coordinates GC efforts in a distributed setting for cloud systems. Facade [80] uses region-based memory management to reduce GC costs for Big Data applications. Gerenuk [78] develops a compiler analysis and runtime system that enable native representation of data for managed analytics systems such as Spark and Hadoop. Espresso [99] and Panthera [95] are designed for systems with non-volatile memory. Platinum [98] is a GC that aims to reduce tail latency for interactive applications. NUMAGiC [47] is a GC developed for the NUMA architecture. However, NUMAGiC assumes that NUMA nodes are completely symmetric (with the same CPU, the same amount of local memory, and the same GC algorithm) — which is not the case for disaggregated clusters. DMOS [53] is a distributed GC algorithm that has not been implemented and whose performance in a real-world setting is unclear.

8 Conclusions

Semeru is a managed runtime designed for efficiently running managed applications with disaggregated memory. It achieves superior efficiency via a co-design of the runtime and swap system as well as careful coordination of different GC tasks.

A Artifact Appendix

A.1 Artifact Summary

Semeru is a managed runtime built for a memory-disaggregated cluster where each managed application uses one CPU server and multiple memory servers. When launched on *Semeru*, the process runs its application code (mutator) on the CPU server, and the garbage collector on both the CPU server and memory servers in a coordinated manner. Due to task offloading and moving computation close to data, *Semeru* significantly improves the locality for both the mutator and GC and, hence, the end-to-end performance of the application.

A.2 Artifact Check-list

- **Hardware:** Intel servers with InfiniBand
- **Run-time environment:** OpenJDK 12.02, Linux-4.11-rc8, CentOS 7.5(7.6) with MLNX-OFED 4.3(4.5)
- **Public link:** <https://github.com/uclasytem/Semeru>
- **Code licenses:** The GNU General Public License (GPL)

A.3 Description

A.3.1 *Semeru*'s Codebase

Semeru contains the following three components:

- the Linux kernel, which includes a modified swap system, block layer and a RDMA module,
- the CPU-server Java Virtual Machine (JVM),
- the Memory-server lightweight Java Virtual Machine (LJVM).

These three components and their relationships are illustrated in Figure 14.

Figure 14: Overview of *Semeru*'s codebase.

A.3.2 Deploying *Semeru*

To build *Semeru*, the first step is to download its source code:

```
git clone
git@github.com:uclasytem/Semeru.git
```

When deploying *Semeru*, install the three components in the following order: the kernel on the CPU server, the *Semeru* JVM on the CPU server, and the LJVM on each memory server. Finally, connect the CPU server with memory servers before running applications.

Kernel Installation. We first discuss how to build and install the kernel.

- **Modify grub and set transparent_hugepage to madvise:**

```
sudo vim /etc/default/grub
+transparent_hugepage=madvise
```

- **Install the kernel and restart the machine:**

```
cd Semeru/Linux-4.11-rc8
sudo ./build_kernel.sh build
sudo ./build_kernel.sh install
```

- **Build the *Semeru* RDMA module:**

```
# Add the IP of each memory server into
# Semeru/linux-4.11-rc8/include/
# linux/swap_global_struct.h
# e.g., the Infiniband IPs of the 2 memory servers
# are 10.0.0.2 and 10.0.0.4.

char* mem_server_ip[][] = {"10.0.0.2",
"10.0.0.4"};
uint16_t mem_server_port = 9400;

# Then build the Semeru RDMA module
make
```

Install the CPU-Server JVM. We next discuss the steps to build and install the CPU-server JVM.

- **Download Oracle JDK 12 to build *Semeru* JVM:**

```
# Assume jdk 12.02 is under path
# ${home_dir}/jdk12.0.2
# Or change the path in shell script
# Semeru/CPU-Server/build_cpu_server.sh
boot_jdk="${home_dir}/jdk12.0.2"
```

- **Build the CPU-server JVM:**

```
# ${build_mode} can be one of the three modes:
# slowdebug, fastdebug, or release.
# We recommend fastdebug to debug the JVM code
# and release to test the performance.
# Please make sure both the CPU server and
# memory servers use the same build mode.

cd Semeru/CPU-Server/
./build_cpu_server.sh ${build_mode}
./build_cpu_server.sh build

# Take fastdebug mode as example — the compiled
# JVM will be in:
# Semeru/CPU-Server/build
# /linuxx86_64serverfastdebug/jdk
```

Install the Memory-Server LJVM. The next step is to install the LJVM on each memory server.

- Download OpenJDK 12 and build the LJVM:

```
# Assume OpenJDK12 is under the path
${home_dir}/jdk-12.0.2
# Or you can change the path in the script
# Semeru/Memory-Server/build_mem_server.sh
boot_jdk="${home_dir}/jdk-12.0.2"
```

- Change the IP addresses:

```
# E.g., mem-server #0's IP is 10.0.0.2, ID is 0.
# Change the IP address and ID in file:
# Semeru/Memory-Server/src/hotspot/share/
# utilities/globalDefinitions.hpp
#@Mem-server #0
#define NUM_OF_MEMORY_SERVER 2
#define CUR_MEMORY_SERVER_ID 0
static const char cur_mem_server_ip[] =
"10.0.0.2";
static const char cur_mem_server_port[]
= "9400";
```

- Build and install the LJVM:

```
# Use the same ${build_mode} as the CPU-server
# JVM.
cd Semeru/CPU-Server/
./build_memory_server.sh ${build_mode}
./build_memory_server.sh build
./build_memory_server.sh install
# The compiled Java home will be installed under:
# {home_dir}/jdk12u-self-build/jvm/
# openjdk-12.0.2-internal
# Set JAVA_HOME to point to this folder.
```

A.3.3 Running Applications

To run applications, we first need to connect the CPU server with memory servers. Next, we mount the remote memory pools as a swap partition on the CPU server. When the application uses more memory than the limit set by `cgroup`, its data will be swapped out to the remote memory via RDMA.

- Launch memory servers:

```
# Use the shell script to run each memory server.
# ${execution_mode} can be execution or gdb.
#@Each memory server
cd Semeru/ShellScript
run_rmem_server_with_rdma_service.sh
Case1 ${execution_mode}
```

- Connect the CPU server with memory servers:

```
#@CPU server
cd Semeru/ShellScript/
install_semeru_module.sh semeru
# To close the swap partition, do the following:
#@CPU server
cd Semeru/ShellScript/
install_semeru_module.sh close_semeru
```

- Set a cache size limit for an application:

```
# E.g., Create a cgroup with 10GB memory limitation.
#@CPU server
cd Semeru/ShellScript
cgroupv1_manage.sh create 10g
```

- Add a Spark executor into the created `cgroup`:

```
# Add a Spark worker into the cgroup, memctl.
# Its sub-process, executor, falls into the same cgroup.
# Modify the function start_instance under
# Spark/sbin/start-slave.sh
#@CPU server
cgexec -sticky -g memory:memctl
"${SPARK_HOME}/sbin" /sparkdaemon.sh
start $CLASS $WORKER_NUM -webui-port
"$WEBUI_PORT" $PORT_FLAG $PORT_NUM
$MASTER "$@"
```

- Launch a Spark application:

Some *Semeru* JVM options need to be added for both CPU-server JVM and LVJMs. CPU-server JVM and memory server LVJMs should use the value for the same JVM option.

```
# E.g., under the configuration of 25% local memory
# 512MB Java heap Region
#@CPU server
-XX:+SemeruEnableMemPool
-XX:EnableBitmap -XX:-UseCompressedOops
-Xnoclassgc -XX:G1HeapRegionSize=512M
-XX:MetaspaceSize=0x10000000
-XX:SemeruLocalCachePercent=25
#@Each memory server
# ${MemSize}: the memory size of current memory
server
# ${ConcThread}: the number of concurrent threads
-XX:SemeruEnableMemPool
-XX:-UseCompressedOops
-XX:SemeruMemPoolMaxSize=${MemSize}
-XX:SemeruMemPoolInitialSize=${MemSize}
-XX:SemeruConcGCThreads=${ConcThread}
```

More details of *Semeru*'s installation and deployment can be found in *Semeru*'s code repository.

Caladan: Mitigating Interference at Microsecond Timescales

Joshua Fried, Zhenyuan Ruan, Amy Ousterhout[†], Adam Belay
MIT CSAIL, [†]UC Berkeley

Abstract

The conventional wisdom is that CPU resources such as cores, caches, and memory bandwidth must be partitioned to achieve performance isolation between tasks. Both the widespread availability of cache partitioning in modern CPUs and the recommended practice of pinning latency-sensitive applications to dedicated cores attest to this belief.

In this paper, we show that resource partitioning is neither necessary nor sufficient. Many applications experience bursty request patterns or phased behavior, drastically changing the amount and type of resources they need. Unfortunately, partitioning-based systems fail to react quickly enough to keep up with these changes, resulting in extreme spikes in latency and lost opportunities to increase CPU utilization.

Caladan is a new CPU scheduler that can achieve significantly better quality of service (tail latency, throughput, etc.) through a collection of control signals and policies that rely on fast core allocation instead of resource partitioning. Caladan consists of a centralized scheduler core that actively manages resource contention in the memory hierarchy and between hyperthreads, and a kernel module that bypasses the standard Linux Kernel scheduler to support microsecond-scale monitoring and placement of tasks. When colocating memcached with a best-effort, garbage-collected workload, Caladan outperforms Parties, a state-of-the-art resource partitioning system, by 11,000 \times , reducing tail latency from 580 ms to 52 μ s during shifts in resource usage while maintaining high CPU utilization.

1 Introduction

Interactive, data-intensive web services like web search, social networking, and online retail commonly distribute requests across thousands of servers. Minimizing tail latency is critical for these services because end-to-end response times are determined by the slowest individual response [4, 14]. Efforts to reduce tail latency, however, must be carefully balanced with the need to maximize datacenter efficiency; large-scale datacenter operators often pack several tasks together on the same machine to improve CPU utilization in the presence of variable load [22, 57, 66, 71]. Under these conditions, tasks must compete over shared resources such as cores, memory bandwidth, caches, and execution units. When shared resource contention is high, latency increases significantly; this slowdown of tasks due to resource contention is called *interference*.

The need to manage interference has led to the development of several hardware mechanisms that *partition* resources. For

example, Intel’s Cache Allocation Technology (CAT) uses way-based cache partitioning to reserve portions of the last level cache (LLC) for specific cores [21]. Many systems use these partitioning mechanisms to improve performance isolation [8, 12, 28, 38, 62, 73]. They either statically assign enough resources for peak load, leaving significant CPU utilization on the table, or else make dynamic adjustments over hundreds of milliseconds to seconds. Because each adjustment is incremental, converging to the right configuration after a change in resource usage can take dozens of seconds [8, 12, 38].

Unfortunately, real-world workloads experience changes in resource usage over much shorter timescales. For example, network traffic was observed to be very bursty in Google’s datacenters, sometimes consuming more than a dozen cores over short time periods [42], and a study of Microsoft’s Bing reports highly bursty thread wakeups on the order of microseconds [27]. Phased resource usage is also common. For example, we found that tasks that rely on garbage collection (GC) periodically consume all available memory bandwidth (§2). Detecting and reacting to such sudden changes in resource usage is not possible with existing systems.

Our goal is to maintain both high CPU utilization and strict performance isolation (for throughput and tail latency) under realistic conditions in which resource usage, and therefore interference, changes frequently. A key requirement is faster reaction times, as even microsecond delays can impact latency after an abrupt increase in interference (§2). There are two challenges toward achieving microsecond reaction times. First, there are many types of interference in a shared CPU (hyperthreading, memory bandwidth, LLC, etc.), and obtaining the right control signals that can accurately detect each of them over microsecond timescales is difficult. Second, existing systems face too much software overhead to either gather control signals or adjust resource allocations quickly.

To overcome these challenges, we present an interference-aware CPU scheduler, called *Caladan*. Caladan consists of a centralized, dedicated scheduler core that collects control signals and makes resource allocation decisions, and a Linux Kernel module, called *KSCHED*, that efficiently adjusts resource allocations. Our scheduler core distinguishes between high-priority, latency-critical (LC) tasks and low-priority, best-effort (BE) tasks. To avoid the reaction time limitations imposed by hardware partitioning (§3), Caladan relies exclusively on core allocation to manage interference.

Caladan uses a carefully selected set of control signals and corresponding actions to quickly and accurately detect and respond to interference over microsecond timescales. We

observe that interference has two interrelated effects: first, interference slows down the execution speed of cores (more cache misses, higher memory latency, etc.), impacting the *service times* of requests; second, as cores slow down, *compute capacity* drops; when it falls below offered load, queueing delays increase dramatically.

Caladan’s scheduler targets these effects. It collects fine-grained measurements of memory bandwidth usage and request processing times, using these to detect memory bandwidth and hyperthreading interference, respectively. It then restricts cores from the antagonizing BE task(s), eliminating most of the impact on service times. For LLC interference, Caladan cannot eliminate service time overheads directly, but it can still prevent a decrease in compute capacity by allowing LC tasks to steal extra cores from BE tasks.

The KSCHED kernel module accelerates scheduling operations such as waking tasks and collecting interference metrics. It does so by amortizing the cost of sending interrupts, offloading scheduling work from the scheduler core to the tasks’ cores, and providing a non-blocking API that allows the scheduler core to handle many inflight operations at once. These techniques eliminate scheduling bottlenecks, allowing Caladan to react quickly while scaling to many cores and tasks, even under heavy interference.

To the best of our knowledge, Caladan is the first system that can maintain both strict performance isolation and high CPU utilization under frequently changing interference and load. To achieve these benefits, Caladan imposes two new requirements on applications: the adoption of a custom runtime system for scheduling and the need for LC tasks to expose their internal concurrency (§8). In exchange, Caladan is able to converge to the right resource configuration $500,000\times$ faster than the typical speed reported for Parties, a state-of-the-art resource partitioning system [12]. We show that this speedup yields an $11,000\times$ reduction in tail latency when colocating memcached with a BE task that relies on garbage collection. Moreover, we show that Caladan is highly general, scaling to multiple tasks and maintaining the same benefits while colocating a diverse set of workloads (memcached, an in-memory database, a flash storage service, an x264 video encoder, a garbage collector, etc.). Caladan is available at <https://github.com/shenango/caladan>.

2 Motivation

In this section, we demonstrate how performance can degrade when interference is not quickly mitigated. Many workloads exhibit phased behavior, drastically changing the types and quantities of resources they use at sub-second timescales. Examples include compression, compilation, Spark compute jobs, and garbage collectors [49, 59]. The request rates issued to tasks can also change rapidly, with bursts occurring over microsecond timescales [5, 27, 42]; these bursts in load can cause bursts of resource usage. In both cases, abrupt changes

Figure 1: Periodic GC in a background task (shaded regions) increases memory bandwidth usage (top), causing severe latency spikes for a colocated memcached instance (bottom). Note the log-scaled y-axis in the bottom graph.

in resource usage can abruptly increase interference. This degrades request service times and causes request queues to grow when the rate of arriving requests exceeds the rate at which a task can process them.

To better understand the challenges associated with time-varying interference, we consider what happens when we colocate an LC task, memcached [43], with a BE workload that exhibits phased behavior due to garbage collection. In this example, we use the Boehm GC (see §7), which employs the mark-sweep algorithm to reclaim dead heap objects [10]. We have observed similar problems with more sophisticated, incremental GCs, such as the Go Language Runtime [60].

In this experiment, we offer a fixed load to memcached and statically partition cores between the two tasks. memcached is given enough cores to keep its 99.9th percentile tail latency below $50\ \mu\text{s}$ when run in isolation. As shown in Figure 1, this allocation is sufficient to protect tail latency when the GC is not running but it fails when the GC starts. The GC pauses normal execution of the BE task for 100–200 ms and scans the entire heap using all cores available to the BE task, which saturates memory bandwidth. During this brief period, each memcached request experiences a higher rate of cache misses and larger memory access latencies, causing the rate at which memcached can service requests to drop by about half and queues to build up. As a result, memcached’s queueing delay increases at a rate of $5\ \mu\text{s}$ every $10\ \mu\text{s}$, eventually reaching a tail latency that is $1000\times$ higher than normal.

This example illustrates that fixed core partitioning is insufficient, and also indicates what core reallocation speed is necessary in order to effectively mitigate interference. If changes in interference can instantaneously reduce the request service rate by half, then in order to keep latencies from increasing by X , the CPU scheduler must detect and respond to interference within $2X$. Thus, preventing a latency increase of $50\ \mu\text{s}$ requires reaction times within $100\ \mu\text{s}$. Unfortunately, existing systems are not designed to respond this quickly (§3), forcing datacenter operators to either tolerate severe tail latency spikes, or else isolate these tasks on different servers.

System	Decision Interval	Typical Convergence	Requires CAT	Supports HT
Heracles [38]	2–15 s	30 s	✓	✗
Parties [12]	500 ms	10–20 s	✓	✗
Caladan	10–20 μ s	20 μ s	✗	✓

Table 1: A comparison of Caladan to state-of-the-art systems that use partitioning to manage interference. Caladan can converge to the right resource configuration 500,000 \times faster.

3 Background

Throughout this paper, we discuss three forms of interference that can occur when sharing a CPU: hyperthreading interference, memory bandwidth interference, and LLC interference. Hyperthreading interference is usually present at a baseline level whenever tasks are running on *sibling* cores because the CPU divides certain physical core resources (e.g., the micro-op queue), but it can become more severe depending on whether shared resources (L1/L2 caches, prefetchers, execution units, TLBs, etc.) are contended. Memory bandwidth and LLC interference, on the other hand, can vary in intensity, but impact all cores that share the same physical CPU. As memory bandwidth usage increases, memory access latency slowly increases due to interference, until memory bandwidth becomes saturated; access latency then increases exponentially [62]. LLC interference is determined by the amount of cache each application uses: when demand exceeds capacity, LLC miss rates increase.

In this section, we discuss why existing systems are unable to manage abrupt changes in interference (§3.1) and explore the limitations imposed on them by the hardware extensions available in commercial CPUs (§3.2).

3.1 Existing Approaches to Interference

State-of-the-art systems such as Heracles [38] and Parties [12] handle interference by dynamically partitioning resources, such as cores and LLC partition sizes. However, both Heracles and Parties make decisions and converge to new resource allocations too slowly to manage bursty interference (Table 1). There are two main reasons. First, both systems detect interference using application-level tail latency measurements, which must be measured over hundreds of milliseconds in order to obtain stable results; the Parties authors found that shorter intervals produced “noisy and unstable results” [12]. Second, both systems make incremental adjustments to resource allocations, gradually converging to a configuration that can meet latency objectives. These systems lack the ability to identify the source of interference (application and contended resource) directly, so convergence can involve significant trial-and-error as different resources are throttled, requiring seconds to converge to a new resource allocation. During the adjustment period, latency often continues to suffer because the LC task must wait to be given enough resources to reduce its queueing delay buildup.

Thus, both Heracles and Parties take at least 50 \times as long to adapt to changes in interference as the duration of a GC cycle in our example. As a result, operators must make tradeoffs based on tunable parameters: either tail latency tolerances (e.g., 99.9th percentile tail latency) can be set higher, causing the GC interference to be tolerated without resource reallocations, or they can be set lower, causing the GC workload to be throttled continuously. Because the GC workload causes minimal interference during the majority of its execution (while not collecting garbage), faster reaction times are needed to keep cores busy without compromising tail latency.

In addition to convergence speed, existing systems suffer from scalability limitations. For example, a typical datacenter server must handle several LC and BE tasks simultaneously [66, 71], but Heracles is limited to only a single LC task (and many BE tasks). Parties can support multiple LC and BE tasks, but because it can only guess at which task is causing interference, its convergence time increases with each additional task.

The hardware mechanisms on which these systems rely also impose limitations. For example, hyperthreads lack control over resource partitioning, so Heracles and Parties turn them off entirely. Using both hyperthreads on a core simultaneously can yield up to 30% higher throughput than using a single hyperthread [40, 44, 45, 54], so this lowers system throughput significantly. Furthermore, the available hardware partitioning mechanisms that can be controlled constrain both reaction speeds and scalability. We discuss this problem next.

3.2 Limitations of Hardware Extensions

Intel has added several extensions to its server CPUs that are designed to partition and monitor the LLC and memory bandwidth. These extensions are optimized for scenarios where resource demand changes slowly, but as shown in our study of the GC workload, this assumption does not always hold. To better understand these limitations, we discuss each component in more detail.

The most commonly used extension is CAT, a technology that divides portions of the LLC between tasks to increase performance determinism [21]. CAT’s way-based hardware implementation suffers from two limitations. First, changes to the partition configuration can take considerable time to have an effect; Intel cautions that “a reduction in the performance of [CAT] may result if [tasks] are migrated frequently” [26, sec. 17.19.4.2]. Appropriately sizing a partition, however, is challenging under time-varying demand because it must be large enough to accommodate peak usage. Second, CAT must divide a finite number of set-associative ways between partitions, reducing associativity within each partition. Unfortunately, performance can degrade significantly as associativity decreases [56, 67]; KPart avoids this by grouping complementary tasks together in the same partition, but it relies on frequent online profiling to identify groupings, resulting in high tail latency [18].

Another extension called Memory Bandwidth Allocation (MBA) applies a per-core rate limiter to DRAM accesses to throttle bandwidth consumption. MBA is necessary for systems that statically assign cores because it is the only method they can use to limit bandwidth consumption. Unfortunately, it is at odds with our goal of achieving high CPU utilization: a core that is heavily rate-limited by MBA will spend the majority of its time stalling. Instead, we found it is more efficient to allocate fewer cores, achieving the same throughput for a task, but with higher per-core utilization.

Finally, configuring partitioning mechanisms effectively requires the attribution of resource usage to specific tasks. To help with this goal, Intel introduced Cache Monitoring Technology (CMT) and Memory Bandwidth Monitoring (MBM) [72]. Unfortunately, these mechanisms are unable to detect changes in system conditions quickly. For example, when monitoring a streaming task with CMT, it takes 112 ms for its cache occupancy measurement to stabilize [21]. Similarly, we discovered experimentally that MBM requires milliseconds to accurately estimate memory bandwidth usage.

4 Challenges and Approach

Our overarching goal is to maintain performance isolation while maximizing CPU utilization. Achieving this goal is difficult because managing changes in interference requires microsecond-scale reaction times. Partitioning resources in hardware is too slow for these timescales (§3.2), so Caladan’s approach is to instead manage interference by controlling how cores are allocated to tasks. Prior systems have adjusted cores as part of their strategy for managing interference [12, 28, 38, 70], but Caladan is the first system to rely exclusively on core allocation to manage multiple forms of interference. To mitigate interference quickly enough, we had to overcome two key challenges:

1. **Sensitivity:** For fast and targeted reactions, Caladan requires control signals that can identify the presence of interference and its source—task and contended resource—within microseconds. Commonly used performance metrics like CPI [71] or tail latency [12, 38] (as well as hardware mechanisms like MBM and CMT) are too noisy to be useful over short timescales. Metrics like queueing delay [8, 42, 47, 68] can be measured over microsecond timescales, but cannot identify the source of interference, only that a task’s performance is degrading.
2. **Scalability:** Existing systems depend heavily on the Linux Kernel in order to gather control signals and adjust resource allocations (e.g., using `sched_setaffinity()` to adjust core allocations) [8, 12, 20, 38, 47, 52, 68]. Unfortunately, Linux adds overhead to these operations, and these overheads increase in the presence of interference and as the number of cores and tasks increase.

We address the challenge of sensitivity by carefully selecting control signals that enable fast detection of interference

Caladan’s Actions to Mitigate Interference		
Contended Resource	Impact of Interference	
	↑ Service Times	↓ Compute Capacity
Hyperthreads	idle sibling core	add victim cores
Memory Bandwidth	throttle antagonist	add victim cores
LLC	none	add victim cores

Table 2: When a resource (left) becomes contended, Caladan takes action to avoid increased service times (middle). When this is insufficient to maintain compute capacity, Caladan takes additional action (right).

and by dedicating a core to monitor these signals and take action to mitigate interference as it arises. We address the challenge of scalability with a Linux Kernel module named KSCHED. We describe these in more detail below.

4.1 Caladan’s Approach

Caladan dedicates a single core, called the *scheduler*, to continuously poll and gather a set of *control signals* over microsecond timescales. The scheduler uses these signals to detect interference and then reacts by adjusting core allocations. The scheduler is designed to manage several forms of interference (§3), using control signals tailored to each. For hyperthreads, we assume interference is always present when both siblings are active (because some physical core resources are partitioned) and focus on reducing interference for the requests that will impact tail latency—that is, the longest running requests [70]. We measure request processing times to identify these requests. For memory bandwidth, we measure global memory bandwidth usage to detect DRAM saturation and measure per-core LLC miss rates to attribute usage to a specific task. For cases like the LLC where we cannot directly measure or infer interference, we can still measure a key side effect of interference: increased queueing delays, caused by reductions in compute capacity. By focusing on interference-driven control signals, Caladan can detect problems before quality of service is degraded.

Table 2 summarizes the actions Caladan takes to mitigate interference. We first try to prevent service time increases by reducing interference directly. For example, Caladan reduces hyperthreading interference by controlling which logical cores (hyperthreads) may be used, idling a logical core when its sibling exceeds a request processing time threshold. In addition, it reduces memory bandwidth interference by limiting how many cores each task may use; this is effective because reducing the number of cores allocated to a task reduces its memory bandwidth usage. However, reducing LLC interference is more difficult: the magnitude of LLC interference is determined primarily by how much LLC capacity a task uses, but reducing a task’s number of cores reduces its LLC access rate rather than its LLC capacity. Therefore, Caladan compensates for LLC interference—and any remaining hyperthreading and memory bandwidth interference—by granting extra cores to victim tasks, allowing them to recoup

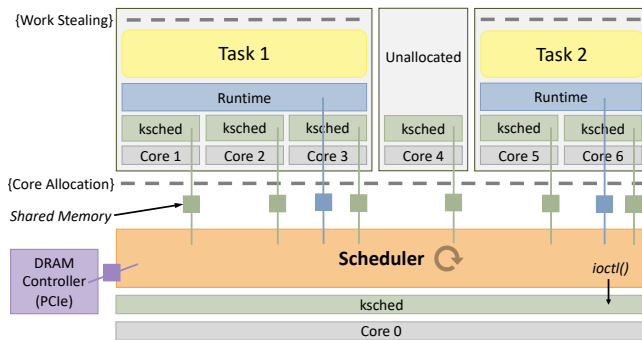

Figure 2: Caladan’s system architecture. Caladan relies on a scheduler core to gather control signals from shared memory regions (provided by KSCHED, runtimes, and the DRAM controller). It uses these control signals to adjust core allocations via KSCHED.

the compute capacity lost to interference. Although this cannot fully protect service times, it can prevent queueing delays.

Finally, Caladan introduces a Linux Kernel module called KSCHED. KSCHED performs scheduling functions across many cores at once in a matter of microseconds, even in the presence of interference. KSCHED achieves these goals with three main techniques: (1) it runs on all cores managed by Caladan and shifts scheduling work away from the scheduler core to cores running tasks; (2) it leverages hardware support for multicast interprocessor interrupts (IPIs) to amortize the cost of initiating operations on many cores simultaneously; and (3) it provides a fully asynchronous scheduler interface so that the scheduler can initiate operations on remote cores and perform other work while waiting for them to complete.

5 Design

5.1 Overview

Figure 2 presents the key components of Caladan and the shared memory regions between them. Caladan shares some architectural and implementation building blocks with Shenango [47]: each application is linked with a runtime system, and a dedicated scheduler core (run with root privileges) busy polls shared memory regions to gather control signals and make core allocations. Both systems are designed to interoperate in a normal Linux environment, potentially managing a subset of available cores.

Despite these commonalities, Caladan adopts a radically different approach to scheduling and relies on different scheduling mechanisms. Shenango uses queueing delay as its only control signal to manage changes in load; Caladan uses multiple control signals to manage several types of interference as well as changes in load. Moreover, Shenango’s scheduler core combines network processing with CPU scheduling; Caladan’s scheduler core is only responsible for CPU scheduling, eliminating packet processing bottlenecks (§6). Finally, Shenango relies on standard Linux system calls to allocate cores, limiting its scalability; Caladan uses KSCHED to more efficiently perform its scheduling functions, including pre-

empting tasks, assigning cores to tasks, detecting when tasks have yielded voluntarily, and reading performance counters from remote cores.

Caladan’s runtimes share many properties with those of Shenango. Applications managed by Caladan run inside normal Linux processes, which we refer to as *tasks*. Within each task, the runtime provides “green” threads (light-weight, user-level threads) and kernel-bypass I/O (networking and storage). Runtimes use work stealing to balance load across the cores that are allocated to them—a best practice for minimizing tail latency [51]—and yield cores when they run out of work to steal. Handling threading and I/O in userspace makes managing interference easier in two ways. First, by performing all processing inside the task that needs it, we can better manage the resource contention it generates. By contrast, the Linux Kernel handles I/O on behalf of its tasks, making it difficult to attribute resource usage or interference to a specific task. Second, we can easily instrument the runtime system to export the right per-task control signals (discussed further in §5.2).

Provisioning cores: Users provision each task with a discrete number of *guaranteed cores* (zero or more) that are always available when needed. They can also allocate tasks additional *burstable cores* beyond the number guaranteed, allowing them to make use of any idle capacity. Additionally, each task is designated as LC or BE. BE tasks operate at a lower priority: they are only allocated burstable cores when LC tasks do not need them, they are always provisioned zero guaranteed cores, and they are throttled as needed to manage interference.

In some configurations, it may not be possible to manage interference without harming the performance of LC tasks. To prevent these cases, we recommend a configuration that leaves a small number of cores that are not guaranteed to any task, providing enough slack to manage interference. Caladan can also detect when provisioning constraints prevent it from mitigating interference. As a last resort, this information could be reported back to the cluster scheduler so that it could migrate tasks to other machines. A rich body of prior work has explored adding similar types of interference coordination, as well as identifying complementary workloads, at the cluster scheduler layer [12, 15, 16, 41, 69, 71].

5.2 The Caladan Scheduler

Figure 3 shows the scheduler’s key components, the control signals they each use, and their interactions. Separate controller modules detect memory bandwidth and hyperthreading interference, each placing constraints on how cores can be allocated and revoking cores as necessary. The memory bandwidth controller restricts how many cores can be assigned to a task, while the hyperthread controller bans cores within sibling pairs. A top-level core allocator incorporates these restrictions and decides when to grant additional cores to tasks. It tries to minimize queueing delay (to manage changes in load and any unmitigated interference), allocating cores to tasks in a way that respects constraints from the controllers and each

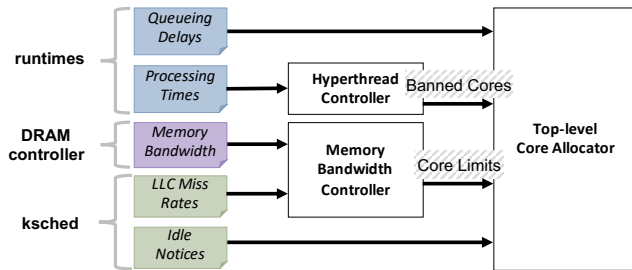

Figure 3: The flow of information through Caladan’s scheduler. Control signals flow from runtimes, the DRAM controller, and KSCHED to the controllers and top-level allocator. The hyperthread and memory bandwidth controllers impose constraints on which and how many cores the top-level allocator may grant.

task’s resource configuration (the number of guaranteed cores, BE vs. LC, etc.). The controllers and core allocator run once every $10\ \mu\text{s}$ on the scheduler’s dedicated core. Because the scheduler can reallocate cores so quickly, it is possible to allocate fractional cores to tasks on average over time (e.g., when less than a full core is needed to accommodate load). This is made efficient through KSCHED’s scheduling optimizations (§5.3).

The scheduler gathers control signals from three sources. First, runtimes provide information about request processing times and about queueing delays. Second, the DRAM controller provides information about global memory bandwidth usage. Third, KSCHED provides information about per-core LLC miss rates and notifies the scheduler core when a task has yielded voluntarily. We now discuss each component in more detail. We present each algorithm as synchronous code for clarity, but to handle many tasks concurrently without delaying the scheduler, all code is asynchronous in practice. Each algorithm relies on one tunable parameter; these are described in more detail in Appendix A.

5.2.1 The Top-level Core Allocator

The goal of the top-level core allocator is to grant more cores to tasks that are experiencing queueing delays, whether these delays are due to lingering interference (as shown in the rightmost column of Table 2) or due to changes in load. Algorithm 1 shows its basic operation. The core allocator periodically checks the queueing delay of each task, and, when permitted by the memory bandwidth controller, tries to add cores to the tasks that have delays above a configurable per-task threshold (THRESH_QD). Queueing can occur in each runtime core’s green thread runqueue, network ingress queue, storage completion queue, and timer heap. Each queued element contains a timestamp of its arrival time, and all queues are placed in shared memory. `QueueingDelay()` computes the delay for each core by summing the delays experienced by the oldest element in each of its queues. It then reports the maximum delay observed across the task’s cores.

When a task’s delay exceeds its THRESH_QD , the allocator

```

1 while True:
2     for each task T:
3         if QueueingDelay(T) < THRESH_QD[T]:
4             continue;
5         if T is limited by BW controller:
6             continue;
7         // try to allocate a core
8         for each core C:
9             if C is banned by HT controller:
10                continue;
11             if task_on_core[C] has priority over T:
12                continue;
13             score[C] = CalculateScore(C, T);
14             find core C with highest score;
15             allocate C to T (if found);
16         sleep(10 μs);

```

Algorithm 1: The top-level core allocator.

loops over all cores, checking which cores are allowed by the hyperthread controller and checking which tasks are running on each core. An idle core can be allocated to any task, but a busy core can only be preempted if the core provisioning configuration allows it. For example, if an LC task is only using guaranteed cores, it cannot be preempted by another task. Moreover, a BE task can never preempt an LC task.

Finally, `CalculateScore()` assigns a score to each core, and the core allocator picks the allowed core with the highest score (if one is found). Our scoring function is based on three factors (in order of priority). First, we prefer sibling pairs that are both idle because they have no hyperthreading interference. Second, we prefer hyperthread pairings between *different* tasks because hyperthreading is most efficient when tasks have different performance bottlenecks [31, 45]. Finally, we optimize for temporal locality: Caladan keeps track of the time each task last used each core, and gives the most recent timestamp the highest score. Timestamps are shared between hyperthread siblings, reflecting their shared cache resources.

The core allocator also receives notifications from KSCHED whenever a runtime yields a core voluntarily (not shown in Algorithm 1). When this happens, it updates the `task_on_core` array and immediately tries to grant the core to another task, reducing the cycles the core spends idling.

5.2.2 The Memory Bandwidth Controller

Algorithm 2 shows our memory bandwidth controller. Our aim is to use the majority of available memory bandwidth while avoiding saturation. The memory bandwidth controller periodically polls the DRAM controller’s global memory bandwidth usage counter, calculating the access rate since the last polling interval, and triggers when it crosses a saturation threshold (THRESH_BW). It then attributes memory bandwidth usage to a specific task by relying on KSCHED to efficiently sample LLC misses from the performance monitoring unit (PMU) [25] of each scheduled core. We found that LLC misses are a good indicator of overall memory bandwidth

```

1 while True:
2     if GlobalMemBandwidth() < THRESH_BW:
3         increment the core limit on the most limited task;
4         sleep(10  $\mu$ s);
5         continue;
6     for each core C:
7         start[C] = ReadLLCMisses(C);
8     sleep(10  $\mu$ s);
9     for each core C:
10        end = ReadLLCMisses(C);
11        misses[task_on_core[C]] += end - start[C];
12    find task T that is BE and has the highest misses;
13    decrement task T's core limit and revoke a core;

```

Algorithm 2: The memory bandwidth controller.

```

1 while True:
2     for each core C:
3         T = task_on_core[C]
4         if T is LC and now - GetRequestStartTime(C)  $\geq$ 
5             THRESH_HT[T]:
6             ban sibling of C;
7         else:
8             unban sibling of C;
9     sleep(10  $\mu$ s);

```

Algorithm 3: The hyperthread controller.

usage, with the exception that they exclude non-temporal memory accesses, which don't allocate lines in the cache. Fortunately, these are rarely used, but we recommend they be counted in future CPUs. Waiting 10 μ s between samples is enough to accurately estimate LLC misses. The bandwidth controller revokes one core from the worst offending task every time it runs until memory bandwidth is no longer saturated. When one task is throttled, another task (that consumes less memory bandwidth) can still use the throttled core.

While Algorithm 2 summarizes this controller's basic behavior, we had to take extra steps to improve its accuracy. First, because `ReadLLCMisses()` initiates PMU counter reads with IPIs (see §5.3), there can be timing skew. Therefore, KSCHEd includes the local timestamp counter (TSC), which is stable across cores, when it stores PMU results. This allows us to calculate an LLC miss rate instead of a raw miss count. Second, we discard samples from tasks that have yielded or have been preempted during the measurement interval.

5.2.3 The Hyperthread Controller

Caladan's hyperthread controller detects hyperthread interference and then bans use of the sibling hyperthread until the current request completes (Algorithm 3). Runtimes place timestamps in shared memory to indicate when each hyperthread begins handling a green thread. The hyperthread controller then uses `GetRequestStartTime()` to retrieve these timestamps and check if the current thread has been running for more than a per-task processing time threshold (*THRESH_HT*).

When the threshold has been exceeded, the controller bans

use of the sibling hyperthread via KSCHEd. The sibling's runtime receives a request from KSCHEd to preempt the core and places the current green thread back into its runqueue. The top-level core allocator can detect this as an increase in queueing delay and add back a different (not banned) core. Then KSCHEd places the sibling in the shallow C1 idle state using the `mwait` instruction; `mwait` parks the local hyperthread and reallocates shared physical core resources to the sibling, increasing its performance.

Caladan's hyperthread controller benefits from global knowledge. First, it will only ban a sibling that is handling an LC task if that LC task can be allocated another core, to avoid degrading throughput under high load. Second, if there are not enough cores available, it will prioritize speeding up the green threads that have spent the most time processing a request, keeping tail latency as low as available compute capacity permits. The hyperthread controller can also unban cores, respecting the same priority, when the top-level core allocator needs to allocate a guaranteed core, but none are available due to bans.

Caladan's approach to managing hyperthread interference was inspired by Elfen Scheduling [70]. Our policy for identifying interference is similar to Elfen's refresh budget policy, and both use `mwait` to idle hyperthreads. However, Caladan's approach differs in two key ways. First, Elfen relies on trusted BE tasks to measure interference and yield voluntarily, while Caladan's scheduler makes and enforces these decisions, leveraging the benefits of global knowledge. Second, Elfen can only support pinning one LC task and one BE task to each hyperthread pair. Instead, we allow any pairing (even self pairings) and can handle interference between LC tasks. This enables significantly higher throughput because all logical cores are available for use by any task (§7.3).

5.2.4 An Example: Reacting to Garbage Collection

As an example, we explain how Caladan's scheduler responds when a GC cycle begins, causing memory bandwidth interference for an LC task (the workload depicted in Figure 1). As soon as global memory bandwidth usage exceeds *THRESH_BW*, the memory bandwidth controller will revoke cores from the GC task, revoking one core every 10 μ s until total memory bandwidth usage falls below *THRESH_BW* (Algorithm 2). In the meantime, the LC task may suffer from interference, increasing its queueing delay. This will cause the top-level core allocator to grant it additional cores, beginning with any idle cores, but preempting additional cores from the GC task if necessary. It will add one core every 10 μ s until the LC task's queueing delay falls below its *THRESH_QD* again (Algorithm 1). Once the GC interference has been successfully mitigated, the LC task will yield the extra cores.

5.3 KSCHEd: Fast and Scalable Scheduling

KSCHEd's goal is to efficiently expose control over CPU scheduling to the userspace scheduler core. A scheduler core

that relies on the current Linux Kernel system call interface is subject to its limitations; KSCHEd must overcome these. First, Linux system calls, like `sched_set_affinity()`, perform computationally expensive work (e.g., locking runqueues) on the core that calls them. Second, Linux system calls block and reschedule while waiting for their operation to complete, preventing the scheduler core from performing other work. Third, Linux system calls can only perform one operation at a time, squandering any opportunity to amortize costs across multiple operations and cores. Finally, cores may only directly read their own performance counters and Linux provides no efficient mechanism to query those on other cores.

KSCHEd adopts a radically different approach from Linux's existing mechanisms, supporting direct communication between the scheduler core and kernel code running on other cores via per-core, shared-memory regions. The scheduler core writes commands into these regions and then uses an `ioctl()` to *kick* the remote cores by sending them IPIs. KSCHEd then executes the commands (in kernelspace on the remote cores) and writes back results.

KSCHEd supports three commands: waking tasks (potentially preempting the current task), idling cores, and reading performance counters. Before preempting a task or idling a core, KSCHEd delivers a signal to the runtime to give it a few microseconds to yield cleanly, saving the current green thread's register state and placing it back in the runqueue. Then, to wake a new task on a core, KSCHEd locks the task's affinity so that Linux cannot migrate it to another core and calls into the Linux scheduler. To idle a core instead, KSCHEd calls `mwait`. Finally, KSCHEd can sample any performance counter on any core, and includes the TSC in the response.

When the scheduler kicks a core, the IPI handler immediately processes any pending commands. Commands can also be processed without IPIs by cores that are idle through efficient polling. To achieve this, KSCHEd bypasses the standard Linux idle handler, setting a flag that notifies the scheduler core that the current task has yielded voluntarily. KSCHEd then checks for new commands; if none are available, it runs the `monitor` instruction, telling the core to watch the cache line containing the shared region. Finally, it parks the core with the `mwait` instruction, placing it in the shallow `C1` idle state. `mwait` monitors cache coherence messages and immediately resumes execution when the shared region is written to by the scheduler core.

One of the most expensive operations that both Linux and KSCHEd must perform is sending IPIs. When there are multiple operations, KSCHEd leverages the multicast capability of the interrupt controller to send multiple IPIs at once, significantly amortizing costs. To facilitate this, the scheduler core writes all pending operations to shared memory and then passes a list of cores to kick to an `ioctl()` that initiates IPIs. In addition, all of KSCHEd's commands are issued asynchronously, so that the scheduler core can perform other work while waiting for them to complete. Finally, KSCHEd

performs expensive operations such as sending signals and affinizing tasks to cores on the targeted cores rather than on the scheduler core. In combination, these three properties allow KSCHEd to perform scheduling operations with low overhead, enabling Caladan to support high rates of core reallocation and performance counter sampling even with many concurrent tasks (§7.3).

6 Implementation

Caladan is derived from the open-source release of Shenango [61], but we implemented a completely new scheduler and the KSCHEd kernel module, which are 3,524 LOC and 533 LOC, respectively. Shenango was a good starting point for our system because of its feature-rich runtime with support for green threads and TCP/IP networking. Moreover, Shenango's runtime is already designed to handle signals to cleanly preempt cores [47].

We modified Shenango's runtime in two important ways. First, Shenango relies on its scheduler core to forward packets in software to the appropriate runtime over shared memory queues. Instead, we linked the `libibverbs` library directly into each runtime, providing fast, kernel-bypass access to networking. This implementation strategy allowed us to completely eliminate the packet forwarding bottlenecks imposed by Shenango and also reduced our scheduler core's exposure to interference, by reducing its memory and computational footprint. Our scheduler core measures packet queueing delay by mapping the NIC's RX descriptor queues (for each task) over shared memory and accessing the packet arrival timestamps encoded in the descriptors by the NIC. Second, we augmented the runtime with support for NVMe storage using Intel's SPDK library to bypass the kernel. These changes required us to add 2,943 new LOC to the runtime, primarily to add integration with `libibverbs` and SPDK.

To support idling in KSCHEd, each per-core shared memory region uses a single cache line (64 bytes) because `mwait` can only monitor regions of this size. We packed these cache lines into a contiguous array so that our scheduler core could take advantage of hardware prefetching to speed up polling. KSCHEd allows the scheduler core to control which idle state `mwait` enters, but we have not yet explored power management. We also modified the Linux Kernel source to accelerate multicast IPIs; although the Linux Kernel provides an API called `smp_call_function_many()` that supports this feature, it imposes additional software overhead, especially under heavy memory bandwidth interference.

7 Evaluation

We evaluate Caladan by answering the following questions:

1. How does Caladan compare to previous systems (§7.1)?
2. Can Caladan colocate different tasks while maintaining low tail latency and high CPU utilization (§7.2)?

3. How do the individual components of Caladan’s design enable it to perform well (§7.3)?

Experimental setup: We evaluate our system on a server with two 12 physical core (24 hyperthread) Xeon Broadwell CPUs and 64 GB of RAM running Ubuntu 18.04 with kernel 5.2.0 (modified to speed up multicast IPIs). We do not consider NUMA, and direct all interrupts, memory allocations, and threads to the first socket. The server is equipped with a 40 Gb/s ConnectX-5 Mellanox NIC and a 280 GB Intel Optane NVMe device capable of performing random reads at 550,000 IOPS. To generate load, we use a set of quad-core machines with 10 Gb/s ConnectX-3 Mellanox NICs connected to our server via a Mellanox SX1024 non-blocking switch. We tune the machines for low latency in accordance with recommended practices, disabling TurboBoost, CPU idle states, CPU frequency scaling, and transparent hugepages [37]. We also disable Meltdown [2] and MDS [24] mitigations, since these vulnerabilities have been fixed by Intel in recent CPUs. When evaluating Linux’s performance, we run BE tasks with low-priority using `SCHED_IDLE` and use kernel version 5.4.0 to take advantage of recent improvements to `SCHED_IDLE`. We use *loadgen*, an open-loop load generator, to generate requests with Poisson arrivals over TCP connections [61]. Unless stated otherwise, we configure all Caladan experiments with 22 guaranteed cores for LC tasks, leaving one physical core for the scheduler.

Evaluated applications: We evaluate three LC tasks. First, *memcached* (v1.5.6) is a popular in-memory, key-value store that has been extensively studied [43]. We generate a mix of reads and writes based on Facebook’s `USR` request distribution [6] (service times of about 1 μ s). Second, *silos* is a state-of-the-art, in-memory, research database [64]. We feed it the TPC-C request pattern, which has high service time variability (20 μ s median; 280 μ s 99.9%-ile) [63]. Silo is only a library, so we integrated it with a server that can handle RPCs, performing one transaction per request. Finally, we built a new NVMe block storage server inspired by Reflex [34], that we call *storage*. We added compression (using Snappy [1]) and encryption (using AES-NI [46]) to study the hyperthreading effects of RPC frameworks that rely on vector processing. We preload the SSD with XML-formatted data from Wikipedia [39], and issue requests for blocks of varying lengths (99% 4KB, 1% 44KB) to evaluate service time variability (35 μ s and 250 μ s for each respective size).

For BE tasks, we use workloads from the PARSEC benchmark suite [9]. In particular, we evaluate *x264*, an H.264/AVC video encoder, *swaptions*, a portfolio pricing tool, and *stream-cluster*, an online clustering algorithm. We modified *swaptions* to use the Boehm garbage collector to allocate its memory objects [10], allowing us to study the interference caused by garbage collection; we call this version *swaptions-GC*. All three workloads exhibit phased behavior, changing their resource usage over regular intervals (some have much larger variance than others). Finally, we evaluate a synthetic antago-

nist that continuously reads and writes arrays of memory in two configurations: *stream-L2* displaces the L2 cache, while *stream-DRAM* displaces the LLC and consumes all available memory bandwidth.

All applications run in our modified Shenango runtime, which supports standard abstractions such as TCP sockets and the pthread interface (via a shim layer), making it relatively straightforward to port and develop applications (§8).

Parameter tuning: Caladan has three parameters that are user-tunable and can make tradeoffs between latency and CPU efficiency. Appendix A explains how to tune these parameters and shows how sensitive Caladan’s performance is to particular choices of these parameters. In our evaluation, we tuned all three for low latency. First, we set `THRESH_QD` (the queueing delay threshold) to 10 μ s for all tasks. Second, we set `THRESH_BW` (the memory bandwidth threshold) to 25 GB/s. Finally, we set a `THRESH_HT` (the processing time threshold) for each LC task (not supported for BE tasks). We set it to 25 μ s for silo, 40 μ s for storage, and infinite for memcached.

Comparison with Parties: Parties [12] is the most relevant prior work for mitigating interference. It builds upon Heracles [38] by adding support for multiple LC tasks. Ideally, we would compare directly to Parties, but its source code is not publicly available, and we were unable to obtain it from the Parties authors. Instead, we reimplemented Parties in accordance with the details described in its paper.

By implementing Parties ourselves, we were able to use the same runtime system for both Caladan and Parties, so they could benefit equally from kernel-bypass I/O, allowing us to evaluate only differences in scheduling policy. We did not implement some components in Parties that were not relevant to our experiments. Specifically, our workloads do not contend over disk, network, or memory capacity. Managing these resources is important but unrelated to our focus on CPU interference. Moreover, we did not include the CPU frequency scaling controller, as reducing energy consumption is outside the scope of our work. We did implement all of Parties’ key mechanisms, including core allocation, CAT, and an external measurement client that samples tail latencies over 500 ms periods. We also invested considerable effort in tuning Parties’ latency thresholds to yield the best possible performance.

Normally, Parties leaves hyperthreads disabled because it is unable to manage this form of interference, reducing its CPU throughput. Instead, we enabled hyperthreads with a policy that prefers self pairings. For specifically memcached—the workload we evaluated—this forms a complementary pairing that has minimal effect on latency, but allowed us to conduct a direct comparison with the same number of cores. The addition of kernel-bypass networking and hyperthread pairing enable our version of Parties to significantly outperform the reported performance of the original, so we refer to it as *Parties**.

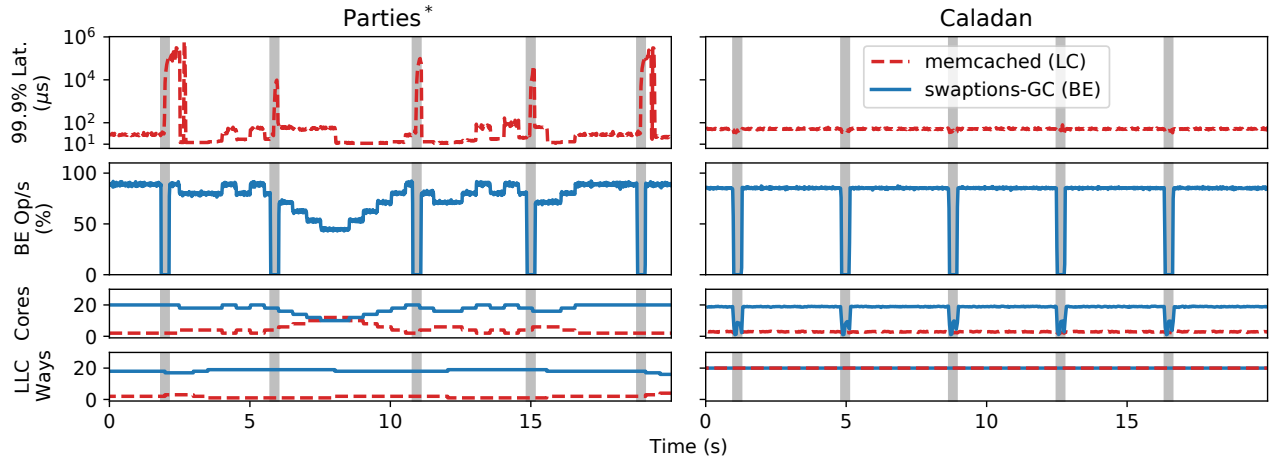

Figure 5: Timeseries of memcached colocated with a garbage-collected BE task for Parties* (left) and Caladan (right). Gray bars indicate GC cycles in the BE task. The Parties* resource controller algorithm is unable to provide performance isolation and high CPU utilization when tasks have dynamic resource demands, while Caladan maintains both. Top graphs have log-scaled y-axes.

Figure 4: Constant memory bandwidth interference degrades memcached performance for Linux and Shenango, but Caladan and Parties* can mitigate it. Note the log-scaled y-axis.

7.1 Comparison to Other Systems

Constant interference: To demonstrate the necessity of managing interference, we first compare Parties* and Caladan to systems that do not explicitly manage interference. We evaluate a relatively less challenging scenario, where an LC task (memcached) is colocated with stream-DRAM, a BE task that generates constant memory bandwidth interference.

Figure 4 illustrates that, as expected, both Linux and Shenango suffer significant increases in tail latency in the presence of colocation, reaching tail latencies up to $235\times$ and $6\times$ higher than without interference, respectively. Shenango’s throughput also decreases by 75% in the presence of interference, because its scheduler core becomes overloaded with packet processing, due to higher cache miss rates and memory access latency caused by stream-DRAM. In contrast, Caladan and Parties* are both able to maintain similar tail latency with and without interference, because they manage it explicitly. Both also achieve much higher throughput than Linux and Shenango because runtime cores send and receive packets directly using our runtime’s kernel-bypass network stack (§6),

preventing the Linux network stack or the scheduler core from becoming a bottleneck. While adapting Shenango to use our runtime’s kernel-bypass network stack would eliminate this throughput bottleneck, it would not improve the tail latency of LC tasks suffering from interference.

Phased interference: We now focus on interference caused by phased behavior, a more difficult and realistic case that Caladan is designed to solve. We revisit the garbage collection experiment from Section §2, colocating an instance of memcached with swaptions-GC. We issue 800,000 requests per second to memcached for a period of 120 seconds and measure its tail latency over 20 ms windows. We show the first 20 seconds of the experiment in Figure 5, which we found to be representative of the behavior during the entire experiment.

Caladan throttles the BE task’s cores as soon as each GC cycle starts, preventing latency spikes, and it gives back cores to the BE task as soon as the GC cycle ends, maintaining high BE throughput. Parties* attempts to find an allocation of cores and cache ways that minimizes latency and maximizes resources for the BE task, but it is unable to converge when resource demands are shifting at timescales much smaller than its 500 ms adjustment interval. Often Parties* grants additional cores in response to GC cycles, but these adjustments happen too slowly to prevent latency spikes. As a result, Parties* experiences 99.9% latency that is $11,000\times$ higher than Caladan during GC cycles. In addition, Parties* also harms BE throughput, achieving an average of 5% less than Caladan because it punishes swaptions-GC by too much and for too long. These results show that faster reaction times are essential when handling tasks with phased behaviors.

7.2 Diverse Colocations

Two tasks: To understand if Caladan can maintain its benefits in diverse situations, we evaluate 15 colocations between pairs of LC and BE tasks with different resource usages, service

Figure 6: Caladan can colocate many combinations of LC and BE applications with only modest latency penalties for LC tasks (top), while maintaining excellent throughput for BE tasks (bottom).

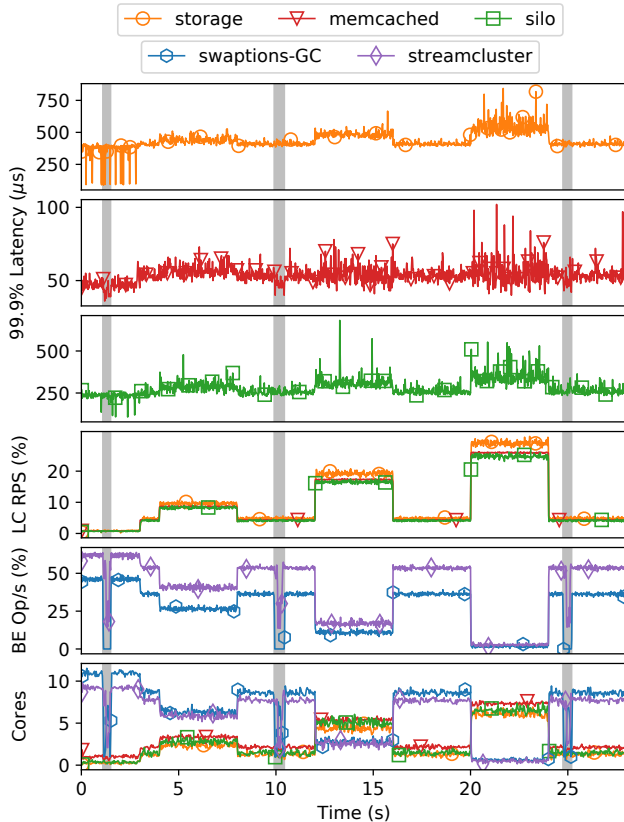

Figure 7: Caladan can colocate multiple LC and BE apps while providing performance isolation and high utilization. Gray bars indicate GC cycles in swaptions-GC.

time distributions, and throughputs. 9 out of 15 pairings include BE tasks with phased behaviors. We consider the impact on each LC task’s tail latency and the amount of throughput the BE task can achieve by using burststable cores.

In this experiment (Figure 6), each data point represents a different fixed average load offered to an LC task (columns), while it is paired with a BE task (colors/linetypes). Caladan is highly effective at mitigating interference: storage and mem-

cached achieve nearly the same tail latency as they do without colocation. Silo experiences a small increase in tail latency at low load because it is sensitive to LLC interference, leading to service time but not queueing delay increases. At higher load, silo generates self interference, so it experiences similar tail latency with and without colocation. Overall, Caladan can easily maintain microsecond-level tail latency under challenging colocation conditions.

At the same time, Caladan yields excellent BE task throughput. The exact BE throughput depends on the degree of resource contention with the LC task. For example, x264, swaptions-GC, and stream-L2 use less memory bandwidth (on average), so they can linearly trade CPU time with the LC task. Streamcluster and stream-DRAM both consume a larger amount of memory bandwidth, so they are throttled by our memory bandwidth controller. However, they also pair well with LC tasks as siblings (especially memcached) because they use different physical core resources. At higher LC load, these BE tasks are given fewer cores so they use less memory bandwidth and are then throttled less. Overall, BE throughput depends on the specific interactions between the BE and LC tasks, and varies with LC load. To the best of our knowledge, Caladan is the first system to achieve both microsecond-level LC tail latency and high BE throughput under such a broad range of conditions.

Many tasks: To demonstrate Caladan’s ability to manage many tasks simultaneously, we colocate all 3 of the LC tasks along with swaptions-GC and streamcluster (each LC task is configured with 6 guaranteed cores). Figure 7 shows a 30-second trace from this experiment, during which the load of each of the LC apps changes multiple times (4th graph) and swaptions-GC performs garbage collection three times (gray bars). When load or interference changes, Caladan converges nearly instantly. When GC is not running, the combination of streamcluster and swaptions-GC does not saturate memory bandwidth. However, when GC begins, both tasks together saturate DRAM bandwidth and are throttled by Caladan. Cal-

Figure 8: (a) KSCHED dramatically increases scheduling scalability over Linux. (b) Aggregated latency for 11 LC apps scheduled using KSCHED vs. Linux mechanisms. (c) The impact of each Caladan sub-controller on tail latency for storage paired with stream-DRAM.

adan’s fast reactions (up to 230,000 core reallocations per second) enable all three LC tasks to maintain low tail latency (top three graphs) throughout constantly shifting load and interference.

7.3 Microbenchmarks

KSCHED: To evaluate the benefits of KSCHED’s faster scheduling operations, we run a simple microbenchmark where we continuously rotate tasks to different cores. To measure scalability, we migrate different numbers of tasks together in groups. We run the benchmark both with KSCHED and with a variant that uses standard Linux system calls such as `sched_setaffinity()`, `tgkill()`, and `eventfd()`.

Figure 8a shows both the scheduling work (time spent by the scheduler core) and the scheduling latency (time until the migration completes) per migration. Both metrics benefit tremendously from KSCHED’s multicast IPIs, allowing it to amortize the cost of multiple simultaneous migrations. By contrast, Linux’s system call interface suffers from overhead and because it cannot support batching; operations must be serialized, increasing scheduling work by $43\times$ and scheduling latency by $5\times$ when moving 22 tasks. In addition, KSCHED maintains low scheduling work even with many tasks by offloading expensive operations such as sending signals to remote cores.

We demonstrate the value of these improvements in an experiment with 11 synthetic LC tasks and 2 synthetic non-interfering BE tasks. The LC tasks have $5\mu s$ average service times that are exponentially distributed and each is configured with 2 guaranteed cores. We compare against an earlier version of Caladan that employed the Linux scheduling mechanisms evaluated above. In Figure 8b, we show that Caladan is able to maintain much lower tail latency for the LC tasks (close to that of running with cores pinned). In this experiment, Caladan performs up to 560,000 core reallocations per second at its peak (at a load of 0.65 million RPS), while the version using Linux mechanisms bottlenecks at around 285,000 allocations per second. KSCHED provides similar benefits for sampling performance counters (not shown).

Controllers: We found that both the memory bandwidth and hyperthread controllers were necessary in order to ensure

Figure 9: Caladan enables higher LC throughput than Elfen by allowing arbitrary tasks to co-run on a physical core (including the same LC task).

isolation across a variety of tasks and loads. To provide one concrete example, Figure 8c evaluates the contribution of each controller module to the storage LC task when colocated with the stream-DRAM BE task. At very low loads, the bandwidth controller is sufficient to provide low tail latency. This is because as Caladan revokes cores from the BE task, it leaves the hyperthread pair cores of the LC task idle, rendering the hyperthread controller unnecessary. However, at higher LC loads, both controllers are necessary in order for the storage task to achieve nearly the same tail latency as it would have without colocation.

Next we focus on the hyperthread controller and evaluate the benefits of allowing any two tasks to co-run on a physical core (e.g., two LC tasks or even two hyperthreads in the same task). Figure 9 compares Caladan to two modified versions of Caladan that implement Elfen’s [70] scheduling policies, when colocating storage and stream-L2. Elfen’s borrow idle policy disallows co-running, only allowing the BE to run on a physical core when it is not being used by the LC; this yields low tail latency for the LC task but also low BE throughput. Elfen’s refresh budget policy, which Caladan generalizes (§5.2.3), yields higher BE throughput at the cost of a slight increase in tail latency, demonstrating the benefits of using both hyperthreads simultaneously. Caladan achieves 37% more LC throughput than Elfen by enabling the LC task to co-run with itself. Similarly, at low LC loads, Caladan is able to achieve 5% higher BE throughput than Elfen since BE tasks can use both hyperthread lanes. Finally, running Caladan with the hyperthread controller disabled yields slightly higher BE

throughput but at a cost of up to 117 μ s higher tail latency, highlighting the need to explicitly manage hyperthread interference to achieve both high throughput and low tail latency.

8 Discussion

Compatibility: Caladan requires applications to use its runtime system because it depends on it to export control signals to the scheduler, and to rapidly map threads and packet processing work across a frequently changing set of available cores. Our runtime is not fully Linux compatible, but it provides a realistic, concurrent programming model (inherited from Shenango) that includes threads, mutexes, condition variables, and synchronous I/O [47]. Caladan also includes a partial compatibility layer for system libraries (e.g., libpthread) that can support PARSEC [9] without modifications, giving us some confidence our design is flexible enough to support unmodified Linux applications in the future. Applications that do not use our runtime can coexist on the same machine, but they must run on cores that are not managed by Caladan, and they cannot be throttled if they cause interference.

The more fundamental requirement for Caladan is the need for LC tasks to expose their internal concurrency to the runtime (e.g., by spawning green threads), potentially requiring changes to existing code. If there is insufficient concurrency, a task will be unable to benefit from additional cores, hindering Caladan's ability to manage shifts in load or interference. In general, we recommend that tasks expose concurrency by spawning either a thread per connection or a thread per request. For example, normally memcached multiplexes multiple TCP connections per thread, but we modified it to instead spawn a separate thread to handle each TCP connection.

On the other hand, Caladan can support BE tasks that do not expose their internal concurrency, as it can still throttle them if they cause too much interference. For example, if a BE task is single-threaded (i.e., has no concurrency), and it consumes too much memory bandwidth, Caladan will oscillate between giving it one and zero cores, effectively time multiplexing its memory bandwidth usage. However, BE tasks can optionally achieve higher performance by exposing their internal concurrency: load will be more evenly balanced and they will be able to take advantage of burstable cores.

Limitations: Our current implementation of Caladan has two limitations. First, it is unable to manage interference across NUMA nodes. NUMA introduces additional shared resources that are vulnerable to interference, including an inter-socket interconnect and separate memory controllers per node. Fortunately, high-precision performance counters are available for these resources, and we plan to explore NUMA-aware interference mitigation strategies in the future, such as revoking cores or migrating tasks between nodes. Second, our scheduling policies do not minimize the threat of transient execution attacks across hyperthread siblings [3, 11, 65]. Ideally, only mutually-trusting tasks should be allowed to run on sibling

cores. At the time of writing, a similar capability is under development for the Linux Kernel [13].

Future work: One promising opportunity for future work is to incorporate hardware partitioning back into Caladan's design. For example, if a BE task uses high memory bandwidth and lacks temporal locality, many of the cache lines it occupies in the LLC will be wasted. Under these conditions, Caladan is still effective at preventing latency increases, but it must allocate extra cores to victim tasks. If future hardware partitioning mechanisms could be designed to accommodate frequently shifting LLC usage—or if static LLC usage could be identified and managed through existing mechanisms—CPU efficiency could be further improved.

9 Related Work

Interference management: Many prior systems manage interference between LC and BE tasks by statically partitioning resources [19, 28, 50, 62]. While this approach can reduce interference, it sacrifices CPU utilization because each task must be provisioned enough resources to accommodate peak load. Heracles [38], Parties [12], and PerfIso [27] instead adjust partitions dynamically. However, unlike Caladan, these systems cannot manage changes in interference while maintaining microsecond latency and high utilization.

Efforts to isolate the network [35, 36, 53] or storage [34] are complementary to Caladan. We do not currently focus on power management [32, 58] or TurboBoost [23], because we optimize for the setting in which all cores are fully utilized, but it should be possible to integrate power management with Caladan to improve its CPU efficiency at lower utilization.

User-level core allocators: To enable low latency in the face of fluctuating load, systems like IX [8], PerfIso [27], Shenango [47], and Arachne [52] introduce user-level core allocators that estimate load and reallocate cores to BE tasks when they are not needed by LC tasks. Similarly, TAS [33] and Snap [42] adjust cores in response to changes in packet processing load. Like these systems, Caladan manages changes in load through core allocations, but it goes a step further by using core allocation to manage interference too.

Scheduling optimizations: Shinjuku [30] proposes fine-grained preemption to reduce tail latency, using Dune [7] to provide fast, direct access to IPIs in userspace. KSCHED includes kernel optimizations that allow for similar performance when sending an IPI to a single core, but it speeds up IPIs over Shinjuku's reported speeds when sending more than one IPI at a time because of its multicast IPI optimization.

Dataplane systems: There has also been significant work on optimizing OS networking for throughput and latency [8, 29, 33, 48, 52, 55]. ZygOS proposes work stealing as a technique to reduce tail latency under variable service times [51]. Arachne [52] and Shenango [47] build a similar latency reduction strategy on top of green threads to improve programmability. Caladan builds upon all of these ideas to eliminate

Figure 10: Parameter sensitivity for the storage LC task; the parameters used in our evaluation appear in bold. (a) `THRESH_QD` allows an operator to achieve better tail latencies at the expense of BE throughput. (b) `THRESH_HT` reins in the latency of long requests, but setting it too low reduces BE throughput. (c) `THRESH_BW` is set to avoid exponential increases in memory access latencies.

network processing and queuing bottlenecks, allowing it to manage interference unperturbed by software overheads or load imbalances.

10 Conclusion

This paper presented Caladan, an interference-aware CPU scheduler that significantly improves performance isolation while maintaining high CPU utilization. Caladan’s effectiveness comes from its speed: by matching control signals and actions to the same timescale that interference affects performance, Caladan can mitigate interference before it can harm quality of service. Caladan relies on a carefully selected set of control signals to manage multiple forms of interference in a coordinated fashion, and combines a wide range of optimizations to rapidly gather control signals and make core allocations faster. These contributions allow Caladan to deliver microsecond-level tail latency and high CPU utilization while colocating multiple tasks with phased behaviors.

11 Acknowledgments

We thank our shepherd Kathryn S. McKinley, the anonymous reviewers, Frans Kaashoek, Malte Schwarzkopf, Akshay Narayan, and other members of PDOS for their useful feedback. We thank CloudLab [17] and Eitan Zahavi at Mellanox for providing equipment used to test and evaluate Caladan. This work was funded by the DARPA FastNICs program under contract #HR0011-20-C-0089, by a Facebook Research Award, and by a Google Faculty Award.

A Parameter Tuning and Sensitivity

In this Appendix, we describe how to set Caladan’s three user-tunable parameters and show how sensitive Caladan’s performance is to particular choices of these parameters. To illustrate the behavior of `THRESH_QD` and `THRESH_HT`, we colo-

cate the storage workload with stream-L2. For `THRESH_BW`, we colocate the storage workload with stream-DRAM. In each case, we vary a single parameter, while fixing other parameters to the values used in our evaluation.

`THRESH_QD` represents the per-task queuing delay limit before the top-level core allocator tries to grant another core. As shown in Figure 10a, an operator can trade some LC tail latency for higher BE throughput using a value of `THRESH_QD` larger than Caladan’s default 10 μ s. For example, a `THRESH_QD` of 100 μ s enables 7% more BE throughput at the cost of 54 μ s higher LC tail latency for these workloads. We chose to optimize for tail latency, and found that values below 10 μ s degraded BE throughput without further improving LC tail latency.

`THRESH_HT` places a worst-case limit on how long a request can be delayed by a task generating interference on its hyperthread sibling. If it is set too low (i.e., most request processing requires a dedicated physical core), BE throughput will suffer and LC latency will degrade at high load due to insufficient compute capacity. For a skewed service time distribution, like our storage workload, choosing a value above the median is a good heuristic. Figure 10b illustrates that setting `THRESH_HT` below the median of 35 μ s significantly lowers BE throughput, while values that are slightly above the median yield increased BE throughput and good tail latency. For workloads with service times less than 5 μ s (e.g., memcached), we recommend setting `THRESH_HT` to infinite because `mwait` requires a few microseconds to park a hyperthread.

Finally, `THRESH_BW` represents the global maximum allowed memory bandwidth usage before Caladan begins to throttle tasks. `THRESH_BW` should be set once per machine to a bandwidth just low enough to avoid the exponential increase in memory access latency that occurs close to memory bandwidth saturation. We use 25 GB/s for our machine (70–80% of its capacity), which keeps memory latency low for any access pattern. Figure 10c shows this setting trades a small amount of BE throughput in exchange for predictable latency.

Overload Control for μ s-Scale RPCs with Breakwater

Inho Cho Ahmed Saeed Joshua Fried Seo Jin Park Mohammad Alizadeh Adam Belay
MIT CSAIL

Abstract

Modern datacenter applications are composed of hundreds of microservices with high degrees of fanout. As a result, they are sensitive to tail latency and require high request throughputs. Maintaining these characteristics under overload is difficult, especially for RPCs with short service times. In this paper, we consider the challenging case of microsecond-scale RPCs, where the cost of communicating information and dropping a request is similar to the cost of processing a request. We present Breakwater, an overload control scheme that can prevent overload in microsecond-scale services through a new, server-driven admission control scheme that issues credits based on server-side queueing delay. Breakwater contributes several techniques to amortize communication costs. It engages in demand speculation, where it assumes clients have unmet demand and issues additional credits when the server is not overloaded. Moreover, it piggybacks client-side demand information in RPC requests and credits in RPC responses. To cope with the occasional bursts in load caused by demand speculation, Breakwater drops requests when overloaded using active queue management. When clients' demand spikes unexpectedly to $1.4 \times$ capacity, Breakwater converges to stable performance in less than 20 ms with no congestion collapse while DAGOR and SEDA take 500 ms and 1.58 s to recover from congestion collapse, respectively.

1 Introduction

Modern datacenter applications are composed of a set of microservices [15, 16, 36], which use Remote Procedure Calls (RPCs) to interact. To satisfy the low latency requirements of modern applications, microservices often have strict Service Level Objectives (SLOs), some measured in microseconds. Examples of microsecond-scale microservices include services that operate on memory-resident data, such as key-value stores [2, 25] or in-memory databases [41, 47]. Achieving microsecond-scale SLOs is possible under normal loads due to recent advances in operating systems [40] and network hardware [1]. However, maintaining tight SLOs remains a

challenge during overload, when the load on a server approaches or exceeds its capacity.

Server overload can cause *receive livelock* [33], where the server builds up a long queue of requests that get starved because the server is busy processing new packet arrivals instead of completing pending requests. This scenario is especially challenging for microsecond-scale RPCs because small delays or bottlenecks can cause SLO violations. Further, the small resource requirements of a short RPC allows a single server to process millions of requests per second, potentially from thousands of clients [10, 35, 50]. Thus, server overload can be caused by “RPC incast” [39, 48], where a large number of clients make requests simultaneously, leading to large queue build-up at the server.

The goal of overload control is to shed excess load to ensure both high server utilization and low latency. Existing overload control schemes broadly fall into two categories. One class of approaches drop requests at an overloaded server or proxy [11, 32, 38]. Other schemes throttle the sending rate of requests at clients [4, 29, 46]. Neither of these approaches performs well for short, microsecond-scale RPCs. Dropping very short requests at the server is not practical as the overhead is comparable to the service time of the request. On the other hand, client-based rate limiting requires clients to know the state of congestion at the server to accurately configure their rate limit, but it takes at least a network round-trip time (RTT) to obtain this information. For requests with service times comparable to the RTT, the delay in reacting to congestion can hurt performance significantly.

A further challenge is to scale the overload control system to large numbers of clients. In a large-scale system, many clients have sporadic demand for a specific server, sending it requests infrequently. Determining the right rate limit for such clients is difficult since they have a stale view of the extent of congestion at the server when making a request. One solution is to explicitly probe the server before sending a request. However, exchanging messages per request to obtain congestion information can impose a high overhead for microsecond-scale RPCs.

In this paper, we present Breakwater, an overload control system for μ s-scale RPCs. Breakwater relies on a server-driven admission control scheme where clients are allowed to send requests only when they receive credits from the server. It uses queuing delay at the server as the overload signal. If queuing delay is below an SLO-dependent threshold, Breakwater issues more credits to clients. Otherwise, it reduces the number of credits it issues.

Breakwater minimizes the overhead of coordination (i.e., the communication overhead for the server to know which clients need credits) using *demand speculation*. In particular, a Breakwater server only receives demand information from clients when such information can be piggybacked on requests. When all known demand is satisfied, the server distributes credits randomly to clients. This approach does not require coordination messages to determine demand in clients. However, demand speculation can lead to issuing credits to clients who do not need them at that moment. These unused credits lower server utilization. Thus, Breakwater issues extra credits to ensure high utilization. Such overcommitment introduces the potential for queue buildup at the server if many clients with credits send requests simultaneously (i.e., RPC incast). To mitigate the negative side effects of incast, Breakwater employs delay-based AQM to drop requests that arrive in bursts.

We implemented Breakwater as an RPC library on top of the TCP transport layer. Our extensive evaluation of various workloads demonstrates that Breakwater achieves higher goodput with lower tail latency compared to SEDA [48] and DAGOR [51], the best available overload control systems. For example, Breakwater achieves 6.6% more goodput and $1.9\times$ lower 99%-ile latency with clients' demand of $2\times$ capacity, compared to DAGOR with a synthetic workload. In addition, Breakwater scales to a large number of clients without degrading its benefits. For example, when serving 10,000 clients with memcached, Breakwater achieves 14.3% more goodput and $2.9\times$ lower 99%-ile latency than DAGOR. Compared to SEDA for the same workload, Breakwater achieves 5% more goodput and $1.8\times$ lower 99%-ile when the clients' demand is $2\times$ capacity.

Breakwater is available as open-source software at <https://inchocho89.github.io/breakwater/>.

2 Motivation and Background

2.1 Problem Definition and Objectives

Overload control is key to ensuring that backend services remain operational even when processing demand exceeds available capacity. Overload was identified as the main cause of cascading failures in large services [11]. Transient overload can occur for a variety of reasons. For example, it may not be cost-effective to provision enough capacity for maximum load [51]. Services can also experience unexpected overload conditions (faulty slow nodes, thermal throttling, hashing hot spots, etc.) despite capacity planning.

Without proper overload control, a system could experience livelock [33], where incoming requests are starved because the server is busy processing interrupts for new packet arrivals, producing no useful work as the majority of requests fail to meet their SLOs. Even when the average of clients' demand is less than the capacity, short-timescale bursty request arrival can degrade latency for short requests. Microsecond-timescale RPCs are much more prone to performance degradation due to short-lived congestion than RPCs with longer service times [45].

RPCs with microsecond-scale execution time are prevalent in modern datacenters. Such RPCs span a variety of operations on data residing in memory or fast storage like M.2 NVMe SSDs (e.g., key-value stores [2, 25] or in-memory databases [41, 47]). The move towards microservice architectures has only increased the prevalence of such RPCs [15, 16, 36]. Further, a single server must process μ s-scale requests at very high rates, possibly from thousands of clients [10, 35, 50]. To cope with μ s-scale RPCs, an ideal overload control mechanism should provide the following properties:

1. *No loss in throughput.* An RPC server should be processing requests at its full capacity regardless of overload, avoiding livelock scenarios. Further, the overhead of performing the overload control must be minimal.
2. *Low latency.* An ideal overload control scheme should ensure that any request that gets processed spends minimal time queued at the server. Low queuing latency ensures that processed RPCs meet their SLOs, and is particularly important for μ s-scale RPCs which tend to have tight SLOs.
3. *Scaling to a large number of clients.* For such short RPCs, clients with sporadic demand consume very little resources at the server. Thus, high server utilization requires scaling to a large number of clients. The ideal overload control system should be resilient to "incast" scenarios when a large number of clients send requests within a short period of time. In particular, overload control should prevent queue build-ups that result from incast without harming throughput.
4. *Low drop rate.* Dropping requests wastes resources at the server because it must spend time processing and parsing packets that will eventually be dropped. Furthermore, dropping requests harms the tail latency of RPCs, especially when network round-trip time (RTT) is comparable to RPC execution time, making retries more expensive. Thus, overload control should minimize the drop rate at the server.
5. *Fast feedback.* Clients have more flexibility to decide the next action if they can discover when a request is unlikely to be served within its SLO. Thus, if a server expects a request will violate its SLO, it should notify the client as soon as possible so that it can decide an alternative action without having to wait for the request to timeout (e.g., giving up on the request, sending it to another replica, issuing a sim-

(a) Goodput vs. clients' demand (b) Goodput vs. # clients with 1,000 clients clients' demand of 2M reqs/s

Figure 1: Goodput of CoDel and window-based rate limiting with different clients' demands and different numbers of clients

pler alternative request, degrading the quality of the service, etc. [18]).

Next, we examine existing overload control mechanisms, which were developed for RPCs with relatively long execution times. Our goal is to understand the challenges of designing an overload control system for μ s-scale RPCs.

2.2 Overload Control in Practice

The fundamental concept in overload control is to shed excess load before it consumes any resources [33]. This is typically achieved by either dropping excess load at the server or throttling the sending rate of requests at the client. We look at the performance impairments of these two popular overload control approaches, developed for RPCs with long execution times, when used for μ s-scale RPCs.

Active Queue Management (AQM). Such approaches operate as circuit breakers, dropping requests at a server or at a separate proxy under certain conditions of congestion. The simplest approach maintains a specific number of outstanding requests in the queue at the server, typically manually tuned by the server operator [11, 32, 37]. More advanced algorithms can improve performance and avoid the need for manual tuning. For example, CoDel maintains the queuing delay within a specific target value, dropping requests if the queuing delay exceeds the target [11, 32, 38]. RPC servers are typically required to report on success and on failure to avoid expensive timeouts [2, 37, 51]. This means that packets are processed, and failure messages are generated for dropped requests. This overhead is trivial when the message rate is low with a long execution time. However, it becomes a significant overhead in the case of μ s-scale RPCs.

To demonstrate the limitations of the AQM approach, we implemented an RPC server that uses CoDel for AQM. Our main evaluation metric is the *goodput* of the server, defined as the throughput of requests whose response time is less than the SLO. Figures 1 (a) and (b) demonstrate the goodput of CoDel with different clients' demands and different numbers of clients. This experiment uses a synthetic workload of requests with exponentially-distributed service time, with a mean of 10 μ s. The drop threshold parameter is tuned to achieve the highest goodput given an SLO of 200 μ s. As the clients' demand increases, more CPU is used for packet

processing even though majority of requests are dropped at server. As a result, less CPU can be used for RPC execution, which leads to goodput degradation. The goodput degradation gets worse with more number of clients. The reason is that the overhead of sending failure messages increases with more clients since fewer messages can be coalesced with the increased number of clients.

Client-side Rate limiting. In order to eliminate the overhead caused by dropping requests at the server, some overload control mechanisms limit the sending rate at the clients. With client-side rate limiting, clients probe the server, detect its capacity, and adjust their rate to avoid overloading the server [4, 29, 46, 49]. The reaction of clients to overload is delayed by a network RTT, which can lead to long delays when the execution time of RPCs is comparable to or less than the RTT. Further, the delay in getting feedback increases with the number of clients; consider the impact this has on overload control performance.

When the number of clients is small, the load generated by each individual client is large and each client exchanges messages with the server at a high frequency. This means that each client has a fresh view of the state of the server, allowing it to react quickly and accurately to overload. In this case, client-based approaches outperform AQM approaches because they have fresh enough information to prevent overload at the server.

As the number of clients increases, the load generated by each client becomes more sporadic and messages are exchanged at a lower frequency between any individual client and the server. This means that in the presence of a large number of clients, each client will have a stale or inaccurate estimate of server overload, leading to clients undershooting or overshooting the available capacity at the server. When many clients overshoot server capacity, it can lead to incast congestion, causing large queueing delays. AQM avoids high tail latency by dropping excess load at the server, leading to AQM outperforming client-based approach for a large number of clients, despite having less than ideal goodput.

To illustrate the limitation of client-side rate limiting with μ s-scale execution time, we implement window-based rate limiting used in ORCA [29]. The mechanism is similar to TCP congestion control. The client maintains a window size representing the maximum number of outstanding requests. Upon receiving a response, if the response time is less than the SLO, it additively increases the window size; otherwise, it multiplicatively decreases the window size. Figure 1 (a) and (b) depict the goodput of window-based rate limiting for exponentially-distributed service time of 10 μ s (SLO = 200 μ s) on average. We optimized the parameters (i.e. additive factor and multiplicative factor) to achieve the highest goodput. Window-based schemes typically support a minimum of one open slot in the window (i.e., a minimum of one outstanding request at the server). This is problematic when there is a large number of clients as each client can

always send one request, leading to incast and overwhelming the server. Rate-based rate limiting [4, 49] overcomes this limitation, but it still suffers from incast with a larger number of clients which results in high latency and low goodput.

Hybrid approaches that combine client-side rate limiting and AQM have also been proposed. We provide a more comprehensive evaluation of rate-based rate limiting and hybrid approaches in §5.

2.3 Challenges

Existing overload control schemes, developed for long RPCs, suffer significant performance degradation when handling μ s-scale RPCs. The fundamental challenge facing existing schemes is the need for coordination of clients in order to schedule access to the server under very tight timing constraints. This challenge is exacerbated by the following characteristics of short RPCs:

1. Short average service times. We aim to support execution times for RPCs on the order of microseconds. This requires devising an overload control scheme that can react at microsecond granularity while keeping coordination overheads significantly less than request service times. Achieving this compromise is challenging, and any errors in devising or implementing the overload control scheme can lead to either long queues and overload, or underutilization of the server.

2. Variability in service times. RPC execution times typically follow a long-tailed distribution [11, 17, 18]. The stochastic nature of RPC service times limits the accuracy of any coordination or scheduling at the client or server. Accurate scheduling requires knowledge of the execution time of each request in advance, which is not possible in the presence of long-tailed variability of execution times. Further, this variability creates ambiguity for overload detection because a single request can be long enough to cause significant queueing delay.

3. Variability in demand. Scheduling the access of clients to the server requires some knowledge of both the demand of clients and the capacity of the server. RPCs have various arrival patterns, and clients can have sporadic demand with periods of inactivity [10, 50]. Variability in demand can lead to low utilization because clients that are granted access to server capacity might not have enough demand to utilize it.

4. Large numbers of clients. All previous challenges are exacerbated as the number of clients increases: accurate coordination becomes more challenging and overheads become higher (§5.2). Furthermore, a larger number of clients increases demand variability because it makes the system more susceptible to bursts (i.e., many clients generating demand simultaneously).

The challenges a server overload control system faces bear some similarities to those observed in network congestion control. At a surface level, network and compute congestion can be managed by similar mechanisms, but they each have fundamentally different requirements. Both are necessary to

achieve good performance. Network congestion control aims to maintain short packet queues at switches while maximizing network link utilization. By contrast, overload control aims to maintain short request queues at the RPC server while maximizing CPU utilization. There are two critical differences between these problems: (a) RPC processing often has high dispersion in request service times while packet processing times are constant, and (b) client-side demand can fluctuate more significantly at the RPC layer because clients may give up after a timeout or choose to send an RPC to a backup server. On the other hand, once a network flow starts, it generally completes. With such high variability in processing time and demand, designing an overload control system requires overcoming different challenges than a network congestion control system.

2.4 Our Approach

Our work begins with insights from receiver-driven mechanisms proposed in recent work on datacenter congestion control. In receiver-driven congestion control, a receiver issues explicit credits to senders for controlling their packet transmissions, which provides better performance than conventional sender-based schemes [14, 24, 34]. Inspired by this line of work, our design has the following components:

1. Explicit server-based admission control: A client is only allowed to send a request if it receives explicit permission from the server. A server-based scheme allows for coordination that is based on the accurate estimation of the state of the server. Explicit admission control means that the load received by the server is completely controlled by the server itself. This allows for more accurate control that maintains high utilization and low latency. Server-based admission control can add an extra RTT for a client to request admission. We avoid this through piggybacking and overcommitting credits, as detailed later.

2. Demand speculation with overcommitment: The server requires knowledge of clients' demand in order to decide which client should be permitted to send requests. This is comparable to the need for clients to know about the state of the server in client-based schemes. Exchanging such information introduces significant overhead as the number of clients increases. Furthermore, as the execution time of RPCs decreases, the frequency of exchanging the demand information increases, further increasing overhead. The key difference between server-based schemes and client-based schemes is that we can relax the need for the server to have full information about clients' demand without harming performance. In particular, we allow the server to speculate about clients' demand and avoid lowering server utilization by allowing the server to overcommit, issuing more credits than its capacity.

3. AQM: Due to overcommitment, the server can occasionally receive more load than its capacity. Thus, we rely on AQM to shed the excess load. In our scheme, the need for AQM to drop requests is rare, as credits are only issued when the server is not overloaded.

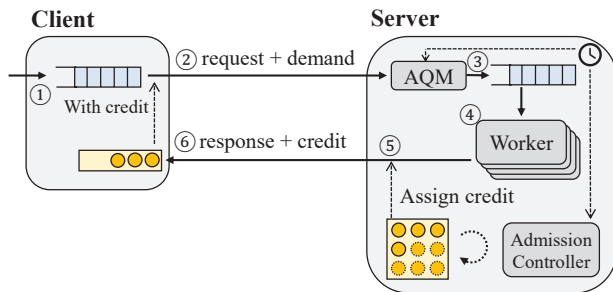

Figure 2: Breakwater overview

3 System Design

We present Breakwater, a scalable overload control system for μ s-scale RPCs. Figure 2 depicts an overview of the interaction between a Breakwater client and server pair. A new client joining the system sends a register message to the server, indicating the number of requests it has in its queue. The client piggybacks its first request to the registration message. The server adds the client to its client list, and if it is not overloaded it executes the request. The server then replies to the client with the execution result or a failure message. The server piggybacks with the response any credits it issued to the client depending on the demand indicated by the client. The client issues more requests depending on the number of credits it received. When the client has no further requests, it sends a deregister message to the server returning back any unused credits.

For the rest of the section, we present how Breakwater detects overload and how it reacts to it. In particular, we present how a server determines the number of credits it can issue, how to distribute them among clients, and how clients react to credits or the lack thereof.

3.1 Overload Detection

There are multiple signals we can utilize to determine whether a server is congested. CPU load is a popular congestion signal—it is often used to make auto-scaling decisions in cloud computing [5]. However, CPU utilization indicates only one type of resource contention that can affect RPC latency. For instance, requests contending for a hard disk can have high latency, but CPU utilization will remain low [22]. Moreover, using CPU utilization as a signal does not allow an overload controller to differentiate between the ideal scenario of 100% utilization with no delayed RPCs and a livelock state.

Another potential congestion signal is queue length at the server. A similar signal is widely used in network congestion control [8, 52]. Unfortunately, when RPC service times have high dispersion, queue length is a poor indicator of request latency. A more reliable signal is queuing delay, as it is accurate even under RPC service time variability. Furthermore, it is intuitive to map a target SLO to a target queuing delay at the server. Thus, Breakwater uses queuing delay as its congestion signal.

Effective overload control requires accurate measurement of the queuing delay signal. In particular, the signal should

account for the sum of each of the queuing delay stages a request experiences, ignoring non-overload induced delays. This ensures that the system only curbs incoming requests when it is overloaded. This is especially critical for microsecond-scale RPCs, as they leave little room for error.

Breakwater has two stages of queuing. Packets are queued while they await processing to create a request. Then, threads created to process requests are queued awaiting execution. Breakwater tracks and sums queuing delay at both of these stages. In particular, for every queue in the system, each item (e.g., a packet or a thread) is timestamped when it is enqueued. Each queue maintains the oldest timestamp of enqueued elements in a shared memory region, and this timestamp is updated on every dequeue. When the delay of a queue needs to be calculated, Breakwater computes it by taking the difference between the current time and the queue’s oldest timestamp. We use this approach instead of measuring explicit delays of each request (i.e., the timestamp difference between request arrival and the request execution) because we must keep track of the total queuing delay as a request moves from one queuing stage to another.

There are multiple sources of delay that are not caused by high utilization or overload. For example, long delays due to head-of-line blocking do not indicate a thread is waiting for resources, but rather it is a sign of poor load balancing. Accurate queuing delay measurement requires the system to avoid such delays. We find that the biggest source of such delays is the threading model used by the system. Our initial approach for developing Breakwater relied on the in-line threading model [19, 25] where a single thread handles both packet processing and request processing. This choice was made as the in-line model provides the lowest CPU cost. However, it leads to head-of-line blocking as a single request with a large execution time can block other requests waiting at the same core. The alternative is relying on the dispatcher threading model [41] where a dispatcher thread processes packets and spawns a new thread for request processing incurring inter-thread communication overhead. However, this overhead is minimal when the dispatcher model is implemented using lightweight threads in recently proposed low-latency stacks (e.g., Shenango [40] and Arachne [43]). Thus, Breakwater employs the dispatcher model for request processing.

3.2 Overload Control

During overload, the system has to decide which requests to admit for processing and which requests to drop or possibly queue at the client. In this section, we explain our design for Breakwater’s approach to overload control.

3.2.1 Server-driven Credit-based Admission Control

A Breakwater server controls the admission of incoming requests through a credit-based scheme. Server-driven admission control avoids the need for clients to probe the server to know what rate to send at. It also allows the server to receive the exact load it can handle. A credit represents availability

at the server to process a single request by the client that receives the credit. A Breakwater server manages a global pool of credits (C_{total}) that is then distributed to individual clients. C_{total} represents the load the server can handle while maintaining its SLO. This is achieved by controlling C_{total} such that the measured queuing delay (d_m) remains close to a target queuing delay (d_t), which is set based on the SLO of the RPC.

Every network RTT, Breakwater updates C_{total} based on the measured queuing delay (d_m). If d_m is less than d_t , Breakwater increases C_{total} additively.

$$C_{total} \leftarrow C_{total} + \mathcal{A} \quad (1)$$

Otherwise, it decreases C_{total} multiplicatively, proportional to the level of overload.

$$C_{total} \leftarrow C_{total} \cdot \max(1.0 - \beta \cdot \frac{d_m - d_t}{d_t}, 0.5) \quad (2)$$

Note that \mathcal{A} controls the overcommitment and aggressiveness of the generation of credits. On the other hand, β controls the sensitivity of Breakwater to queue build-up. We explain how we select \mathcal{A} and β in the next section.

Once C_{total} is decided, credits are distributed to clients. When C_{total} increases, new credits are issued to clients by piggybacking the issued credits to response messages sent to the clients. Explicit *credit* messages are only generated when piggybacking is not possible (i.e., server has no messages bound for the client). When C_{total} decreases, the server does not issue additional credits to the clients, or if the clients have unused credits, the server sends negative credits to revoke the credits issued earlier. The server can tell how many unused credits each client has by keeping track of the number of credits issued and the number of requests received. In the following section, we explain how Breakwater decides which client should be issued credits.

3.2.2 Demand Speculation with Overcommitment

There is a tradeoff between accurate credit generation and messaging overhead. Choosing which client should receive a credit can be simply determined based on the demand at the client. This requires clients to inform the server whenever their number of pending requests changes. The server can then select which clients to send a credit to based on demand. This ensures that all issued credits are used, allowing the server to generate credits that accurately represent its capacity. However, as we scale the number of clients, the overhead of exchanging demand messages overwhelms the capacity of the server.

In our design of Breakwater, we choose to eliminate the messaging overhead completely. A client notifies the server of its demand only if the demand information can be piggybacked on a request (i.e., the client already has a credit and can send a request to the server). The server therefore does not have accurate information about clients with sporadic demand as they can't update the server as soon as their demand

changes. Thus, Breakwater speculatively issues credits based on the latest demand information even though it may be stale. Speculative generation of credits means that some clients that receive credits will not be able to use them immediately. If credits are generated to exactly match capacity, the server may experience underutilization because some credits are left unused when they are issued to clients with no queued requests. To achieve high utilization, speculative demand estimation is coupled with credit overcommitment to ensure that enough clients receive credits to keep the server utilized.

Overcommitment is achieved by setting the \mathcal{A} and β parameters of the admission control algorithm. In particular, we set \mathcal{A} to be proportional to the number of clients (n_c).

$$\mathcal{A} = \max(\alpha \cdot n_c, 1) \quad (3)$$

where α controls the aggressiveness of the algorithm. Further, each client is allowed to have more credits than its latest demand. The number of overcommitted credits per client (C_{oc}) is based on the number of clients (n_c), the total number of credits in the credit pool (C_{total}), and the total number of credits presently issued to clients (C_{issued}).

$$C_{oc} = \max(\frac{C_{total} - C_{issued}}{n_c}, 1) \quad (4)$$

The server makes sure that each client does not have unused credits more than its (latest) demand plus C_{oc} by revoking already issued credits if necessary.

Further, Breakwater attempts to avoid generating explicit credit messages whenever possible. This means that a new credit will be given to a client to whom the server is about to send a response unless that client has reached the maximum number of credits it can receive. Explicit credit messages are only generated when piggybacking a credit on a response is not possible. In the current version of Breakwater, the client that receives an explicit credit message is selected randomly, but we expect the selection could be smarter with per-client statistics. For example, the server can choose a client based on its average request rate to increase the likelihood of the client using the credit immediately.

3.2.3 AQM

The drawback of credit overcommitment is that the server may occasionally receive a higher load than its capacity, leading to long queues. To ensure low tail latency at all times, Breakwater relies on delay-based AQM to drop requests if the queuing delay exceeds an SLO-derived threshold. In our results, we find that drops are rare because our credit-based admission control scheme avoids creating bursts. Drops can be further reduced with by setting a large SLO budget. In particular, a system administrator can set a large threshold for AQM to reduce the drop rate at the expense of having a looser SLO.

3.3 Breakwater Client

Breakwater allows a client to queue requests if it does not have a credit for it. Client-side queuing is critical in a server-driven system as the client has to wait for the server to admit a request before it can send it. However, if the client queue is too long, the request will experience high end-to-end latency. In Breakwater, in order to achieve high throughput and low end-to-end latency, we allow requests to expire at the client. The request expiration time is set based on its SLO.

When a client receives credits, it can immediately consume them if its queue length is equal to or larger than the number of credits it receives. Due to overcommitment, a client can receive credits which it cannot immediately consume (c_{unused}). When a client receives negative credits with decreased C_{total} at the server, the client decrements c_{unused} . However, if a client has already consumed all of its credits (i.e., $c_{unused} = 0$), no action is taken by the client.

4 Implementation

Breakwater requires a low-latency network stack in order to ensure accurate estimation of the queuing delay signal. This requires minimal variability in packet processing and no head-of-line-blocking between competing requests. We use Shenango [40], an operating system designed to provide low tail latency for μ s-scale applications with fast core allocations, lightweight user-level threads, and an efficient network stack. Shenango achieves low latency by dedicating a busy-spinning core to reallocate cores between applications every 5 μ s to achieve high utilization and minimize the latency of packets arriving into the server.

We implement Breakwater as an RPC library on top of the TCP transport layer. Breakwater handles TCP connection management, admission control with credits, and AQM at the RPC layer. Breakwater abstracts connections and provides a simple individual RPC-oriented interface to applications, leaving applications to only specify request processing logic. Breakwater provides a single RPC layer per application (i.e., overload signal, credit pool, etc.) regardless of the number of cores allocated to the application and the number of clients of that application. A request arriving at a Shenango server is first queued in a packet queue. Then a Shenango kernel thread processes packets and moves the payload to the socket memory buffer of the connection. Once all the payload of a request is prepared in the memory buffer, a thread in Breakwater parses the payload to a request and creates a thread to process it. Threads are queued pending execution, and when they execute, they execute to completion.

Threading model. As explained earlier, Breakwater relies on a dispatcher threading model for accurate queuing delay measurement. A Breakwater server has a listener thread and the admission controller thread running. When a new connection arrives, the listener thread spawns a receiver thread and a sender thread per connection. Receiver threads read incoming packets and parse them to create requests. After parsing a

request, AQM is performed, dropping requests if the current queuing delay is greater than the AQM drop threshold. If a request is not dropped, the receiver thread spawns a new thread for the request. The new thread is enqueued to the thread queue. The sender thread is responsible for sending responses (either success or reject) back to the clients. If there are multiple responses, the sender thread coalesces them to reduce the messaging overhead. For all threads in Breakwater, we use lightweight threads provided by Shenango's runtime library.

Queueing Delay Measurement. With a separate receiver thread minimizing the delay from the socket memory buffer, the two main sources of queueing delay in Shenango are packet queueing delay (i.e., time between when a packet arrives till it is processed by a Shenango kernel thread) and thread queueing delay (i.e., time between when a thread is created to process a request until it starts executing). In Shenango, each core has a packet queue and a thread queue shared with IOKernel. We instrumented packet queues and thread queues so that each queue maintains the timestamp of the oldest item, and we modified Shenango's runtime library to export the queueing delay signal to the RPC layer. When Shenango's runtime is asked for the queueing delay, it returns the maximum of the packet queue's delays plus the maximum of the thread queue's delays.

Lazy credit distribution. The admission controller updates C_{total} every RTT. Once the credit pool size is updated, the admission controller can re-distribute credits to clients to achieve max-min fairness based on the latest demand information. However, this requires the admission controller to scan the demand information of all clients, requiring $O(N)$ steps. To reduce the credit distribution overhead, Breakwater approximates max-min fair allocation with lazy credit distribution. In particular, Breakwater delays determining the number of credits a client can receive until it has a response to send to that client. The sender thread, responsible for sending responses to a client, decides whether to issue new credits, not to issue any credits, or to revoke credits based on C_{issued} , C_{total} , and the latest demand information. It first calculates the total number of credits the server should grant to client x (c_x^{new}). If C_{issued} is less than C_{total} , c_x^{new} becomes

$$c_x^{new} = \min(demand_x + C_{oc}, c_x + C_{avail}) \quad (5)$$

where $demand_x$ is the latest demand of client x , c_x is the number of unused credits already issued to client x and C_{avail} is the number of available credits the server can issue ($C_{avail} = C_{total} - C_{issued}$). If C_{issued} is greater than C_{total} , c_x^{new} becomes

$$c_x^{new} = \min(demand_x + C_{oc}, c_x - 1) \quad (6)$$

The sender thread then piggybacks the number of credits newly issued for client x ($c_x^{new} - c_x$) to the response. It also updates c_x to c_x^{new} and C_{issued} accordingly.

5 Evaluation

Our evaluation answers the following questions:

- Does Breakwater achieve the objectives of overload control defined in §2 even given tight SLOs?
- Can Breakwater maintain its advantages regardless of load characteristics (i.e., average RPC service time and service time distribution)?
- Can Breakwater scale to large numbers of clients?
- Can Breakwater react quickly to a sudden load shift?
- What is the impact of Breakwater’s key design decisions: demand speculation and credit overcommitment?
- How sensitive is Breakwater’s performance to different parameters?

5.1 Evaluation Setup

Testbed: We use 11 nodes from the Cloudlab xl170 cluster [20]. Each node has a ten-core (20 hyper-thread) Intel E5-2640v4 2.4 GHz CPU, 64 GB ECC RAM, and a Mellanox ConnectX-4 25 Gbps NIC. Nodes are connected through a Mellanox 2410 25 Gbps switch. The RTT between any two nodes is 10 μ s. We use one node as the server and ten nodes as clients. The server application uses up to 10 hyper-threads (5 physical cores) for processing requests, and the client application uses up to 16 hyper-threads (8 physical cores) to generate load. All nodes dedicate a hyper-thread pair for Shenango’s IOKernel.

Baseline. We compare Breakwater to DAGOR [51] and SEDA [48]. DAGOR is a priority-based overload control system used for WeChat microservices. Priorities are assigned based on business requirements across applications and at random across clients. We only consider a single application in our evaluation. DAGOR uses queueing delay to adjust the priority threshold at which a server drops incoming requests (i.e., requests with a priority lower than the threshold are dropped). To reduce the overhead of dropped requests, the server advertises its current threshold to clients, piggybacked it in responses. Clients use that threshold to drop the requests. Note that DAGOR does not drop its threshold to zero, meaning that a request with the highest priority value (i.e., a priority of one) will never be dropped. SEDA uses a rate-based rate limiting algorithm. It sets rates based on the 90%-ile response time. Since we evaluate the performance of Breakwater using the 99%-ile latency metric, we modified SEDA’s algorithm so that it adjusts rates based on 99%-ile response time. We implement DAGOR and SEDA as an RPC layer in Shenango with the same dispatcher model as Breakwater.

Setting end-to-end SLO. We set tight SLOs to support low-latency RPC applications. We budget SLOs based on the server-side request processing time and the network RTT. An SLO is set as 10 \times the sum of the average RPC service time measured at the server and the network RTT; the multiplicative factor of 10 was inspired by recent work on μ s-scale RPC work [17, 42]. The RTT in our setting is 10 μ s, leading to SLOs of 110 μ s, 200 μ s, and 1.1 ms for workloads with 1 μ s,

10 μ s, and 100 μ s average service times, respectively. These are comparable with SLO values used in practice [30].

Evaluation metrics: We report goodput, 99%-ile latency, drop rate, and reject message delay. Goodput represents the number of requests processed per second that meet their SLO. Reported latency captures all delays faced by a request from the moment it is issued till its response is received by the client. This includes any queuing delay at the client, communication delay, and all delays at the server. We report drop rate at the server only, as it is the factor that directly impact overall system performance. *Note that SEDA does not support any AQM at the server and has zero drop rate in all experiments.* Reject message delay represents the delay between the departure of a request from a client and the arrival of a reject message back to the client when that request is dropped at the server.

Parameter tuning. We tune the parameters of all systems so that they achieve the highest possible goodput. We re-tune the parameters when we change the average service time, service time distribution, and the number of clients. Note that Breakwater and DAGOR do not require parameter re-tuning for a different number of clients while SEDA does. Specifically, we need to scale adj_i parameter in SEDA based on the number of clients to get the best goodput. For Breakwater, we set $\alpha = 0.1\%$, $\beta = 2\%$, d_t to 40% of SLO, and AQM threshold to $2 \cdot d_t$ (e.g., $d_t = 80\mu$ s and AQM threshold = 160 μ s for exponential service time distribution with 10 μ s average and 200 μ s SLO). For DAGOR and SEDA, which are devised for ms-scale RPCs, we scale down the hyperparameters from the default values. For DAGOR, we update the priority threshold every 1 ms (instead of 1 s) or every 2,000 requests and use $\alpha = 5\%$ and $\beta = 1\%$. We assign random priority for each request ranging from 1 to 128, which is the default priority setting with one type of service in DAGOR [51]. We tune $DAGOR_q$ for each workload (e.g., $DAGOR_q = 70\mu$ s for exponential service time distribution with 10 μ s on average). For SEDA, we used the same default parameter from [48] except for *timeout*, adj_i , and adj_d . We set *timeout* = 1 ms (instead of 1 s) and tune adj_i and adj_d for each workload (e.g., $adj_i = 40$, $adj_d = 1.04$ for exponential workload with 10 μ s average with 1,000 clients). AQM in Breakwater and DAGOR drops requests right after parsing packets to requests, following the drop-as-early-as-possible principle [33]. We run all the experiments for four seconds. We measure steady state performance with converged adaptive parameters by collecting data two seconds after an experiment starts.

5.2 Performance for Synthetic Workload

Workload: We run 1,000 clients divided equally between the ten nodes in our CloudLab setup. We generate the workload with exponential, constant, and bimodal service time distributions with 1 μ s, 10 μ s, and 100 μ s average where each client generates the load with an open-loop Poisson process. We change the demand by varying the average arrival rate of requests at the server between $0.1 \times$ to $2 \times$ of server capac-

Figure 3: Performance of Breakwater, DAGOR, and SEDA for synthetic workloads with the exponential distribution of 10μs average

Figure 4: Goodput and drop rate with different service time distribution of 10μs average with 1,000 clients (The label represents the goodput gain compared to the worst of baselines.)

ity. Exponential service time distribution models applications waiting for a shared resource while busy-spinning; constant distribution models applications with a fixed amount of latency such as fetching value from memory or flash drive; bimodal distribution models applications that caches frequently requested values, which will have shorter execution time compared non-cached results. In particular, 20% of the requests take four times the average service time, and 80% of the requests take one fourth of the average following the Pareto principle.

Overall performance: Figure 3 shows the performance for a workload whose service time follows an exponential distribution with 10μs average. The capacity of the server in this case is around 850k requests per second.

When the clients' demand is less than the capacity, all three systems perform comparably in terms of goodput, latency, and drop rate. The only noticeable difference among them is that, at 700k reqs/s, SEDA has a 15% higher 99%-ile latency than Breakwater or DAGOR. This is because SEDA doesn't drop requests at servers.

When the clients' demand is around the capacity of the server, Breakwater achieves 801k requests per second for goodput (or 808k reqs/s of throughput), which is around 5% overhead when compared to the maximum throughput with no overload control. Other systems have higher overhead than Breakwater.

When the demand exceeds the capacity, incast becomes the dominant factor impacting performance. Breakwater handles incast well by preventing clients from sending requests unless they have credits, limiting the maximum queue size. Thus, Breakwater achieves higher goodput with lower and bounded tail latency. On the other hand, SEDA experiences high tail latency because clients do not coordinate their rate increase, making multiple clients increase their rate simultaneously and overwhelm the server. Delayed reaction to overload does not allow SEDA to react quickly to incast. DAGOR's high tail latency is also explained by delayed reaction as it updates its priority threshold every 1 ms or every 2,000 requests. Breakwater is also impacted by incast due to the overcommitted credits, which lead to increased tail latency and higher drop rate with overload. However, Breakwater relies on delay-based AQM which effectively bounds the tail latency while maintaining a comparable drop rate to DAGOR.

Impact of Workload Characteristics: To verify that Breakwater's performance benefits are not confined to a specific workload, we repeat the experiments with different service time distributions and different average service time values. Figure 4 shows goodput and drop rate with three different distributions of the service time whose average is 10μs, where the load generated by 1,000 clients is 0.9×capacity, 1.2× capacity, and 2× capacity. The service time distributions are aligned over the x-axis in ascending order of variance. Break-

Figure 5: Goodput and drop rate with different average service time with 1,000 clients

water achieves the highest goodput regardless of the load and service time distribution. All three systems experience small goodput reduction with a higher variance, especially when the load is $2\times$ the server capacity. The goodput reduction of DAGOR and SEDA comes from their poor reaction to incast, whose size increases as the load increases. As a result, Breakwater's goodput benefit becomes larger as the clients' demand increases. Breakwater achieves 5.7% more goodput compared to SEDA and 6.2% more goodput compared to DAGOR with exponential distribution at a load of $2\times$ capacity. With a higher variance of the service time distribution, the drop rate of the Breakwater tends to increase because a larger number of credits are overcommitted with higher variance, but it is still comparable to DAGOR.

Figure 5 depicts performance with an exponential service time distribution and different average service times with 1,000 clients. Breakwater outperforms DAGOR and SEDA regardless of the clients' demand and the average service time. As the average service time increases, clients and servers exchange messages less frequently, exposing the delayed reaction problem in SEDA and DAGOR. With short service times (i.e., $1\mu s$), clients and servers exchange messages very frequently, giving clients a fresh view of the state of the server in case of DAGOR and SEDA, allowing clients to react quickly to overload. With high demand, the size of incast gets larger which is poorly handled by SEDA and DAGOR. With clients' demand of $2\times$ capacity with $100\mu s$ (i.e., $180k$ reqs/s), Breakwater achieves 17.5% more goodput than SEDA and 10.2% more goodput with a comparable drop rate compared to DAGOR.

Scalability to a Large Number of Clients: We vary the number of clients from 100 to 10,000 with synthetic workload whose service time follows exponential service time distribution of $10\mu s$ average. Note that the server capacity is around 850k requests per second. Figure 6 depicts the goodput with different numbers of clients. As clients' demand nears and exceeds the capacity, the goodput of all systems degrades as the number of clients increases. As the number of clients increases, the size of incast increases, leading to

Figure 6: Goodput with different numbers of clients for exponential workload with $10\mu s$ average service time

performance degradation. This is problematic for Breakwater as well since overcommitment can occasionally result in large bursts of incoming requests. The performance of DAGOR and SEDA drops more than Breakwater as the number of clients increases. This is because each client exchanges messages with the server less frequently as the number of clients increases. The stale view of the server status leads clients to overwhelm the server. Note that for SEDA's best performance, we scale the additive rate increase factor (adj_i) to the number of clients. This helps mitigate any bursty behavior that can result from multiple clients sharply increasing their rate simultaneously. A small increase factor is not practical for a small number of clients as it will lead to slow ramp-up of rates after an overload, leading to lower utilization of the server. Because of this issue, SEDA has a much slower convergence time to the right rate, making it impractical for load shift scenarios as we show next.

Further, it is hard to tune SEDA dynamically. The rate control algorithm in SEDA is implemented at the client, and dynamic tuning requires each client to know the total number of *active* clients. Such a dynamic approach will lead to performance degradation as the client will retune its parameter to at least an RTT after the number of clients changes. The drawbacks of such a delayed reaction can be seen in the behavior of DAGOR. Further, exchanging such information might not be feasible in practice due to messaging overhead as well as privacy concerns (e.g., a FaaS cloud provider will not want any of its clients to know the total number of clients). Note that even though Breakwater also scales the number

of newly issued credits to the number of clients (Equation 1 and 3), Breakwater is server-driven, and the server has perfect knowledge of the number of active clients at all times with no need to expose this information outside. In SEDA, by contrast, each client cannot have perfect knowledge of the number of active clients. Each client would have to guess or receive feedback from the server to scale the increment factor.

Reaction to Sudden Shifts in Demand: An RPC server may experience sudden shifts in demand for many reasons, such as load imbalance, packet bursts, unexpected user traffic, or redirected traffic due to server failure. To verify Breakwater’s ability to converge after a shift in demand, we measure its performance with a shifting load pattern. We use a workload whose service time follows an exponential distribution with $10\mu\text{s}$ average and calculate goodput, 99%-ile latency, and mean reject message delay every 20 ms. When the experiment starts, 1,000 clients generate requests at 400k reqs/s ($0.5\times$ capacity). Then, clients double their request rate to 800k reqs/s ($0.9\times$ capacity) at time = 2 s, then triple their demand to 1.2M reqs/s ($1.4\times$ capacity) at time = 4 s. Clients sustain their demand at 1.2M reqs/s for 2 seconds. Then, clients reduce their demand back to 800k reqs/s at time = 6 s and finally to 400k reqs/s at time = 8 s. Figure 7 depicts a time series behavior of all systems.

When the clients’ demand is far less than the capacity, all three overload control schemes maintain comparable goodput and tail latency at a steady state. When demand increases to near server capacity, Breakwater converges fast, exhibiting a stable behavior in terms of both goodput and tail latency. On the other hand, DAGOR and SEDA experience higher tail latency because of the poor reaction to the transient server overload. As the server becomes persistently overloaded with a sudden spike at time = 4 s, Breakwater converges quickly while DAGOR and SEDA suffer from congestion collapse. Breakwater experiences a momentary tail latency increase (reaching $1.4\times$ the SLO) with the sudden increase of clients’ demand due to more incast caused by overcommitted credits. However, credit revocation and AQM rapidly limit the impact of any further incast. When demand returns back below the capacity at time = 6 s, Breakwater doesn’t show a noticeable goodput drop while the DAGOR and SEDA experience a temporary goodput drop down to 77.5% and 82.6% of the converged goodput, respectively.

SEDA reacts slowly to the demand spike since each client needs to wait for a hundred responses or 1 ms to adjust its rate. After the demand spikes beyond the capacity, the server builds up long queues, and the latency goes up beyond SLO, resulting in almost zero goodput. SEDA takes around 1.6 s to recover its goodput. DAGOR also has the delayed reaction problem, but its goodput converges more quickly than SEDA thanks to AQM, taking 500 ms to recover its goodput. During the congestion collapse period, the 99%-ile latency of DAGOR soars up to 300 ms and its mean delay of reject message reaches 220 ms. This is problematic as clients cannot

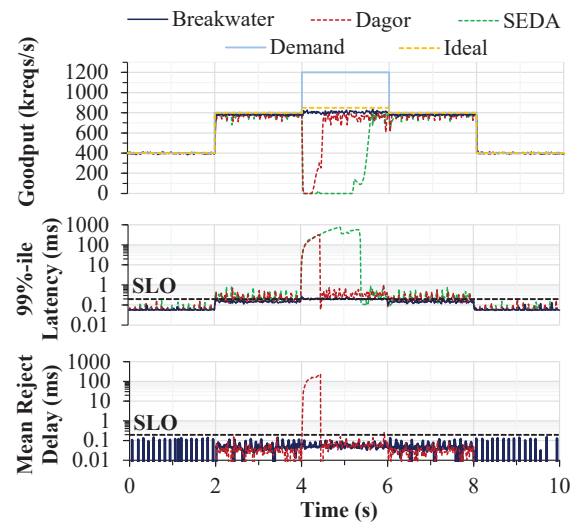

Figure 7: Goodput, 99%-ile latency, and mean rejection delay with a sudden shift in demand with 1,000 clients

receive the feedback in a timely manner, making them rely on expensive timeout.

The Value of Demand Speculation: To quantify the performance benefits of demand speculation, we compare the two strategies for collecting demand information: demand synchronization and demand speculation. With demand synchronization, clients notify the server whenever their demand changes using explicit demand messages, and the server generates explicit credit messages to clients if it cannot be piggybacked to responses. With demand speculation, the server speculatively estimates client demands based on the latest demand information and piggybacks credits to the responses as much as possible. The load is generated by 1,000 clients where the service time per request follows an exponential distribution with an average of $10\mu\text{s}$. The message overhead is measured by the number of packets received (RX) and sent (TX) at the server. With demand synchronization, both RX and TX message overhead increase as the clients’ demand increases, leading to goodput degradation (Figure 8 (a)). In particular, explicit demand and credit messages doubles RX and TX message overhead below and at the capacity (i.e., 850k requests per second). As the system gets overloaded, the overhead of demand messages keeps increasing because per-client demand changes more frequently with increased clients’ demand. Further, the overhead of generating credits contributes to the cost of synchronization. The server sends more credit messages during low demand as they cannot be piggybacked on responses due to low request rates. As load increases beyond capacity, more credits can be piggybacked to the responses, which results in the reduction of TX overhead. Demand synchronization has a smaller number of overcommitted credits, leading to a lower drop rate than demand speculation (Figure 8 (c)). Overall, the cost of synchronization between the clients and the server is high in terms of goodput degradation and network overhead, with the small

Figure 8: Goodput, message overhead, and drop rate with demand speculation and demand synchronization in Breakwater

Figure 9: Breakwater performance breakdown

benefit of lowering the drop rate at the server.

Performance Breakdown: To quantify the contribution of each component of Breakwater to its overall performance, we measure the throughput and 99%-ile latency after incrementally activating its three major components: credit-based admission control, demand speculation, and delay-based AQM. The results are shown in Figure 9. We use the synthetic workload whose service time is exponentially distributed with $10\mu s$ average ($SLO = 200\mu s$). With no overload control at all, throughput starts to degrade, and tail latency soars, making almost all requests violate their SLO as demand becomes higher than server capacity. Credit-based admission control effectively lowers and bounds the tail latency, but throughput still suffers due to the messaging overhead. Demand speculation with message piggybacking reduces the messaging overhead, but it worsens tail latency due to incast caused by credit overcommitment. By employing delay-based AQM, Breakwater effectively handles incast, leading to high throughput and low tail latency.

Parameter Sensitivity: Breakwater parameters are set aggressively to maximize the goodput, resulting in a relatively high drop rate. With less aggressive parameters, Breakwater can drop fewer requests sacrificing goodput. Figure 10 demonstrates the trade-off between the goodput and the drop rate for the workload with exponential service time distribution with $10\mu s$ average with 1M reqs/s demand from 1,000 clients. The values of pairs of α and β are aligned in descending order of aggressiveness over the x-axis. Breakwater achieves 0.7% of drop rate by sacrificing 2.2% of goodput (with $\alpha = 0.1\%$, $\beta = 8\%$) and 0.4% of drop rate by sacrificing 5.1% of goodput (with $\alpha = 0.05\%$, $\beta = 10\%$).

In practice, it is not easy to find the best parameter con-

Figure 10: Goodput and drop rate with different aggressive parameters of Breakwater

figuration for an operational system. It is even more difficult when traffic patterns change over time because parameter adjustments could be required to achieve the best possible performance. Thus, it is desirable to develop systems that are robust to parameter misconfiguration and changes in traffic patterns, providing consistently good performance even with small errors in parameter settings. Breakwater is robust. In particular, it provides high throughput and low tail latency despite parameter misconfiguration. We compare it against DAGOR and SEDA, measuring their performance for the same workload while varying their parameters. Specifically, we measure the throughput and 99%-ile latency after reconfiguring the three most sensitive parameters for each system: target delay, increment factor, and decrement factor (d_t, α, β for Breakwater; threshold of the average queueing time, α, β for DAGOR; and $target, adj_i, adj_d$ for SEDA). Given the set of parameters producing best goodput, we measure 27 data points with $-10, 0, +10\mu s$ of target queueing delay, $0.5\times, 1\times, 2\times$ of the increment factor, and $0.5\times, 1\times, 2\times$ of the decrement factor. We use a synthetic workload with exponentially distributed service times with $10\mu s$ average with 1,000 clients. The results are shown in Figure 11 where the circles filled with light color indicate the performance with the parameters tuned for the best goodput. All configurations of Breakwater achieve comparable performance in terms of both throughput and tail latency, achieving better throughput and latency trade-offs and more consistent performance with different sets of parameters. DAGOR tends to provide high throughput, but its tail latency is as high as four times the SLO in the worst case. SEDA's worst case tail latency is lower than DAGOR,

Figure 11: Throughput and 99%-ile latency trade-off with different sets of parameters (circle with light color indicates the point producing best goodput)

but it suffers from severe throughput degradation when its parameters are too conservative.

5.3 Performance under Realistic Workload

To evaluate Breakwater in a more realistic scenario, we create a scenario where one memcached instance serves 10,000 clients. We use the USR workload from [9] where 99.8% of the requests are GET, and other 0.2% are SET. Each client generates the load according to an open-loop Poisson process. We set an SLO of 50 μ s considering that the latency of GET operation of memcached is less than 1 μ s. Figure 12 shows goodput, median latency, 99%-ile latency, and drop rate of Breakwater, DAGOR, and SEDA. Breakwater achieves steady goodput, low latency, and low drop rate, whereas both DAGOR and SEDA suffer from goodput degradation with high tail latency caused by incast when the server becomes overloaded. With clients' demand of 2 \times capacity, Breakwater achieves 5% more goodput and 1.8 \times lower 99%-ile latency than SEDA; and 14.3% more goodput and 2.9 \times lower 99%-ile latency than DAGOR. Because of bimodally distributed service time with a mix of GET and SET requests, Breakwater shows around 25 μ s higher 99%-ile latency than its SLO and about 1.5% point higher drop rate than DAGOR.

6 Discussion and Future Work

Auto-scaling. We do not consider auto-scaling [5, 23, 31] in this paper, where more resources are provisioned as load increases, as a potential solution for overload control. Auto-scaling can allocate enough capacity over time, but because it operates at the timescale of minutes, it is too slow to resolve microsecond-scale imbalances. Furthermore, overprovisioning resources can be cost-inefficient if used to handle transient spikes in demand, such as those that occur during temporary failures [3].

Fairness. When the server has a sufficient number of credits, it tries to approximate max-min fairness when distributing credits to clients. However, when the number of available credits is less than the number of clients, Breakwater does not provide fairness to clients. Instead, it favors clients for which it is currently processing requests. This allows the server to piggyback credits to the responses and avoid sending explicit

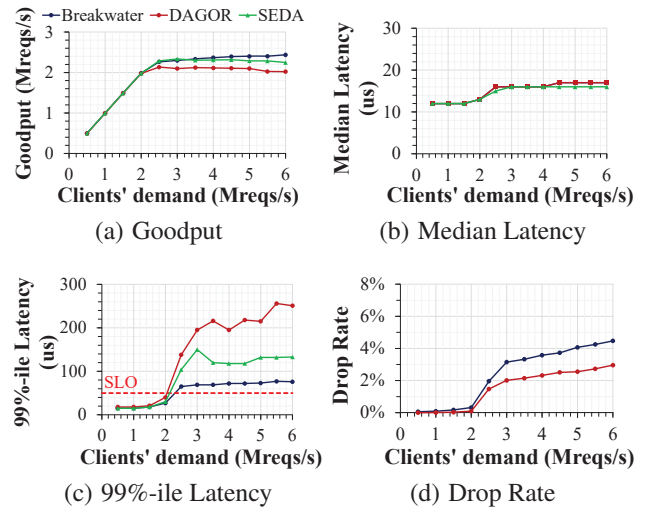

Figure 12: Memcached performance for USR workload with 10,000 clients (SLO = 50 μ s)

credit messages. This preference toward a subset of clients is common in production services [51]. If a service operator wants to provide fairness among clients, the clients receiving the most credits could be timed-out over a longer timescale, so clients starved of credits can get a chance to send instead.

Overload control for multi-layer services. In this paper, we only consider a single-layer, single-server overload control scenario. Breakwater's receiver-driven, credit-based approach can be applied to multiple layers of microservices, preventing overload at each individual layer. However, when an overload occurs in an intermediate layer of a multi-layer service, the work performed in earlier layers is wasted. We leave propagating overload signals and coordinating overload control across several layers of microservices for future work.

7 Related Work

Receiver-driven transport protocols. Homa [34], NDP [24], and ExpressPass [14] schedule network packets with a receiver-driven mechanism to achieve high throughput and low latency. While Homa and Breakwater share some similarities including a credit-based, receiver-driven scheme and credit overcommitment, they are different in three significant aspects. First, Homa handles network congestion, whereas Breakwater handles server overload, which means that Breakwater must handle the additional challenges posed by overload control discussed in §2.3. Second, Homa relies on full knowledge of clients' demand, whereas Breakwater does not. Instead, the Breakwater server speculates clients' demand based on the latest demand information, the number of clients, and the number of available credits to minimize the message overhead. Third, both the motivation and the mechanism of overcommitment are different. Homa overcommits a fixed number of credits to handle an all-to-all workload, where a sender may get credits from multiple receivers and therefore not be able to send to all of them

simultaneously. In Breakwater, however, the server does not know which clients have demand. Thus, it dynamically increases the amount of overcommitted credits until it receives sufficient requests to keep itself busy with demand speculation.

Transport protocol for μ s-scale RPCs. R2P2 [28] is a request/response-aware transport protocol designed for μ s-scale RPCs. It implements JBSQ inside a programmable switch to better load balance requests among multiple servers. R2P2 limits the number of requests in a server's queue by explicitly pulling the requests from the switch. Through this mechanism, R2P2 provides bounded request queueing and low tail latency when the clients' demand is less than the servers' capacity. However, R2P2 does not provide any server overload control mechanism. If the clients' demand exceeds the servers' capacity, the request queue will build up at the switch, causing requests to violate their SLO. SVEN [27] builds upon R2P2 by adding a server overload control mechanism. Specifically, it drops requests at the switch if sampled tail latency exceeds an SLO-derived threshold. SVEN avoids the cost of request drops at the server by dropping requests early at the switch. However, unlike Breakwater, message overhead increases as clients' demand increases.

Circuit breaker in proxy. Envoy [6], HAProxy [7], NGINX [44], and GateKeeper [21] provide circuit breaker mechanisms to prevent back-end server overload. These proxies sit in front of a back-end server and stop forwarding requests to the server when one of the load metrics (e.g., the number of connections, the number of outstanding requests, the response time, estimated load) exceeds a threshold. However, since those thresholds must be set manually, it's challenging to find the right threshold value that maximizes resource utilization while keeping latency low.

Server overload control. Session-based admission control [12, 13] prevents web server overloads by limiting the creation of new sessions based on the number of successfully completed sessions or QoS metrics. However, they are not compatible with request-response models as they cannot prevent server overloads caused by a single session from a proxy that forwards requests from multiple clients. CoDel [38] controls the queueing delay of a server to prevent server overloads. Still, if the incoming packet rate is high and CPU is used more for packet processing, the server becomes less CPU efficient and degrades throughput. ORCA [29], SEDA [48], and Doorman [4] rate limit clients so that their sending rates do not exceed the server capacity. Doorman requires manually setting of the server capacity threshold. Both ORCA and SEDA may suffer from long queueing delays or underutilization if clients make mistakes on their sending rate with stale congestion information from the server. DAGOR [51] takes a hybrid approach using both AQM and client-side rate limiting using adaptive parameter based on queueing delay. However, as DAGOR server updates congestion status with responses, clients still can undershoot or overshoot the server

capacity with stale information on server congestion when client demand is sporadic.

Flow control. TCP flow control prevents the sender from transmitting more bytes than the receiver can accommodate. The objective of TCP flow control is to avoid memory overrun at the server, not to prevent server overload or SLO violations. More recently, an SLO-aware TCP flow control mechanism [26] was proposed where the server adjusts receive window size in TCP header based on SLO and the queueing delay at the server. This approach limits the "bytes" of the incoming requests to prevent server overload, but it's challenging to decide the appropriate receive window size, especially when the request size is variable.

8 Conclusion

In this paper, we presented Breakwater, a server-driven, credit-based overload control system for microsecond-scale RPCs. Breakwater achieves high throughput and low latency regardless of the RPC service time, the load at the server, and the number of clients generating the load. Breakwater generates credits based on queueing delay at the server, maintaining high utilization by targeting non-zero queueing delay while avoiding queue buildup. To minimize the overhead of coordination between the clients and the server, we propose demand speculation and credit overcommitment to realize the credit-based design for overload control with minimal overhead. By estimating clients' demand and issuing more credits than their capacity, Breakwater eliminates the extra messaging cost which is often required with a credit-based approach. Additionally, Breakwater reduces its remaining messaging overhead significantly by piggybacking demands and credits to requests and responses, respectively. Our evaluation of Breakwater shows that it outperforms state-of-the-art overload control systems. In particular, Breakwater achieves $25\times$ faster convergence with 6% higher converged goodput than DAGOR and $79\times$ faster convergence with 3% higher converged goodput than SEDA when the clients' demand suddenly spikes to $1.4\times$ capacity.

AIFM: High-Performance, Application-Integrated Far Memory

Zhenyuan Ruan Malte Schwarzkopf[†] Marcos K. Aguilera[‡] Adam Belay
MIT CSAIL [†]Brown University [‡]VMware Research

Abstract. Memory is the most contended and least elastic resource in datacenter servers today. Applications can use only local memory—which may be scarce—even though memory might be readily available on another server. This leads to unnecessary killings of workloads under memory pressure and reduces effective server utilization.

We present *application-integrated far memory* (AIFM), which makes remote, “far” memory available to applications through a simple API and with high performance. AIFM achieves the same common-case access latency for far memory as for local RAM; it avoids read and write amplification that paging-based approaches suffer; it allows data structure engineers to build *remoteable*, hybrid near/far memory data structures; and it makes far memory transparent and easy to use for application developers.

Our key insight is that exposing application-level semantics to a high-performance runtime makes efficient remoteable memory possible. Developers use AIFM’s APIs to make allocations remoteable, and AIFM’s runtime handles swapping objects in and out, prefetching, and memory evacuation.

We evaluate AIFM with a prototypical web application frontend, a NYC taxi data analytics workload, a memcached-like key-value cache, and Snappy compression. Adding AIFM remoteable memory to these applications increases their available memory without performance penalty. AIFM outperforms Fastswap, a state-of-the-art kernel-integrated, paging-based far memory system [6] by up to $61\times$.

1 Introduction

Memory (RAM) is the most constrained resource in today’s datacenters. For example, the average memory utilization on servers at Google [73] and Alibaba [46] is 60%, with substantial variance across servers, compared to an average CPU utilization of around 40%. But memory is also the most inelastic resource: once a server runs out of available memory, some running applications must be killed. In a month, 790k jobs at Google had at least one instance killed, in many cases due to memory pressure [73]. A killed instance’s work and accumulated state are lost, wasting both time and energy. This waste happens even though memory may be available on other servers in the cluster, or even locally: around 30% of server memory are “cold” and have not been accessed for minutes [41], suggesting they could be reclaimed.

Operating systems today support memory elasticity primarily through *swap* mechanisms, which free up RAM by pushing unused physical memory pages to a slower tier of memory,

Throughput [accesses/sec]	64B object	4KB object
Paging-based (Fastswap [6])	582K	582K
AIFM	3,975K	1,059K

Figure 1: AIFM achieves $6.8\times$ higher throughput for 64B objects and $1.81\times$ higher throughput for 4KB objects, compared to Fastswap [6], a page-granular, kernel-integrated far memory approach. AIFM performs well since it (i) avoids IO amplification and (ii) context switches while waiting for data.

such as disks or remote memory. But OS swap mechanisms operate at a fixed and coarse granularity and incur substantial overheads. To swap in a page, the OS must handle a page fault, which requires entering the kernel and waiting until the data arrives. Figure 1 shows the throughput a recent page-based far memory system (*viz.*, Fastswap [6]) achieves when accessing remote objects using up to four CPU cores. Kernel swapping happens at the granularity of 4KB pages, so page-based far memory suffers read/write amplification when accessing small objects, as at least 4KB must always be transferred. Moreover, the Linux kernel spins while waiting for data from swap to avoid the overheads of context switch and interrupt handling. That means the wait time (about 15–20k cycles with Fastswap’s RDMA backend) is wasted.

We describe a fundamentally different approach: *application-integrated far memory* (AIFM), which ties swapping to individual application-level memory objects, rather than the virtual memory (VM) abstraction of pages. Developers write *remoteable* data structures whose backing memory can be local and “far”—*i.e.*, on a remote server—without affecting common-case latency or application throughput. When AIFM detects memory pressure, its runtime swaps out objects and turns all pointers to the objects into remote pointers. When the application dereferences a remote pointer, a lightweight green threads runtime restores the object to local memory. The runtime’s low context switch cost permits other green threads to make productive use of the wait cycles, which hides remote access latency and maintains high throughput. Due to these fast context switches, AIFM achieves 81% higher throughput than page-based approaches when accessing 4KB objects, and because AIFM avoids amplification, it achieves $6.8\times$ higher throughput for small objects (Figure 1).

AIFM’s programming interface is based on four key ideas: a fast, low-overhead *remoteable pointer* abstraction, a pauseless memory evacuator, runtime APIs that allow data struc-

tures to convey semantic information to the runtime, and a *remote device* interface that helps offload light computations to remote memory. These AIFM APIs allow data structure engineers to build hybrid local/remote data structures with ease, and provide a developer experience similar to C++ standard library data structures. The pauseless memory evacuator ensures that application threads never experience latency spikes due to swapping. Because data structures convey their semantics to the runtime, AIFM supports custom prefetching and caching policies—*e.g.*, prefetching remote data in a remoteable list and streaming of remote data that avoids polluting the local memory cache. Finally, AIFM’s offloading reduces data movement and alleviates the network bottleneck that most far-memory systems experience.

The combination of these ideas allows AIFM to achieve object access latencies bounded only by hardware speed: if an object is local, its access latency is comparable to an ordinary pointer dereference; when it is remote, AIFM’s access latency is close to the hardware device latency.

We evaluate AIFM with a real-world data analytics workload built on DataFrames [16], a synthetic web application frontend that uses several remoteable data structures, as well as a memcached-style workload, Snappy compression, and microbenchmarks. Our experiments show that AIFM maintains high application request throughput and outperforms a state-of-the-art, page-based remote memory system, Fastswap, by up to $61\times$. In summary, our contributions are:

1. Application-integrated far memory (AIFM), a new design to extend a server’s effective memory size using “far” memory on other servers or storage devices.
2. A realization of AIFM with convenient APIs for development of applications and remoteable data structures.
3. A high-performance runtime design using green threads and a pauseless memory evacuator that imposes minimal overhead on local object accesses and avoids wasting cycles while waiting for remote object data.
4. Evaluation of our AIFM prototype on several workloads, and microbenchmarks that justify our design choices.

Our prototype is limited to unshared far memory objects on a single memory server. Future work may add multi-server support, devise strategies for dynamic sizing of remote memory, or investigate sharing.

2 Background and Related Work

OS swapping and far memory. Operating systems today primarily achieve memory elasticity by *swapping* physical memory pages out into secondary storage. Classically, secondary storage consisted of disks, which are larger and cheaper but slower than DRAM. The use of disk-based swap has been rare in datacenters, since it incurs a large performance penalty. More recent efforts consider swapping to a faster tier of memory or *far memory*, such as the remote memory of a host [3, 6, 21, 27, 28, 31, 40, 45, 48, 67] or a compression cache [24, 41, 81, 82]. Since swapping is integrated

with the kernel virtual memory subsystem, it is transparent to user-space applications. But this transparency also forces swapping granularity to the smallest virtual memory primitive, a 4KB page. Combined with memory objects smaller than 4KB, this leads to *I/O amplification*: when accessing an object, the kernel must swap in a full 4KB page independent of the object’s actual memory size. Moreover, supplying application semantic information, such as the expected memory access pattern, the appropriate prefetch strategy, or memory hotness, is limited to coarse and inflexible interfaces like `madvise`.

AIFM uses far memory in a different way from swapping, by operating at *object granularity* rather than page-granularity—an idea that we borrow from prior work on distributed shared memory (see below), memory compression [75], and SSD storage [1]. These investigations all point to page-level I/O amplification as a key motivation.

AIFM provides transparent access to far memory using smart pointers and dereference scopes inspired by C++ weak pointers [69], and Folly RCU guards [26].

Disaggregated and distributed shared memory. Disaggregated memory [58] refers to a hardware architecture where a fast fabric connects hosts to a pool of memory [29, 33], which is possibly managed by a cluster-wide operating system [33, 66]. Disaggregated memory requires new hardware that has not yet made it to production. AIFM focuses on software solutions for today’s hardware.

Distributed shared memory (DSM) provides an abstraction of shared memory implemented over message passing [7, 10, 44, 50, 64, 65]. Like far memory, DSM systems can be page-based or object-based. DSM differs from far memory both conceptually and practically. Conceptually, DSM provides a different abstraction, where data is *shared* across different hosts (the “S” in DSM). Practically, this abstraction leads to complexity and inefficiency, as DSM requires a cache coherence protocol that impairs performance. For instance, accessing data must determine if a remote cache holds a copy of the data. By contrast, data in far memory is private to a host—a stricter abstraction that makes it possible to realize far memory more efficiently. Finally, DSM systems were designed decades ago, and architectural details and constants of modern hardware differ from their environments.

Technologies to access remote data. TCP/IP is the dominant protocol for accessing data remotely, and AIFM currently uses TCP/IP. Faster alternatives to TCP/IP exist, and could be used to improve AIFM further, but these technologies are orthogonal or complementary to AIFM’s key ideas.

RDMA is an old technology that has recently been commoditized over Ethernet [32], generating new interest. Much work is devoted to using RDMA efficiently in general [39, 51, 76] or for specific applications, such as key-value stores (*e.g.*, [38, 49]) or database systems [11]. Smart NICs use CPUs or FPGAs [47, 52, 70] to provide programmable remote functionality [18, 43, 68]. AIFM requires no specialized hardware.

Abstractions for remote data. Remote Procedure Calls (RPCs) [12] are widely used to access remote data, including over RDMA [19, 71] or TCP/IP [37]. Memory-mapped files can offer remote memory behind a familiar abstraction [2, 67], while data structure libraries for remote data [4, 15], offer maps, sets, multisets, lists, and other familiar constructs to developers. This is similar in spirit to data structure libraries for persistent memory [59, 62]. AIFM offers a lower-level service that helps programmers develop such data structures.

I/O amplification. As mentioned, page-based access leads to I/O amplification, a problem studied extensively in the context of storage systems [1, 61] and far-memory systems [17], where hardware-based solutions can reduce amplification by tracking accesses at the granularity of cache lines.

Garbage collection and memory evacuation. Moving objects to remote memory in AIFM (“evacuation”) is closely related to mark-compact garbage collection (GC) in managed languages. The main difference is that AIFM aims to increase memory capacity by moving cold, but live objects to remote memory, while GCs focus on releasing dead, unreferenced objects’ memory. AIFM uses referencing counting to free dead objects, avoiding the need for a tracing stage. Instead of inventing a new evacuation algorithm, AIFM borrows ideas from the GC literature and adapts them to far-memory systems. Like GCs, AIFM leverages a read/write barrier to maintain object hotness [5, 14, 34], but AIFM uses a one-byte hotness counter instead of a one-bit flag, allowing more fine-grained replacement policies. Like AIFM, some copying collectors optimize data locality by separating hot and cold data during GC, but target different memory hierarchies; *e.g.*, the cache-DRAM hierarchy [34], the DRAM-NVM hierarchy [5, 79, 80], and the DRAM-disk hierarchy [14]. Finally, memory evacuation interferes with user tasks and impacts their performance. To reduce the interference, AIFM adopts an approach similar to the pauseless GC algorithms in managed languages [20], as opposed to the stop-the-world GC algorithms [36].

3 Motivation

Kernel paging mechanisms impose substantial overheads over the fundamental cost of accessing far memory.

Consider Figure 2, which breaks down the costs of Linux (v5.0.0) retrieving a swapped-out page from an SSD. The device’s hardware latency is about 6 μ s, but Linux takes over 15 μ s (2.5 \times) due to overheads associated with locking (P1, P5), virtual memory management (P2, P3, P5), accounting (P4), and read IO amplification (P3). Moreover, due to the high cost of context switches, Linux spins while waiting for data (P3), wasting 11.7 μ s of possible compute time.

AIFM, by contrast, provides low-overhead abstractions and an efficient user-space runtime that avoid these costs, bringing its latency (6.8 μ s) close to the hardware limit of 6 μ s. We explain these concepts in the next two sections.

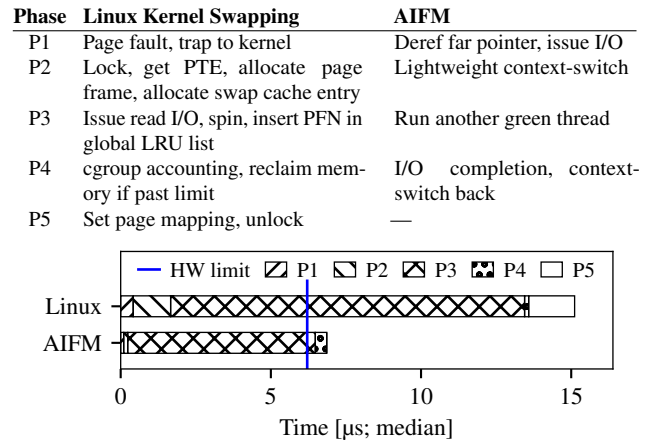

Figure 2: Linux kernel-based swapping has high overheads over hardware I/O limits (blue line, 6 μ s). Both Linux and AIFM use an SSD device backend in this experiment.

Figure 3: Applications use remoteable data structures (gray), and data structure developers rely on the AIFM runtime (yellow) to handle local memory management and interact with remote memory. Data structures can have active remote components (*i.e.*, the “DS code” box) to offload light computation.

4 AIFM Design

The goal of Application-Integrated Far Memory (AIFM) is to provide an easy-to-use, efficient interface for far memory without the overheads of page-granular far memory.

4.1 Overview

AIFM targets two constituencies: application developers and data structure developers. AIFM provides application developers with data structures with familiar APIs, allowing developers to treat these *remoteable* data structures mostly as black boxes; and AIFM provides simple, but powerful APIs to data structure engineers, allowing them to implement a variety of efficient remoteable memory data structures. Figure 3 shows a high-level overview of AIFM’s design: applications interact with data structures (gray) implemented using primitives and APIs provided by the AIFM runtime (yellow).

For an **application developer**, programming applications that use far memory should feel almost the same as programming with purely local data structures. In particular, the developer should not need to be aware of whether an object is currently local or remote (*i.e.*, far memory is *transparent*), and remoteable memory data structures should offer the same

performance as local ones in the common case. For example, idiomatic C++ code for reading several hash table entries and an array element computed from them might look as follows:

```
std::unordered_map<key_t, int> hashtable;
std::array<data_t> arr;

void print_data(std::vector<key_t>& request_keys) {
    int sum = 0;
    for (auto key : request_keys) {
        sum += hashtable.at(key);
    }
    std::cout << arr.at(sum) << std::endl;
}
```

The same code written using AIFM looks like this:

```
RemHashtable<key_t, int> hashtable;
RemArray<data_t> arr;

void print_data(std::vector<key_t>& request_keys) {
    int sum = 0;
    for (auto key : request_keys) {
        DerefScope s1; // Explained in Section 4.2.2.
        sum += hashtable.at(key, s1);
    }
    DerefScope s2;
    std::cout << arr.at(sum, s2) << std::endl;
}
```

The remoteable memory data structures themselves (RemHashtable and RemArray above) are written by **data structure engineers**, who use AIFM’s runtime APIs to include remoteable memory objects in their data structures. When memory becomes tight, AIFM’s runtime moves some of these memory objects to remote memory; when the data structure needs to access remote objects, the AIFM runtime fetches them. Data structure engineers have substantial design freedom: they can rely entirely on AIFM to fetch remote objects, or they can deploy custom logic on the remote side.

Remote servers store the actual remote data in their memory, and run a counterpart AIFM runtime, which may call into custom data structure logic. This is helpful, *e.g.*, if the remoteable memory data structure needs to chase pointers, which would otherwise require multiple round-trips.

4.2 Remoteable Memory Abstractions

AIFM is designed around four core abstractions: *remoteable pointers*, *dereference scopes*, *evacuation handlers*, and *remote devices*. We designed the abstractions such that they impose minimal overheads (as low as three micro-ops) on “hot path” access to local objects, and try to ensure that the “cold path” remote access incurs little latency above hardware limits.

4.2.1 Remoteable Pointers

A remoteable pointer represents a memory object (*i.e.*, an allocation) that is currently either local, or remote (in “far” memory). AIFM supports unique and shared remoteable pointers, whose interface makes them suitable for use in any place where a data structure would use an ordinary, local pointer.

(a) Local object. H: hot, P: present, S: shared, D: dirty, E: evacuating.

(b) Remote (swapped-out) object. DS ID means data structure ID.

Figure 4: Remoteable unique pointer representations for local and remote objects. AIFM inverts the H/P/D bit meaning (0 = hot/present/dirty) for a more efficient hot path execution.

Memory representation. Unique remoteable pointers, which correspond to C++’s `std::unique_ptr`, have the same size as ordinary 64-bit pointers, while shared pointers are 128-bits wide (like `std::shared_ptr`). Figure 4 shows the memory layout of a remoteable unique pointer. Depending on whether a remoteable pointer is local or remote, we adopt a different format. If the memory is local (Figure 4a), the pointer contains a virtual memory address in its lower 47 bits (enough to represent user-space addresses), and control bits in the upper 17 bits, including standard dirty (D) and present (P) bits (cf. page tables). It also contains bits to track whether the pointer is hot (H) and whether it is being concurrently evacuated (E). For unique pointers, the shared (S) bit is set to 0. We byte-align the D, E, and H bits, allowing each of them to be accessed by mutators and runtime evacuators concurrently and atomically, as a byte is the smallest read/write unit.

If the memory is remote (Figure 4b), it contains metadata to assist in retrieving the object from remote memory, such as the data structure ID, the object size, and the object ID. Each data structure instance has a unique data structure ID managed by the runtime. The object ID refers to a data structure-specific object identifier (such as a key in a hash table), which is used by the remote memory server to identify the object.

AIFM’s remoteable shared pointer, which allows pointer aliasing and corresponds to C++’s `std::shared_ptr` differs from the unique pointer in two ways. First, its S bit is set to 1; and second, the pointer has an additional 8 bytes for chaining the shared pointers to the same object. When AIFM’s runtime evacuates the referred object or moves it locally (§5.3), it traverses the chain to update all shared pointers.

API. Listing 1 shows the API of the remoteable unique pointer (the shared pointer’s API is largely identical). `RemUniquePtr` has two constructors: one for already-local objects and one for currently remote objects. The second constructor allows data structures to form remoteable pointers to objects that are currently remote. This helps data structure engineers reference remote objects from their data structures without having to fetch those objects.

To turn a remote pointer into a local one, the programmer dereferences it via the `deref` and `deref_mut` API methods.

```

class RemUniquePtr<T> {
    uint64_t metadata; // 64 bits, see Figure 4.
    // Construct local object
    RemUniquePtr(DSID, T* obj_addr);
    // Construct remote object
    RemUniquePtr(DSID, ObjID);
    const T* deref(DerefScope& scope); // Immutable.
    T* deref_mut(DerefScope& scope); // Mutable.
}

```

Listing 1: AIFM remoteable unique pointer API.

Dereferencing. When the dereferencing methods are called, the runtime inspects the present bit of the remoteable pointer. If the object is local, it sets the hot bit and returns the address stored in the pointer. Otherwise, the runtime fetches it from the remote server, sets the hot bit and dirty bit (in `deref_mut`), and returns a local pointer to the data.

AIFM’s hot path for local access is carefully optimized and takes five x86-64 machine instructions: one `mov` to load the pointer, one `andl` to check present and evacuating bits, a conditional branch to the cold path if neither is set, a shift (`shrq`) to extract the object address, and a `mov` to return it. Modern x86-64 processors macro-fuse the second and third instructions (test and branch), so the hot path requires four micro-ops, a three-micro-op overhead over an ordinary pointer dereference. The cold path is slower, as it calls into the AIFM runtime to potentially swap in a remote object.

One challenge to making this API work is managing the local lifetime of the dereferenced data: while the application holds a pointer returned from dereferencing a `RemUniquePtr`, the runtime must never swap out the object. This is hard to achieve in unmanaged languages like C/C++, since after getting the raw address, application code could store it virtually anywhere (*e.g.*, on the heap, stack, or even in registers). The runtime lacks sufficient information to detect whether any such pointer continues to exist, and thus whether the data is still being used. The Boehm garbage collector [13] tackles a similar reference lifetime problem by scanning the whole address space to find any possible references. Such scans would impose an unacceptable performance overhead for AIFM. Our solution is to instead leverage application semantics to tie the lifetime of the local, dereferenced data to the lifetime of the AIFM’s dereference scopes.

4.2.2 Dereference Scopes

Listing 2 demonstrates the usage of `DerefScope`. Before accessing the remoteable object, the developer must construct a `DerefScope`. AIFM container’s API provides a compile-time check by taking a `DerefScope&` argument. (This is also why the remoteable pointer has its own dereferencing methods, rather than overloading `operator*`.)

Under the hood, `DerefScope`’s constructor creates an evacuation fence, which blocks upcoming evacuations until it is destructed. The lifetime of all local dereferenced data is therefore tied to the scope lifetime. Accessing dereferenced data

```

RemVector<value_t> vec;
// ...
for (uint64_t i = 0; i < vec.size(); i++) {
    {
        DerefScope scope;
        auto& value = vec->at(i, scope);
        // process value
    }
    // scope destroyed, can evacuate value’s object
}

```

Listing 2: AIFM dereference scope example.

outside the dereference scope is undefined behavior. In the future, AIFM might leverage static analysis to catch lifetime violations, as in the Rust compiler [78].

Our scope API is familiar to C/C++ programmers; it shares similarity with C++11’s `std::weak_ptr` and, *e.g.*, the `rcu_reader` guard in Facebook’s RCU API [26]. Note that the lifetime of the `DerefScope` is separate from the lifetime of the remoteable pointer: a remoteable pointer may still be alive even when its data has been swapped to the remote. This is unlike, *e.g.*, `std::unique_ptr`, where the pointer’s destructor terminates the lifetime of the object data.

Dereference scopes require developers to modify the application code. An alternative API might avoid the need for a dereference scope at the cost of copying the object into local memory on dereference. AIFM’s core APIs aim to achieve maximum performance, so we avoid copying by default. The overhead of a copying API is highly application-dependent; our experiments suggest that 3–8% overhead are typical for applications with high compute/memory access ratios.

4.2.3 Evacuation Handlers

When an object is not protected by a `DerefScope`, AIFM’s runtime may evacuate it to far memory. Evacuation changes the pointer to this object from local to remote status, and future dereferences will cause AIFM to swap the object back in. But some use cases may wish to implement custom behavior on evacuation. For example, when AIFM evacuates an object contained in a hash table, the hash table may register an evacuation handler to remove the key and object pointer to save local space. (In this case, future lookup misses for the key will reconstitute the key and pointer, and add them to the hash table.) AIFM offers *evacuation handlers* for this purpose, enabling developers to incorporate the data structure semantics into the runtime evacuator.

Evacuation handlers are also critical for handling embedded remoteable pointers inside objects. For example, data structure engineers can use evacuation handlers to support embedded remoteable unique pointers in objects that are themselves remoteable. When an object is remotized, any embedded remoteable pointers must either be moved to the local heap, or the object it references must be moved to remote memory, and the remoteable pointer must be updated with an identifier to later retrieve the remote object from a remote device (§4.2.4). As a result, the evacuator never has to retrieve remote memory

```
// The AIFM runtime will invoke the handler on evacuating
// the object to the remote server (phase 4 in Section 5.3).
using EvacHandler = std::function<
    void(Object&, const Runtime::CopyToRemoteFn&>;
// Registers an evacuation handler for a data structure ID.
void Runtime::RegisterEvacHandler(DSID id, EvacHandler h);
```

Listing 3: AIFM evacuation handler API.

to update a remoteable pointer.

AIFM provides an evacuation handler API (Listing 3). The evacuation handler gets invoked on evacuating the object to the remote server (phase 4 in §5.3), right before the runtime frees the object’s local memory. The runtime passes two arguments to `EvacHandler`—the object to be evacuated and the function that triggers the runtime to copy the object to the remote side. The first argument allows the handler to mutate the object data before copying (e.g., modify the state of its embedded pointers) and further cleanup the local data structure after copying (e.g., remove its pointer from the hash table index). The second argument offers the flexibility in the timing of copying the object to remote.

Data structure developers register their evacuation handlers by invoking `RegisterEvacHandler`. An evacuation handler is tied to a unique data structure ID, which each data structure allocates in its constructor, and which data structure engineers must use consistently. This way, different data structures or instances of the same data structure coexist in the same application, while the runtime invokes the appropriate handler.

4.2.4 Remote Devices

AIFM’s `RemDevice` provides functionality at the remote memory server (Listing 4). The remote device, by default, uses a key-value store abstraction: when the client dereferences a remote pointer, the runtime sends the data structure ID and object ID to the remote server, which looks up the object by data structure ID and object ID, and sends the object data back. When evacuating an object, the runtime sends IDs and object data to the remote server, which inserts the object.

AIFM also gives datastructure engineers the flexibility to override this default behavior to integrate custom active components at the remote server. This is accomplished by registering their implementation on their own data structure type to the remote device (`register_active_component`). A custom active component is especially beneficial when the application’s compute intensity is low, as this setting often makes it more efficient to perform operations on remote memory than paying the cost of bringing the objects into local memory. After registering the active component at the remote, data structure engineers invoke `RemDevice`’s client-side bindings to interact with the remote components. They use `construct` and `destruct` to instantiate and destroy remote components. If an object is not present when dereferencing a remote pointer, the runtime invokes the `read_obj` to swap in the missing object. On evacuation, the evacuator invokes `write_obj` to swap out cold objects and `delete_obj` to release dead objects. In

```
class RemDevice {
    void register_active_component(DSType, ActiveComponent&);
    DSID construct(DSType, ByteArray params);
    void destruct(DSID);
    void read_obj(DSID, ObjID, ByteArray& obj_data);
    void write_obj(DSID, ObjID, ByteArray obj_data);
    bool delete_obj(DSID, ObjID);
    void compute(DSID, OpCode, ByteArray in, ByteArray& out);
};
```

Listing 4: AIFM remoteable device API.

addition, the `compute` method invokes a custom function, executing a lightweight computation on the remote server. This is useful, for example, for efficiently aggregating a sum across objects in a data structure without wasting network bandwidth to bring all objects into local memory first.

We implemented remote active components to improve the performance of hashtables (§8.2.1) and DataFrames (§8.1.2).

4.2.5 Semantic Hints

AIFM’s APIs allow injecting information about application- and object-specific semantics into the runtime.

Hotness tracking. To dereference a remoteable pointer, the user invokes our library, which sets the hot bit of the pointer. Under memory pressure, the memory evacuator uses this hotness information to ensure that frequently accessed objects are local. On evacuation, the evacuators clear the hot bit. AIFM initialization allows developers to customize the number of hot bits to use in the pointer (up to eight) and the replacement policy by data structure ID. With several hot bits, AIFM supports, e.g., a CLOCK replacement policy [72].

Prefetching. AIFM includes a library that data structures can use to maintain a per-thread window of the history of dereferenced locations and predict future accesses using a finite-state machine (FSM). It updates the window and the FSM on each dereference. The FSM detects patterns of sequential access and strided access. When a pattern is detected, it starts prefetcher threads that swap in objects from the remote server. With enough prefetching, application threads always access local memory when dereferencing remoteable pointers. The library estimates the prefetch window size conservatively using the network bandwidth-delay product. Data structure engineers can also add custom prefetching policies.

Nontemporal Access¹. For remoteable pointers to objects without temporal locality, it makes sense to limit the local memory used to store their object data. This avoids polluting local memory, which multiple data structures may share, with data that a data structure engineer knows is unlikely to be accessed again. To achieve this, AIFM’s pointer API supports *non-temporal* dereferences (Listing 5). This immediately marks the object pointed to by `rmt_ptr` as reclaimable, though the actual evacuation happens only after the

¹We use “nontemporal” in the sense of x86’s nontemporal load/store instructions [35], which conceptually bypass the CPU cache to avoid pollution.

```

DerefScope scope;
// non-temporal dereference ↓ allows immediate reclaim
T* p1 = rmt_ptr1.deref_mut<true>(scope);
// temporal deref; deref_mut(scope) works too
T* p2 = rmt_ptr2.deref_mut<false>(scope);

```

Listing 5: Non-temporal and temporal dereferences.

DerefScope ends. Without a hint, a dereference is temporal by default; §8.1.1 evaluates the benefit of the hint.

5 AIFM Runtime

AIFM’s runtime is built on “green” threads (light-weight, user-level threading), a kernel-bypass TCP/IP networking stack, and a pauseless memory evacuator. Applications link the runtime into their user-space process. This allows us to co-design the runtime with AIFM’s abstractions and provides high-performance far memory without relying on any OS kernel abstractions.

Two high-level objectives guide our runtime design: (i) the runtime should productively use the cycles spent waiting during the inevitable latency when fetching objects from remote memory; and (ii) application threads should never have to wait for the memory evacuator.

5.1 Hiding Remote Access Latency

We want to hide the latency of fetching data from far memory by doing useful work during the fetch.

Existing OS kernel threads pay high context-switching costs: *e.g.*, on Linux, rescheduling a task takes around 500ns. These costs are a nontrivial fraction of remote memory latency, so Linux and Fastswap adopt a design where they busy-spin while waiting for a network response [6]. This avoids context-switch overheads, but also wastes several microseconds of processing time. This approach also places tremendous pressure on network providers to support even lower latency to reduce the amount of wasted cycles [9, 28]. AIFM takes a different approach: it relies on low-overhead green threads to do application work while waiting for remote data fetches.

Consistent with literature on garbage collection (GC), we refer to normal application threads as *mutator threads* in the following. Each mutator thread accesses far memory, blocking whenever it needs to fetch a remote object. When that happens, another mutator thread can run and make productive use of available CPU cycles. Moreover, AIFM’s runtime spawns prefetcher threads to pull in objects that it predicts will be dereferenced in the future, allowing it to avoid blocking mutator threads when the predictions are correct.

Using green threads, AIFM tolerates network latency without sacrificing application-level throughput, wasting fewer cycles than systems that busy-poll for network completion.

5.2 Remoteable Memory Layout

For the local memory managed by AIFM, its runtime embraces the idea of log-structured memory [63], which splits

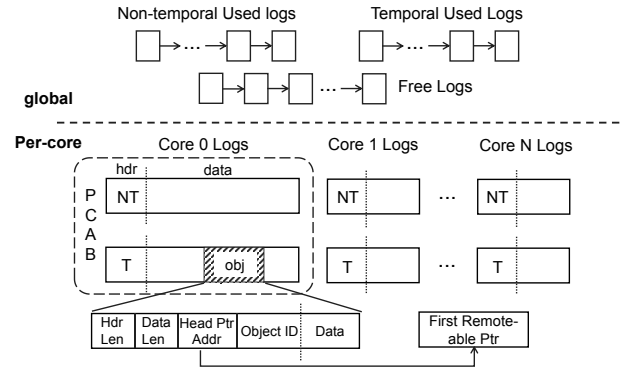

Figure 5: The layout of local remoteable memory in AIFM. There are three global lists: a free list, a temporal used list, and a non-temporal used list. Each list stores many logs, and each log stores many objects. There is a per-core allocation buffer (PCAB) that keeps two free logs to allocate new objects, one log for temporal objects, the other for non-temporal ones.

and manages the local remoteable memory in the granularity of logs (Figure 5). The log size is 2MB, which helps reduce TLB misses by allocating huge pages. The runtime maintains three global lists: a free list, a non-temporal used list, and a temporal used list. Each list stores many logs. For core scalability, each core owns two logs for new allocations: one log for temporal objects, the other for non-temporal ones. The logs are kept in a per-core allocation buffer (PCAB). To allocate an object, the runtime first tries to allocate from a log in the PCAB. If that log runs out of space, the runtime appends the log to the global non-temporal or temporal used list, and obtains a new log from the global free list. To free an object, the runtime marks the object as free. AIFM leverages a mark-compact evacuator to achieve a low memory fragmentation ratio, as shown with other copying log allocators [63].

A log has a 1B header indicating whether it stores non-temporal or temporal data. The remaining space stores objects. Each object has a `Hdr Len` bytes header and a `Data Len` bytes data. The 6-byte `Head Ptr Addr` stores the address of the remoteable pointer that points to the object. For a unique pointer, `Head Ptr Addr` stores the address of the only pointer; for a shared pointer, it stores the address of the first shared pointer in the chain. Dead objects have `Head Ptr Addr` set to `nullptr`. The variable-sized `Object ID` stores the object’s unique identifier. The header is used on evacuation, when the runtime passes the object ID to write/delete endpoints on the remote device and the remoteable pointer address to the evacuation handler, and when the runtime swaps in an object and passes the object ID to the remote device.

5.3 Pauseless Memory Evacuator

Upon memory pressure, the runtime’s memory evacuator moves cold objects to the remote server. Like with many garbage collectors in managed languages, a key feature of AIFM is to allow mutator threads to run concurrently while

the runtime evacuates local memory. The evacuator executes four phases in sequence, described in the following paragraphs. To ensure correctness under race conditions, the evacuator maintains an invariant: *it only starts to move object O after setting the mutator-side synchronization barrier on accessing O*. The evacuator sets the barrier by setting the pointer evacuation bit (phase 2). The RCU writer wait (phase 3) ensures all mutators have observed the set bits to enforce the timing order in the invariant.

1. Log Selection Phase. The goal of the evacuator is to maintain the local free memory ratio above the *min_free_ratio* (0.12 by default). The *master thread* of the evacuator picks $total_log_cnts \cdot (current_free_ratio - min_free_ratio)$ of logs to be evacuated. The evacuator picks logs in FIFO order from the global non-temporal used list, and then picks from the global temporal used list if necessary, to prioritize non-temporal objects. AIFM could also use more sophisticated schemes, *e.g.*, prioritizing logs by occupancy and age [23].

2. Concurrent Marking Phase. The master evacuation thread spawns *worker threads* and divides the previously-selected logs among them. Each worker thread iterates through the objects in its logs to find live objects. For each such object, the worker sets the evacuation bit of all remoteable pointers of the object by traversing the pointer chain starting from the head pointer address (*i.e.*, the `Head Ptr Addr` field). This marks the object for evacuation.

3. Evacuator Waiting Phase. The runtime can evacuate objects only when they are not being dereferenced by mutator threads. Rather than following a naive approach of having mutators and the evacuator to acquire a per-object lock—which would impose high overhead on the hot path of mutators accessing local objects—AIFM uses an approach inspired by read-copy-update (RCU) synchronization. AIFM’s runtime treats mutators as RCU readers and the evacuator master thread as an RCU writer, thereby moving the synchronization overhead to the evacuator. This choice makes sense because (i) the mutators do application work, so AIFM should steer overhead away from them; and (ii) evacuation is a rare event. The result is that the evacuator master thread waits for a quiescent period to ensure all mutator threads have witnessed the newly-set evacuation bits.

If a mutator thread subsequently dereferences a pointer to an object that the runtime is evacuating, the mutator sees that the evacuation bit is set. A naive approach would now block the mutator thread while the evacuation bit is set. Instead, AIFM opts for an approach that avoids such pauses: the mutator copies the object to another log in its PCAB, and then executes a compare-and-swap (CAS) on the head remoteable pointer (which serves as a synchronization point) to simultaneously clear the evacuation bit, set the present bit, and set the new data location. This CAS will race with the evacuator (see next phase below). If the CAS succeeds, the mutator copied an intact object, so it obtains a local reference. The mutator then updates all pointers in the pointer chain with the head

pointer metadata and continues executing. If the CAS fails, the evacuator has already changed the remoteable pointer to remote status, so the mutator’s copy of the object may be corrupt. Consequently, the mutator frees the copy it made and obtains a remote reference.

4. Concurrent Evacuation Phase. The master thread spawns more worker threads to evacuate objects and run their evacuation handlers. Again, the master divides the previously selected logs among the workers. Each worker iterates through each log and each object within the log. For each cold object, the worker copies the object to the remote and executes a CAS on the head remoteable pointer to simultaneously clear the presence bit and set the remote pointer metadata. If the CAS succeeds, the object has been evacuated, and the worker updates all pointers in the pointer chain with the head pointer metadata and invokes the evacuation handler. Otherwise, a mutator thread succeeded with a racing CAS and has copied the object to another location. Either way, the log entry is now unused and reclaimable. For each hot object, the worker compacts and copies it into a new log, updates the object address in the remoteable pointers, and resets the hot bits.

5.4 Co-design with the Thread Scheduler

Evacuation is an urgent task when the runtime is under memory pressure. With a naive thread scheduler, evacuation can be starved by mutator threads, leading to out-of-memory errors and application crashes. There are two challenges that we need to address. First, a large number of mutator threads may allocate memory faster than evacuation can free memory. Second, evacuation sometimes blocks on mutator threads in a dereference scope, and this creates a dilemma. On one hand, the scheduler needs to execute mutator threads so they can unblock evacuation. On the other hand, executing mutator threads may consume more memory.

To address these issues, we co-design the runtime’s green thread scheduler with AIFM to prioritize the activities necessary for evacuation, both in mutator threads and evacuation threads. First, each thread keeps a status field that is set by the AIFM runtime and read by the scheduler, which allows the scheduler to know whether a thread is in a dereference scope. The scheduler runs a multi-queue algorithm and assigns the first priority to mutators in a dereference scope, second priority to evacuation threads, and third priority to other mutator threads. Second, to avoid priority inversion [42] when the system is short of memory, the allocation function in the AIFM runtime triggers a signal to all running threads to force them to yield their cores back to the scheduler for re-scheduling.

6 Remoteable Data Structure Examples

We implemented six remoteable AIFM data structures.

Array. The remoteable array consists of a native array of `RemUniquePtrs`. Each pointer points to an array element to enable fine-grained data placement decisions. Alternatively, users can configure the pointed object as multiple consecutive

array elements to reduce the memory overhead of pointer metadata. The object IDs of pointers are their remote-side object addresses. The prefetcher records accessed indices at all array access APIs; it starts prefetching when detecting a strided access pattern.

Vector. The remoteable vector is similar to the remoteable array except that it is dynamically sized, and uses a `std::vector` to store `RemUniquePtrs`. Additionally, the vector has an active remote component that supports offloading operations like copies and aggregations, which are used by the `DataFrame` application (§8.1.2).

List. The remoteable list is similar to the remoteable vector, except that it uses a local list that stores `RemUniquePtrs` to support efficient `insert` and `erase` operations. The list supports traversals in forward and reverse directions, which offers strong semantic hints to the prefetcher. When detecting a direction, the prefetcher walks through the local list in the same direction to prefetch remote list objects.

Stack and Queue. The remoteable stack and queue are simple wrappers around remoteable lists.

Hashtable. The remoteable hashtable consists of a table index (stored on the local heap) and key-value data (stored in AIFM’s remoteable heap). In the index, each hash bucket stores a `RemUniquePtr` to a key-value object. The object IDs of pointers are their hashtable keys. The hashtable has an active remote component that maintains a separate hashtable in remote memory. In this architecture, the local hashtable is a cache (inclusive or exclusive) of its remote counterpart. When the referenced object is missing from the local cache, the active remote component assists the chain lookup at the remote hashtable to avoid multiple network round-trips. Data structure engineers might also realize different hashtable designs via AIFM’s APIs.

7 Implementation

AIFM’s implementation consists of the core runtime library (§5) and the data structure library (§6). The core runtime is built on top of Shenango [55] to leverage its fast user-level threading runtime and I/O stack. AIFM is written in C and C++, with 6,451 lines in the core runtime, 5,535 lines in the data structure library, and 750 lines of modifications to the Shenango runtime. The system runs on unmodified Linux.

We integrated two far memory backends into AIFM: a remote memory server based on a DPDK-based TCP stack, and an NVMe SSD using an SPDK-based storage stack. Unlike the remote memory backend, the SSD backend does not support active remote components (since the storage drive does not have a general compute unit), and it has an inherent I/O amplification because it is limited to a fixed block size. Our evaluation focuses on the remote memory backend.

The current implementation has some limitations. First, we do not support TCP offloading or RDMA, which would reduce CPU overhead of our runtime. Second, a local compute server

connects to a single remote memory server, and the remote memory cannot be shared by different clients. Finally, the local and remote memory size cannot be changed at runtime. We plan to address them in the future.

8 Evaluation

Our evaluation of AIFM seeks to answer three questions:

1. What performance does AIFM achieve for end-to-end applications, including ones that combine multiple remoteable data structures? (§8.1)
2. How does AIFM’s performance compare to a state-of-the-art far memory system, Fastswap [6]? (§8.1–§8.2)
3. What factors contribute to AIFM’s performance? (§8.3)

Setup. We run experiments on two `x1170` nodes on Cloud-Lab [25] with 10-core Intel Xeon E5-2640 v4 CPUs (2.40 GHz), 64GB RAM, and a 25 Gbits/s Mellanox ConnectX-4 Lx MT27710 NIC. We enabled hyper-threads, but disabled CPU C-states, dynamic CPU frequency scaling, transparent huge pages, and kernel mitigations for speculation attacks in line with prior work [55]. We use Ubuntu 18.04.3 (kernel v5.0.0) and DPDK 18.11.0, except for experiments with Fastswap, which use Linux kernel v4.11, the latest version Fastswap supports. All AIFM experiments use the default configuration settings and the default built-in prefetchers of remoteable data structures. We do not tune prefetching policy specifically for evaluated applications.

8.1 End-to-end Performance

We evaluate AIFM’s end-to-end performance with two applications. First, we designed a synthetic application that mimics a typical web service frontend to understand AIFM’s performance with multiple remoteable data structures and the impact of semantic hints. Second, we also ported an open-source C++ `DataFrame` library [16] with an interface similar to `Pandas` [56] to AIFM, and use it to understand the porting effort required and AIFM’s performance for an existing application.

8.1.1 Synthetic Web Service Frontend

In response to client requests, the application fetches structured data (*e.g.*, a list of user IDs) from an in-memory key-value store, and then uses the retrieved values to compute an index into a large collection of 8KB objects (*e.g.*, profile pictures). Finally, the application fetches one 8KB object, encrypts it, and compresses it for the response to the client.

This application uses our remoteable hashtable (for the key-value pairs) and our remoteable array (for the 8KB objects). Each client request looks up 32 keys in the hashtable and fetches a single 8KB array element. We load the hashtable with 128M key-value pairs (10GB total data, of which 6GB are index data and 4GB are value data), and create an array of 2M objects of 8KB each (16GB total). The two data structures share 5GB of available local memory, *i.e.*, the local memory size is 19% of the total data set size. We generate closed-loop client requests from a Zipf distribution with parameter s : a uni-

(a) Latency as a function of offered load. (b) Throughput as a function of local memory. (c) AIFM miss rates in Figure 6b.

Figure 6: In a web frontend-like application with a hashtable and array, AIFM outperforms Fastswap by $20\times$ (a) and achieves 90% of local memory performance with $5\times$ less memory (b), as non-temporal array access avoids polluting local memory (c). “AIFM(NT)”: non-temporal access; “AIFM(T)”: temporal access; “Local Only”: entire working set in local memory.

form distribution corresponds to $s = 0$, while values of s close to 1 indicate high skew. Each request accesses Zipf-distributed keys in the hashtable and uses their values to calculate an (also Zipf-distributed) array index to access; the request then encrypts the array data via AES-CBC using crypto++ [22] and compresses the result using Snappy [30]. We compare two AIFM settings—with and without non-temporal dereferences for array elements—against Fastswap [6] and an idealized baseline with all 26GB in local memory. A good result for AIFM would show improved performance over Fastswap, a benefit to non-temporal array accesses, and performance not much lower than keeping the entire data in local memory.

Figure 6a shows a throughput-latency plot for a Zipf parameter of $s = 0.8$ (i.e., a skewed distribution). The x -axis shows the offered load in the system, and the y -axis plots the measured 90th percentile latency. Each setup eventually encounters a “hockey-stick” when it can no longer keep up with the offered load. Fastswap tolerates a load of up to 19k requests/second, but its overheads and the amplification for the hashtable lookups quickly dominate. AIFM with a temporal array dereference scales $7\times$ further, but fails to keep up beyond 140k requests/second because the 8KB array accesses pollute its local memory. To make room for an 8KB array element, the runtime often evicts hundreds of hashtable entries, causing a high miss rate on hashtable lookups. AIFM with non-temporal access to the array, however, scales to 370k requests/second ($20\times$ Fastswap’s maximum throughput). This is 16% lower throughput than the 440k requests/second achieved by an idealized setup with 26GB in local memory. In other words, AIFM achieves 84% of the performance of an entirely local setup with $5\times$ less local memory.

Additional local memory helps bring AIFM performance closer to the in-memory ideal. Figure 6b shows the percentage of the all-local memory throughput achieved by the non-temporal version of AIFM when varying the local memory

size (on the x -axis, as a fraction of 26GB). While Fastswap’s throughput starts near zero and grows roughly in proportion to the local memory size, AIFM’s throughput starts at 30% of the ideal and quickly reaches 85% of the in-memory throughput at 5.0GB local memory (20% of 26GB).

Figure 6c illustrates why this happens. At the left-hand side of the plot (5% local memory), AIFM sees high miss rates in both hashtable (52%) and array (89%). But as local memory grows, the hashtable miss rate quickly drops to near-zero, since AIFM’s non-temporal dereferences for the array ensure that most of the local memory is dedicated to hash table entries. Correspondingly, the array miss rate drops more slowly and in proportion to the local memory available. By contrast, Fastswap (not shown here) has high miss rates in both data structures, as its page-granular approach manages local memory inefficiently.

8.1.2 DataFrame Application

The DataFrame abstraction, popularized in Pandas [56], provides a convenient set of APIs for data science and ML workloads. A DataFrame is a table-structured, in-memory datastructure exposing various slicing, filtering, and aggregation operations. DataFrames often have hundreds of columns and millions of rows, and their full materialization in memory often pushes the limits of available memory on a machine [54, 57, 60]. By making remote memory available, AIFM can help data scientists interactively explore DataFrames without worrying about running out of memory.

We ported a popular open-source C++ DataFrame library [16] to AIFM’s APIs. The primary data structure used in the library is an `std::vector` storing DataFrame columns and indexes, and we replaced this vector with the AIFM-enabled equivalent. In addition, we also added support for offloading key operations with low compute intensity but high memory access frequency to the remote side. We achieve this by offloading three operations using AIFM’s remote device

DataFrame API		Offloaded Rem. Dev. Operations		
		Copy	Shuffle	Aggregate
	Filter	✓		
	Range extraction	✓		
	Add column/index	✓		
	Sort by column		✓	
	GroupBy		✓	✓

Table 1: DataFrame APIs (rows) and the offloaded operations they use via AIFM’s remote device API (columns). Copy and Shuffle are memory-only operations, while Aggregate performs light remote-side computation.

Figure 7: An AIFM-enabled DataFrame library [16] achieves 78–97% of in-memory throughput for a data analytics workload [53], outperforming Fastswap. Offloading operations with low compute intensity is crucial to AIFM’s performance.

API (§4.2.4). The *Copy* and *Shuffle* operations copy a vector (*i.e.*, a DataFrame column), with shuffle also reordering rows by index positions in another column; *Aggregate* computes aggregate values (sums, averages, etc.). These three operations are used in five DataFrame API calls, including filters, column creation, sorts, and aggregations (Table 1). To achieve coverage sufficient to run the New York City taxi trip analysis workload [53], we modified 1,192 lines of code in the DataFrame library (which has 24.3k lines), and wrote 233 lines of remote device code. These modifications took one author about five days.

We benchmark our AIFM-enabled DataFrame with the Kaggle NYC taxi trip analysis workload [53], which explores trip dimensions including the number of passengers, trip durations, and distances, on the NYC taxi trip dataset [74] (16GB). The workload’s full in-memory working set is 31GB. In the experiment, we vary the size of available local memory between 1GB and 31GB. We compare AIFM with Fastswap and a baseline with all data in local memory. In addition, we also investigate the impact of offloading on this workload, which consists of an operation with low compute intensity (*Aggregate* in Table 1) and some pure memory-copy operations (*Copy* and *Shuffle*). We would hope to find AIFM outperform Fastswap and come close to the local memory baseline.

Figure 7 shows the results. AIFM achieves 78% of in-memory throughput even with 1GB of local memory (3.2%) and exceeds 95% of ideal performance from about 20% (6GB) local memory. Fastswap, by contrast, achieves only 20% of in-memory performance at 1GB and only comes close to it once

Figure 8: Performance gains from offloading the operations in Table 1. AIFM benefits most from offloading *Copy*, which increases throughput by 18–38%.

over 90% of the working set are in local memory. AIFM’s high performance comes from avoiding Fastswap’s page fault overheads, and from reducing expensive data movements over network by offloading operations with low compute intensity. Without offloading, AIFM outperforms Fastswap until 60% of the working set are local, as Fastswap incurs frequent minor faults. Beyond 60%, the fault rate in Fastswap drops sufficiently for most memory accesses to outperform AIFM’s dereference-time overhead for low compute intensity operations (*e.g.*, memory copies). Offloading these operations to the remote side helps AIFM avoid this cost, while high compute-intensity operations amortize the dereference cost and happen locally. We also prototyped a batched API for AIFM that amortizes the dereference overhead across groups of vector elements when offloading is not possible, and found that it improves AIFM’s throughput without offloading to 60–80% of in-memory throughput. We believe this could make a good future addition to AIFM’s API to speed up low compute intensity operations if they must be performed locally.

Figure 8 breaks down the effect of offloading. Offloading *Copy* contributes the largest throughput gains (18%–38%); offloading *shuffle* contributes 2.9%–13%; and offloading *Aggregate* contributes 4.5%–12%. These results show that AIFM achieves high performance with small local memory for a real-world workload, and that AIFM’s operation offloading is crucial to good performance when a workload includes operations with low compute intensity.

8.2 Data Structures

We pick two representative data structures—the hashtable and the array—from §6. We evaluate them in isolation, and explore the impact of prefetching, non-temporal local storage, and read/write amplification-reducing techniques.

8.2.1 Hashtable

Hash tables provide unordered maps that typically see random accesses, often with high temporal locality. A remoteable hash table should benefit from temporal caching of popular key-value (KV) pairs in local memory. Note that with AIFM, the caching policy is controlled by the data structure engi-

Figure 9: An AIFM hash table is competitive with local memory when the access distribution is skewed (Zipf factors ≥ 0.8), and outperforms a hashtable in Fastswap by up to $61\times$ as Fastswap suffers from amplification and other overheads.

neer, while with Fastswap (or any swap-based far memory system), the caching policy is determined by the kernel page-reclamation policy, which in turn is based on page-granular hotness information.

Comparison. We evaluate the hashtable over Fastswap and AIFM with a memcached-style workload that issues `GET` requests, with keys sampled from a Zipf distribution whose parameter s we vary. Our key and value sizes are based on those reported for Facebook’s USR memcached pool [8]. We load the hash table with 128M KV pairs (10GB total data), and compare performance to a baseline that keeps the entire hash table in local memory. Fastswap and AIFM instead allow a maximum of 5GB local data, split as follows. In Fastswap, the OS manages the both hashtable index (6GB) and value data (4GB) in swappable memory, with least recently used (LRU) [77] eviction at page granularity to decide on remote pages. In AIFM, we provision 3GB local memory region for index data and the other 2GB local memory region for value data; the runtime manages them separately. The hashtable’s own object-granular `CLOCK` replacement algorithm guides AIFM’s memory evacuator to pick KV pairs to evict to remote memory. In this experiment, we use a hashtable configured as an exclusive cache, *i.e.*, the evacuation handler removes local index entries for remote key-value pairs.

Figure 9 shows the throughput achieved as a function of the Zipf parameter s , ranging from near-uniform at zero to highly skewed at $s = 1.35$. AIFM achieves about 17M operations/second at low skew ($\approx 60\%$ miss rate at $s = 0$), about one third of the 53M operations/second that a fully-local hash table achieves. As skew increases and the miss rate drops, AIFM comes closer to local-only performance: for example, at $s = 0.8$ (1% miss rate), it reaches 57M operations/second; and from $s = 0.8$, it matches the performance of the local-only hashtable. Fastswap, by contrast, sees a throughput of 0.54M operations/second at $s = 0$ ($30\times$ less than AIFM) and only matches the local-only baseline beyond $s = 1.3$. At $s = 0.8$, AIFM has its largest advantage over Fastswap ($61\times$).

(a) `GET` throughput as a function of the miss rate. (b) `GET` throughput as a function of thread count (80% miss rate).

Figure 10: AIFM hash table microbenchmarks.

This difference comes from three factors against Fastswap: (i) amplification due to page-granular swapping, (ii) lack of per-KV pair hotness information, and (iii) the overheads of kernel paging. Since a page contains 128 key-value pairs, page-granular swapping incurs up to $128\times$ read and write amplification. This amplification increases the network bandwidth required and pollutes the local memory, increasing Fastswap’s miss rate with identical memory available. For example, at $s = 1.25$, Fastswap still uses 140MB/s of network bandwidth, while AIFM’s bandwidth use rapidly drops beyond $s = 0.8$. Fastswap also cannot swap out only cold key-value pairs, as a page contains entries with varying hotness, but the kernel tracks access only at page granularity. Finally, Fastswap incurs the cost of kernel crossings, page faults, identifying and reclaiming victim pages (38% of cycles at $s = 0.8$) and wasted cycles waiting for I/O (49%). AIFM’s overheads are limited to running the evacuator (0.8% of cycles at $s = 0.8$), TCP stack overheads (1.7%), and thread scheduler overhead (14%).

Microbenchmarks. Figure 10a shows how hash table performs at different miss rates when requests are uniformly, rather than Zipf-distributed. It achieves a best-case throughput of 53M requests/second, reduced to 10M requests/second when it is close to 100% miss rate. Figure 10b measures, for the same uniform distribution and an 80% miss rate, the throughput AIFM achieves with an increasing number of application threads. Up to 160 threads, AIFM extracts more throughput by scheduling additional requests while it waits for requests to complete.

8.2.2 Array

Depending on the access pattern, an array may benefit from caching (for random access with temporal locality), prefetching (for sequential access), and non-temporal storage (if there is no temporal locality).

We evaluate our array with the Snappy library [30]. The benchmark performs in-memory compression/decompression by reading input files from a `RemArray` and writing output files to another `RemArray`. For benchmarking compression, we use 16 input files of 1GB each. For decompression, we use

Figure 11: AIFM achieves nearly identical performance to local memory when compressing/decompressing an array with Snappy [30] (sequential access), and outperforms Fastswap.

30 input files of 0.5GB each. The compression ratio is around 2. Both operations perform streaming, sequential access to the array and never revisit any object. We compare Fastswap and an ideal, completely local in-memory baseline.

AIFM’s array prefetcher captures application semantics through the array access APIs and performs prefetching entirely in user space. OS-based paging systems, by contrast, must rely on page faults (major faults for unprefetched pages and minor faults for prefetched pages) to pass application semantics, which imposes high overheads. For each system, we measure performance with different amounts of local memory available (for Fastswap, we restrict memory via cgroups; for AIFM, we set the local memory size). A good result would avoid AIFM’s slow path, as every far pointer dereference would find local data already.

Figure 11 shows the results. We see that AIFM achieves performance close to the in-memory baseline, independent of the local memory size, while Fastswap’s performance depends on local memory size and only matches AIFM when nearly all memory is local. This demonstrates the benefit of AIFM’s non-temporal access and prefetching.

8.3 Design Drill-Down

We now evaluate specific aspects of the AIFM design using microbenchmarks.

8.3.1 Fast/Slow Path Costs

AIFM seeks to provide access to local objects with latency close to normal memory access. This means that AIFM’s remoteable pointer must minimize overheads on the “fast path”, when no remote memory access is required.

We measured the hot path latency of dereferencing a `RemUniquePtr` and compared it to the latency for dereferencing a C++ `unique_ptr`, both when the pointer and data pointed to are cached and uncached. Figure 12a shows that AIFM offers comparable latency to an ordinary C++ smart pointer. For an object in L1 cache, AIFM has a 4× latency overhead: four micro-ops vs. a single pointer dereference operation. In practice, modern CPU’s instruction-level parallelism

90 th percentile latency [cycles]	read	write
C++ <code>unique_ptr</code> (uncached)	570	408
AIFM object (uncached)	489	309

(a) Hot path (local object).

90 th percentile latency [cycles]	read	write
Fastswap total	23,712	26,382
... of which RDMA transfer (4KB)	16,521	16,521
Overheads	7,191	9,861
AIFM total (64B object)	18,582	18,369
... of which TCP transfer (64B)	17,694	17,673
Overheads	888	696
AIFM total (4KB object)	27,183	27,279
... of which TCP transfer (4KB)	26,055	26,121
Overheads	1,128	1,158

(b) Cold path (remote object).

Figure 12: AIFM is competitive with an ordinary pointer dereference, and it has lower overheads than Fastswap.

hides some of this latency, and we observe a 2× throughput overhead for L1 hits.

We also measured AIFM’s cold path latency, and compared it to Fastswap’s. Fastswap always fetches at least 4KB from the remote server, but its RDMA backend is faster than AIFM’s TCP backend. This might amortize some of the overheads associated with page-granular far memory that Fastswap suffers from. A good result would show AIFM with comparable latency to Fastswap for large objects (4KB), and lower latency for small objects (64B).

Figure 12b shows the results. While Fastswap’s raw data transfers are indeed faster than AIFM’s, AIFM achieves lower latency for cache-line-sized (64B) objects due to its 10× lower overheads. For 4KB objects, AIFM is close to Fastswap, but has 10% higher latency on reads; AIFM with an RDMA backend would come closer. In addition, AIFM can productively use its wait cycles, which yields a 1.8–6.8× throughput increase over Fastswap (Figure 1).

8.3.2 Operating Point

AIFM is designed for applications that perform some compute for each remoteable data structure access, as this compute allows AIFM to hide the latency of far memory by prefetching. But if an application has a huge amount of compute per data structure access, AIFM will offer limited benefit over page-granular approaches like Fastswap, despite their overheads. We ran a sensitivity analysis with a synthetic application that spins for a configurable amount of time in between sequential accesses into a remoteable array. This should allow AIFM’s prefetcher to run ahead and load successive elements before they are dereferenced. We compare to Fastswap, which we configure with the maximum prefetching window (32 pages).

Figure 13 shows the results, normalized to the benchmark runtime against a purely in-memory array. AIFM becomes competitive with local memory access from about 1.2μs of compute between array accesses. Fastswap’s overheads amor-

Figure 13: AIFM becomes competitive with local memory access at around $1.2\mu\text{s}$ of compute per sequential far memory access (4KB object) in a microbenchmark, while kernel-based swapping mechanisms require higher compute ratios (ca. $50\mu\text{s}$ per memory access; not shown) to compete.

Figure 14: Pauseless evacuation is essential for low latency accesses: a stop-the-world (STW) evacuator frequently encounters $10\times$ higher latency as it swaps out objects.

tize more slowly—its line converges with AIFM’s around $50\mu\text{s}$ of compute per array access. This demonstrates that AIFM supports efficient remote memory in a wider range of applications than page-granular approaches like Fastswap.

8.3.3 Memory Evacuator

We evaluate two key aspects of AIFM’s memory evacuator design: the choice to never pause mutator threads (§5.3) and the thread scheduler co-design (§5.4).

Pauseless Evacuation. In this experiment, we run 10 mutator threads (the number of physical CPU cores in our machine) that keep entering the dereference scope, dereferencing and marking dirty 4MB of data each time. Therefore, the runtime periodically triggers memory evacuation. We compare AIFM’s pauseless evacuator design to a stop-the-world memory evacuator, and measure the latency per mutator iteration (4MB write). Figure 14 shows that a stop-the-world evacuator design causes periodic mutator latency spikes up to 340ms. By contrast, AIFM’s pauseless evacuator consistently runs an iteration in about 25ms. (The tiny spikes of the pauseless line are mainly caused by hyperthread and cache contention between evacuators and mutators.) This confirms that a pauseless evacuator is essential to consistent application performance.

Figure 15: Thread prioritization in the runtime is essential to ensure that evacuation always succeeds. 12% free memory is the threshold for AIFM to trigger evacuation.

Thread Scheduler Co-design. In this experiment, we run 100 mutator threads that each iterates to read 1MB of data from a remoteable array and perform 20ms of computation. We run AIFM with the scheduler’s thread prioritization (§5.4) enabled and disabled, and measure the free local memory over time. For a responsive system, local memory should never run out entirely, and the evacuator should be able to free memory fast enough to keep up with the mutators.

Figure 15 shows that the runtime without prioritization fails to keep up and runs out of memory after around 0.7 seconds. AIFM’s prioritizing scheduler, on the other hand, ensures that sufficient memory remains available. This illustrates that the benefit of co-locating thread scheduler and memory evacuator in a user-space runtime.

9 Conclusion

We presented Application-Integrated Far Memory (AIFM), a new approach to extending a server’s available RAM with high-performance remote memory. Unlike prior, kernel-based, page-granular approaches, AIFM integrates far memory with application data structures, allowing for fine-grained partial remoting of data structures without amplification or high overheads. AIFM is based on four key components: (i) the remote pointer abstraction; (ii) the pauseless memory evacuator; (iii) the data structure APIs with rich semantics; (iv) and the remote device abstraction. All parts work together to deliver high performance and convenient APIs for application developers and data structure engineers.

Our experiments show that AIFM delivers performance close to, or on par with, local DRAM at operating points that prior far memory systems could not efficiently support.

AIFM is available as open-source software at <https://github.com/aifm-sys/aifm>.

Performance-Optimal Read-Only Transactions

Haonan Lu^{*}, Siddhartha Sen[†], Wyatt Lloyd^{*}

^{*}Princeton University, [†]Microsoft Research

Abstract

Read-only transactions are critical for consistently reading data spread across a distributed storage system but have worse performance than simple, non-transactional reads. We identify three properties of simple reads that are necessary for read-only transactions to be performance-optimal, i.e., come as close as possible to simple reads. We demonstrate a fundamental tradeoff in the design of read-only transactions by proving that performance optimality is impossible to achieve with strict serializability, the strongest consistency.

Guided by this result, we present PORT, a performance-optimal design with the strongest consistency to date. Central to PORT are version clocks, a specialized logical clock that concisely captures the necessary ordering constraints. We show the generality of PORT with two applications. Scylla-PORT provides process-ordered serializability with simple writes and shows performance comparable to its non-transactional base system. Eiger-PORT provides causal consistency with write transactions and significantly improves the performance of its transactional base system.

1 Introduction

Large-scale web services are built on distributed storage systems. Sharding data across machines enables distributed storage systems to scale capacity and throughput. Sharding, however, complicates building correct applications because read requests sent to different shards may arrive at different times and thus return an inconsistent view of the data.

Consistently interacting with data in a distributed storage system thus requires transactional *isolation*, which unifies the view of data across shards. While general transactions provide isolation for reading and writing across shards, this paper focuses on *read-only transactions* that only read data. Read-only transactions are prevalent: they are used in systems without general transactions [4, 14, 31, 32, 34] and, even for systems with general transactions, they are often implemented with a specialized algorithm [10, 11, 34, 37, 38, 39, 51]. Read-only transactions are practically important because reads dominate real-world workloads: Facebook reported 99.8% reads for TAO [8] and Google reported three orders of magnitude more reads than general transactions for the ads workload (F1) that runs on Spanner [10]. They are also theoretically important because they provide a lower bound for other classes of transactions: anything impossible for read-only transactions is also impossible for any class of transactions that includes reads.

The dominance of reads in real-world workloads makes their performance the primary determinant of end-user latency and overall system throughput. Unfortunately, read-only transactions perform worse than simple, non-transactional reads due to the coordination required to present a consistent view across shards. Whether a view is consistent is determined by a system's *consistency model*: stronger consistency provides an abstraction closer to a single-threaded environment, greatly simplifying application code [33]. Thus, ideal read-only transactions would provide the strongest consistency *and* have optimal performance.

What is the “optimal” performance? Although recent work has studied optimality through the lens of latency [34], it did not consider throughput, which adds a fundamentally new dimension to this question. In this paper, we formalize the notion of optimality for read-only transactions and use it to explore the tradeoff between their consistency and performance. We posit that optimality should be defined by the algorithmic properties of simple reads that comprise a read-only transaction. *Simple reads* do not provide transactional isolation and thus capture the minimum work required to read data in a distributed storage system: **One** round of **Non**-blocking communication with a **Constant** amount of meta-data. As we elaborate in §3, these algorithmic properties (N, O, and C) precisely capture the additional coordination incurred by read-only transactions to present a consistent view. Thus, we define *performance-optimal* read-only transactions to be those with the same NOC properties as simple reads.

Our main theoretical result is that performance optimality is impossible in a system that provides **Strict** serializability—the strongest type of consistency. Specifically, our NOCS Theorem states that no read-only transaction algorithm can be performance optimal and provide strict serializability. This result holds even in systems that only support non-transactional writes, and thus applies to systems with and without more general types of transactions. It shows there is a fundamental choice in the design of distributed storage systems: they can either provide the strongest consistency or the best performance for read-only transactions, not both.

Guided by our impossibility result, we present the PORT design, which enables performance-optimal read-only transactions with the strongest consistency to date: process-ordered serializability. Previous performance-optimal transactions only provided relatively weak consistency (§5.1). PORT provides performance-optimal read-only transactions without harming either the latency or throughput of writes. The main mechanism enabling our design is a new special-

ized logical clock, called *version clocks*, that concisely capture the ordering constraints imposed by process-ordered serializability on read and write operations. PORT uses version clocks to tightly co-design its components. Version clock values index its multi-versioning framework, control what read-only transactions see, and control where writes are applied. They also enable optimizations that avoid the work of applying some concurrent writes (*write omission*) and limit the staleness of reads (*data freshness*).

We use the PORT design with the write omission and data freshness optimizations to build a new storage system, Scylla-PORT, that adds performance-optimal read-only transactions to ScyllaDB [47] while providing process-ordered serializability. As a single-versioned, non-transactional system, ScyllaDB provides a clean slate for implementing PORT and allows us to quantify the overhead of our performance-optimal read-only transactions relative to simple reads. ScyllaDB's simple reads are a challenging baseline as the system is aggressively engineered for high performance, including core-level sharding and custom lock-free data structures. Our evaluation shows that PORT's read-only transactions introduce low overhead, achieving throughput and latency within 3% of ScyllaDB on most of the workloads we test, and within 8% in the worst case. Our evaluation also compares PORT to a variant of OCC that is optimized for read-only transactions. PORT significantly outperforms OCC with at least double the throughput and at most half the latency because Scylla-PORT always finishes in one round while OCC's best case is two rounds.

We also applied PORT with data freshness optimizations to Eiger [32] to make its read-only transactions performance optimal while preserving the system's causal consistency and write transactions. Eiger is a challenging baseline because it can complete read-only transactions in a single round. Our evaluation shows that Eiger-PORT significantly improves performance with throughput up to $3\times$ higher and latency up to 60% lower than Eiger. These improvements do come with some staleness relative to strongly consistent systems, but our data freshness optimizations keep the staleness low.

In summary, this work makes the following contributions:

- A fundamental understanding of the tradeoff between performance and consistency for read-only transactions. This includes a precise definition of performance optimality (§3) and the NOCS Theorem that proves optimality is impossible with strict serializability (§4).
- The PORT design that achieves performance-optimal read-only transactions with the strongest consistency to date by leveraging version clocks, a new type of logical clock that concisely captures the necessary ordering constraints (§6).
- The implementation and evaluation of two new systems based on the PORT design. Scylla-PORT is a clean-slate application of PORT to a non-transactional system, ScyllaDB (§7). Eiger-PORT makes the read-only transaction algorithm of Eiger performance optimal (§8, §9).

2 Background

Web service architecture. Web services are typically built using two tiers of machines: a stateless frontend tier and a stateful storage tier. The frontends handle end user requests by executing application logic that generates sub-requests to read or write data in the storage tier. We refer to the frontends as *clients* and the storage machines as *servers*, as is common. Web services are often replicated across multiple datacenters. For simplicity, we focus on a single datacenter setting, but our results also apply to multi-datacenter settings.

Read-only transactions. Read-only transactions provide a consistent, unified view of data spread across servers in a storage tier. They consist of one or more logical rounds of simple read requests issued in parallel to the servers, which collectively return a view satisfying the consistency model of the system. *One-shot transactions* [23] know the data locations of all reads prior to the transaction start. In contrast, *multi-shot transactions* may include key dependencies, where the data read in one shot determines what data to read in later shots. We study one-shot transactions for simplicity, because they are common, and because what is impossible for them is also necessarily impossible for multi-shot transactions. The NOCS Theorem thus also applies to multi-shot transactions. The PORT design for read-only transactions can be easily extended to support multi-shot transactions.

3 Performance-Optimal Read Transactions

This section explains the challenges of reasoning about performance, the rationale of our approach, and the set of algorithmic properties that define optimal performance.

3.1 Reasoning About Performance

The key challenges to reasoning about performance are identifying the fundamental overhead of read-only transactions and modeling it in a way that connects with practical designs.

Capturing the fundamental overhead. As a layer built upon simple reads, the performance of a read-only transaction is impacted by both the engineering factors in executing simple reads and the algorithmic properties of coordinating simple reads to find a consistent view. Engineering factors, such as load balancing, batching, and networking, equally affect simple reads and the read-only transactions built on them. In contrast, the algorithmic properties, such as rounds of communication, only affect read-only transactions. For instance, a read-only transaction protocol that requires multiple round trips incurs overhead due to those extra rounds of messages, while the read requests in each round are engineered the same as simple reads.

Thus, this work focuses on the algorithmic properties that capture the fundamental overhead of read-only transactions. These properties capture the additional overhead to coordinate a consistent view and are orthogonal to underlying engineering factors. More specifically, we answer the question,

“given a system, how low can we make the performance overhead of read-only transactions relative to the system’s simple reads?”

Being useful in practice. Our goal is to model optimal performance in a way that is both *theoretically insightful* and *practically useful*. Theoretical insights help clarify fundamental tradeoffs between performance and guarantees. Practically useful guidance helps us design better systems. Our NOCS Theorem (§4.1) and properties yield theoretical insights that lead to a better design, PORT (§6), that achieves better performance in practice. This shows that our modeling is practically useful (§5).

3.2 Approach Overview

To reason about optimal performance in a practically useful way, we examine the mechanisms used in existing systems to coordinate a consistent view across shards. These coordination mechanisms include blocking, extra messages, and metadata. Some systems *block* read operations until a consistent view is ready—e.g., systems that use two-phase locking. Almost all systems use *extra messages* to determine a consistent view, such as multiple round trips on the critical path of reads—e.g., OCC [24]—or approaches that asynchronously coordinate a consistent view—e.g., COPS-SNOW [34], GentleRain [15], Cure [3]. Finally, all systems we are aware of use *metadata* to help compute a consistent view for read-only transactions to return—e.g., timestamps, transaction ids. Figure 9 in Section 10 shows representative systems that use these mechanisms.

These coordination mechanisms cause read-only transactions to have worse performance than simple reads, as they consume additional system resources. Therefore, we define performance-optimal read-only transactions to be those that require the least amount of each coordination mechanism, making their performance closest to that of simple reads.

3.3 NOC: Optimal Performance

We now explain the NOC properties, which we use to define optimal performance for read-only transactions.

N: Non-blocking. A read-only transaction algorithm is *non-blocking* if servers process each read request without waiting for any external event, such as a lock to become available, a message to arrive, or a timer to expire.

Blocking for a read request increases the latency of the read-only transaction: the more time spent blocking, the longer the transaction takes to complete. It also decreases throughput due to the overhead of context switches. In practice, blocking can incur more serious performance issues, e.g., CPU underutilization and deadlocks, which are increasingly pronounced in modern services [44, 52].

O: One-round communication. A read-only transaction algorithm has *one-round communication* if it uses exactly one parallel round of on-path messages and does not have any off-path messages. This matches the messages of simple

reads: the client sends a single request to each server holding relevant data, and each server sends a single response back. It excludes algorithms that use extra messages, such as those that require multiple rounds of on-path communication, e.g., to abort/retry. It also disallows coordinating through *off-path messages*, i.e., messages that are necessary for the read-only transactions but lie off the critical path of reads.

A message is an off-path message for read-only transactions if its removal affects *only* the correctness of read-only transactions. For example, COPS-SNOW [34] adds extra messages to writes. These messages are used for read-only transactions to find a consistent snapshot and are not necessary for processing writes. Because only the correctness of read-only transactions is affected if these messages are removed, they are off-path messages.

Additional rounds of on-path messages increase the latency of read-only transactions. Both extra on-path and off-path messages decrease system throughput because transmitting and processing them consume network and CPU resources that could otherwise be used to service requests.

C: Constant metadata. Metadata is the information required by a read-only transaction algorithm to coordinate consistent values. It is information a server needs to find the specific version of the data that will produce a consistent cross-shard view across reads in the same transaction. Examples of metadata include timestamps [2, 10], transaction ids [34, 41], and identifiers of participating servers [5].

A read-only transaction algorithm has *constant metadata* if the amount of metadata required to process each of its read requests is constant, i.e., it does not increase with the size of the system, the size of the transaction, or the number of concurrent operations. An example of constant metadata is one timestamp per read request for snapshot reads in Spanner [10]. An example of non-constant metadata is COPS-SNOW [34], which requires information about *many* concurrent read-only transactions to process each read request.

Transmitting and/or processing extra metadata consumes more resources, increasing latency and decreasing throughput. Its negative impact on performance has been reported in recent work [13, 14, 15]. We use Big-O notation, i.e., “constant,” to capture the algorithmic complexity of metadata required for coordination. In practice, system designers should aim for as low a constant as possible. We realize this in our PORT design, which uses a single integer per read request.

Performance optimality. We deem an algorithm *performance optimal* if it satisfies the N+O+C properties because they capture the least coordination overhead and thus enable performance as close as possible to simple reads.

4 The NOCS Theorem

An ideal system would have performance-optimal read-only transactions that provide the strongest consistency. Our NOCS Theorem proves this ideal is impossible.

S: Strict serializability. Strict serializability is the strongest form of consistency, equivalent to linearizability [22] with the addition of transactional isolation. It requires that there exists a legal total order of transactions that respects the real-time order between transactions [42]. A *legal total order* ensures that the results of transactions are equivalent to a single entity processing them one by one. The *real-time order* ensures that if transaction T_2 starts after transaction T_1 ends, then T_1 must appear before T_2 in the total order. If T_1 and T_2 have overlapping lifetimes, then they are concurrent and can be placed in either order. Strict serializability gives application programmers the powerful abstraction of programming in a single-threaded, transactionally isolated environment.

4.1 NOCS is Impossible

Our main result is that performance-optimal read-only transactions (N+O+C) cannot provide strict serializability (S). This section presents a condensed version of the proof. The full proof appears in our accompanying technical report [35].

The NOCS Theorem. *No read-only transaction algorithm satisfies all NOCS properties.*

System model. We model a distributed system as a set of processes that communicate by sending and receiving messages. This model is similar to that used in FLP [17]. A set of client processes (clients) issue requests to server processes (servers) that store the data. Processes are modeled as deterministic automata: in each atomic step, they may receive a message, perform deterministic local computation, and send one or more messages to other processes.

A transaction (operation) starts when a client sends the request messages to servers and ends when the client receives the last necessary server response. Two transactions (operations) are concurrent if their lifetimes overlap, i.e., neither begins after the other ends. If concurrent transactions (operations) access the same data item, then they conflict.

Assumptions. We make the following assumptions:

(A-0) There are ≥ 2 servers and ≥ 2 clients. Otherwise, optimal performance and strict serializability are trivial. All reads and writes eventually complete.

(A-1) The network and processors are reliable. Every message is eventually delivered and processed by the destination process. Processes are correct and never crash. By proving our impossibility result under these favorable conditions, it will necessarily hold when the system can fail.

(A-2) The network is either asynchronous [20], i.e., messages can be arbitrarily delayed, or partially synchronous [16], i.e., physical clocks ensure bounded delays.

Proof intuition. Due to network asynchrony, it is always possible for a read-only transaction to conflict with write operations and other concurrent read-only transactions. These requests occupy an *unstable region* in the system's history, where conflicts are possible and a total order has not yet been established. In contrast, the *stable region* is the part

of history that precedes the unstable region, where all writes have committed and system states are finalized. Reading in the stable region is easy as there are no conflicting writes. However, we show that the real-time order requirement of S requires read-only transactions that are N+O to interact with the most recent writes in the unstable region (Lemma 1). Doing this while ensuring a legal total order requires transferring metadata between the servers (Lemma 2), either proactively through read requests or through the write protocol. By extending this construction, we show that processing a set of read-only transactions requires metadata that is asymptotically larger than the total size of the transactions, regardless of how the metadata is transferred (Lemma 3). This violates C, proving the theorem.

Proof. Suppose the system has two servers, S_1 and S_2 , and multiple clients. Let ALG be any read-only transaction algorithm that satisfies N+O+S. Let $R = \{r_1, r_2\}$ be a read-only transaction that executes ALG, issued by client C_R . Let w_1 and w_2 be simple write requests issued by client $C_w \neq C_R$, where $w_1 \rightarrow w_2$ in real-time, i.e., w_2 is sent after the response for w_1 is received. We place no restrictions on the write protocol (beyond assumption A-0). Consider the execution e_1 :

S_1 : r_1, w_1
 S_2 : w_2, r_2

Suppose there is no metadata in the system, i.e., no information for coordinating consistent values between requests.

Lemma 1. *Without metadata, a read-only transaction that is N+O+S must observe any write that precedes it at a server.*

Proof Summary. Without metadata, S_2 cannot distinguish between an execution where w_2 and R are concurrent and one with $w_2 \rightarrow R$ in real-time. The latter requires $r_2 \in R$ to observe w_2 to satisfy S's real-time order. ■

Lemma 2. *Processing e_1 while satisfying N+O+S requires dependency $R \rightarrow w_1$ to be transferred from S_1 to S_2 .*

Proof Summary. Lemma 1 states that, without metadata, r_2 must observe w_2 , implying $w_2 \rightarrow R$. But r_1 must be processed before w_1 to satisfy N+O, implying $R \rightarrow w_1$. Since $w_1 \rightarrow w_2$ by construction, this creates a cycle, violating the legal total order of S. Using basic two-party communication complexity, we show that legalizing the total order requires transferring $R \rightarrow w_1$ from S_1 to S_2 . ■

We now extend e_1 with more read-only transactions, servers, and write requests, and apply the structure above to force more dependency metadata to transfer between servers. We then quantify this metadata and show that it violates C.

Proof of the NOCS Theorem. Suppose the system has $M^2 + 1$ servers $S_1, S_2, \dots, S_{M^2+1}$. Let R_1, R_2, \dots, R_N be N read-only transactions that execute ALG, where each R_i sends a read request to S_1 and $M - 1$ other servers, such that every server other than S_1 receives N/M read requests. (In practice $M^2 \ll N$, but our construction works for any $N, M \geq 1$.) The

specific mapping of read requests to servers is unimportant; we lay them out sequentially by transaction index below. Let $r_{i,j}$ be a read request of R_i assigned to S_j . We assign one read request from each of R_1 to $R_{N/M}$ to S_2 , one read request from each of $R_{N/M+1}$ to $R_{2N/M}$ to S_3 , and so on, restarting at R_1 after reaching R_N . Let $w_1, w_2, \dots, w_{M^2+1}$ be $M^2 + 1$ simple writes issued to each server by a distinct client C_w that does not issue any read-only transactions. Suppose w_1 precedes all other writes, i.e., $w_1 \rightarrow w_j$ for $j = 2, \dots, M^2 + 1$, and all read-only transactions are concurrent with all writes. Consider the execution e_* :

$S_1 :$	$r_{1,1}, \dots, r_{N,1}, w_1$
$S_2 :$	$w_2, r_{1,2}, \dots, r_{N/M,2}$
$S_3 :$	$w_3, r_{N/M+1,3}, \dots, r_{2N/M,3}$
\vdots	
$S_{M+1} :$	$w_{M+1}, r_{N-N/M+1,M+1}, \dots, r_{N,M+1}$
$S_{M+2} :$	$w_{M+2}, r_{1,M+2}, \dots, r_{N/M,M+2}$
\vdots	
$S_{M^2+1} :$	$w_{M^2+1}, r_{N-N/M+1,M^2+1}, \dots, r_{N,M^2+1}$

By decomposing this execution into layers, we can inductively quantify the metadata required to process it. Let e_1 be the execution fragment containing all write requests and only the read requests of R_1 . Let e_i contain the requests of e_{i-1} plus all read requests of R_i , for $i = 2, \dots, N$. Thus $e_N = e_*$.

Lemma 3. *Processing e_k while satisfying $N+O+S$ requires $\Omega(kM^2)$ metadata, for $k = 1, \dots, N$.*

Proof Summary. The proof is by induction. For the base case of e_1 , Lemma 2 requires us to transfer $R_1 \rightarrow w_1$ from S_1 to all $M - 1$ servers targeted by R_1 . We show that the write protocol cannot efficiently transfer this metadata, since it does not know which servers R_1 targets, and hence must send $R_1 \rightarrow w_1$ to all M^2 servers, or $\Omega(M^2)$ metadata. Alternatively, $r_{1,1}$ can convey the list of target servers, but due to asynchrony, a different execution could cause a different target server S_j to play the role of S_1 , making it impossible to know which $r_{1,j}$ will appear before a write. Thus, every $r_{1,j}$ must include the list of M servers, requiring $\Omega(M * M) = \Omega(M^2)$ metadata. In the inductive step, we show that e_k cannot rely on previous metadata transferred in e_{k-1} , and thus requires an additional $\Omega(M^2)$ metadata. ■

Completion of the proof. By Lemma 3, $e_* = e_N$ requires $\Omega(NM^2)$ metadata. Since R_1, \dots, R_N issue NM read requests total, the amortized metadata required per read request is $\Omega(\frac{NM^2}{NM}) = \Omega(M)$, which is not constant, violating C. ■

4.2 The Broad Scope of NOCS

We prove NOCS is impossible in the specific setting of one-shot read-only transactions in failure-free systems. When it comes to an impossibility result, the more restricted the setting it is proved in, the stronger the result, because any

setting that is more general is also subject to the impossibility result (the general setting *includes* the restricted setting as a special case). Thus, the NOCS Theorem also applies to more general settings, such as those with read-write transactions, multi-shot transactions, and/or failures.

4.3 NOCS Is Tight

While all properties are impossible to achieve together, we find that NOCS is “tight” in the sense that any combination of three properties is possible. Spanner’s [10] read-only transactions are one-round, use constant metadata, but block reads in order to return strictly serializable results (O+C+S). Many systems use multiple non-blocking round trips to coordinate strongly consistent results (N+C+S), e.g., DrTM [49], RIFL [29]. To the best of our knowledge, no existing system provides strict serializability in one round of non-blocking communication (N+O+S). We present the design of such a system, PORT-SEQ, and a proof of its correctness in our technical report [35]. The design uses a centralized write sequencer to totally order writes, and requires a linear amount of metadata for read-only transactions. We are aware of two systems that have performance-optimal read-only transactions (N+O+C): MySQL Cluster [39] and the snapshot read API of Spanner. These systems provide weak consistency, however, as we discuss below.

5 NOCS Connects Theory with Practice

This section discusses the value of the NOCS Theorem in understanding the design space and in guiding system designs.

5.1 Theoretical Insights

Proving the impossible. NOCS is philosophically similar to other impossibility results like CAP and SNOW, in that it helps system designers avoid attempting the impossible and instead identifies a fundamental choice they must make: their system can either have performance-optimal read-only transactions or provide strict serializability, but not both.

Identifying the possible. The crux of NOCS’s impossibility is that the real-time requirement of strict serializability forces read-only transactions to confront conflicting requests (Lemma 1). This suggests optimal performance could be possible with even *slightly* relaxed consistency models that do not require real-time ordering, and thus can avoid the unstable region. In particular, the second strongest consistency model we are aware of—process-ordered serializability [34]—does not require real-time ordering.

Yet, there is a large gap in the current design space. The only two existing systems whose read-only transactions are performance optimal provide weak consistency. MySQL Cluster’s read-committed consistency does not isolate transactions. Spanner’s snapshot read API can be used to get performance optimality, but it does not ensure clients see their own recent writes when used in this way (§10). Between these weak guarantees and strict serializability are

many stronger consistency models, such as read-atomic [5], causal consistency [31], and process-ordered serializability [34]. We bridge this gap by presenting the PORT design that provides performance-optimal read-only transactions and the strongest consistency to date: PORT provides process-ordered serializability in systems with only simple writes (§6), and it provides causal consistency in systems with write transactions (§8). (We conjecture causal consistency is the upper bound for performance-optimal read-only transactions when transactional writes are present.)

5.2 Guiding System Designs

NOCS is also useful in guiding system designs. First, to make a design performance-optimal, it must satisfy the NOC properties: each transaction must succeed using a single round of non-blocking messages with constant metadata. Therefore, the NOC properties indicate we must avoid validation-based and stabilization-based techniques to satisfy O, avoid techniques based on distributed lock management to satisfy N, and ensure the complexity of processing a read does not depend on the level of contention—i.e., the number of conflicting reads and/or writes—to satisfy C. Second, the NOCS Theorem suggests a path towards designing NOC protocols by avoiding how it derives its impossibility: read-only transactions should always execute on system states outside the unstable region. These implications of the NOC properties and the NOCS proof significantly reduced the design space of algorithm we needed to explore and led us to two high-level techniques for PORT: explicit ordering control and multi-versioning.

Explicit ordering control. There are two methods for ensuring reads avoid the unstable region by explicitly controlling the ordering of concurrent operations. First, reads can request versions of the data that lie before the unstable region begins, which orders a read-only transaction before ongoing writes. Second, servers can reorder operations when a read requests data in the unstable region.

Explicitly controlling ordering is not compatible with strict serializability because the real-time requirement forces a specific ordering of operations (Lemma 1) that cannot be communicated in a performance-optimal system (Lemma 3). Consistency models without the real-time requirement, however, might be compatible with an explicitly controlled ordering while satisfying NOC. PORT confirms this, by using version clocks to capture this explicit ordering. PORT uses both types of explicit control on top of multi-versioning to provide its consistency guarantees and optimal performance.

Multi-versioning. Enabling reads to control what version of data they request requires multi-versioning on servers. Multi-versioning introduces storage overhead to temporarily keep additional version around, but this overhead is minor as storage is inexpensive and extra versions are not kept long. It also introduces some processing overhead to look up the correct version of data to return, reflected by our C property.

The need for multi-versioning to support efficient reads is not new. The existing performance-optimal systems, Spanner and MySQL Cluster, are multi-versioned. In fact, all existing systems whose read-only transactions are guaranteed to terminate—i.e., have a bounded number of retries and/or bounded blocking—are multi-versioned (Table 9). On the other hand, multi-versioning alone does not ensure optimal performance: most MVCC protocols require either extra on-path messages to query a timestamp oracle [6, 43], off-path messages to compute stable snapshots [3, 15], or blocking reads if the client-provided timestamp in MVTSO-based protocols points to the future [30, 45]. PORT’s novelty is in how it uses version clocks to explicitly control ordering by manipulating the multi-versioning framework in order to achieve optimal performance.

6 PORT Design

PORT is a new system design that enables performance-optimal read-only transactions with process-ordered serializability, the strongest consistency to date.

Process-ordered serializability. Process-ordered serializability guarantees there exists a legal total order of transactions that respects the ordering of transactions within each process [34]. It is equivalent to sequential consistency [27] with the addition of transactional isolation. It preserves all the properties of strict serializability (§4) except for the real-time order across processes (clients). That is, it preserves the real-time order within each process, i.e., process order, and a total order across processes, but a client may not see the most recent updates of other clients. *Process order* ensures that each client interacts with the system monotonically, e.g., sees her own recent writes. *Total order* ensures that concurrent transactions are observed by all clients in the same order.

6.1 Version Clocks

This section describes *version clocks* (§6.1), a new specialized logical clock that tightly couples all the components of PORT (§6.2). Version clocks also allow us to avoid the work of applying some writes (*write omission*, §6.3) and limit the staleness of reads (*data freshness*, §6.4).

Version clocks are designed in the context of distributed storage systems and have two features: they ensure process order by concisely capturing the ordering constraints between requests and enable optimal performance by reading at the most recent snapshot in the stable region.

Enforcing process order. Version clocks take advantage of two observations. First, process order is a per-client order, and thus can be explicitly controlled by clients. Second, read and write requests have different semantics, i.e., writes modify system state while reads do not. Therefore, they should be treated differently: it is unnecessary to enforce an order among the read requests that observe the same system state.

Capturing the stable frontier. Version clocks follow the practical guidance of the NOCS Theorem (§5.2) to avoid the

```

1 Client Side
2 versionstamp = 0 # clock value
3 view[]          # max known versionstamp per server
4
5 # Sending requests
6 function get_vs_read():
7     versionstamp = tick(min{view[]}) # stable frontier
8     return versionstamp
9
10 function get_vs_write():
11     versionstamp++
12     return versionstamp
13
14 # Receiving a response msg from server svr
15 function recv_response(maxVS):
16     view[svr] = max{view[svr], maxVS}
17     if msg.for_write is true
18         versionstamp = tick(maxVS)
19     return
20
21 function tick(vs):
22     return max{vs, versionstamp}
23
24 Server Side
25 maxVS = 0 # max seen versionstamp
26 # ... return maxVS when sending response msg

```

Figure 1: Pseudocode for version clocks.

unstable region by capturing the stable frontier. The stable frontier is the most recent snapshot in which all writes are in the stable region. Each server tracks the final versionstamp of its most recent write. A version clock tracks the minimum of such versionstamps across all servers the client has contacted, which is exactly the stable frontier the client knows. Version clocks direct read messages to the stable frontier when possible. PORT takes care of the cases when reads have to confront conflicting requests beyond the stable frontier. “Promotion” is used in systems with simple writes to advance the stable frontier beyond the versionstamp of an incoming read to ensure a total order. “Per-client ordering” is used in systems with write transactions to logically move a client’s own writes before the stable frontier so the client can always safely read at the stable frontier (§8.2). Both techniques enforce the necessary order between concurrent reads and writes without blocking either reads or writes.

Clock structure. Figure 1 shows the pseudocode of version clocks. *versionstamp* stores the current clock value (line 2), which is embedded in every read/write message to explicitly control their ordering. When versionstamps are the same for two operations of the same type, the server orders them arbitrarily. When versionstamps for a read and a write are the same, the server orders the read after the write. A server responds with the highest versionstamp it has seen (line 26). A client uses *view* to track the highest versionstamps of the servers it has contacted (line 3) and uses them to find the stable frontier (line 7) before sending a read message (lines 6–8). *view* is updated upon receiving a response (line 16). If the response is for a write message, then the clock is advanced so that future read messages will have greater versionstamps than the write (lines 17–18), ensuring read-your-writes. Because versionstamps increase monotonically and reads have

```

1 Client Side
2 function read_only_txn(<keys>):
3     vs = VersionClock.get_vs_read()
4     for k in keys # in parallel
5         vals[k], maxVS = read(k, vs)
6     VersionClock.recv_response(maxVS)
7     return vals # replies to end user
8
9 function write(key, val):
10    vs = VersionClock.get_vs_write()
11    maxVS = write(key, val, vs)
12    VersionClock.recv_response(maxVS)
13    return # replies to end user
14
15 Server Side
16 vers[keys][] # multi-versioned storage
17 function read(key, vs):
18     if vers[key][vs] exists
19         return vers[key][vs], VersionClock.maxVS
20     else # return nearest version to not block
21         near_vs = find_nearest_earlier(ver)
22         # ensure future writes have higher vs
23         vers[key].max_r_vs = max(vers[key].max_r_vs, vs)
24         return vers[key][near_vs], VersionClock.maxVS
25
26 function write(key, val, vs):
27     if vs <= vers[key].max_w_vs
28         return VersionClock.maxVS # omit write
29     if vers[key].max_r_vs >= vs
30         vs = max_r_vs + 1 # commit after promoted versions
31     vers[key][vs] = val
32     vers[key].max_w_vs = vs
33     if vs > VersionClock.maxVS
34         VersionClock.maxVS = vs
35     return VersionClock.maxVS

```

Figure 2: Pseudocode for PORT.

non-smaller versionstamps than earlier writes, version clocks preserve process ordering.

6.2 Basic PORT Design

The basic PORT design includes a multi-versioning framework, a read-only transaction algorithm, and a write algorithm. We co-design these components tightly by leveraging version clocks. Figure 2 shows PORT’s pseudocode.

Client library. The read-only transaction and write algorithms are executed by a client library. For each read-only transaction or write, the client obtains a versionstamp from its version clock and embeds it in the request message(s). This per-client versionstamp decides which system version on the servers the operation must read (or write) to ensure the client’s process order (lines 3, 10). The server-side logic ensures a total order on top of the process order on each client to guarantee process-ordered serializability.

Multi-versioning framework. Servers store written values in a multi-versioning framework (line 16). Since PORT uses version clocks to track the ordering between operations, it is natural and efficient to index the historical values of each data item with versionstamps. In this way, the multi-versioning framework and transaction layer are nicely coupled via versionstamps. We omit a detailed discussion of garbage collection, which uses standard mechanisms similar to those used to provide at-most-once semantics.

(a) orders w_1 before w_2 by arrival.

(b) orders w_2 before w_1 by arrival.

(c) orders w_2 before w_1 by omission.

Figure 3: Space-time diagrams showing three executions of writes w_1 and w_2 that are concurrent and conflicting. The value underneath S_x indicates the value stored by the server. Process-ordered serializability allows w_1 , w_2 to be ordered either way. This enables us to omit w_2 in (c) because it is equivalent to the ordering in (b), i.e., (w_2, w_1) .

Read-only transactions. To process a read request, a server executes it against the system version specified by its versionstamp. Executing a read is thus equivalent to returning the value indexed at versionstamp. If the server has the requested version, then the read is inside the stable region and it returns the version directly (lines 18, 19). Otherwise, it uses promotion to ensure a total order between the read and any concurrent writes at the specified versionstamp, without blocking either the read or write (lines 20–24).

Promotion logically copies the value of the nearest earlier version to all empty positions between that version and the one requested by versionstamp. Logical versions are used as placeholders to ensure a total order: once a version has been read by any client, no earlier versions can be modified to ensure different clients observe them in the same order. For example, if a read request has $vs = 4$ and the data item has committed values at $vs = 1, 2$, the version at $vs = 2$ is the nearest earlier version and is promoted to positions 3, 4. A conflicting write at $vs = 3, 4$ will be “bumped up” to $vs = 5$ when it arrives. We implement promotion with a single variable (line 23) that marks earlier positions as immutable.

Writes. When receiving a write request, a server finds the position specified by the write’s versionstamp in the multi-versioning framework. If the position is empty, then the write is applied at the versionstamp (line 31). If the position has been marked immutable by read promotion, the server finds the next available position to write the version at (lines 29–31). The write protocol also includes a mechanism for safely skipping concurrent writes (lines 27–28), discussed next.

6.3 Write Omission

Write omission is a special conflict resolution mechanism that skips an incoming write if it is concurrent with an already applied write. Omitting a write is desirable because it saves the computation needed to apply it, reduces the number of stored versions, and saves the work of replicating it.

Write omission is safe. Consistency models in general, and process-ordered serializability specifically, allow conflicting writes to be ordered either way. For instance, if two processes concurrently issue $w_1 : \text{write}(x = 1)$ and $w_2 : \text{write}(x = 2)$, then they can be ordered as either (w_1, w_2) or (w_2, w_1) . Typically, systems apply writes in the order that

they arrive, e.g., w_1 then w_2 . But if instead we use the opposite order, then this is equivalent to omitting w_2 , as shown in Figure 3: skipping the later write is equivalent to ordering it before the earlier write and immediately overwriting it with the latter. Write omission does not affect the total order requirement: all clients observe concurrent writes in the same order, because omitted writes are never seen by any client.

Knowing a write is concurrent. Version clocks enable PORT to identify when writes are concurrent, allowing a later concurrent write to be omitted. PORT omits an incoming write if its versionstamp, vs_{omit} , is less than or equal to the highest committed versionstamp of the data item, $vs_{highest}$ (lines 27–29). The write with the highest committed versionstamp cannot have happened-before [26] the omitted write because $vs_{highest} \geq vs_{omit}$. More specifically, version clocks guarantee the invariant: if write x happens-before write y , then $vs_x < vs_y$. The omitted write cannot have happened-before the write with the highest committed versionstamp because it has not happened yet. Therefore, the two writes are concurrent, and it is safe to omit the incoming write.

Omitting a write is equivalent to applying it immediately before the write with the highest versionstamp. A client’s future reads must observe the “higher” write if its own write was overwritten in this way. Therefore, the server returns the versionstamp of its highest applied write to the client (line 29), which uses it to update its versionstamp as normal.

6.4 Keeping Reads Fresh

To avoid the unstable region, we must sometimes return values staler than what strict serializability would return (§5.2). PORT limits data staleness in two ways, neither of which incurs extra messages, blocking, or non-constant metadata. That is, they do not forfeit optimal performance (NOC).

Reducing staleness with version clocks. Instead of naively returning versions far behind the stable frontier, version clocks try to track the stable frontier precisely. They use *view* to track the most recent versionstamp on each server a client has contacted, so a client’s version clock never ticks slower than the servers it is aware of. This significantly improves the freshness of data requested by read-only transactions.

Reducing staleness via co-location. Many storage systems co-locate “end users” on the same client machine [12, 18,

40], i.e., each client (machine) has many sessions (threads), one per end user. We leverage co-location to help user sessions keep each other fresh by sharing one version clock among them on the same client, which ensures no user session is staler than the freshest session it is co-located with.

6.5 Correctness and Generality

The only technique PORT relies on is version clocks, which can easily be added to systems with existing physical/logical clocks, or implemented from scratch. We demonstrate both by applying PORT to a system without transactions (shown by Scylla-PORT) and a system with existing sub-optimal read-only transactions (shown by Eiger-PORT). We present a proof of correctness for PORT in our technical report [35].

Failures. PORT can tolerate server failures using typical techniques such as state machine replication [46]. To tolerate client—i.e., frontend—failures, clients can send versionstamps back to end-user machines that then include the versionstamp in subsequent requests to the application (e.g., via cookies). This ensures process ordering is maintained even if an end user’s later requests go to a different frontend due to load-balancing or frontend failure.

7 PORT Implementation and Evaluation

This section discusses Scylla-PORT, the implementation of PORT on a clean slate base system.

7.1 Implementation

We build PORT on ScyllaDB [47], a clean slate, non-transactional base system that supports only simple reads and simple writes. ScyllaDB is a production system that serves as a drop-in replacement for Cassandra [25] and provides an order-of-magnitude better performance. It is well-engineered and aggressively-optimized for performance, including a new implementation in C++14, core-level sharding that avoids cross-core locking and context switches, and customized lock-free data structures.

Rationale and takeaways. We chose to implement PORT on ScyllaDB for three reasons. First, it stresses the efficiency of PORT: as a highly efficient baseline system, it is sensitive to any additional overheads, and thus amplifies any performance cost introduced by PORT. Second, ScyllaDB is single-versioned. The negligible performance overhead shown in our evaluation includes the cost of making it multi-versioned (§5.2), which shows the efficiency of co-designing the multi-versioning framework and the transaction layer enabled by version clocks. Third, PORT is compatible with all the customized engineering decisions of ScyllaDB, which demonstrates the generality of the design of PORT.

7.2 Evaluation Overview

We evaluate Scylla-PORT against ScyllaDB (the clean slate, non-transactional base system) and Scylla-OCC (an implementation of OCC atop ScyllaDB). We compare their

throughput, latency, scalability, and quantify data staleness.

Scylla-OCC. We implemented a variant of OCC optimized for read-only transactions, similar to Rococo’s read-only transaction algorithm [37]. It includes an initial round of optimistic reads and then a validation round. If the values read in the optimistic round match the values in the validation round the transaction succeeds. If not, the read-only transaction is aborted and retried. This variant has strictly better performance than traditional distributed OCC because it avoids the need for distributed commit: its best case is two rounds compared to traditional distributed OCC’s best case of three rounds (read, validate/prepare, commit).

Code. We implemented our server-side logic in ScyllaDB’s codebase (release 2.1-RC3) in C++14 and our client-side logic in the Java Thrift client of the YCSB benchmark (release 0.10.0) [9]. Version clocks are implemented on both servers and clients. Scylla-PORT adds ~1,300 LOC.

Experimental setting. We run experiments on Emulab [50]. Each machine has two 2.4 GHz 8-Core Xeon CPUs, 64 GB RAM, and a 10 Gbps network interface. We use a single datacenter setting. All experiments, except for scalability tests, use 8 servers loaded by 8 client machines. The scalability tests use up to 64 machines. Each client issues 10 million requests in each experiment, which takes 5–10 minutes to complete, sufficiently long to minimize warm-up and cool-down effects and provide stable results. Experiments are CPU-bound on servers.

Configuration and workloads. We use YCSB’s standard workloads B (read-heavy, 95% reads) and C (read-only) with customized read-to-write ratios of up to 25% writes. We use YCSB’s default parameters: 1 million records, 10 fields per record, 100 B values per field, and Zipf constant of 0.99. Each request (a read-only transaction or a group of simple writes) accesses 5 records and all fields in each record.

Results summary. Transactional overhead is generally evident with read-write conflicts and under skewed workloads, so we focus our evaluation in such scenarios to amplify Scylla-PORT’s cost. Our results show that Scylla-PORT can almost match its performance to that of non-transactional ScyllaDB: 1–3% overhead in throughput and latency in most settings and less than 8% even in the worst case. Scylla-PORT outperforms OCC by an order-of-magnitude in such contended scenarios due to OCC’s retries, and outperforms OCC under low contention (OCC’s best case) by at least two times. Scylla-PORT scales as well as ScyllaDB and scales better under contention. More than 40% of its reads return fresh values.

7.3 Throughput and Latency

Figure 4a shows the overall performance of the systems as we gradually increase the system load by using more closed-loop client threads. Scylla-PORT has similar performance to the baseline ScyllaDB. Their largest difference before Scyl-

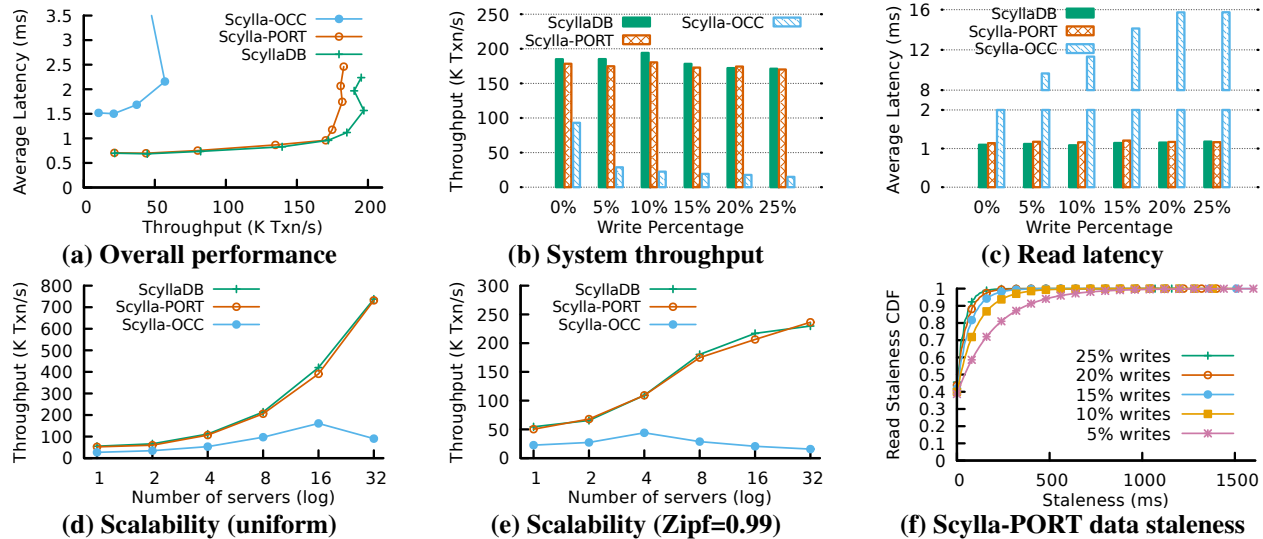

Figure 4: The performance of Scylla-PORT closely matches non-transactional ScyllaDB and is significantly better than OCC, Scylla-PORT scales even better than ScyllaDB with skewed workloads, and half of its reads return fresh data.

laDB becomes overloaded is evident with 32 client threads: 5.6% in throughput and 5% in latency. All later experiments report throughput and latency at this operating point, i.e., with 32 client threads. OCC initially has latency that is twice that of ScyllaDB and Scylla-PORT because it takes at least two rounds to complete instead of one. As load increases, OCC's latency increases quickly and its throughput decreases slightly because contention forces it to retry.

Varying write percentage. Figure 4b and 4c show the throughput and latency as we vary the read-to-write ratio. Scylla-PORT's throughput is within 4% of ScyllaDB's for five of the experiments and within 7% for the remaining one. Similarly, its latency is within 2% (20 μ s) of ScyllaDB's for two of the experiments and within 7% (107 μ s) for the other four. As the write percentage increases, the overhead disappears because of write omission: doing slightly more work during reads is offset by doing less work during writes. When there are only reads, Scylla-PORT has double the throughput and half the latency of OCC because OCC's read-only transactions require at least two rounds. With writes, OCC's performance drops quickly due to retries.

7.4 Scalability

Figure 4d compares the scalability of the three systems under a uniform workload as we increase the number of servers while increasing the number of clients to keep the servers CPU-bound. Scylla-PORT scales as well as ScyllaDB; the differences in throughput are negligible. Interestingly, Scylla-PORT outperforms ScyllaDB under a skewed workload, as shown in Figure 4e. ScyllaDB stops scaling at 16 servers because the server holding the hottest keys becomes the bottleneck, and adding more servers does not help. (We have confirmed this finding with ScyllaDB's develop-

ers.) Scylla-PORT scales better than ScyllaDB under skewed workloads because it can avoid the work of some writes to the hottest keys due to write omission. Since write omission only applies to conflicting writes, this rarely occurs under a uniform workload. OCC initially shows a similar scaling pattern starting from its lower throughput. OCC's scaling stops, however, as more concurrent clients accessing the same keys lead to higher contention and thus more retries.

7.5 Data Staleness

Figure 4f shows the staleness of Scylla-PORT under a skewed workload with varying write percentages. Staleness is measured relative to strict serializability, which always has a staleness of 0: it is the amount of time since a newer version has been committed. For example, if v_0 , v_1 are consecutive versions, v_0 is returned at 0:05, and v_1 committed at 0:00, then the staleness of v_0 is 5 seconds.

Scylla-PORT returns the most recent data ~40% of the time, and 90% of reads return values no staler than 500 ms. Scylla-PORT returns fresher data as the write percentage increases because version clocks advance versionstamps more frequently when there are more writes. Scylla-PORT leverages version clocks to precisely capture the stable frontier, but does not utilize client co-location. Sharing one clock among co-located user sessions would further decrease staleness, but also decreases the rate at which write omission can be used. We leave investigating this tradeoff to future work.

7.6 Low Contention Evaluation

We focused here on high contention workloads because those are where any differences between Scylla-PORT and ScyllaDB would appear. Scylla-OCC did poorly in this setting as is expected because OCC is better suited to low contention

settings. We present the results of evaluating the three systems under low contention in our accompanying technical report [35]. Even in that setting, Scylla-PORT significantly outperforms Scylla-OCC with at least double the throughput and at most half the latency because Scylla-PORT always finishes in one round while OCC’s best case is two rounds.

8 Improving an Existing System

This section adapts PORT to improve Eiger, an existing system that has both read-only and write transactions.

8.1 Eiger Overview and Rationale

Eiger is a geo-replicated, causally consistent system that has read-only transactions and write transactions. Each machine implements a Lamport clock and attaches a Lamport timestamp to each committed write that is guaranteed to be larger than any earlier write it causally depends on. Eiger’s write transaction protocol is a variant of two-phase commit [21, 28] that always commits. Eiger’s read-only transaction protocol takes between one and three non-blocking rounds of communication. If there are no concurrent write transactions, it completes in a single round. Otherwise, it requires a second round of messages to a subset of the servers, followed by a third round if the concurrent write transactions are still pending when the second-round requests arrive. In the third round, each read request needs to query the states of all write transactions it conflicts with, and thus the required metadata increases linearly with respect to the number of conflicting write transactions.

Rationale. We choose Eiger as a base system because of its guarantees and the efficiency of its read-only transactions. First, it provides causal consistency, not strict serializability, so it may be possible to add performance-optimal read-only transactions to it. Second, it includes write transactions, which present a new challenge for the PORT design. Third, it is the only system with write transactions and causal (or stronger) consistency that completes read-only transactions in a bounded number of non-blocking rounds of communication (Figure 9). Finally, its read-only transactions often complete in a single non-blocking round, making them a more difficult baseline than other algorithms such as OCC.

8.2 Eiger-PORT

Eiger’s read-only transactions are non-blocking, require up to three rounds of on-path communication, and use linear-sized metadata in the third round. We make them performance-optimal by making them always finish in one round using only constant metadata. The major challenge is to ensure write isolation, i.e., return a system state that is either before all updates in a write transaction or after.

More specifically, when a read-only transaction must read beyond the stable frontier, e.g., to ensure read-your-writes, PORT reorders the read-only transaction and the conflicting writes without blocking by using “promotion” (§6.2). How-

```

1 Client Side
2 lst_map[[]] # maps server to its local safe time
3 gst        # global safe time
4
5 function read_only_txn(<keys>):
6   gst = get_read_ts(min{lst_map.valueSet()})
7   for k in keys # messages in parallel
8     vals[k], lst = read(k, gst, cl_id)
9     lst_map[k.server] = lst # lst is monotonic
10  return vals
11
12 function write_txn(<keys, vals>):
13   for k, v in <keys, vals> # in parallel
14     if k.server is coord # the coordinator
15       lst = write_coord(k, v, cl_id, gst)
16     else # a cohort
17       lst = write_cohort(k, v, cl_id, gst)
18       lst_map[k.server] = lst # lst is monotonic
19   return
20
21 function get_read_ts(ts):
22   return max{ts, gst}

```

4 function read(k, rts, cl_id):
5   ver = DS[k].at(rts) # vers are sorted by commit_t
6   for v in DS[k].newer_than(ver.commit_t)
7     # ensure read-your-writes, from newer ver to old
8     if v.cl_id == cl_id
9       return v.val, lst
10  if ver.cl_id != cl_id
11    return ver.val, lst
12  else # ensure write isolation
13    v = find_isolated(ver)
14    return v.val, lst
15
16 function find_isolated(ver):
17   # iterate from newer version to old
18   while v in DS[k].newer_than(ver.gst)
19     and v in DS[k].older_than(ver.commit_t)
20     if v.cl_id != ver.cl_id
21       return v
22   else
23     return find_isolated(v)
24  return ver

```

Figure 6: Read-only transaction logic for Eiger-PORT.

ever, promotion does not work for Eiger because it cannot ensure that all writes in the same write transaction are promoted at the same time since they can be on different servers. Our solution, *per-client ordering*, enables clients to observe conflicting writes in different orders, as allowed by causal consistency. Specifically, it pulls back any of a client’s recent writes that are beyond the stable frontier. This allows the client to read at the stable frontier while also always seeing their own writes. Figures 5, 6, and 7 show the pseudocode, written in a way that favors clarity over efficiency.

Client-side logic. Figure 5 shows the client-side logic. Each client maintains two variables (lines 2, 3). *lst_map* tracks the local safe time, *lst*, of each server. Global safe time, *gst*, is the minimum *lst* across all servers (line 6) and advances monotonically. *gst* is used as the read timestamp for each

```

2 lst          # local safe time
3 pending_wtxns # uncommitted write txns
4 DS[[]]       # multi-versioned k-v data store
5
6 function write_coord(k, v, cl_id, gst): # coordinator
7     # PREPARE
8     ver, prepared_t = prepare_write(k, v, cl_id, gst)
9     # ... get yes-vote-msgs from all cohorts
10    # COMMIT
11    commit_t = max{yes-vote-msgs.prepared_t, prepared_t}
12    commit-msg = {"commit", commit_t}
13    # ... send commit-msg to all cohorts
14    commit_write(ver, commit_t)
15    return lst
16
17 function write_cohort(k, v, cl_id, gst): # cohort
18    # PREPARE
19    ver, prepared_t = prepare_write(k, v, cl_id, gst)
20    yes-vote-msg = {"yes", prepared_t}
21    # ... send yes-vote-msg to coordinator
22    # ... wait for commit-msg
23    # COMMIT
24    commit_t = commit-msg.commit_t
25    commit_write(ver, commit_t)
26    return lst
27
28 function prepare_write(k, v, cl_id, gst):
29    pending_t = LamportClock.current()
30    pending_wtxns.append(pending_t)
31    LamportClock.advance()
32    ver = DS[k].create_new_ver(v, cl_id, gst, pending_t)
33    ver.is_pending = true
34    return ver, LamportClock.current()
35
36 function commit_write(ver, commit_t):
37    ver.commit_t = commit_t
38    ver.is_pending = false
39    pending_wtxns.remove(ver.pending_t)
40    if pending_wtxns is empty
41        lst = LamportClock.current()
42    else
43        lst = pending_wtxns.head() # min of pending_wtxns
44    return

```

Figure 7: Write transaction logic for Eiger-PORT.

read-only transaction. Both *lst* and *gst* are Lamport timestamps as used in Eiger. A client sends all read requests in a read-only transaction in parallel. Each read request includes the key, the read timestamp *gst*, and the unique identifier of this client (line 8). The server responds with the requested value and *lst* on that server. A client issues a write transaction by sending the write requests in parallel (lines 12–19). One server is randomly chosen as the coordinator (line 14) for 2PC with the others as cohorts. Each write request contains the key, the value, the client ID, and the client’s current *gst* (lines 15, 17). *gst* specifies the stable frontier this write transaction causally depends on. The client updates *lst_map* after each read/write request (lines 9, 18).

Write transactions. Figure 7 shows the server-side logic of write transactions. When a server receives a write request, it records the current Lamport time (line 29) and creates a new pending version (lines 8, 19, 32, 33). *pending_wtxns* tracks ongoing write transactions by keeping an ordered list of *pending_times*. The running minimum of *pending_wtxns* is the *lst* on this server, i.e., no pending writes exist before *lst*. Because Lamport clocks advance monotonically, inser-

tion, removal, and fetching the minimum of *pending_wtxns* have a cost of $O(1)$. At the end of the “prepare” phase of 2PC, each cohort sends a yes-vote message to the coordinator, which includes the *prepared_time* of this pending write transaction. *prepared_time* is guaranteed to be greater than *pending_time* by clock ticking (line 31).

To commit a write transaction, the coordinator calculates the commit time by taking the maximum across all *prepared_times* (line 11) and then sends a commit message to the cohorts and commits its local pending version (lines 13, 14). When a cohort receives the commit message, it commits its local pending version (lines 25, 38) with the commit time (lines 24, 37). It then removes this write transaction’s *pending_time* from *pending_wtxns* and updates *lst* (lines 39–43). The server returns its *lst* to the client upon commit. Eiger-PORT made minimum changes to Eiger’s write transactions, i.e., the management of *pending_wtxns*.

Read-only transactions. Figure 6 shows the server-side logic of read-only transactions. When a server receives a read request, it finds the version at the read timestamp, *rts* (line 5), and checks if the same client has made a recent write later than *rts*. It returns the most recent write by the same client to ensure read-your-writes (lines 6–9). If the version at *rts* was written by the same client, then we need to ensure write isolation by checking whether there exist any versions between the version’s *gst*, which is the snapshot time the version depends on, and the version’s *commit_t* (lines 18, 19). If there exists such a version written by a different client, then that version is returned to satisfy write isolation (lines 20, 21). We need to do this recursively, but our implementation uses a loop instead for better performance. To ensure write isolation (lines 16–24), we go through the multi-versioned data store once, which has the same cost as finding a particular version by timestamp in other algorithms, e.g., MVCC.

Correctness. We show the correctness of Eiger-PORT by proving that any execution in Eiger-PORT satisfies the causal (“happened before”) relation [26] and write isolation for write transactions. We present the full proof in the technical report [35].

9 Eiger-PORT Evaluation

We evaluate Eiger-PORT against Eiger, showing its throughput and latency improvement as well as its data staleness.

Implementation. We implemented Eiger-PORT as a modification to Eiger’s code base, which is built on top of Cassandra [25] and written in Java. Eiger-PORT adds ~1000 LOC.

Experimental setting. We try to match Eiger’s original experimental setup. We run all experiments on Emulab [50], similar to the now-decommissioned PRObE testbed [19] Eiger used. Each machine has one 2.4GHz Quad-Core Xeon CPU, 12GB RAM, and a 1 Gbps network interface. We run 5 trials for each data point, each lasting 65 seconds, and report the median. We exclude the first and last 15 seconds to

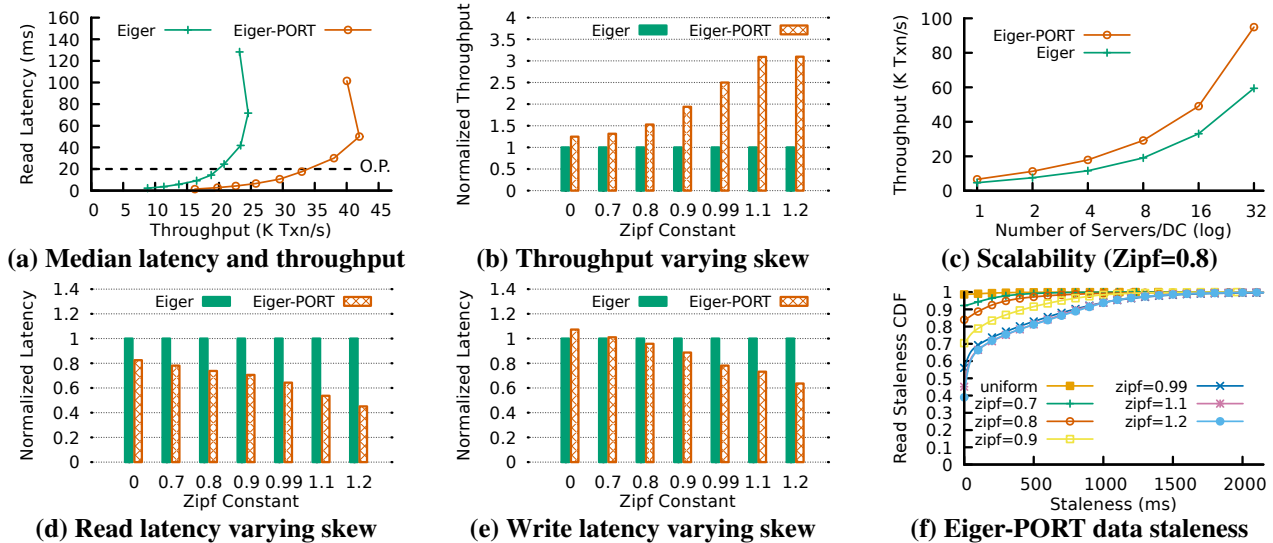

Figure 8: Throughput, latency, scalability, and staleness of Eiger-PORT: up to $3\times$ throughput improvement and 60% latency reduction compared to Eiger, better scalability, and low data staleness. All latencies are median latencies.

avoid artifacts due to warm-up, cool-down, and imperfectly synchronized clients. All experiments are CPU-bound.

Configuration and workloads. We use the same setting as Eiger: two logical datacenters co-located in the testbed. Each datacenter has eight server machines, and uses eight client machines to load the servers. The second datacenter is used as a replica, which applies updates replicated from the first datacenter. We use the dynamic workload generator from Eiger with the same default values: 1 million keys, 128-byte values, 5 columns per key, 5 keys per operation, and a write percentage of 10% unless otherwise specified. We also use a Zipf traffic generator with a default value of 0.8.

9.1 Performance Improvement

Results summary. Eiger-PORT significantly improves the performance of Eiger under different workloads, without degrading write performance: $2\times$ and $3\times$ throughput improvement under mild and high skew, respectively, and 20%–60% latency reduction. The performance improvement comes from Eiger-PORT’s fewer on-path messages and less metadata to process. The improvement is larger in contended workloads because Eiger is more likely to require more than one round and more metadata in the third round when there are more conflicting write transactions.

Throughput improvement. Figure 8a shows the median read latency and system throughput as we double the number of closed-loop client threads loading the system (from 2 to 512). It shows that Eiger-PORT performs strictly better than Eiger: it achieves higher throughput with the same latency and lower latency with the same throughput. We run all other experiments in Figure 8 with 32 threads, representing an operating point with reasonably low latency ($< 20\text{ms}$), i.e., at line “O.P.” in Figure 8a. The improvements are more pro-

found at higher loads. Figure 8b shows normalized throughput with different skew; the improvement stops increasing after Zipf value 1.1, where a single server becomes the bottleneck. Figure 8c shows Eiger-PORT scales better than Eiger due to fewer messages in the system.

Latency improvement. Figure 8d shows the normalized median read latency as we vary skew. Eiger-PORT achieves 20% lower latency under uniform workloads and up to 60% lower latency under contended workloads. Figure 8e shows that Eiger-PORT achieves lower write latency even though we did not intentionally improve writes. The lower latency comes from less queuing delay for writes because reads are faster and there are fewer messages in the system. This demonstrates that PORT can make read-only transactions performance-optimal without making writes more costly.

9.2 Data Staleness

Figure 8f quantifies the read staleness in Eiger-PORT. Staleness is measured relative to strict serializability as in Scylla-PORT’s evaluation. Even with high skew, over 40% of Eiger-PORT’s read-only transactions return up-to-date values, and over 90% of reads experience less than 1s staleness. Eiger-PORT tends to return staler data than Scylla-PORT because the stable frontier moves more slowly in Eiger/Eiger-PORT: write transactions take longer to commit than simple writes.

10 Related Work

This section examines existing read-only transactions with the NOCS Theorem, reviews impossibility results, and discusses the move from latency to performance optimality.

Bridging the gap in the design space. We use the NOCS Theorem as a lens to better understand existing systems and show a set of representative systems in Figure 9. We find

a large gap in the design space. The only existing systems that have performance-optimal read-only transactions provide weak consistency (§4.3). MySQL Cluster [39] provides read-committed, which does not isolate transactions. Spanner’s snapshot reads API [10] cannot always guarantee non-blocking read-your-writes. Suppose a client updates key k in a read-write transaction with commit timestamp ts , and then immediately performs a read-only transaction involving a set S of keys that includes k . To ensure read-your-writes, the client must use a timestamp greater than or equal to ts for its read-only transaction. But doing so may block since other keys in S may be involved in a read-write transaction that is in the midst of two-phase-commit with a commit timestamp less than ts . That is, Spanner must use its externally consistent read-only transaction API, which may block reads in such cases to ensure read-your-writes.

We bridge this gap in the design space with PORT, the first design that provides performance-optimal read-only transactions and the strongest consistency to date.

Other read-only transactions. Some systems choose to trade one performance property for stronger guarantees [1, 10, 29, 49] but still reside on the “tight boundary” of the NOCS Theorem. Many systems neither are performance-optimal nor provide the strongest possible guarantees [3, 5, 13, 15, 31, 32, 34, 36], and thus could potentially be im-

proved by our PORT design.

Impossibility results. Our NOCS Theorem is philosophically similar to other impossibility results, e.g., FLP [17], CAP [7, 20], and SNOW [34], in that it saves system designers’ effort from trying the impossible. The most relevant result is the SNOW Theorem, which we discuss next.

The move from latency to performance. SNOW [34] showed tradeoffs in the design space of read-only transactions with a focus only on latency. It proved optimal latency is impossible if the system is strictly serializable and has write transactions. This work aims for a more complete understanding of the tradeoffs in the design of read-only transactions by considering latency and throughput. The move from latency to performance has two takeaways.

First, optimal latency neither translates to nor forfeits optimal throughput. The former is shown by the two systems built with SNOW, which provided lower latency at the cost of lowering throughput. The latter is shown by our new designs that achieve both optimal latency and optimal throughput. What really matters is a complete understanding of the trade-off between performance and consistency and its insights for designs—the major contributions of this work.

Second, higher demand for performance, e.g., the move from latency only to both latency and throughput, suggests higher difficulty in providing stronger guarantees. Optimal latency is possible in strictly serializable systems without write transactions, but optimal performance is not.

11 Conclusion

Distributed storage systems are a fundamental building block of large-scale web services. They rely on read-only transactions to provide consistent views of sharded data. Our NOCS Theorem proves that read-only transactions cannot have optimal performance in strictly serializable systems. We presented PORT, a performance-optimal read-only transaction design that provides the strongest consistency to date. We applied PORT to design Scylla-PORT and Eiger-PORT. Scylla-PORT has minimal performance overhead compared to its non-transactional baseline. Eiger-PORT significantly improves the performance of its transactional base system.

Acknowledgments

We would like to thank our shepherd, Jinyang Li, for her invaluable feedback that improved this work. We thank the anonymous reviewers for their careful reading of our paper and their many insightful comments and suggestions. We are also grateful to Christopher Hodsdon, Theano Stavrinou, and Jeffrey Helt for their feedback on earlier stages of this work. Our evaluation at scale was made possible by the Emulab testbed. This work was supported by NSF award CNS-1824130 as well as a gift from Microsoft Research.

A Artifact Appendix

A.1 Abstract

This appendix presents the steps for installing Eiger-PORT and running experiments that compare the performance of Eiger-PORT and its base system, Eiger. Eiger-PORT is implemented as a modification to Eiger’s code base, which is built on top of Cassandra and written in Java. The experiments evaluate latency, throughput, and scalability. The results are expected to show that Eiger-PORT outperforms Eiger in all experiments and the performance advantages become more significant under more skewed workloads. Eiger-PORT’s better performance comes from its performance-optimal read-only transactions.

A.2 Artifact check-list

- **Hardware:** 2.4GHz Quad-Core Xeon CPU, 12GB RAM, 1 Gbps network interface
- **Metrics:** latency, throughput, scalability
- **Expected experiment run time:** 10–20 hours
- **Public link:** <http://github.com/princeton-sns/Eiger-PORT.git>

A.3 Description

A.3.1 How to access

The code base of Eiger-PORT is publicly accessible on Github at <http://github.com/princeton-sns/>

[Eiger-PORT.git](https://github.com/princeton-sns/Eiger-PORT.git). It includes a README file that provides step-by-step instructions on how to set up the environment and run experiments.

A.4 Installation

Please clone the code repository under a clean directory on a machine. The scripts in the package will work seamlessly if the repository is cloned under */local*. The required dependencies can be installed by simply running the bash file *install-dependencies.bash*. Apache Ant is used to build the source code. Both the system files and the stress tool need to be compiled. Please see the README file in the repository for more details.

A.5 Experiment workflow

Running experiments as described in the paper requires setting up two clusters with each having 8 servers and 8 clients. One cluster is the active cluster for processing transactions and the other cluster is used as a replica, which passively receives replicated writes from the active cluster. One extra machine is needed for the control node. Therefore, to create an 8-server-8-client environment, 33 machines are needed in total (2 clusters, 16 machines in each, and 1 control node).

When the experiment topology is determined, the configuration files under the directory *vicci_dcl.config* need to be modified accordingly. All the scripts used to run experiments are under the directory *eval-scripts*. Experiments can be launched by executing *latency_throughput.bash*. The experimental parameters, such as Zipfian constant and read-to-write ratio, are specified in the file *dynamic_defaults*. For details, please see the README file.

A.6 Evaluation and expected result

The results of each experiment are stored under the directory *experiments/dynamic*. Throughput numbers are shown in the file *combined.graph*. A set of latency processing scripts are provided under the directory *data_proc_scripts*. Eiger-PORT is expected to have ~2X higher throughput and ~50% latency compared to Eiger. The performance advantages of Eiger-PORT are expected to become more significant under more skewed workloads.

Toward a Generic Fault Tolerance Technique for Partial Network Partitioning

Mohammed Alfatafta, Basil Alkhatib, Ahmed Alquraan, Samer Al-Kiswany
University of Waterloo, Canada

Abstract

We present an extensive study focused on partial network partitioning. Partial network partitions disrupt the communication between some but not all nodes in a cluster.

First, we conduct a comprehensive study of system failures caused by this fault in 12 popular systems. Our study reveals that the studied failures are catastrophic (e.g., lead to data loss), easily manifest, and can manifest by partially partitioning a single node.

Second, we dissect the design of eight popular systems and identify four principled approaches for tolerating partial partitions. Unfortunately, our analysis shows that implemented fault tolerance techniques are inadequate for modern systems; they either patch a particular mechanism or lead to a complete cluster shutdown, even when alternative network paths exist.

Finally, our findings motivate us to build Nifty, a transparent communication layer that masks partial network partitions. Nifty builds an overlay between nodes to detour packets around partial partitions. Our prototype evaluation with six popular systems shows that Nifty overcomes the shortcomings of current fault tolerance approaches and effectively masks partial partitions while imposing negligible overhead.

1 Introduction

Modern networks are complex. They use heterogeneous hardware and software [1], deploy diverse middleboxes (e.g., NAT, load balancers, and firewalls) [2, 3, 4], and span multiple data centers [2, 4]. Despite the high redundancy built into modern networks, catastrophic failures are common [1, 3, 5, 6]. Nevertheless, modern cloud systems are expected to be highly available [7, 8] and to preserve stored data despite failures of nodes, networks, or even entire data centers [9, 10, 11].

We focus our investigation on a peculiar type of network fault: *partial network partitions*¹, which disrupts the communication between some, but not all, nodes in a cluster. Figure 1 illustrates how a partial network partition divides a cluster into three groups of nodes, such that two groups (Group 1 and Group 2) are disconnected, but Group 3 can communicate with Groups 1 and 2.

In our previous work [12] we identified this fault and presented examples of how it leads to system failures. Other than our previous preliminary effort, we did not find any in-depth analysis of partial network partition failures and of their fault tolerance techniques. Nevertheless, we found 51 reports of

Figure 1: Partial partition. Groups 1 and 2 are disconnected, while Group 3 can reach both sides of the partition.

failures caused by partial network partitioning faults² in the publicly accessible issue tracking systems of 12 production-quality systems (Section 4), numerous blog posts and discussions of this fault on developers’ forums (Section 3), and eight popular systems with fault tolerance techniques specifically designed to tolerate this type of fault (Section 5).

Our goal in this work is threefold. First, we aim to study failures caused by partial network partitioning to understand their impact and failure characteristics and, foremost, to identify opportunities to improve systems’ resiliency to this type of fault. Second, we aim to dissect the fault tolerance techniques implemented in popular production systems and identify their shortcomings. Third, we aim to design a generic fault tolerance technique for partial network partitioning. This is the first work to characterize these failures and explore fault tolerance techniques for partial partitioning faults.

It is important to understand that *partial* partitions are fundamentally different from *complete* partitions [12]. Complete partitions split a cluster into two completely disconnected sides and are well studied with known theoretical bounds (CAP theorem [13]) and numerous practical solutions [14, 15, 16, 17]. On the contrary, a cluster experiencing a partial partition is still connected but not all-to-all connected. Consequently, the theoretical bounds of complete partitions do not apply to partial partitions, and fault tolerance techniques for complete partitions are not effective in handling partial partitions (Section 8).

An analysis of partial network partitioning failures. We conduct an in-depth study of 51 partial network partitioning failures from 12 cloud systems (Section 4). We select a diverse set of systems, including database systems (MongoDB and HBase), file systems (HDFS and MooseFS), an object storage system (Ceph), messaging systems (RabbitMQ, Kafka, and ActiveMQ), a data-processing system (MapReduce), a search engine (Elasticsearch), and resource managers (Mesos and DKron). For each considered failure, we carefully study the

¹This is the commonly used name in failure reports and discussion forums.

²A *fault* is the initial root cause. If not properly handled, it may lead to a user-visible system *failure*.

failure report, logs, discussions between users and developers, source code, and code patches.

Failure Impact. Overall, we find that partial network partitioning faults cause silent failures with catastrophic effects (e.g., data loss and corruption) that affect core system mechanisms (e.g., leader election and replication).

Ease of manifestation. Unfortunately, these failures can easily occur. The majority of the failures are deterministic and require less than four events (e.g., read or write request) for the failure to occur. Even worse, all the studied failures can be triggered by partially partitioning a single node. The majority of failures do not require client access or can be triggered by clients only accessing one side of the partition.

Insights. We identify three approaches to improve system resilience: better testing, focused design reviews, and building a generic fault tolerance communication layer. Our analysis of each failure’s manifestation sequence, access patterns, and timing constraints shows that almost all the failures could have been revealed through simple tests and by only using five nodes. Second, the majority of failures are due to design flaws. We posit that design reviews focused on network partitioning could identify these vulnerabilities. Third, building a generic communication layer to mask partial partitions is feasible, simplifies system design, and improves system resiliency.

Finally, we identify that a common deployment approach of Zookeeper introduces a failure vulnerability (Section 5). Our analysis shows that system designers need to design additional mechanisms to handle partial partitions when using Zookeeper or other external coordination services.

Dissecting modern fault tolerance techniques. We dissect the implementation of eight popular systems (VoltDB, MapReduce, HBase, MongoDB, Elasticsearch, Mesos, LogCabin, and RabbitMQ) and study the fault tolerance techniques they employ specifically to tolerate partial partitions (Section 5). For each system, we study the source code, analyze the fault tolerance technique’s design, extract the design principles, and identify the technique’s shortcomings. We identify four principled approaches for tolerating partial partitions: identifying the surviving clique, checking neighbors’ views, verifying failures announced by other nodes, and neutralizing partially partitioned nodes.

Our analysis reveals that the studied fault tolerance techniques are inadequate. They either patch a specific system mechanism, which leaves the rest of the system vulnerable to failures, or unnecessarily shut down the entire cluster or pause up to half of the cluster nodes (Section 5).

Designing a generic fault tolerance technique. Our findings motivate us to build the **network partitioning fault-tolerance layer** (Nifty), a simple, generic, and transparent communication layer that can mask partial network partitions (Section 6). Nifty’s approach is simple; it monitors the connectivity in a cluster through all-to-all heart beating, and when it detects a partial partition, it detours the traffic around the partition through intermediate nodes. Nifty overcomes

all the shortcomings present in the studied fault tolerance techniques.

The main insight of Nifty is that tolerating partial partitioning does not require elaborate techniques such as the ones adopted by current systems (Section 5). Many modern systems already incorporate membership and connectivity monitoring mechanisms based on all-to-all heart beating [18, 19, 20]. Nifty shows that extending these mechanisms with a simple rerouting capability can effectively mask partial partitions.

To demonstrate Nifty’s effectiveness, we deploy it with six systems: HDFS, Kafka, RabbitMQ, ActiveMQ, MongoDB, and VoltDB. We choose these systems because they are data intensive and popular systems. Furthermore, RabbitMQ and VoltDB implement generic techniques to tolerate partial partitions. Our prototype evaluation with synthetic and real-world benchmarks shows that Nifty effectively masks partial partitions while adding negligible overhead.

2 Definitions

A *partial network partition* is a network fault that prevents at least one node (e.g., a node in Group 1 in Figure 1) from communicating with another node (Group 2) in the system, while a third node (Group 3) can communicate with both affected nodes. Nodes in a partially partitioned cluster are still connected but are not all-to-all connected (i.e., they do not form a complete graph [21]). A partial partition divides a cluster into three groups: two sides and one bridge group. We identify a node as a *bridge* node if it can reach at least one node on each side of a partition. A partial partition has two *sides*, all the nodes on one side of the partition cannot reach all the nodes on the other side of the partition. We note that a cluster may suffer from multiple concurrent partial partitions.

We define a *single-node partial partition* as a partial partition that has a single node on one side of the partition, while the rest of the cluster nodes are bridge nodes or are on the other side of the partition. For instance, a single-node partial partition can be caused by a firewall misconfiguration that prevents a node from communicating with some other nodes.

3 Causes of Partial Network Partitioning

Recent reports indicate that network partitioning faults are common and happen at various scales. Connectivity loss between data centers [1] leads to network partitions in geo-replicated systems. Wide area network partitions happen as frequently as once every four days [6]. Switch failures can cause a network partition in a data center [5]. Switch failures caused 40 network partitions in two years at Google [3] and 70% of the downtime at Microsoft [5]. On a single node, NIC [22] or software failures can partition a node that may host multiple VMs. Finally, network partitions caused by cor-

Table 1: List of studied systems and the number of studied failures. The shaded rows are systems that implemented a fault tolerance technique for partial network partitioning.

System	Category	Failures	
		Total	Catastrophic
Elasticsearch [32]	Search engine	17	17

Ceph [20]	Storage system	2	2
MooseFS [37]	File system	2	2
Kafka [38]	Messaging	2	2
ActiveMQ [39]	Messaging	1	1
DKron [40]	Resource mngr.	1	1
Total	-	51	39

related failures are common [4, 5, 6] and often caused by system-wide maintenance tasks [3, 5].

We found 51 failure reports detailing system failures due to partial network partitions, and numerous articles and on-line discussions discussing the fault [23, 24, 25, 26]. Some of these reports and discussions mention the root cause of the partial partition. Partial partitions are caused by a connectivity loss between two data centers [1] while both are reachable by a third center, the failure of additional links between racks [27, 28], network misconfiguration [29], firewall misconfiguration [29], network upgrades [30], and flaky links between switches [31]. Unfortunately, we did not find failure reports that detail partial partitioning faults in production networks.

4 Analysis of Partial Network-Partitioning Failures

We conduct an in-depth study of partial network partitioning failures reported in 12 popular systems (Table 1). We aim to understand the impact and characteristics of these failures and to identify opportunities for improving system resilience.

4.1 Methodology

We choose 12 diverse and widely used systems (Table 1), including two databases, a data analysis framework, two file systems, three messaging systems, a storage system, a search engine, and two distributed resource managers.

We selected the 51 failures in our study from publicly accessible issue-tracking systems. First, we used the search tools in the issue-tracking systems to find tickets related to partial network partitioning. Users did not classify network partitioning failures based on the partition type, so we had to search for all network partitioning failures and manually

identified partial partitioning failures. We used the following keywords: “network partition,” “partial network partition,” “partial partition,” “network failure,” “switch failure,” “isolation,” “split-brain,” and “asymmetric partition.” Second, we considered tickets that were dated 2011 or later. Third, we excluded tickets marked as “Minor.” For each ticket, we studied the failure description, system logs, developers’ and users’ comments, and code patches. For tickets that lacked enough details (e.g., missing output logs or did not have details about the affected mechanism), we manually reproduced them using NEAT [12]. Finally, during our evaluation, we found and reported bugs in Kafka and Elasticsearch. We included these failures in our study.

We differentiate failures by their manifestation sequences. In a few cases, the same faulty mechanism leads to two different failure paths. We count these as separate failures, even if they are reported in a single ticket. Similarly, although the exact failure is sometimes reported in multiple tickets, we count it once in our study.

4.2 Limitations

As with any characterization study, our findings may not be generalizable. Here, we list four potential sources of bias and describe our best efforts to address them.

1. *Representativeness of the studied systems.* Although we study 12 diverse systems (Table 1), our results may not be generalizable to systems we did not study. The selected systems follow diverse designs from strongly consistent (MongoDB, HBase, and Ceph) to eventually consistent (Elasticsearch) designs and from systems persisting data on disks and replicating data in-memory across nodes to caching systems. They follow a primary-backup or peer-to-peer architecture and use synchronous or asynchronous replication. The selected systems are widely used: Kafka, ActiveMQ, and RabbitMQ are the most popular open-source messaging systems; MapReduce, HDFS, and HBase are the core of the Hadoop platform; Elasticsearch is a popular search system; and MongoDB is a popular database.
2. *Limited number of tickets.* We study all 51 tickets that we found following our methodology. Statistical inference indicates that 30 samples can sufficiently represent the entire population [41]. More rigorously, if we assume the tickets we found represent a random sample of partial network partition failures in the wild, the central limit theorem predicts that our analysis of 51 tickets has a 13% margin of error at a 95% confidence level. To increase confidence in our findings, we only report findings that apply to at least two-thirds of the studied failures. A third of our findings apply to all failures.

Table 2: Failure impact and percentages of how many failures caused the corresponding impact.

Impact	%	
Data loss	23.5%	} Catastrophic (74.5%)
System unavailability	21.6%	
Stale read	15.7%	
Data corruption	5.9%	
Dirty read	3.9%	
Data unavailability	3.9%	
Reduced availability	23.5 %	
Other	2%	

3. *Priority bias.* We include only high-impact tickets and avoid tickets marked by the developers as low-priority. This sampling methodology may bias the results.
4. *Observer error.* To reduce the chance for observer errors, two team members study every failure report using the same classification methodology. Then, we discuss the failure in a group meeting before reaching a verdict.

4.3 Findings

This subsection presents nine general findings. Our study indicates that partial network partitioning leads to catastrophic, silent failures. Surprisingly, these failures are easy to manifest. The majority of failures are deterministic, require a single-node partial partition, and require a few events to manifest. However, our study also identifies failure characteristics that can inform system designs and improve testing. Finally, we find that the majority of the studied failures are due to design flaws, indicating that developers do not expect networks to fail in this way.

Finding 1: *A significant percentage (74.5%) of the studied failures have a catastrophic impact.*

A failure is said to be catastrophic if it leads to a system crash or violates the system’s guarantees (Table 2). Failures that reduce availability (e.g., crash of a single replica) or degrade performance are not considered catastrophic.

Data loss is the most common impact of partial network failures. For instance, in HBase, region servers store their logs on HDFS. When a log reaches a certain size, the region server creates a new log and informs the master of the new log location. If a partial partition isolates a region server from the master while both can reach HDFS, the master assumes that the region server has failed and assigns its logs to a new region server. If the old region server creates a new log, the master will not know about it, and the entries in the new log will be lost [42].

The second most common catastrophic impact of partial partitions is complete cluster unavailability, from which the majority of the studied systems suffer. A glaring example of this failure is the common deployment approach of Zookeeper. For instance, in ActiveMQ, a ZooKeeper service [43] moni-

tors the cluster master and selects a new master if the current one fails. If a partial partition isolates the master from all ActiveMQ nodes while all nodes are reachable from ZooKeeper, the nodes will pause their operations because they cannot reach the master. Because ZooKeeper can reach the current master, it neither detects the problem nor selects a new master. The cluster remains unavailable until the partial partition heals [44]. Kafka and Mesos use Zookeeper in a similar fashion and suffer from a similar failure. The rest of the catastrophic failures lead to stale reads, data corruption, loss of data availability, and dirty reads.

In 23.5% of the failures, a partial partition unnecessarily reduces system availability. For example, leader election in MongoDB is based on a majority vote, with an arbiter node included to break ties. Unfortunately, this design leads to cluster unavailability under partial network partitions. For instance, consider a shard that has two replicas (A and B), with A being the leader. If a partial partition disrupts the communication between A and B while both can reach an arbiter, B will detect that A is unreachable and calls for a leader election. Because there is only one candidate in the system, the arbiter votes for it, and B becomes the leader. The arbiter will inform A of the new leader, and A steps down. A will detect that the leader (B) is unreachable, call for a leader election, become a leader, and then B steps down. This leader-election thrashing continues until the network partition heals [45]. The system is unavailable during leader election, so this failure significantly reduces system availability. We discuss the resolution of this failure in Section 5.

Finding 2: *Most of the studied failures (84.3%) are silent — the user is not informed about their occurrence.*

Despite the dangerous impact of partial partitioning faults, most systems do not report to the user that a failure has occurred. This is unsettling because a lack of error or warning notification delays failure detection. Some systems return a warning to the user when an operation fails due to partial network partitioning, but these warnings are ambiguous with no clear mechanisms for resolution. For example, in Elasticsearch, if a client sends a request to a replica that is partially isolated from the other replicas, the replica will return “a rejected execution” exception [46]. This confusing warning does not inform the user of the problem’s actual cause nor the steps needed to resolve it.

Finding 3: *Leader election, configuration change, and replication protocol are the mechanisms most vulnerable to partial network partitioning.*

Leader election is the mechanism most vulnerable to partial network partitions (Table 3). In most cases, these failures lead to electing two leaders, one at each side of the partition [47, 48].

Configuration change is the second-most affected mechanism. For instance, each node in RabbitMQ maintains a membership log that lists the current nodes in the cluster. If

Table 3: Failure percentages per affected mechanism.

Mechanism	%
Leader election	37.3%
Configuration change	19.6%

nodes have conflicting views on which nodes are part of the cluster, the RabbitMQ cluster crashes. For instance, in a cluster with three nodes (A, B, and C), when a partial partition disconnects B and C, B assumes that C crashed and removes it from the membership log, and C assumes that B crashed and removes it from the membership log. This inconsistency in the cluster membership leads to a complete cluster crash [49].

The replication mechanism is the third-most affected mechanism. For instance, if a partial partition in Elasticsearch isolates a shard’s leader from the majority of that shard’s replicas, the leader will wait for a period of time before stepping down. In this period, the leader continues to accept client write operations and acknowledges them before successfully replicating them [50]. If a client writes to the leader and later reads from one of the other replicas, it may read stale data.

Finding 4: *Most failures (60.8%) do not require client access or require only that clients access one side of the partition.* To reduce the network partition’s impact, some systems limit client access to one side of the partition [51, 52, 53]. However, our analysis shows that 60.8% of failures require no client access at all or only client access to one side of the partition. As an example of a failure that does not require client access, in MongoDB, balancer servers monitor the cluster load and migrate data chunks between nodes to rebalance the load across nodes. After rebalancing the data, a balancer updates Mongo’s metadata server with the new data location. If during a re-balance operation of a particular shard a partial partition isolates the balancer from the metadata service, the cluster metadata will be in an inconsistent state, leading to the unavailability of that shard [54].

This finding highlights that system designers should consider the impacts of partial partitioning faults on all operations, including background operations.

Finding 5: *The majority of failures (68.6%) require three or fewer events (other than the partial partition) to manifest.* Only a few events need to occur for a failure to happen. An event is a user request, a hardware or software fault, or a start of a background operation (e.g., leader election and data rebalancing). This is alarming because a small number of events can lead to catastrophic failures. Especially that in real deployments, many users interact with the system, increasing the probability of failure. Table 4 shows that, in 13.7% of fail-

Table 4: Number of events required for a partial network partitioning failure to manifest.

Number of events	%
1 (Just a partial partition)	13.7%
2	9.8%
3	31.4%
4	13.7%
>4	31.4%

Table 5: System connectivity during a partial partition.

Network Partition Characteristic	%

Partition a specific node	66.6%
• Leader	45.1%
• Nodes with a special role	9.8%
• A central service	7.8%
• New nodes	2%

ures, a partial partition, without any additional events, leads to a failure.

Finding 6: *All the studied failures can be triggered by a single-node partial partition, with 33.3% of them happen by partitioning any node.*

Arguably, single-node partial partitions (Section 2) are generally more likely than partitioning more than one node. These partitions could happen due to a single ToR switch malfunction or by misconfiguring a single machine’s firewall.

We further study which nodes need to be isolated for a failure to manifest (Table 5). Of the failures, 33.3% manifest by partitioning any node in the system—regardless of its role. Among the failures that require partitioning a specific node, partitioning the leader replica is most common (45.1%). In real deployments, partitioning a leader is likely because almost every node in the cluster is a leader for some shard. Partitioning a node with a special role (such as an arbiter in MongoDB) causes 9.8% of the failures.

Finding 7: *All the studied failures, except one, are deterministic or have known time constraints.*

Table 6 shows the timing constraints of the studied failures. Almost all the failures are either deterministic with no timing constraints (i.e., whenever the event sequence happens, a failure happens) or have known timing constraints, such as the period before considering a node to have failed. Only one failure is nondeterministic, as an interleaving of multiple threads causes it.

Table 6: Failures’ timing constraints.

Timing constraint	%
No timing constraints	64.7%
Known timing constraints	33.3%
Nondeterministic	2%

Table 7: Percentage of design and implementation flaws.

Flaw type	%	Average Time to Resolution
Design	41.2%	260 days
Implementation	31.4%	98 days
Unresolved	27.5%	-

Table 8: Number of nodes needed to reproduce a failure.

Number of nodes	%
3 nodes	76.5%
4 nodes	21.6%
5 nodes	2%

Finding 8: *The resolution of 56.8% of the fixed failures required changing the design of a protocol or a mechanism.*

We consider a code patch to be fixing a design flaw if it significantly changes the implemented protocol or logic, such as changing the mechanism to select a master in Elasticsearch.

Most of the fixed failures are caused by a design flaw (Table 7). This indicates that system designers overlook partial network partitioning failures in the design phase. We argue that a design review focused on partial partitions would detect a system’s vulnerability to these failures.

Finding 9: *All failures can be reproduced with five nodes, and all but one can be reproduced using a fault injection tool.* These failures can be easily reproduced with small clusters of five or fewer nodes (Table 8), and 76.5% require only three nodes. Furthermore, all the failures except one can be reproduced using a fault-injection framework that can inject partial partitioning faults such as NEAT [12].

4.4 Insights

Our analysis shows that partial partitions lead to catastrophic silent failures that are easy to manifest, are deterministic, and can be triggered by a single-node partial partition and a sequence of a few events.

Fortunately, we identify three approaches for improving system resilience to partial partitions. First, because these faults are deterministic and can be reproduced on a small cluster, improved testing can reveal the majority of the studied failures. Our analysis finds timing, client access, and partition characteristics that significantly reduce the number of sufficient test cases. Second, our study of the code patches reveals that focused design reviews can identify system vulnerabilities early in the design process.

Third, partial network partitions have two characteristics that imply that a generic fault tolerance technique is possible. These faults can be detected by exchanging information between the nodes, and by definition, there are alternative paths in the network to reconnect the system. We leverage these two characteristics in building Nifty (Section 6).

Most of the studied failures are caused by the underlying assumption that, if a node can reach a service, all nodes can

reach that service, and if a node cannot reach a service then the service is down. Our analysis shows the danger of such assumptions; this leads to a confusing state, wherein some of the system’s parts start executing a fault tolerance mechanism, while others presume the whole system is healthy and carry on normal operations. The mix of these two operation modes is poorly understood and tested.

Finally, we identify that a common usage of external coordination services (e.g., Zookeeper) introduces a vulnerability to partial network partitioning fault. System designers need to build additional techniques to detect and handle partial partitions when using external coordination services.

5 Dissecting Modern Fault Tolerance Techniques

We studied the code patches related to the tickets included in our study. Six of the systems in Table 1 (MongoDB, Elasticsearch, RabbitMQ, HBase, MapReduce, and Mesos) changed the system design to incorporate a fault tolerance technique specific to partial network partitioning faults. The rest of the systems either patched the code with an implementation-specific workaround or did not fix the reported bugs yet.

Furthermore, we found that two additional systems, VoltDB [19, 55] and LogCabin [56] (the original implementation of the Raft [14] consensus protocol), implement fault tolerance techniques for partial partitions. For these two systems, we did not find failure reports related to partial partitioning faults in their issue tracking systems, but VoltDB announced that their recent version tolerates partial partitions [57]. We experimented with LogCabin to understand the impact partial partitions have on strongly consistent systems and found that LogCabin incorporates a technique to tolerate partial partitions. We included VoltDB and LogCabin in our study.

For each of the eight systems, we study the source code, and extract and analyze the design principles of their fault tolerance technique. We identify four approaches for tolerating partial partitions: detecting a surviving clique of nodes, checking neighbors’ views, verifying failure reports received from other nodes, and neutralizing one side of the partial partition. Unfortunately, these techniques have severe shortcomings that may lead to a complete system shutdown or to the unavailability of a major part of the system. In this section, we detail these techniques and discuss their shortcomings.

5.1 Identifying the Surviving Clique

Main idea. Upon a partial network partition, the system identifies the maximum clique of nodes [58], which is the largest subset of nodes that are completely connected. All nodes that are not part of the maximum clique are shut down. VoltDB follows this approach.

VoltDB Implementation. VoltDB [19, 55] is a popular ACID, sharded, and replicated relational database. VoltDB

Figure 2: VoltDB’s surviving clique. Gray nodes shut down as they are not in the clique.

Figure 3: The probability of a VoltDB cluster shutdown. Different lines represent different cluster sizes. The x-axis shows the number of nodes that are not in the clique.

follows a peer-to-peer approach to implement this technique. Every node in the system periodically sends a heartbeat to all nodes. If a node loses connectivity to any node, it suspects that a partial network partition occurred and starts the recovery procedure. The recovery procedure has two phases. In the first phase, the node that detects the failure broadcasts a list of nodes it can reach. When a node in the cluster receives this message, it broadcasts its list of reachable nodes to all nodes in the cluster. In phase two, every node independently combines the information from the other nodes into a graph representing the cluster connectivity. Each node analyzes this graph to detect the maximum completely connected clique of nodes. Every node that finds that it is not part of this “surviving” clique shuts itself down. Figure 2 shows an example in which a partial partition disrupts the communication between nodes 2, 3, and 4 on one side and nodes 5 and 6 on another. Nodes 5 and 6 are not part of the clique and will shut down.

After identifying the surviving clique, the system verifies that it did not lose any data by verifying that the surviving clique has at least one replica of every data shard. If the clique is missing one shard, such as when all the replicas of a shard are shut down, the entire system shuts down.

Shortcomings. This fault tolerance approach has two severe shortcomings. First, it unnecessarily shuts down up to half of the cluster nodes, reducing the system’s performance and fault tolerance. Second, this approach causes a complete cluster shutdown if the surviving clique is missing a single data shard. To understand how likely a cluster is to shut down, we conduct a probabilistic analysis (detailed in our technical report [59]). Figure 3 shows the probability of a complete cluster shutdown while varying the cluster size and the number of nodes that shut down (i.e., nodes that are not part of the surviving clique – the x-axis in Figure 3). Each shard has three replicas. Our analysis shows that isolating only 10% of the nodes leads to more than a 50% probability of shutting down the entire cluster, and isolating only 20% of the nodes leads to a staggering 90% chance of a complete cluster shutdown.

5.2 Checking Neighbors’ Views

Main idea. When one node (e.g., node S) loses its connection to another node D, it verifies whether the connection is lost due to a partial partition. To this end, S asks all nodes in the cluster whether they can reach D. If a node reports that it can reach D, this indicates that the cluster is suffering a partial network partition.

If S detects a partial network partition, S either disconnects from all nodes that can reach D, which effectively makes the partition a complete partition, or pauses its operation. RabbitMQ and Elasticsearch follow this approach.

5.2.1 RabbitMQ

RabbitMQ [18] is a popular messaging system that replicates message queues for reliability. In RabbitMQ, if a node detects that its communication with another node (e.g., node D) is affected by a partial partition, it applies one of the following policies depending on its configuration.

1. *Escalate to a complete partition.* The node will drop its connection with any node that can reach node D. The goal of this policy is to create a complete partition in which both sides work independently. This configuration leads to data inconsistency and requires running a data consolidation mechanism after the partition heals.
2. *Pause:* To avoid data inconsistency, once a node discovers the partial partition, it pauses its activities. It resumes its activities only when the partition heals. The result of this policy is that a subset of nodes will continue to operate. This subset will be completely connected and will run without sacrificing data consistency.
3. *Pause if anchor nodes are unreachable:* RabbitMQ’s configuration can specify a subset of nodes to act as anchor nodes. If a node cannot reach any of the anchor nodes, it pauses. This may lead to creating multiple complete partitions if the anchor nodes become partially partitioned. This may lead to pausing all nodes if all the anchor nodes are isolated.

After a partition heals, RabbitMQ employs two data consolidation techniques: administrator intervention, in which the administrator decides which side of the partition should become the authoritative version of the data, and auto-heal, in which the system makes this determination based on the number of clients connected to each side. Both techniques may lead to data loss or inconsistency [12].

Shortcomings. RabbitMQ’s policies have serious shortcomings. Changing a partial partition to a complete partition (policies 1 and 3) may lead to multiple inconsistent copies of the data, whereas the *pause* policy (policy 2) may pause the entire system or the majority of the nodes. For instance, in Figure 4, if every node except node 1 detects that it cannot reach a

Figure 4: A scenario for RabbitMQ’s *pause* policy. Every non-bridge node pauses (gray nodes) as it detects that it cannot reach one node on the other side.

node on the other side of the partition, it pauses, leading to a complete cluster pause.

In the case of the *pause* policy (policy 2), to determine how many nodes pause under different partial partition scenarios, we conduct an experiment in which we deploy a 15-node RabbitMQ cluster, introduce a partial partition, and observe how many nodes pause. In all experiments, we inject a partition such that one node remains unaffected and able to reach all nodes. Figure 5 shows the median number of paused nodes under various partition configurations. We run each configuration 30 times. Surprisingly, in all configurations almost all the cluster nodes pause because each node detects that it cannot reach at least one node on the other side of the partition. Even isolating a single node (configuration (1,13) in Figure 5) leads to pausing 12 nodes. Our investigation reveals that nodes declare another node unreachable after missing its heartbeats for a timeout period. In RabbitMQ, the default timeout period is 1 minute, which gives enough time for many nodes to detect the partition and pause. Using a shorter timeout periods causes some nodes to declare prematurely that other nodes have failed, even without a partial partition.

5.2.2 Elasticsearch

Elasticsearch [32] is a popular search engine. Its master election protocol uses a fault tolerance technique based on checking neighbors’ views. In Elasticsearch, the node with the lowest ID is the master. If a node (e.g., S) cannot reach the master, it contacts all nodes to check whether they can reach the master. If any node reports that it can reach the master, S pauses its operations. If none of the nodes can reach the master, the node with the lowest ID becomes the new master. **Shortcomings.** First, this approach can affect cluster availability quite severely, as all nodes that cannot reach the master pause. In the worst case, it can cause a complete cluster unavailability. For instance, in Figure 6, none of the nodes can reach the master except node 2, which refuses to become the new master because it can reach a node with a lower ID (node 1). Consequently, all the nodes in the cluster pause. Further-

Figure 5: The median number of paused nodes in a cluster of 15 nodes. In all runs, one node is unaffected by the partition. The notation (i, j) shows the number of nodes on each side of the partition.

Figure 6: Elasticsearch unavailability scenario. The master node cannot reach a majority of nodes, and all nodes pause because they cannot reach the master.

Figure 7: A Mesos cluster better pauses because it cannot reach a majority of nodes, and all nodes pause because they cannot reach the master.

more, because the master cannot reach a majority of nodes, it also pauses, which leads to system unavailability [60]. Second, Elasticsearch uses this approach only to fortify the master election protocol, which leaves the rest of the system vulnerable to partial partitions.

5.3 Failure Verification

Main idea. If a node (e.g., S) receives a notification from another node that a third node (D) has failed, node S first verifies that it cannot reach D before taking any fault tolerance steps. This approach is used in the leader election protocols of MongoDB [33] and LogCabin [56]. It was also used in an earlier version of Elasticsearch.

In MongoDB and LogCabin, if a leader is on one side of a partial partition but can still reach the majority of nodes, the nodes on the other side of the partition unnecessarily call for leader election. Finding 1 in Section 4 discusses a scenario in which a partial partition leads to continuous leader election thrashing and to system unavailability [45]. To avoid unnecessary elections, when a node receives a call for election, it first verifies that the current leader is unreachable. A node participates in an election only if it cannot reach the current leader, else it will ignore the failure report.

Shortcomings. This approach has two major shortcomings. First, it leads to the unavailability of a large number of nodes. Second, it is mechanism specific. Designing a system-wide fault tolerance mechanism using this approach is tricky because one cannot ignore every failure notification. For instance, using this approach in an earlier version of Elasticsearch backfired [61]. During data migration from a primary replica of a shard to a secondary replica, if a partial partition isolates the primary replica from the secondary replica while both are reachable from the master node, the primary requests a new secondary replica. Because the master can reach the secondary replica, it ignores the failure report. This leads to the unavailability of the affected shard [61]. Broadly applying

Table 9: Summary of shortcomings. (D) indicates that the nodes shut down. (P) indicates that the nodes pause until the partition heals. In the worst case, RabbitMQ pauses all nodes except one. We consider this a complete cluster loss (1). Under different RabbitMQ policies, (2) and (3) can occur. (S) indicates a system-wide technique, whereas (M) is a mechanism-specific technique.

	Surviving Clique	Checking w/ Neighbors		Failure Verification	Neutralizing Nodes		Nifty
	VoltDB	Elasticsearch	RabbitMQ	MongoDB/LogCabin	MapReduce/HBase	Mesos	
Reduced Availability	\times^D	\times^P	\times^P	\times^P	\times^D	\times^P	
Complete Unavailability	\times	\times	\times^1				
Complete Partition			\times^2				
Double Execution						\times	
Data Unavailability			\times^3				
Scope (System/Mechanism)	S	M	S	M	M	M	S

this fault tolerance technique is not feasible because designers have to revisit the design of every system mechanism, consider the consequences of ignoring failure reports, and examine the interaction of various mechanisms under partial partitions.

5.4 Neutralizing Partitioned Nodes

Main idea. One challenge related to handling partial network partitions is that nodes may update a shared state that is reachable from both sides of the partition, leading to data loss and inconsistency. To avoid this problem, this approach attempts to neutralize one side of the partition. However, the neutralization method is implementation-specific. HBase, MapReduce, and Mesos use this approach.

HBase Implementation. In HBase, data shards are managed by an HBase node but are stored on HDFS. If the HBase leader cannot reach one of the HBase nodes, it neutralizes that node by renaming the shard’s directory in HDFS. Renaming a shard’s directory effectively prohibits the old HBase node from making further changes to the shard [42]. The leader then assigns the shards of that node to a new HBase node.

MapReduce Implementation. In MapReduce, a manager node assigns tasks to AppMaster nodes. If the manager cannot reach an AppMaster, it reschedules the tasks assigned to that AppMaster to a new AppMaster. With partial network partitions, this approach may result in two AppMasters working on the same task, which leads to data corruption [62]. To fix this problem, when an AppMaster completes a task, it writes a completion record in a shared log on HDFS. Before an AppMaster executes a new task, it checks the shared log for a completion record. If it finds one, it does not re-execute the task.

Mesos Implementation. In Mesos, a master node assigns tasks to worker nodes. A Zookeeper instance selects the master node. The master sends periodic heartbeats to workers. If a partial partition isolates a worker node from the master, it pauses its operations. Figure 7 shows a worst-case scenario in which the partial partition isolates the master and its backup from all workers, which leads to a complete cluster unavailability. Finally, if a master detects that one of the workers is unavailable, it marks the tasks that were running on

the unreachable worker as lost and reschedules them on new workers. This may lead to the double execution of a task [63].

Shortcomings. First, it is not practical to use this approach for system-wide fault tolerance, as this approach is specific to a certain protocol and implementation. The presented three systems use this approach for different mechanisms. To use this approach broadly, designers must go through the daunting task of independently designing a fault tolerance technique for every mechanism in the system and understanding the interaction between these mechanisms. Second, this approach leaves the nodes on one side of the partition idle, which reduces system performance and availability.

5.5 Summary

Table 9 summarizes the shortcomings of the current fault tolerance techniques, none of which are adequate for modern cloud systems. All current techniques severely affect system availability, as they unnecessarily lose a significant number of nodes. Failure verification and neutralizing partitioned nodes are used to fortify *specific* mechanisms, rather than providing *system-wide* fault tolerance. Using mechanism-specific fault tolerance techniques requires the independent fortification of all system mechanisms and the analysis of the interactions between various mechanisms. This approach complicates system design, fault analysis, and debugging. An example of a system that uses multiple mechanism-specific techniques to tolerate partial partitions is Elasticsearch, which uses checking neighbors’ view, failure verification [61], and neutralizing partitioned nodes [64] in different mechanisms. However, Elasticsearch has the highest number of reported failures due to partial partitions (Table 1).

Detecting the surviving clique and checking neighbors’ views can be used to build a *system-wide* fault tolerance technique. However, as Table 9 shows, these techniques lead to a complete system shutdown or significant loss of system capacity. This realization motivated us to build Nifty (Section 6), a system-wide fault tolerance technique that overcomes the aforementioned shortcomings.

Figure 8: A Nifty routing example. A partial network partition isolates node 1 from nodes 3 and 4, and another partial partition isolates node 4 from nodes 1 and 2. Communication between 1 and 4 is routed through nodes 2 and 3.

6 Nifty Design

To overcome the limitations of current fault tolerance techniques, we design a simple, transparent network-partitioning fault-tolerant communication layer (Nifty).

Nifty follows a peer-to-peer design in which every node in the cluster runs a Nifty process. These processes collaborate in monitoring cluster connectivity. When Nifty detects a partial partition, it reroutes the traffic around the partition through intermediate nodes (i.e., bridge nodes). For instance, in Figure 8, if two partial partitions isolate node 1 from node 4, Nifty reroutes packets exchanged between nodes 1 and 4 through nodes 2 and 3.

Although Nifty keeps the cluster connected, it may increase the load on the bridge nodes, leading to a lower system performance. System designers who use Nifty may optimize the data or process placement or employ a flow-control mechanism to reduce the load on bridge nodes. To facilitate system-specific optimization, Nifty provides an API to identify bridge nodes.

Connectivity monitoring. Each Nifty process uses heartbeating to monitor its connectivity with all other Nifty processes. Each Nifty process maintains a distance vector that includes the distance, in number of hops, to every node in the cluster. If a Nifty process misses three heartbeats from another Nifty process, it assumes that the communication with that process is broken and updates its distance vector. To detect when the communication between nodes recovers, Nifty processes continue to send heartbeats to disconnected nodes.

Recovery. Each Nifty process sends its distance vector (piggybacked on heartbeat messages) to all other nodes. Every Nifty process then uses these vectors to build and maintain a routing table.

When a Nifty process detects a change in the cluster (e.g., a node becomes unreachable or reachable), it initiates the route discovery procedure to find new routes. In our prototype, we use the classical Bellman–Ford distance-vector protocol [65, 66]. We use hop count as the link weight. By hop, we mean a hop between end nodes. Using hop count naturally favors direct connections, when they exist, over rerouting through intermediate nodes.

An entry in the routing table has a destination IP address, hop count, and output MAC address. If a packet is received with a destination IP address that matches an entry in the routing table, Nifty will change the destination MAC address of the packet to equal the output MAC address found in the routing table, then send the packet out.

Route deployment. Nifty uses OpenFlow [67] and Open vSwitch [68] to deploy the new routes. For instance, to reroute packets sent from node 1 to node 4 through nodes 2 and 3 in Figure 8, the Nifty process on node 1 installs rules on its local Open vSwitch to change the destination MAC address of any packet destined to node 4 to the MAC address of node 2. Whenever node 2 receives a packet with node 4 IP address as its destination, it changes the destination MAC address to node 3 MAC address and sends the packet out. Finally, when node 3 receives a packet with node 4 IP address, it changes the MAC address to node 4 MAC and sends the packet out.

Node classification. A system using Nifty can be optimized to reduce the amount of data forwarded through bridge nodes. The approach to do so is system-specific and may entail relocating processes in a cluster, dropping client requests, or reducing query result quality [7].

To facilitate the implementation of these mechanisms, Nifty identifies which nodes are on the same side of the network partition and which nodes serve as bridge nodes. It then provides this node classification to the system running atop of it. Section 7.3 demonstrates how this information can facilitate optimizing process placement in a VoltDB cluster.

7 Evaluation

Our evaluation answers three questions. How much overhead does Nifty impose when there are no network partitions? What is a system’s performance with Nifty under a network partition? What is the utility of Nifty’s classification API?

Testbed. We conduct our experiments using 40 nodes at the Cloudlab Utah cluster. Each node has an Intel Xeon E5 10-core CPU, 64 GB of RAM, and a Mellanox ConnectX-4 25 Gbps NIC. To inject a network partition fault, we modify the Open vSwitch rules on the nodes to drop packets between the affected nodes. In all our experiments, we report the average for 30 runs. We note that the standard deviation in all our experiments is lower than 5%.

7.1 Overhead Evaluation

To evaluate Nifty’s overhead, we measure its impact on the performance of a synthetic benchmark using iperf [69] and six data-centric systems (i.e., storage, database, and messaging systems). The iperf experiment uses a 100-node cluster to measure Nifty’s impact on larger clusters. The systems we selected are:

- HDFS: We deploy HDFS (v3.3.0) on six nodes (one name node and five data nodes) and with a replication

Figure 9: Nifty’s overhead. The average throughput for HDFS (a) and the average throughput vs. average latency for the rest of the systems. (-P) denotes the results with a partial partition.

level of three. To avoid disk access, we configure data nodes to use tmpfs. We use the HDFS standard benchmark (TestDFSIO). The benchmark reads and writes 1 GB files.

- **Kafka:** We deploy Kafka (v2.6.0) on five nodes. We distribute the queues (aka, topics) among nodes to balance the load. Each message is replicated on three nodes. We use Kafka’s benchmarking tool to generate load on the system. The experiments use a set of producers and consumers. Each producer sends messages to a dedicated queue and each queue has one consumer.
- **ActiveMQ:** We deploy ActiveMQ Artemis (v2.15.0) on five nodes with each queue being replicated on two nodes. The experiments use a set of producers and consumers. Each producer sends messages to a dedicated queue and each queue has one consumer.
- **MongoDB:** We deploy MongoDB (v4.4.1) on six nodes (one config server and five mongod nodes) and with a replication level of three. We discuss our results with the Yahoo benchmark workload B (95% reads and 5% writes) with a uniform distribution [70]. We use 10 million records. The rest of the Yahoo benchmark workloads shows similar results.
- **VoltDB:** We deploy VoltDB (v9.0) on nine nodes, with data sharding enabled and a replication level of three. We use the Yahoo benchmark and the TCP-C benchmark. Figure 9.e shows the throughput-latency curve under Yahoo benchmark workload B (95% reads and 5% writes)

with a uniform distribution. The results using the TPC-C benchmark and the Yahoo benchmark workloads A and C with uniform and skewed loads show similar low overhead.

- **RabbitMQ:** We deploy RabbitMQ (v3.8.2) on three nodes. We use the mirrored mode in which each queue has a leader replica and two backup replicas. We distribute the queue masters among brokers to distribute the load. The experiments use a set of producers and consumers. Each producer sends messages to a dedicated queue and each consumer reads messages from a dedicated queue.

Results. We compare the throughput and average latency of each system with and without Nifty when there is no partial network partition. We evaluate Nifty with a partial partition in Section 7.2.

Figure 9 shows the write throughput of HDFS (Figure 9.a) and the throughput-latency curve for Kafka (Figure 9.b), ActiveMQ (Figure 9.c), MongoDB (Figure 9.d), VoltDB (Figure 9.e), and RabbitMQ (Figure 9.f). The results show that Nifty does not add noticeable overhead; for all systems, the curves almost completely overlap. This is because Nifty processes exchange a negligible number of packets. Each Nifty process sends a single UDP heartbeat packet every 200 ms to other nodes in the system. Consequently, in the largest deployment of nine nodes, each node sends only 40 packets every second.

Scalability evaluation. Nifty uses all-to-all heart beating to monitor a cluster’s connectivity. Consequently, Nifty’s overhead increases with the cluster size. To measure Nifty’s scal-

Figure 10: Scalability evaluation. Average throughput while increasing the number of nodes.

ability, we evaluate its overhead on a 100-node CloudLab Utah cluster. For this experiment, we limit the throughput of each node to 1 Gbps, as CloudLab can not support a full 10-Gbps connectivity between the 100 nodes we managed to book. To generate network intensive load, we use iperf [69]. Half of the nodes run an iperf server, and the other half run an iperf client. Each client communicates with a single server. Figure 10 shows the aggregate throughput of the iperf servers when deployed with and without Nifty. The figure shows that Nifty’s overhead is negligible. When using 100 nodes, Nifty degrades the aggregate throughput by only 3.5%. Nevertheless, this monitoring approach will not scale to clusters with thousands of nodes. We are currently exploring the design of a fault tolerance technique that can scale to larger clusters.

7.2 Handling Partial Partitions

To demonstrate the effectiveness of the proposed approach, we evaluate Nifty’s performance with the six aforementioned systems under a partial partition fault. We note that RabbitMQ and VoltDB implemented two different techniques for tolerating partial partitions (Section 5).

Partial partition setup. We use the same deployment of the six aforementioned systems. Each system is deployed on an odd number of replicas. We introduce a partial partition that leaves one node as a bridge node and puts an equal number of nodes on each side of the partition. Client nodes are not affected by the partition. We partition the cluster this way to create maximum pressure on the bridge node.

Figure 9 shows the system performance when the cluster suffers from the partial partition. We notice that all the six systems are severely effected by the partial partition. HDFS, ActiveMQ, MongoDB, and VoltDB suffer a complete cluster pause or shutdown when deployed without Nifty. The VoltDB cluster shuts down because, after detecting the surviving clique, the system misses at least one shard. This confirms our analysis in Section 5.1.

RabbitMQ uses the checking neighbor’s views fault tolerance approach. In our deployment, each queue is mirrored on a backup replica. Due to the strong consistency requirement, we configure RabbitMQ to pause in case of partial partition.

(a) VoltDB tail latency.

(b) RabbitMQ tail latency.

Figure 11: Tail latency evaluation. Average throughput vs. 99th percentile of latency.

We deploy RabbitMQ on three nodes. Unfortunately, we could not use a larger RabbitMQ cluster because partial partitions often lead to the pause of the entire RabbitMQ cluster when Nifty is not used (Figure 4). Even with three nodes, partial partitions sometimes lead to pausing two out of three nodes. We discard those results and only include results in which one node pauses. Consequently, our results show the best possible performance of RabbitMQ under partial partitions. Pausing a broker in RabbitMQ leads to more than 50% reduction in throughput (RabbitMQ-P in (Figure 9.f)).

Kafka uses Zookeeper to monitor a cluster nodes. If a partial partition isolates a queue leader from the majority of replicas while Zookeeper runs on a bridge node, Zookeeper will not select a new leader and the entire cluster pauses (Finding 1 in Section 4). To mitigate this, we made sure that Zookeeper falls on one side of the partition. In this case, all the nodes on the other side of the partition that cannot reach Zookeeper are removed from the cluster. In our experiment, the partial partition causes two nodes to pause, which leads to almost a 50% reduction in system throughput (Figure 9.b).

Figure 9 shows that Nifty effectively masks the partial partition, so none of the nodes shut down or pause. Figure 9.a shows the write operation throughput for HDFS. With a replication level of three, each file has replicas on both sides of a partial partition. Consequently, for every 1 GB of data written, 1 or 2 GB of data are rerouted through the bridge node. This reduces the system throughput by up to 45%. We note that having a partial partition result in a performance degradation is better than a complete system unavailability when HDFS is deployed without Nifty. For the rest of the systems, during the partial partition, almost 50% of client requests and responses are rerouted through the bridge node. Even so, the system throughput only decreases by 2-6.7% and latency only increases by 3-7.8%. This shows that Nifty can effectively mask partial partitions and is able to utilize remaining connections to reduce the performance impact.

Figure 11 shows the tail latency for VoltDB and RabbitMQ for the same experiments presented in Figure 9. The figure shows the average throughput and the 99th percentile of latency while increasing the load on the system. The figure shows that Nifty increases the 99th percentile latency by up to 6.8% without a partial partition and by 15% under a partial partition failure.

7.3 Classification API Utility

In this section, we demonstrate the utility of Nifty’s classification API. In VoltDB, a single server (aka, multi-data-partition initiator or MPI) processes all multi-shard operations. The MPI divides a multi-shard query (e.g., a join) to sub-queries, such that each sub-query targets a single shard. The MPI forwards each sub-query to its shard leader, gathers the intermediate results, performs final query processing, and sends the result to the client.

When deploying VoltDB atop Nifty, if the MPI node is on one side of the partition, a potentially significant volume of intermediate data passes through the bridge node. In our setup, when the MPI is on one side of the partition, 50% of the intermediate results are rerouted through the bridge node. This increases operation latency and the load on bridge nodes.

To improve the performance of multi-shard operations, the MPI process can be migrated to a bridge node. This effectively eliminates the need to reroute any traffic for multi-shard queries. We modify VoltDB to use Nifty’s API to identify bridge nodes and migrate the MPI to a bridge node.

To evaluate this optimization’s effectiveness, we evaluate the effect of the MPI’s location on system performance. We restrict clients to contacting VoltDB nodes on one side of the partition and compare the system performance of three MPI placements: on clients side of the partition (client side in Figure 12), on the bridge node (bridge), and on the side opposite to the clients (opposite side). Bridge placement represents our optimization.

Setup and Workload. We use the same VoltDB configuration and partial partition setup detailed in the previous sections. Unfortunately, VoltDB has limited support for join queries, so it cannot run standard benchmarks such as TPC-H [71]. In our experiments, we use a simple synthetic benchmark that joins two tables. The benchmark has two sharded tables of 20 fields each. Each field is 50 bytes, leading to approximately 1 KB rows. To use multiple shards, clients issue a range query that joins the two tables on the primary key. The client issues a query with a range that includes four primary keys. Consequently, the query result size is limited to four rows, with a total size of almost 8 KB. We populate the database with 20 GB of data before running the experiments. We report the average and standard deviation for 30 runs.

Results. Figure 12 shows the system throughput (a) and the average latency (b) for the three possible MPI placements. During a partial partition fault, placing the MPI on a bridge node decreases the latency by up to 11% and improves throughput by 11% compared to client and opposite side placements. Placing the MPI on a bridge node reduces the number of hops the join query must make before the MPI accumulates all the results and sends the query reply. Furthermore, bridge placement achieves throughput and latency within 4% of VoltDB’s performance when there is no partition (“no partition” in Figure 12).

Figure 12: The impact of MPI placement on VoltDB’s performance. Figure shows the average latency (a) and average throughput (b). Standard deviation was less than 2%.

We measure the amount of data forwarded through the bridge nodes for each one of those configurations; placing the MPI on the bridge node imposes the least overhead. When using 128 clients, 72 MB, 5 GB, and 6.5 GB of data are forwarded through the bridge node when the MPI is placed on the bridge, client side, and opposite side, respectively. The opposite side rerouts more data than the client side placement, as the client request and the result are also rerouted through the bridge node.

8 Related Work

To the best of our knowledge, this is the first study to focus on partial network partitioning, characterize its failures, dissect modern fault tolerance techniques, and explore the design of a generic fault tolerance technique for this type of fault.

A number of previous efforts analyzed failures in distributed systems, including characterizing specific component failures [5, 6, 72, 73, 74, 75] and characterizing failures in a specific domain such as HPC [76, 77, 78], IaaS clouds [79], data-mining services [80], hosting services [8, 81], data-intensive systems [82, 83, 84], and cloud systems [85]. Our work complements these efforts by focusing on failures triggered by partial network partitions.

In our previous work [12], we studied 136 network partitioning failures focusing on complete partitions. This previous work identified partial partitions, presented examples of how they can lead to system failures, and presented NEAT, a testing tool that can inject complete and partial network partitioning faults. We use NEAT to reproduce some of the reported failures. This paper presents an in-depth analysis of partial partition failures and fault tolerance techniques and proposes a novel fault-tolerant communication layer.

Comparing the characteristics of partial and complete partitions [12] shows that they have similar catastrophic impact and manifestation and reproducibility characteristics. Partial partitions seem easier to manifest. While all partial partition failures are triggered by a single-node partial partition and almost all of the failures are deterministic, 88% of the complete partitions manifest by isolating a single node and 80% of them are deterministic. Furthermore, we found twice as many failure reports reporting complete partitions than partial partitions.

Despite their similarity in causing catastrophic failures and being easy-to-manifest, partial and complete partitions are fundamentally different faults. Unlike complete partitions, a cluster suffering a partial partition is still connected but not all-to-all connected. Consequently, the CAP theorem bounds [13] do not apply to partial partitions. Furthermore, fault tolerance techniques for complete partitions cannot handle partial partitions or lead to pausing up to half of the cluster nodes. For instance, using majority vote to elect a leader is an effective mechanism to tolerate complete partitions. This approach alone is not effective in handling partial partitions, as there could be multiple completely connected subgroups with each connecting a majority of nodes. Section 5 shows how using only majority voting can lead to leader election thrashing and system unavailability.

Software-defined networking capabilities have been used to engineer traffic and optimize system operations, including offering network virtualization [86]; building network overlays [87]; performing network measurements [88, 89]; and implementing in-network firewalls [90], load balancers [91, 92], and key-value-based routing [93, 94]. Nifty is similar in spirit to these systems, as we use Open vSwitch capabilities to implement an overlay to mask partial partitions.

9 Concluding Remarks

Our work sheds light on a peculiar type of infrastructure fault and highlights the need for further research to understand such faults and explore techniques to improve systems' resiliency.

This is the first work to focus on partial network partitioning fault and present an in-depth analysis of system failures triggered by this fault. We identify characteristics that can facilitate better test design. Our findings highlight that focused design reviews can identify vulnerabilities early in the design process. We dissect the implementation of eight popular systems and study their fault tolerance techniques. In doing so, we identify four main approaches for tolerating partial partitions. Unfortunately, all implemented fault tolerance techniques have severe shortcomings.

We, therefore, build Nifty to overcome the limitations of modern fault tolerance techniques. Nifty is a simple, transparent communication layer that reroutes packets around partial partitions. We note that modern systems already incorporate a membership and connectivity monitoring. We show that extending the current implementations with a detour mechanism is an effective and low overhead fault tolerance technique to partial partitions. The source code for Nifty is available at <https://github.com/UWASL/NIFTY>

PACEMAKER

Avoiding HeART attacks in storage clusters with disk-adaptive redundancy

Saurabh Kadekodi, Francisco Maturana, Suhas Jayaram Subramanya, Juncheng Yang,
K. V. Rashmi, Gregory R. Ganger
Carnegie Mellon University

Abstract

Data redundancy provides resilience in large-scale storage clusters, but imposes significant cost overhead. Substantial space-savings can be realized by tuning redundancy schemes to observed disk failure rates. However, prior design proposals for such tuning are unusable in real-world clusters, because the IO load of transitions between schemes overwhelms the storage infrastructure (termed *transition overload*).

This paper analyzes traces for millions of disks from production systems at Google, NetApp, and Backblaze to expose and understand transition overload as a roadblock to disk-adaptive redundancy: transition IO under existing approaches can consume 100% cluster IO continuously for several weeks. Building on the insights drawn, we present PACEMAKER, a low-overhead disk-adaptive redundancy orchestrator. PACEMAKER mitigates transition overload by (1) proactively organizing data layouts to make future transitions efficient, and (2) initiating transitions proactively in a manner that avoids urgency while not compromising on space-savings. Evaluation of PACEMAKER with traces from four large (110K–450K disks) production clusters show that the transition IO requirement decreases to never needing more than 5% cluster IO bandwidth (0.2–0.4% on average). PACEMAKER achieves this while providing overall space-savings of 14–20% and never leaving data under-protected. We also describe and experiment with an integration of PACEMAKER into HDFS.

1 Introduction

Distributed storage systems use data redundancy to protect data in the face of disk failures [13, 15, 56]. While it provides resilience, redundancy imposes significant cost overhead. Most large-scale systems today erasure code most of the data stored, instead of replicating, which helps to reduce the space overhead well below 100% [13, 24, 44, 48, 62, 67]. Despite this, space overhead remains a key concern in large-scale systems since it directly translates to an increase in the number of disks and the associated increase in capital, operating and energy costs [13, 24, 44, 48].

Storage clusters are made up of disks from a mix of makes/models acquired over time, and different makes/models have highly varying failure rates [27, 32, 41]. Despite that, storage clusters employ a “one-size-fits-all-disks” approach to choosing redundancy levels, without considering failure rate differences among disks. Hence, space overhead is often inflated by overly conservative redundancy levels, chosen to ensure sufficient protection for the most failure-prone disks in the cluster. Although tempting, the overhead

Figure 1: Fraction of total cluster IO bandwidth needed to use disk-adaptive redundancy for a Google storage cluster’s first three years. The state-of-the-art proposal [27] shown in (a) would require up to 100% of the cluster bandwidth for extended periods, whereas PACEMAKER shown in (b) always fits its IO under a cap (5%). The light gray region shows the disk count (right Y-axis) over time.

cannot be removed by using very “wide” codes (which can provide high reliability with low storage overhead) for all data, due to the prohibitive reconstruction cost induced by the most failure-prone disks (more details in § 2). An exciting alternative is to dynamically adapt redundancy choices to observed failure rates (AFRs)¹ for different disks, which recent proposals suggest could substantially reduce the space overhead [27].

Adapting redundancy involves dynamic transitioning of redundancy schemes, because AFRs must be learned from observation of deployed disks and because AFRs change over time due to disk aging. Changing already encoded data from one redundancy scheme to another, for example from an erasure code with parameters k_1 -of- n_1 to k_2 -of- n_2 (where k -of- n denotes k data chunks and $n - k$ parity chunks; more details in § 2), can be exorbitantly IO intensive. Existing designs for disk-adaptive redundancy are rendered unusable by overwhelming bursts of urgent transition IO when applied to real-world storage clusters. Indeed, as illustrated in Fig. 1a, our analyses of production traces show extended periods of needing 100% of the cluster’s IO bandwidth for transitions. We refer to this as the *transition overload* problem. At its core, transition overload occurs whenever an observed AFR increase for a subset of disks requires too much urgent transition IO in order to keep data safe. Existing designs for

¹ AFR describes the expected fraction of disks that experience failure in a typical year.

disk-adaptive redundancy perform redundancy transitions as a reaction to AFR changes. Since prior designs are reactive, for an increase in AFR, the data is already under-protected by the time the transition to increase redundancy is issued. And it will continue to be under-protected until that transition completes. For example, around 2019-09 in Fig. 1a, data was under-protected for over a month, even though the entire cluster’s IO bandwidth was used solely for redundancy transitions. Simple rate-limiting to reduce urgent bursts of IO would only exacerbate this problem causing data-reliability goals to be violated for even longer.

To understand the causes of transition overload and inform solutions, we analyse multi-year deployment and failure logs for over 5.3 million disks from Google, NetApp and Backblaze. Two common transition overload patterns are observed. First, sometimes disks are added in tens or hundreds over time, which we call *trickle* deployments. A statistically confident AFR observation requires thousands of disks. Thus, by the time it is known that AFR for a specific make/model and age is too high for the redundancy used, the oldest thousands of that make/model will be past that age. At that point, all of those disks need immediate transition. Second, sometimes disks are added in batches of many thousands, which we call *step* deployments. Steps have sufficient disks for statistically confident AFR estimation. However, when a step reaches an age where the AFR is too high for the redundancy used, *all* disks of the step need immediate transition.

This paper introduces PACEMAKER, a new disk-adaptive redundancy orchestration system that exploits insights from the aforementioned analyses to eliminate the transition overload problem. PACEMAKER proactively organizes data layouts to enable efficient transitions for each deployment pattern, reducing total transition IO by over 90%. Indeed, by virtue of its reduced total transition IO, PACEMAKER can afford to use extra transitions to reap increased space-savings. PACEMAKER also proactively initiates anticipated transitions sufficiently in advance that the resulting transition IO can be rate-limited without placing data at risk. Fig. 1b provides a peek into the final result: PACEMAKER achieves disk-adaptive redundancy with substantially less total transition IO and never exceeds a specified transition IO cap (5% in the graph).

We evaluate PACEMAKER using logs containing all disk deployment, failure, and decommissioning events from four production storage clusters: three 160K–450K-disk Google clusters and a \approx 110K-disk cluster used for the Backblaze Internet backup service [4]. On all four clusters, PACEMAKER provides disk-adaptive redundancy while using less than 0.4% of cluster IO bandwidth for transitions on average, and never exceeding the specified rate limit (e.g., 5%) on IO bandwidth. Yet, despite its proactive approach, PACEMAKER loses less than 3% of the space-savings as compared to an idealized system with perfectly-timed and instant transitions. Specifically, PACEMAKER provides 14–20% average space-savings compared to a one-size-fits-all-disks approach, without ever

failing to meet the target data reliability and with no transition overload. We note that this is substantial savings for large-scale systems, where even a single-digit space-savings is worth the engineering effort. For example, in aggregate, the four clusters would need \approx 200K fewer disks.

We also implement PACEMAKER in HDFS, demonstrating that PACEMAKER’s mechanisms fit into an existing cluster storage system with minimal changes. Complementing our longitudinal evaluation using traces from large scale clusters, we report measurements of redundancy transitions in PACEMAKER-enhanced HDFS via small-scale cluster experiments. Prototype of HDFS with Pacemaker is open-sourced and is available at <https://github.com/thesys-lab/pacemaker-hdfs.git>.

This paper makes five primary contributions. First, it demonstrates that transition overload is a roadblock that precludes use of previous disk-adaptive redundancy proposals. Second, it presents insights into the sources of transition overload from longitudinal analyses of deployment and failure logs for 5.3 million disks from three large organizations. Third, it describes PACEMAKER’s novel techniques, designed based on insights drawn from these analyses, for safe disk-adaptive redundancy without transition overload. Fourth, it evaluates PACEMAKER’s policies for four large real-world storage clusters, demonstrating their effectiveness for a range of deployment and disk failure patterns. Fifth, it describes integration of and experiments with PACEMAKER’s techniques in HDFS, demonstrating their feasibility, functionality, and ease of integration into a cluster storage implementation.

2 Whither disk-adaptive redundancy

Cluster storage systems and data reliability. Modern storage clusters scale to huge capacities by combining up to hundreds of thousands of storage devices into a single storage system [15, 56, 63]. In general, there is a metadata service that tracks data locations (and other metadata) and a large number of storage servers that each have up to tens of disks. Data is partitioned into chunks that are spread among the storage servers/devices. Although hot/warm data is now often stored on Flash SSDs, cost considerations lead to the majority of data continuing to be stored on mechanical disks (HDDs) for the foreseeable future [6, 7, 54]. For the rest of the paper, any reference to a “device” or “disk” implies HDDs.

Disk failures are common and storage clusters use data redundancy to protect against irrecoverable data loss in the face of disk failures [4, 15, 24, 41, 43, 44, 48]. For hot data, often replication is used for performance benefits. But, for most bulk and colder data, cost considerations have led to the use of erasure coding schemes. Under a k -of- n coding scheme, each set of k data chunks are coupled with $n-k$ “parity chunks” to form a “stripe”. A k -of- n scheme provides tolerance to $(n-k)$ failures with a space overhead of $\frac{n}{k}$. Thus, erasure coding achieves substantially lower space overhead for tolerating a given number of failures. Schemes like 6-of-9 and 10-of-14

are commonly used in real-world deployments [13, 43, 44, 48]. Under erasure coding, additional work is involved in recovering from a device failure. To reconstruct a lost chunk, k remaining chunks from the stripe must be read.

The redundancy scheme selection problem. The reliability of data stored redundantly is often quantified as *mean-time-to-data-loss* (MTTDL) [17], which essentially captures the average time until more than the tolerated number of chunks are lost. MTTDL is calculated using the disks' AFR and its *mean-time-to-repair* (MTTR).

Large clusters are built over time, and hence usually consist of a mix of disks belonging to multiple makes/models depending on which options were most cost effective at each time. AFR values vary significantly between makes/models and disks of different ages [27, 32, 41, 50]. Since disks have different AFRs, computing MTTDL of a candidate redundancy scheme for a large-scale storage cluster is often difficult.

The MTTDL equations can still be used to guide decisions, as long as a sufficiently high AFR value is used. For example, if the highest AFR value possible for any deployed make/model at any age is used, the computed MTTDL will be a lower bound. So long as the lower bound on MTTDL meets the target MTTDL, the data is adequately reliable. Unfortunately, the range of possible AFR values in a large storage cluster is generally quite large (over an order of magnitude) [27, 32, 41, 52]. Since the overall average is closer to the lower end of the AFR range, the highest AFR value is a conservative over-estimate for most disks. The resulting MTTDLs are thus loose lower bounds, prompting decision-makers to use a one-size-fits-all scheme with excessive redundancy leading to wasted space.

Using wide schemes with large number of parities (e.g., 30-of-36) can achieve the desired MTTDL while keeping the storage overhead low enough to make disk-adaptive redundancy appear not worth the effort. But, while this might seem like a panacea, wide schemes in high-AFR regimes cause significant increase in failure reconstruction IO traffic. The failure reconstruction IO is derived by multiplying the AFR with the number of data chunks in each stripe. Thus, if either of these quantities are excessively high, or both are moderately high, it can lead to overwhelmingly high failure reconstruction IO. In addition, wide schemes also result in higher tail latencies for individual disk reconstructions because of having to read from many more disks. Combined, these reasons prevent use of wide schemes for all data all the time from being a viable solution for most systems.

Disk-adaptive redundancy. Since the problem arises from using a single AFR value, a promising alternative is to adapt redundancy for subsets of disks with similar AFRs. A recent proposal, heterogeneity-aware redundancy tuner (HeART) [27], suggests treating subsets of deployed disks with different AFR characteristics differently. Specifically, HeART adapts redundancy of each disk by observing its fail-

ure rate on the fly² depending on its make/model and its current age. It is well known that AFR of disks follow a “bathtub” shape with three distinct phases of life: AFR is high in “infancy” (1-3 months), low and stable during its “useful life” (3-5 years), and high during the “wearout” (a few months before decommissioning). HeART uses a default (one-size-fits-all) redundancy scheme for each new disk’s infancy. It then dynamically changes the redundancy to a scheme adapted to the observed useful life AFR for that disk’s make/model, and then dynamically changes back to the default scheme at the end of useful life. The per-make/model useful life redundancy schemes typically have much lower space overhead than the default scheme. This suggests the ability to maintain target MTTDL with many fewer disks (i.e., lower cost).

Although exciting, the design of HeART overlooks a crucial element: the IO cost associated with changing the redundancy schemes. Changing already encoded data under one erasure code to another can be exorbitantly IO intensive. Indeed, our evaluation of HeART on real-world storage cluster logs reveal extended periods where data safety is at risk and where 100% cluster IO bandwidth is consumed for scheme changes. We call this problem *transition overload*.

An enticing solution that might appear to mitigate transition overload is to adapt redundancy schemes only by removing parities in low-AFR regimes and adding parities in high-AFR regimes. While this solution eliminates transition IO when reducing the level of redundancy, it does only marginally better when redundancy needs to be increased, because new parity creation cannot avoid reading all data chunks from each stripe. What makes this worse is that transitions that increase redundancy are time-critical, since delaying them would miss the MTTDL target and leave the data under-protected. Moreover, addition / removal of a parity chunk massively changes the stripe’s MTTDL compared to addition / removal of a data chunk. For example, a 6-of-9 MTTDL is 10000× higher than 6-of-8 MTTDL, but is only 1.5× higher than 7-of-10 MTTDL. AFR changes would almost never be large enough to safely remove a parity, given default schemes like 6-of-9, eliminating almost all potential benefits of disk-adaptive redundancy.

This paper analyzes disk deployment and failure data from large-scale production clusters to discover sources of *transition overload* and informs the design of a solution. It then describes and evaluates PACEMAKER, which realizes the dream of safe disk-adaptive redundancy without transition overload.

3 Longitudinal production trace analyses

This section presents an analysis of multi-year disk reliability logs and deployment characteristics of 5.3 million HDDs, covering over 60 makes/models from real-world environments. Key insights presented here shed light on the

²Although it may be tempting to use AFR values taken from manufacturer’s specifications, several studies have shown that failure rates observed in practice often do not match those [41, 50, 52].

Figure 2: (a) AFR spread for over 50 makes/models from NetApp binned by the age of the oldest disk. Each box corresponds to a unique make/model, and at least 10000 disks of each make/model were observed (outlier AFR values omitted). (b) Distribution of AFR calculated over consecutive non-overlapping six-month periods for NetApp disks, showing the gradual rise of AFR with age (outliers omitted). (c) Approximation of useful life length for NetApp disks for 1-5 consecutive phases of useful life and three different tolerance levels.

sources of transition overload and challenges / opportunities for a robust disk-adaptive redundancy solution.

The data. Our largest dataset comes from NetApp and contains information about disks deployed in filers (file servers). Each filer reports the health of each disk periodically (typically once a fortnight) using their AutoSupport [29] system. We analyzed the data for a subset of their deployed disks, which included over 50 makes/models and over 4.3 million disks total. As observed in previous studies [27, 41, 50], we observe well over an order of magnitude difference between the highest and lowest useful-life AFRs (see Fig. 2a).

Our other datasets come from large storage clusters deployed at Google and the Backblaze Internet backup service. Although the basic disk characteristics (e.g., AFR heterogeneity and its behavior discussed below) are similar to the NetApp dataset, these datasets also capture the evolution and behavior in our target context (large-scale storage clusters), and thus are also used in the evaluation detailed in (§7). The particular Google clusters were selected based on their longitudinal data availability, but were not otherwise screened for favorability.

For each cluster, the multi-year log records (daily) all disk deployment, failure, and decommissioning events from birth of the cluster until the date of the log snapshot. Google Cluster1’s disk population over three years included $\approx 350\text{K}$ disks of 7 makes/models. Google Cluster2’s population over 2.5 years included $\approx 450\text{K}$ disks of 4 makes/models. Google Cluster3’s population over 3 years included $\approx 160\text{K}$ disks of 3 makes/models. The Backblaze cluster’s population since 2013 included $\approx 110\text{K}$ disks of 7 makes/models.

3.1 Causes of transition overload

Disk deployment patterns. We observe disk deployments occurring in two distinct patterns, which we label *trickle* and *step*. Trickle-deployed disks are added to a cluster frequently (weekly or even daily) over time by the tens and hundreds. For example, the slow rise in disk count seen between 2018-01 and 2018-07 in Fig. 1 represents a series of trickle-deployments. In contrast, a step-deployment introduces many thousands of disks into the cluster “at once” (over a span of a few days), followed by potentially months of no new step-deployments. The sharp rises in disk count around 2017-12 and 2019-11 in Fig. 1 represent step-deployments.

A given cluster may be entirely trickle-deployed (like the

Backblaze cluster), entirely step-deployed (like Google Cluster2), or a mix of the two (like Google Cluster1 and Cluster3). Disks of a step are typically of the same make/model.

Learning AFR curves online. Disk-adaptive redundancy involves learning the AFR curve for each make/model by observing failures among deployed disks of that make/model. Because AFR is a statistical measure, the larger the population of disks observed at a given age, the lower is the uncertainty in the calculated AFR at that age. We have found that a few thousand disks need to be observed to obtain sufficiently accurate AFR measurements.

Transition overload for trickle-deployed disks. Since trickle-deployed disks are deployed in tiny batches over time, several months can pass before the required number of disks of a new make/model are past any given age. Thus, by the time the required number of disks can be observed at the age that is eventually identified as having too-high an AFR and requiring increased redundancy, data on the older disks will have been left under-protected for months. And, the thousands of already-older disks need to be immediately transitioned to a stronger redundancy scheme, together with the newest disks to reach that age. This results in transition overload.

Transition overload for step-deployed disks. Assuming that they are of the same make/model, a batch of step-deployed disks will have the same age and AFR, and indeed represent a large enough population for confident learning of the AFR curve as they age. But, this means that all of those disks will reach AFR values together, as they age. So, when their AFR rises to the point where the redundancy must be increased to keep data safe, all of the disks must transition together to the new safer redundancy scheme. Worse, if they are the first disks of the given make/model deployed in the cluster, which is often true in the clusters studied, then the system adapting the redundancy will learn of the need only when the age in question is reached. At that point, all data stored on the entire batch of disks is unsafe and needs immediate transitioning. This results in transition overload.

3.2 Informing a solution

Analyzing the disk logs has exposed a number of observations that provide hope and guide the design of PACEMAKER. The AFR curves we observed deviate substantially from the canonical representation where infancy and wearout periods

are identically looking and have high AFR values, and AFR in useful life is flat and low throughout.

AFRs rise gradually over time with no clear wearout. AFR curves generally exhibit neither a flat useful life phase nor a sudden transition to so-called wearout. Rather, in general, it was observed that AFR curves rise gradually as a function of disk age. Fig. 2b shows the gradual rise in AFR over six month periods of disk lifetimes. Each box represents the AFR of disks whose age corresponds to the six-month period denoted along the X-axis. AFR curves for individual makes/models (e.g., Figs. 5b and 5d) are consistent with this aggregate illustration. Importantly, none of the over 60 makes/models from Google, Backblaze and NetApp displayed sudden onset of wearout.

Gradual increases in AFR, rather than sudden onset of wearout, suggests that one could anticipate a step-deployed batch of disks approaching an AFR threshold. This is one foundation on which PACEMAKER’s proactive transitioning approach rests.

Useful life could have multiple phases. Given the gradual rise of AFRs, useful life can be decomposed into multiple, piece-wise constant phases. Fig. 2c shows an approximation of the length of useful life when multiple phases are considered. Each box in the figure represents the distribution over different make/models of the approximate length of useful life. Useful life is approximated by considering the longest period of time which can be decomposed into multiple consecutive phases (number of phases indicated by the bottom X-axis) such that the ratio between the maximum and minimum AFR in each phase is under a given tolerance level (indicated by the top X-axis). The last box indicates the distribution over make/models of the age of the oldest disk, which is an upper bound to the length of useful life. As shown by Fig. 2c, the length of useful life can be significantly extended (for all tolerance levels) by considering more than one phase. Furthermore, the data show that a small number of phases suffice in practice, as the approximate length of useful life changes by little when considering four or more phases.

Infancy often short-lived. Disks may go through (potentially) multiple rounds of so-called “burn-in” testing. The first tests may happen at the manufacturer’s site. There may be additional burn-in tests done at the deployment site allowing most of the infant mortality to be captured before the disk is deployed in production. For the NetApp and Google disks, we see the AFR drop sharply and plateau by 20 days for most of the makes/models. In contrast, the Backblaze disks display a slightly longer and higher AFR during infancy, which can be directly attributed to their less aggressive on-site burn-in.

PACEMAKER’s design is heavily influenced from these learnings, as will be explained in the next section.

4 Design goals

PACEMAKER is an IO efficient redundancy orchestrator for storage clusters that support disk-adaptive redundancy.

Term	Definition
Dgroup	Group of disks of the same make/model.
Transition	The act of changing the redundancy scheme.
RDn transition	Transition to a lower level of redundancy.
RUp transition	Transition to a higher level of redundancy.
peak-IO-cap	IO bandwidth cap for transitions.
Rgroup	Group of disks using the same redundancy with placement restricted to the group of disks.
Rgroup0	Rgroup using the default one-scheme-fits-all redundancy used in storage clusters today.
Unspecialized disks	Disks that are a part of Rgroup0.
Specialized disks	Disks that are not part of Rgroup0.
Canary disks	First few thousand disks of a trickle-deployed Dgroup used to learn AFR curve.
Tolerated-AFR	Max AFR for which redundancy scheme meets reliability constraint.
Threshold-AFR	The AFR threshold crossing which triggers an RUp transition for step-deployed disks.

Table 1: Definitions of PACEMAKER’s terms.

Before going into the design goals for PACEMAKER, we first chronicle a disk’s lifecycle, introducing the terminology that will be used in the rest of the paper (defined in Table 1).

Disk lifecycle under PACEMAKER. Throughout its life, each disk under PACEMAKER simultaneously belongs to a *Dgroup* and an *Rgroup*. There are as many Dgroups in a cluster as there are unique disk makes/models. Rgroups on the other hand are a function of redundancy schemes and placement restrictions. Each Rgroup has an associated redundancy scheme, and its data (encoded stripes) must reside completely within that Rgroup’s disks. Multiple Rgroups can use the same redundancy scheme, but no stripe may span across Rgroups. The Dgroup of a disk never changes, but a disk may transition through multiple Rgroups during its lifetime. At the time of deployment (or “birth”), the disk belongs to *Rgroup0*, and is termed as an *unspecialized disk*. Disks in *Rgroup0* use the default redundancy scheme, i.e. the conservative one-scheme-fits-all scheme used in storage clusters that do not have disk-adaptive redundancy. The redundancy scheme employed for a disk (and hence its Rgroup) changes via *transitions*. The first transition any disk undergoes is an *RDn transition*. A RDn transition changes the disk’s Rgroup to one with lower redundancy, i.e. more optimized for space. Whenever the disk departs from *Rgroup0*, it is termed as a *specialized disk*. Disks depart from *Rgroup0* at the end of their infancy. Since infancy is short-lived (§3.2), PACEMAKER only considers one RDn transition for each disk.

The first RDn transition occurs at the start of the disk’s useful life, and marks the start of its specialization period. As explained in §3.2, a disk may experience multiple useful life phases. PACEMAKER performs a transition at the start of each useful life phase. After the first (and only) RDn transition, each subsequent transition is an *RUp transition*. An RUp transition changes the disk’s Rgroup to one with higher redundancy, i.e. less optimized for space, but the disk is still considered a specialized disk unless the Rgroup that the disk is being RUp transitioned to is *Rgroup0*. The space-

savings (and thus cost-savings) associated with disk-adaptive redundancy are proportional to the fraction of life the disks remain specialized for.

Key decisions. To adapt redundancy throughout a disk’s lifecycle as chronicled above, three key decisions related to transitions must be made

1. *When should the disks transition?*
2. *Which Rgroup should the disks transition to?*
3. *How should the disks transition?*

Constraints. The above decisions need to be taken such that a set of constraints are met. An obvious constraint, central to any storage system, is that of data reliability. The *reliability constraint* mandates that all data must always meet a predefined target MTTL. Another important constraint is the *failure reconstruction IO constraint*. This constraint bounds the IO spent on data reconstruction of failed disks, which as explained in §2 is proportional to AFR and scheme width. This is why wide schemes cannot be used for all disks all the time, but they can be used for low-AFR regimes of disk lifetimes (as discussed in §2).

Existing approaches to disk-adaptive redundancy make their decisions on the basis of only these constraints [27], but fail to consider the equally important *IO caused by redundancy transitions*. Ignoring this causes the transition overload problem, which proves to be a show-stopper for disk-adaptive redundancy systems. PACEMAKER treats transition IO as a first class citizen by taking it into account for each of its three key decisions. As such, PACEMAKER enforces carefully designed constraints on transition IO as well.

Designing IO constraints on transitions. Apart from serving foreground IO requests, a storage cluster performs numerous background tasks like scrubbing and load balancing [5, 38, 49]. Redundancy management is also a background task. In current storage clusters, redundancy management tasks predominantly consist of performing data redundancy (e.g. replicating or encoding data) and reconstructing data of failed or otherwise unavailable disks. Disk-adaptive redundancy systems add redundancy transitions to the list of IO-intensive background tasks.

There are two goals for background tasks: Goal 1: they are not too much work, and Goal 2: they interfere as little as possible with foreground IO. PACEMAKER applies two IO constraints on background transition tasks to achieve these goals: (1) *average-IO constraint* and (2) *peak-IO constraint*. The average-IO constraint achieves Goal 1 by allowing storage administrators to specify a cap on the fraction of the IO bandwidth of a disk that can be used for transitions over its lifetime. For example, if a disk can transition in 1 day using 100% of its IO bandwidth, then an average-IO constraint of 1% would mean that the disk will transition at most once every 100 days. The peak-IO constraint achieves Goal 2 by allowing storage administrators to specify the peak rate (defined as the *peak-IO-cap*) at which transitions can occur so as to limit their interference with foreground traffic. Continuing the pre-

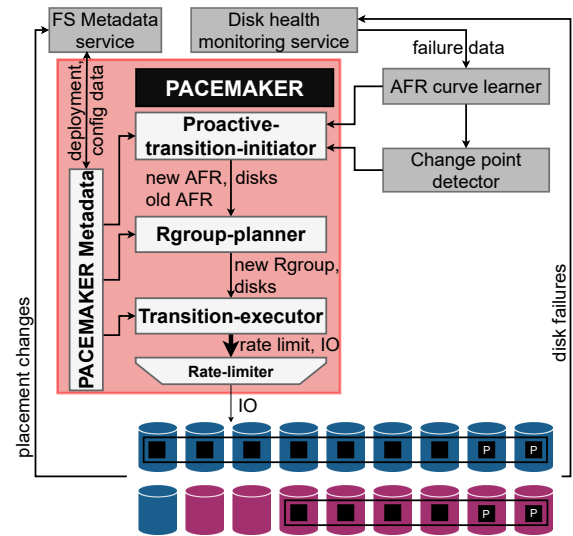

Figure 3: PACEMAKER architecture.

vious example, if the peak-IO-cap is set at 5%, the disk that would have taken 1 day to transition at 100% IO bandwidth would now take at least 20 days. The average-IO constraint and the peak-IO-cap can be configured based on how busy the cluster is. For example, a cluster designed for data archival would have a lower foreground traffic, compared to a cluster designed for serving ads or recommendations. Thus, low-traffic clusters can set a higher peak-IO-cap resulting in faster transitions and potentially increased space-savings.

Design goals. The key design goals are to answer the three questions related to transitions such that the space-savings are maximized and the following constraints are met: (1) reliability constraint on all data all the time, (2) failure reconstruction IO constraint on all disks all the time, (3) peak-IO constraint on all disks all the time, and (4) average-IO constraint on all disks over time.

5 Design of PACEMAKER

Fig. 3 shows the high level architecture of PACEMAKER and how it interacts with some other components of a storage cluster. The three main components of PACEMAKER correspond to the three key decisions that the system makes as discussed in §4. The first main component of PACEMAKER is the *proactive-transition-initiator* (§5.1), which determines when to transition disks using the AFR curves and the disk deployment information. The information of the transitioning disks and their observed AFR is passed to the *Rgroup-planner* (§5.2), which chooses the Rgroup to which the disks should transition. The Rgroup-planner passes the information of the transitioning disks and the target Rgroup to the *transition-executor* (§5.3). The transition-executor addresses how to transition the disks to the planned Rgroup in the most IO-efficient way.

Additionally, PACEMAKER also maintains its own *meta-data* and a simple *rate-limiter*. PACEMAKER metadata interacts with all of PACEMAKER’s components and also the

storage cluster's metadata service. It maintains various configuration settings of a PACEMAKER installation along with the disk deployment information that guides transition decisions. The rate-limiter rate-limits the IO load generated by any transition as per administrator specified limits. Other cluster components external-to-PACEMAKER that inform it are the *AFR curve learner* and the *change point detector*. As is evident from their names, these components learn the AFR curve³ of each Dgroup and identify change points for redundancy transitions. The AFR curve learner receives failure data from the *disk health monitoring service*, which monitors the disk fleet and maintains their vitals.

5.1 Proactive-transition-initiator

Proactive-transition-initiator's role is to determine *when to transition the disks*. Below we explain PACEMAKER's methodology for making this decision for the two types of transitions (RDn and RU_p) and the two types of deployments (step and trickle).

5.1.1 Deciding when to RDn a disk

Recall that a disk's first transition is an RDn transition. As soon as proactive-transition-initiator observes (in a statistically accurate manner) that the AFR has decreased sufficiently, and is stable, it performs an RDn transition from the default scheme (i.e., from Rgroup0) employed in infancy to a more space-efficient scheme. This is the only RDn transition in a disk's lifetime.

5.1.2 Deciding when to RU_p a disk

RU_p transitions are performed either when there are too few disks in any Rgroup such that data placement is heavily restricted (which we term *purging an Rgroup*), or when there is a rise in AFR such that the reliability constraint is (going to be) violated. Purging an Rgroup involves RU_p transitioning all of its disks to an Rgroup with higher redundancy. This transition isn't an imminent threat to reliability, and therefore can be done in a relaxed manner without violating the reliability constraint as explained in §5.3.

However, most RU_p transitions in a storage cluster are done in response to a rise in AFR. These are challenging with respect to meeting IO constraints due to the associated risk of violating the reliability constraints whenever the AFR rises beyond the AFR tolerated by the redundancy scheme (termed *tolerated-AFR*).

In order to be able to safely rate-limit the IO load due to RU_p transitions, PACEMAKER takes a *proactive* approach. The key is in determining when to initiate a proactive RU_p transition such that the transition can be completed before the AFR crosses the tolerated-AFR, while adhering to the IO and the reliability constraints without compromising much on space-savings. To do so, the proactive-transition-initiator assumes that its transitions will proceed as per the peak-IO constraint, which is ensured by the transition-executor. PACEMAKER's methodology for determining when to initiate a

proactive RU_p transition is tailored differently for trickle versus step deployments, since they raise different challenges.

Trickle deployments. For trickle-deployed disks, PACEMAKER considers two category of disks: (1) first disks to be deployed from any particular trickle-deployed Dgroup, and (2) disks from that Dgroup that are deployed later.

PACEMAKER labels the first *C* deployed disks of a Dgroup as *canary* disks, where *C* is a configurable, high enough number of disks to yield statistically significant AFR observations. For example, based on our disk analyses, we observe that *C* in low thousands (e.g., 3000) is sufficient. The canary disks of any Dgroup are the first to undergo the various phases of life for that Dgroup, and these observations are used to learn the AFR curve for that Dgroup. The AFR value for the Dgroup at any particular age is not known (with statistical confidence) until all canary disks go past that age. Furthermore, due to the trickle nature of the deployment, the canary disks would themselves have been deployed over weeks if not months. Thus, AFR for the canary disks can be ascertained only in retrospect. PACEMAKER never changes the redundancy of the canary disks to avoid them from ever violating the reliability constraint. This does not significantly reduce space-savings, since *C* is expected to be small relative to the total number of disks of a Dgroup (usually in the tens of thousands).

The disks that are deployed later in any particular Dgroup are easier to handle, since the Dgroup's AFR curve would have been learned by observing the canaries. Thus, the date at which a disk among the later-deployed disks needs to RU_p to meet the reliability constraints is known in advance by the proactive-transition-initiator, which it uses to issue proactive RU_p transitions.

Step deployments. Recall that in a step deployment, most disks of a Dgroup may be deployed within a few days. So, canaries are not a good solution, as they would provide little-to-no advance warning about how the AFR curve's rises would affect most disks.

PACEMAKER's approach to handling step-deployments is based on two properties: (1) Step-deployments have a large number of disks deployed together, leading to a statistically accurate AFR estimation; (2) AFR curves based on a large set of disks tend to exhibit gradual, rather than sudden, AFR increases as the disk ages (§3.2). PACEMAKER leverages these two properties to employ a simple *early warning* methodology to predict a forthcoming need to RU_p transition a step well in advance. Specifically, PACEMAKER sets a threshold, termed *threshold-AFR*, which is a (configurable) fraction of the tolerated-AFR of the current redundancy scheme employed. For step-deployments, when the observed AFR crosses the threshold-AFR, the proactive-transition-initiator initiates a proactive RU_p transition.

5.2 Rgroup-planner

The Rgroup-planner's role is to determine *which Rgroup should disks transition to*. This involves making two inter-

³The AFR estimation methodology employed is detailed in [26].

dependent choices: (1) the redundancy scheme to transition into, (2) whether or not to create a new Rgroup.

Choice of the redundancy scheme. At a high level, the Rgroup-planner first uses a set of selection criteria to arrive at a set of viable schemes. It further narrows down the choices by filtering out the schemes that are not worth transitioning to when the transition IO and IO constraints are accounted for.

Selection criteria for viable schemes. Each viable redundancy scheme has to satisfy the following criteria in addition to the reliability constraint: each scheme (1) must satisfy the minimum number of simultaneous failures per stripe (i.e., $n - k$); (2) must not exceed the maximum allowed stripe dimension (k); (3) must have its expected failure reconstruction IO ($AFR \times k \times \text{disk-capacity}$) be no higher than was assumed possible for Rgroup0 (since disks in Rgroup0 are expected to have the highest AFR); (4) must have a recovery time in case of failure (MTTR) that does not exceed the maximum MTTR (set by the administrator when selecting the default redundancy scheme for Rgroup0).

Determining if a scheme is worth transitioning to. Whether the IO cost of transitioning to a scheme is worth it or not and what space-savings can be achieved by that transition is a function of the number of days disks will remain in that scheme (also known as *disk-days*). This, in turn, depends on (1) when the disks enter the new scheme, and (2) how soon disks will require another transition out of that scheme.

The time it takes for the disks to enter the new scheme is determined by the transition IO and the rate-limit. When the disks will transition out of the target Rgroup is dependent on the future and can only be estimated. For this estimation, the Rgroup-planner needs to estimate the number of days the AFR curve will remain below the threshold that forces a transition out. This needs different strategies for the two deployment patterns (trickle and step).

Recall that PACEMAKER knows the AFR curve for trickle-deployed disks (from the canaries) in advance. Recall that step-deployed disks have the property that the AFR curve learned from them is statistically robust and tends to exhibit gradual, as opposed to sudden AFR increases. The Rgroup-planner leverages these properties to estimate the future AFR behavior based on the recent past. Specifically, it takes the slope of the AFR curve in the recent past⁴ and uses that to project the AFR curve rise in the future.

The number of disk-days in a scheme for it to be worth transitioning to is dictated by the IO constraints. For example, let us consider a disk running under PACEMAKER that requires a transition, and PACEMAKER is configured with an average-IO constraint of 1% and a peak-IO-cap of 5%. Suppose the disk requires 1 day to complete its transition at 100% IO bandwidth. With the current settings, PACEMAKER will only consider an Rgroup worthy of transitioning to (assuming it is

allowed to use all 5% of its IO bandwidth) if at least 80 disk-days are spent after the disk entirely transitions to it (since transitioning to it would take up to 20 days at the allowed 5% IO bandwidth).

From among the viable schemes that are worth transitioning to based on the IO constraints, the Rgroup-planner chooses the one that provides the highest space-savings.

Decision on Rgroup creation. Rgroups cannot be created arbitrarily. This is because every Rgroup adds *placement restrictions*, since all chunks of a stripe have to be stored on disks belonging to the same Rgroup. Therefore, Rgroup-planner creates a new Rgroup only when (1) the resulting placement pool created by the new Rgroup is large enough to overcome traditional placement restrictions such as “no two chunks on the same rack⁵”, and (2) the space-savings achievable by the chosen redundancy scheme is sufficiently greater than using an existing (less-space-efficient) Rgroup.

The disk deployment pattern also affects Rgroup formation. While the rules for whether to form an Rgroup remain the same for trickle and step-deployed disks, mixing disks deployed differently impacts the transitioning techniques that can be used for eventually transitioning disks out of that Rgroup. This in turn affects how the IO constraints are enforced. Specifically, for trickle deployments, creating an Rgroup for each set of transitioning disks would lead to too many small-sized Rgroups. So, for trickle-deployments, the Rgroup-planner creates a new Rgroup for a redundancy scheme if and only if one does not exist already. Creating Rgroups this way will also ensure that enough disks (thousands) will go into it to satisfy placement restrictions. Mixing disks from different trickle-deployments in the same Rgroup does not impact the IO constraints, because PACEMAKER optimizes the transition mechanism for few disks transitioning at a time, as is explained in §5.3. For step-deployments, due to the large fraction of disks that undergo transition together, having disks from multiple steps, or mixing trickle-deployed disks within the same Rgroup, creates adverse interactions (discussed in §5.3). Hence, the Rgroup-planner creates a new Rgroup for each step-deployment, even if there already exists one or more Rgroups that employ the chosen scheme. Each such Rgroup will contain many thousands of disks to overcome traditional placement restrictions. Per-step Rgroups also extend to the Rgroup with default redundancy schemes, implying a per-step Rgroup0. Despite having clusters with disk populations as high as 450K disks, PACEMAKER’s restrained Rgroup creation led to no cluster ever having more than 10 Rgroups.

Rules for purging an Rgroup. An Rgroup may be purged for having too few disks. This can happen when too many of its constituent disks transition to other Rgroups, or they fail, or they are decommissioned leading to difficulty in fulfilling placement restrictions. If the Rgroup to be purged is

⁴PACEMAKER uses a 60 day (configurable) sliding window with an Epanechnikov kernel, which gives more weight to AFR changes in the recent past [21].

⁵Inter-cluster fault tolerance remains orthogonal to and unaffected by PACEMAKER.

made up of trickle-deployed disks, the Rgroup-planner will choose to RUP transition disks to an existing Rgroup with higher redundancy while meeting the IO constraints. For step-deployments, purging implies RUP transitioning disks into the more-failure-tolerant RGroup (RGroup0) that may include trickle-deployed disks.

5.3 Transition-executor

The transition-executor's role is to determine *how to transition the disks*. This involves choosing (1) the most IO-efficient technique to execute that transition, and (2) how to rate-limit the transition at hand. Once the transition technique is chosen, the transition-executor executes the transition via the rate-limiter as shown in Fig. 3.

Selecting the transition technique. Suppose the data needs to be conventionally re-encoded from a k_{cur} -of- n_{cur} scheme to a k_{new} -of- n_{new} scheme. The IO cost of conventional re-encoding involves reading–re-encoding–writing all the stripes whose chunks reside on each transitioning disk. This amounts to a read IO of $k_{cur} \times \text{disk-capacity}$ (assuming almost-full disks), and a write IO of $k_{cur} \times \text{disk-capacity} \times \frac{n_{new}}{k_{new}}$ for a total IO $> 2 \times k_{cur} \times \text{disk-capacity}$ for each disk.

In addition to conventional re-encoding, PACEMAKER supports two new approaches to changing the redundancy scheme for disks and selects the most efficient option for any given transition. The best option depends on the fraction of the Rgroup being transitioned at once.

Type 1 (Transition by emptying disks). If a small percentage of an Rgroup's disks are being transitioned, it is more efficient to retain the contents of the transitioning disks in that Rgroup rather than re-encoding. Under this technique, the data stored on transitioning disks are simply moved (copied) to other disks within the current Rgroup. This involves reading and writing (elsewhere) the contents of the transitioning disks. Thus, the IO of transitioning via Type 1 is at most $2 \times \text{disk-capacity}$, independent of scheme parameters, and therefore at least $k_{cur} \times$ cheaper than conventional re-encoding.

Type 1 can be employed whenever there is sufficient free space available to move the contents of the transitioning disks into other disks in the current Rgroup. Once the transitioning disks are empty, they can be removed from the current Rgroup and added to the new Rgroup as “new” (empty) disks.

Type 2 (Bulk transition by recalculating parities). If a large fraction of disks in an Rgroup need to transition together, it is more efficient to transition the entire Rgroup rather than only the disks that need a transition at that time. Most cluster storage systems use systematic codes⁶ [8, 13, 14, 36], wherein transitioning an entire Rgroup involves only calculating and storing new parities and deleting the old parities. Specifically, the data chunks have to be only read for computing the new parities, but they do not have to be re-written. In contrast, if only a part of the disks are transitioned, some

fraction of the data chunks also need to be re-written. Thus, the IO cost for transitioning via Type 2 involves a read IO of $\frac{k_{cur}}{n_{cur}} \times \text{disk-capacity}$, and a write IO of only the new parities, which amounts to a total IO of $\frac{n_{new}-k_{new}}{k_{new}} \times \frac{k_{cur}}{n_{cur}} \times \text{disk-capacity}$ for each disk in the Rgroup. This is at most $2 \times \frac{k_{cur}}{n_{cur}} \times \text{disk-capacity}$, which makes it at least $n_{cur} \times$ cheaper than conventional re-encoding.

Selecting the most efficient approach for a transition. For any given transition, the transition-executor selects the most IO-efficient of all the viable approaches. Almost always, trickle-deployed disks use Type 1 because they transition a few-at-a-time, and step-deployed disks use Type 2 because Rgroup-planner maintains each step in a separate Rgroup.

Choosing how to rate limit a transition. Irrespective of the transitioning techniques, the transition-executor has to resolve the competing concerns of maximizing space-savings and minimizing risk of data loss via fast transitions, and minimizing foreground work interference by slowing down transitions so as to not overwhelm the foreground IO. Arbitrarily slowing down a transition to minimize interference is only possible when the transition is not in response to a rise in AFR. This is because a rising AFR hints at the data being under-protected if not transitioned to a higher redundancy soon. In PACEMAKER, a transition without an AFR rise occurs either when disks are being RDn transitioned at the end of infancy, or when they are being RUP transitioned because the Rgroup they belong to is being purged. For all the other RUP transitions, PACEMAKER carefully chooses how to rate limit the transition.

Determining how much bandwidth to allow for a given transition could be difficult, given that other transitions may be in-progress already or may be initiated at any time (we do observe concurrent transitions in our evaluations). So, to ensure that the aggregate IO of all ongoing transitions conforms to the peak-IO-cap cluster-wide, PACEMAKER limits each transition to the peak-IO-cap within its Rgroup. For trickle-deployed disks, which share Rgroups, the rate of transition initiations is consistently a small percentage of the shared Rgroup, allowing disk emptying to proceed at well below the peak-IO-cap. For step-deployed disks, this is easy for PACEMAKER, since a step only makes one transition at a time and its IO is fully contained in its separate Rgroup. The transition-executor's approach to managing peak-IO on a per-Rgroup basis is also why the proactive-transition-initiator can safely assume a rate-limit of the peak-IO-cap without consulting the transition-executor. If there is a sudden AFR increase that puts data at risk, PACEMAKER is designed to ignore its IO constraints to continue meeting the reliability constraint—this safety valve was never needed for any cluster evaluated.

After finalizing the transitioning technique, the transition-executor performs the necessary IO for transitioning disks (read, writes, parity recalculation, etc.). We find that the components required for the transition-executor are already

⁶In systematic codes, the data chunks are stored in unencoded form. This helps to avoid having to decode for normal (i.e., non-degraded-mode) reads.

Figure 4: PACEMAKER-enhanced HDFS architecture.

present and adequately modular in existing distributed storage systems. In §6, we show how we implement PACEMAKER in HDFS with minimal effort.

Note that this design is for the common case where storage clusters are designed for a single dedicated storage service. Multiple distinct distributed storage services independently using the same underlying devices would need to coordinate their use of bandwidth (for their non-transition related load as well) in some way, which is outside the scope of this paper.

6 Implementation of PACEMAKER in HDFS

We have implemented a prototype of PACEMAKER for the Hadoop distributed file system (HDFS) [56]. HDFS is a popular open source distributed file system, widely employed in the industry for storing large volumes of data. We use HDFS v3.2.0, which natively supports erasure coding. Prototype of HDFS with Pacemaker is open-sourced and is available at <https://github.com/thesys-lab/pacemaker-hdfs.git>.

Background on HDFS architecture. HDFS has a central metadata server called Namenode (NN, akin to the master node) and a collection of servers containing the data stored in the file system, called Datanodes (DN, akin to worker nodes). Clients interact with the NN only to perform operations on file metadata (containing a collection of the DNs that store the file data). Clients directly request the data from the DNs. Each DN stores data on its local drives using a local file system.

Realizing Rgroups in HDFS. This design makes a simplifying assumption that all disks belonging to a DN are of the same Dgroup and are deployed together (this could be relaxed easily). Under this simplifying assumption, conceptually, an Rgroup would consist of a set of DNs that need to be managed independent of other such sets of DNs as shown in Fig 4.

The NN maintains a DatanodeManager (DNMGr), which is a gateway for the NN to interact with the DNs. The DNMGr maintains a list of the DNs, along with their usage statistics. The DNMGr also contains a HeartBeatManager (HrtBtMgr) which handles the periodic keepalive heartbeats from DNs. A natural mechanism to realize Rgroups in HDFS is to have one DNMGr per Rgroup. Note that the sets of DNs belonging to the different DNMGr are mutually exclusive. Implementing Rgroups with multiple DNMGr has several advantages.

Right level of control and view of the system. Since the DNMGr resides below the block layer, when the data needs to

be moved for redundancy adaptations, the logical view of the file remains unaffected. Only the mapping from HDFS blocks to DNs gets updated in the inode. The statistics maintained by the DNMGr can be used to balance load across Rgroups.

Minimizing changes to the HDFS architecture and maximizing re-purposing of existing HDFS mechanisms. This design obviates the need to change HDFS’s block placement policy, since it is implemented at the DNMGr level. Block placement policies are notoriously hard to get right. Moreover, block placement decisions are affected by fault domains and network topologies, both of which are orthogonal to PACEMAKER’s goals, and thus best left untouched. Likewise, the code for reconstruction of data from a failed DN need not be touched, since all of the reads (to reconstruct each lost chunk) and writes (to store it somewhere else) will occur within the set of nodes managed by its DNMGr. Existing mechanisms for adding / decommissioning nodes managed by the DN-Mgr can be re-purposed to implement PACEMAKER’s Type 1 transitions (described below).

Cost of maintaining multiple DNMGr is small. Each DN-Mgr maintains two threads: a HrtBtMgr and a DNAdminMgr. The former tracks and handles heartbeats from each DN, and the latter monitors the DNs for performing decommissioning and maintenance. The number of DNMGr threads in the NN will increase from two to $2 \times$ the number of Rgroups. Fortunately, even for large clusters, we observe that the number of Rgroups would not exceed the low tens (§7.4). The NN is usually a high-end server compared to the DNs, and an additional tens of threads shouldn’t affect performance.

Rgroup transitions in HDFS. An important part of PACEMAKER functionality is transitioning DNs between Rgroups. Recall from §5.3 that one of PACEMAKER’s preferred way of transitioning disks across Rgroups is by emptying the disks. In HDFS, the planned removal of a DN from a HDFS cluster is called decommissioning. PACEMAKER re-uses decommissioning to remove a DN from the set of DNs managed by one DNMGr and then adds it to the set managed by another, effectively transitioning a DN from one Rgroup to another.

PACEMAKER does not change the file manipulation API or client access paths. But, there is one corner-case related to transitions when file reads can be affected internally. To read a file, a client queries the NN for the inode and caches it. Subsequently, the reads are performed directly from the client to the DN. If the DN transitions to another Rgroup while the file is still being read, the HDFS client may find that that DN no longer has the requested data. But, because this design uses existing HDFS decommissioning for transitions, the client software knows to react by re-requesting the updated inode from the NN and resuming the read.

7 Evaluation

PACEMAKER-enabled disk-adaptive redundancy using is evaluated on production logs from four large-scale real-world storage clusters, each with hundreds of thousands of disks.

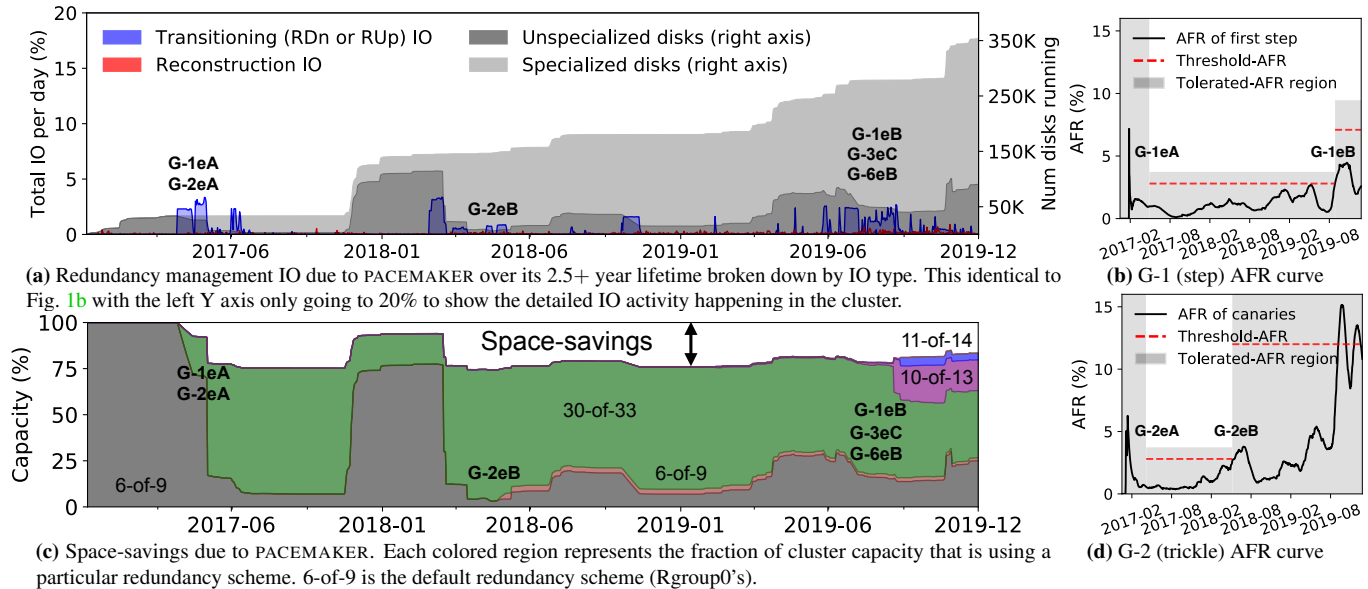

Figure 5: Detailed IO analysis and space savings achieved by PACEMAKER-enabled adaptive redundancy on Google Cluster1.

We also experiment with a proof-of-concept HDFS implementation on a smaller sized cluster. This evaluation has four primary takeaways: (1) PACEMAKER eliminates transition overload, never using more than 5% of cluster IO bandwidth (0.2–0.4% on average) and always meets target MTTDL, in stark contrast to prior work approaches that do not account for transition IO load; (2) PACEMAKER provides more than 97% of idealized-potential space-savings, despite being proactive, reducing disk capacity needed by 14–20% compared to one-size-fits-all; (3) PACEMAKER’s behavior is not overly sensitive across a range of values for its configurable parameters; (4) PACEMAKER copes well with the real-world AFR characteristics explained in §3.2. For example, it successfully combines the “multiple useful life phases” observation with efficient transitioning schemes. This evaluation also shows PACEMAKER in action by measuring disk-adaptive redundancy in PACEMAKER-enhanced HDFS.

Evaluation methodology. PACEMAKER is simulated chronologically for each of the four cluster logs described in §3: three clusters from Google and one from Backblaze. For each simulated date, the simulator changes the cluster composition according to the disk additions, failures and de-commissioning events in the log. PACEMAKER is provided the log information, as though it were being captured live in the cluster. IO bandwidth needed for each day’s redundancy management is computed as the sum of IO for failure reconstruction and transition IO requested by PACEMAKER, and is reported as a fraction of the configured cluster IO bandwidth (100MB/sec per disk, by default).

PACEMAKER was configured to use a peak-IO-cap of 5%, an average-IO constraint of 1% and a threshold-AFR of 75% of the tolerated-AFR, except for the sensitivity studies in §7.3. For comparison, we also simulate (1) an idealized disk-adaptive redundancy system in which transitions are in-

stantaneous (requiring no IO) and (2) the prior state-of-the-art approach (HeART) for disk-adaptive redundancy. For all cases, Rgroup0 uses 6-of-9, representing a one-size-fits-all scheme reported in prior literature [13]. The required target MTTDL is then back-calculated using the 6-of-9 default and an assumed tolerated-AFR of 16% for Rgroup0. These configuration defaults were set by consulting storage administrators of clusters we evaluated.

7.1 PACEMAKER on Google Cluster1 in-depth

Fig. 5a shows the IO generated by PACEMAKER (and disk count) over the ≈3-year lifetime of Google Cluster1. Over time, the cluster grew to over 350K disks comprising of disks from 7 makes/models (Dgroups) via a mix of trickle and step deployments. Fig. 5b and Fig. 5d show AFR curves of 2 of the 7 Dgroups (obfuscated as G-1 and G-2 for confidentiality) along with how PACEMAKER adapted to them at each age. G-1 disks are trickle-deployed whereas G-2 disks are step-deployed. The other 5 Dgroups are omitted due to lack of space. Fig. 5c shows the corresponding space-savings (the white space above the colors).

All disks enter the cluster as unspecialized disks, i.e. Rgroup0 (dark gray region in the Fig. 5a and left gray region of Figs. 5b and 5d). Once a Dgroup’s AFR reduces sufficiently, PACEMAKER RDn transitions them to a specialized Rgroup (light gray area in Fig. 5a). Over their lifetime, disks may transition through multiple RUP transitions over the multiple useful life phases. Each transition requires IO, which is captured in blue in Fig. 5a. For example, the sudden drop in the unspecialized disks, and the blue area around 2018-04 captures the Type 2 transitions caused when over 100K disks RDn transition from Rgroup0 to a specialized Rgroup. The light gray region in Fig. 5a corresponds to the time over which space-savings are obtained, which can be seen in Fig. 5c.

Figure 6: Top two rows show the IO overhead comparison between prior adaptive redundancy system (HeART) and PACEMAKER on two Google clusters and one Backblaze cluster. PACEMAKER successfully bounds all IO under 5% (visible as tiny blue regions in middle graphs, for e.g. around 2017 in (a)). The bottom row shows the 14–20% average space-savings achieved by PACEMAKER across the three clusters.

Many transitions with no transition overload. PACEMAKER successfully bounds all redundancy management IO comfortably under the configured peak-IO-cap throughout the cluster’s lifetime. This can be seen via an imaginary horizontal line at 5% (the configured peak-IO-cap) that none of the blue regions goes above. Recall that PACEMAKER rate-limits the IO within each Rgroup to ensure simultaneous transitions do not violate the cluster’s IO cap. Events *G-1eA* and *G-2eA* are examples of events where both G-1 and G-2 disks (making up almost 100% of the cluster at that time) request transitions at the same time. Despite that, the IO remains bounded below 5%. *G-3eC* and *G-6eB* also show huge disk populations of G-3 and G-6 Dgroups (AFRs not shown) requesting almost simultaneous RUp transitions, but PACEMAKER’s design ensures that the peak-IO constraint is never violated. This is in sharp contrast with HeART’s frequent transition overload, shown in Fig. 1a.

Disks experience multiple useful life phases. G-1, G-3, G-6 and G-7 disks experience two phases of useful life each. In Fig. 5a, events *G-1eA* and *G-1eB* mark the two transitions of G-1 disks through its multiple useful lives as shown in Fig. 5b. In the absence of multiple useful life phases, PACEMAKER would have RUp transitioned G-1 disks to Rgroup0 in 2019-05, eliminating space-savings for the remainder of their time in the cluster. §7.3 quantifies the benefit of multiple useful life phases for all four clusters.

MTTDL always at or above target. Along with the AFR curves, Figs. 5b and 5d also show the upper bound on the AFR for which the reliability constraint is met (top of the gray region). PACEMAKER sufficiently protects all disks throughout their life for all Dgroups across evaluated clusters.

Substantial space-savings. PACEMAKER provides 14% average space-savings (Fig. 5c) over the cluster lifetime to date. Except for 2017-01 to 2017-05 and 2017-11 to 2018-03, which correspond to infancy periods for large batches of new empty disks added to the cluster, the entire cluster achieves $\approx 20\%$ space-savings. Note that the apparent reduction in space-savings from 2017-11 to 2018-03 isn’t actually reduced space in absolute terms. Since Fig. 5c shows relative space-savings, the over 100K disks deployed around 2017-11, and

their infancy period makes the space-savings appear reduced relative to the size of the cluster.

7.2 PACEMAKER on the other three clusters

Fig. 6 compares the transition IO incurred by PACEMAKER to that for HeART [27] for Google Cluster2, Google Cluster3 and Backblaze, along with the corresponding space-savings achieved by PACEMAKER. While clusters using HeART would suffer transition overload, the same clusters under PACEMAKER always had all their transition IO under the peak-IO-cap of 5%. In fact, on average, only 0.21–0.32% percent of the cluster IO bandwidth was used for transitions. The average space-savings for the three clusters are 14–20%.

Google Cluster2. Fig. 6a shows the transition overload and space-savings in Google Cluster2 and the corresponding space-savings. All Dgroups in Google Cluster2 are step-deployed. Thus, it is not surprising that Fig. 7c shows that over 98% of the transitions in Cluster2 were Type 2 transitions (bulk parity recalculation). Cluster2’s disk population exceeds 450K disks. Even at such large scales, PACEMAKER obtains average space-savings of almost 17% and peak space-savings of over 25%. This translates to needing 100K fewer disks.

Google Cluster3. Google Cluster3 (Fig. 6b) is not as large as Cluster1 or Cluster2. At its peak, Cluster3 has a disk population of approximately 200K disks. But, it achieves the highest average space-savings (20%) among clusters evaluated. Like Cluster2, Cluster3 is also mostly step-deployed.

Backblaze Cluster. Backblaze (Fig. 6c) is a completely trickle-deployed cluster. The dark grey region across the bottom of Fig. 6c’s PACEMAKER plot shows the persistent presence of canary disks throughout the cluster’s lifetime. Unlike the Google clusters, the transition IO of Backblaze does not produce bursts of transition IO that lasts for weeks. Instead, since trickle-deployed disks transition a-few-at-a-time, we see transition work appearing continuously throughout the cluster lifetime of over 6 years. The rise in the transition IO spikes in 2019, for HeART, is because of large capacity 12TB disks replacing 4TB disks. Unsurprisingly, under PACEMAKER, most of the transitions are done using Type 1 (transitioning by emptying disks) as shown in Fig. 7c. The average space-savings obtained on Backblaze are 14%.

Figure 7: (a) shows PACEMAKER’s sensitivity to the peak IO bandwidth constraint. (b) shows the advantage of multiple useful life phases and (c) shows the contribution of the two transitioning techniques when PACEMAKER was simulated on the four production clusters.

7.3 Sensitivity analyses and ablation studies

Sensitivity to IO constraints. The peak-IO constraint governs Fig. 7a, which shows the percentages of optimal space-savings achieved with PACEMAKER for peak-IO-cap settings between 1.5% and 7.5%. A peak-IO-cap of up to 7.5% is used in order to compare with the IO percentage spent for existing background IO activity, such as scrubbing. By scrubbing all data once every 15 days [5], the scrubber uses around 7% IO bandwidth, and is a background work IO level tolerated by today’s clusters.

The Y-axis captures how close the space-savings are for the different peak-IO-caps compared to “Optimal savings”, i.e. an idealized system with infinitely fast transitions. PACEMAKER’s default peak-IO-cap (5%) achieves over 97% of the optimal space-savings for each of the four clusters. For peak-IO constraint set to $\leq 2.5\%$, some RUP transitions in Google Cluster1 and Cluster2 become too aggressively rate-limited causing a subsequent AFR rise to violate the peak-IO constraints. We indicate this as a failure, and show it as “∅”. The same situation happens for Google Cluster1 at 3.5%.

Sensitivity to threshold-AFR. The threshold-AFR determines when proactive RUP transitions of step-deployed disks are initiated. Conceptually, the threshold-AFR governs how risk-averse the admin wants to be. Lowering the threshold would trigger an RUP transition when disks are farther away from the tolerated-AFR (more risk-averse), and vice-versa. We evaluated PACEMAKER for threshold-AFRs of 60%, 75% and 90% of the respective Rgroups’ tolerated-AFRs. We found that PACEMAKER’s space-savings is not very sensitive to threshold-AFR, with space-savings only 2% lower at 60% than at 90%. Data remained safe at each of these settings, but would become unsafe with higher values.

Contribution of multiple useful life phases. Fig. 7b compares the increased number of disk-days spent in specialized Rgroups because of considering multiple useful life phases. In the best case, Google Cluster2 spent 33% more disk-days in specialized redundancy, increasing overall space-savings from 16% to 19%. Note that in large-scale storage clusters, even 1% space-savings are considered substantial as it represents thousands of disks.

Contribution of transition types. By proactively keeping step-deployed disks in distinct Rgroups and using specialized transitioning schemes whenever possible, instead of using

simple re-encoding for all transitions, PACEMAKER reduces total transition IO by 92–96% for the four clusters. Fig. 7c shows what percentage of transitions were done via Type 1 (disk emptying) vs. Type 2 (bulk parity recalculation). As expected, Google clusters rely more on Type 2 transitions, because most disks are step-deployed. In contrast, the Backblaze cluster is entirely trickle-deployed and hence mostly uses Type 1 transitions. The small percentage of Type 2 transitions in Backblaze occur when Rgroups are purged.

7.4 Evaluating HDFS + PACEMAKER

This section describes basic experiments with the PACEMAKER-enabled HDFS, focusing on its functioning and operation. Note that PACEMAKER is designed for longitudinal disk deployments over several years, a scenario that cannot be reproduced identically in laboratory settings. Hence, these HDFS experiments are aimed to display that integrating PACEMAKER with an existing storage system is straightforward, rather than on the long-term aspects like overall space-savings or transition IO behavior over cluster lifetime as evaluated via simulation above.

The HDFS experiments run on a PROBE Emulab cluster [16]. Each machine has a Dual-Core AMD Opteron Processor, 16GB RAM, and Gigabit Ethernet. We use a 21-node cluster running HDFS 3.2.0 with one NN and 20 DN. Each DN has a 10GB partition on a 10000 RPM HDD for a total cluster size of 200GB. We statically define the cluster to be made up of two Rgroups of ten DNs each, one using the 6-of-9 erasure coding scheme and the other using a 7-of-10 scheme. DFS-perf [19], a popular open-source HDFS benchmark is used, after populating the cluster to 60% full. Each DFS-perf client sequentially reads one file over and over again (size=768MB), for a total read size of about 1.75TB over 40 iterations. We use 60 DFS-perf clients, running on 20 nodes separate from the HDFS cluster.

We focus on the behavior of a DN as it transitions between Rgroups, compared with baseline HDFS performance (where all DNs are healthy) and its behavior while recovering from a failed DN. Fig. 8 shows the client throughput after the setup phase, followed by a noticeable drop in client throughput when a DN fails (emulated by stopping the DN). This is caused by the reconstruction IO that recreates the data from the failed node. Read latency exhibits similar behavior (not

Figure 8: DFS-perf reported throughput for baseline, with one DN failure and one Rgroup transition.

shown due to space). Eventually, throughput settles at about 5% lower than prior to failure, since now there are 19 DNs.

Fig. 8 also shows client throughput when a node is RDn transitioned from 6-of-9 to 7-of-10. There is minor interference during the transition, which can be attributed to the data movement that HDFS performs as a part of decommissioning. The transition requires less work than failed node reconstruction, yet takes longer to complete because PACEMAKER limits the transition IO. Eventually, even though 20 DNs are running, the throughput is lower by $\approx 5\%$ (one DN’s throughput). This happens because PACEMAKER empties the DN before it moves into the new Rgroup, and load-balancing data to newly added DNs happens over a longer time-frame. Experiments with RUP transition showed similar results.

8 Related work

The closest related work [27] proposes a redundancy adaptation tool called HeART that categorizes disks into groups and suggests a tailored redundancy scheme for each during its useful life period. As discussed earlier, while [27] showcased potential space-savings, it ignored transition overload and hence is made impractical (Fig. 1a). PACEMAKER eliminates transition overload by employing IO constraints (specifically the peak-IO and average-IO constraints) that cap the transition IO to a tiny fraction cluster bandwidth. While HeART was evaluated only for the trickle-deployed Backblaze cluster, our evaluation of PACEMAKER for Google storage clusters exposes the unique challenges of step-deployed clusters. Several design elements were added to PACEMAKER to address the challenges posed by step-deployed disks.

Various systems include support for multiple redundancy schemes, allowing different schemes to be used for different data [12, 14]. Tools have been created for deciding, on a per-data basis, which scheme to use [59, 65]. Keeton et al. [28] describe a tool that automatically provides disaster-resistant solutions based on budget and failure models. PACEMAKER differs from such systems by focusing on efficiently adapting redundancy to different and time-varying AFRs of disks.

Reducing the impact of background IO, such as for data scrubbing, on foreground IO is a common research theme. [1, 3, 30, 31, 38, 53]. PACEMAKER converts otherwise-urgent bursts of transition IO into proactive background IO, which could then benefit from these works.

Disk reliability has been well studied, including evidence of failure rates being make/model dependent [5, 11, 22, 25,

32, 40, 41, 49–51, 55]. There are also studies that predict disk failures [2, 20, 33, 37, 58, 61, 68], which can enhance any storage fault-tolerance approach.

While several works have considered the problem of designing erasure codes that allow transitions using less resources, existing solutions are limited to specific kinds of transitions and hence are not applicable in general. The case of adding parity chunks while keeping the number of data chunks fixed can be viewed [35, 45, 47] as the well-studied reconstruction problem, and hence the codes designed for optimal reconstruction (e.g., [10, 18, 39, 46, 47, 60]) would lead to improved resource usage for this case. Several works have studied the case where the number of data nodes increases while the number of parity nodes remains fixed [23, 42, 64, 66, 69]. In [65], the authors propose two erasure codes designed to undergo a specific transition in parameters. In [34], the authors propose a general theoretical framework for studying codes that enable efficient transitions for general parameters, and derive lower bounds on the cost of transitions as well as describe optimal code constructions for certain specific parameters. However, none of the existing code constructions are applicable for the diverse set of transitions needed for disk-adaptive redundancy in real-world storage clusters.

9 Conclusion

PACEMAKER orchestrates disk-adaptive redundancy without transition overload, allowing use in real-world clusters. By proactively arranging data layouts and initiating transitions, PACEMAKER reduces total transition IO allowing it to be rate-limited. Its design integrates cleanly into existing scalable storage implementations, such as HDFS. Analysis for 4 large real-world storage clusters from Google and Backblaze show 14–20% average space-savings while transition IO is kept small ($<0.4\%$ on average) and bounded (e.g., $<5\%$).

Pegasus: Tolerating Skewed Workloads in Distributed Storage with In-Network Coherence Directories

Abstract

High performance distributed storage systems face the challenge of load imbalance caused by skewed and dynamic workloads. This paper introduces Pegasus, a new storage system that leverages new-generation programmable switch ASICs to balance load across storage servers. Pegasus uses *selective replication* of the most popular objects in the data store to distribute load. Using a novel in-network coherence directory, the Pegasus switch tracks and manages the location of replicated objects. This allows it to achieve load-aware forwarding and dynamic rebalancing for replicated keys, while still guaranteeing data coherence and consistency. The Pegasus design is practical to implement as it stores only forwarding meta-data in the switch data plane. The resulting system improves the throughput of a distributed in-memory key-value store by more than 10× under a latency SLO – results which hold across a large set of workloads with varying degrees of skew, read/write ratio, object sizes, and dynamism.

1 Introduction

Distributed storage systems are tasked with providing fast, predictable performance in spite of immense and unpredictable load. Systems like Facebook’s memcached deployment [50] store trillions of objects and are accessed thousands of times on each user interaction. To achieve scale, these systems are distributed over many nodes; to achieve performance predictability, they store data primarily or entirely in memory.

A key challenge for these systems is balancing load in the presence of highly skewed workloads. Just as a celebrity may have many millions more followers than the average user, so too do some stored objects receive millions of requests per day while others see almost none [3, 67]. Moreover, the set of popular objects changes rapidly as new trends rise and fall [5]. While classic algorithms like consistent hashing [30] are effective at distributing load when all objects are of roughly equal popularity, here they fall short: requests for a single popular object commonly exceed the capacity of any individual server.

Replication makes it possible to handle objects whose request load exceeds one server’s capacity. Replicating *every* object, while effective at load balancing [13, 49], introduces a high storage overhead. *Selective replication* of only a set of hot objects avoids this overhead. Leveraging prior analysis of

caching [17], we show that surprisingly few objects need to be replicated in order to achieve strong load-balancing properties. However, keeping track of which objects are hot and where they are stored is not straightforward, especially when the storage system may have hundreds of thousands of clients, and keeping multiple copies consistent is even harder [50].

We address these challenges with Pegasus, a distributed storage system that uses a new architecture for selective replication and load balancing. Pegasus uses a programmable data-plane switch to route requests to servers. Drawing inspiration from CPU cache coherency protocols [4, 19, 22, 31, 34, 36, 37, 40], the Pegasus switch acts as an *in-network coherence directory* that tracks which objects are replicated and where. Leveraging the switch’s central view of request traffic, it can forward requests to replicas in a load-aware manner. Unlike prior approaches, Pegasus’s coherence directory also allows it to dynamically rebalance the replica set *on each write operation*, accelerating both read- and write-intensive workloads – while still maintaining strong consistency.

Pegasus introduces several new techniques, beyond the concept of the in-network coherence directory itself. It uses a lightweight version-based coherence protocol to ensure consistency. Load-aware scheduling is implemented using a combination of reverse in-network telemetry and in-switch weighted round-robin policy. Finally, to provide fault tolerance, Pegasus uses a simple chain replication [66] protocol to create multiple copies of data in different racks, each load-balanced with its own switch.

Pegasus is a practical approach. We show that it can be implemented using a Barefoot Tofino switch, and provides effective load balancing with minimal switch resource overhead. In particular, unlike prior systems [29, 45], Pegasus stores no application data in the switch, only metadata. This reduces switch memory usage to less than 3.5% of the total switch SRAM, permitting it to co-exist with existing switch functionality and thus reducing a major barrier to adoption [56].

Using 28 servers and a Pegasus switch, we show:

- Pegasus can increase the throughput by up to 10× – or reduce by 90% the number of servers required – of a system subject to a 99%-latency SLO.
- Pegasus can react quickly to dynamic workloads where the set of hot keys changes rapidly, and can recover quickly from server or rack failures.

- Pegasus can provide strong load balancing properties by only replicating a small number of objects.
- Pegasus is able to achieve these benefits for many classes of workloads, both read-heavy and write-heavy, with different object sizes and levels of skew.

2 Motivation

Real-world workloads for storage systems commonly exhibit highly skewed object access patterns [3, 6, 26, 50, 51]. Here, a small fraction of popular objects receive disproportionately more requests than the remaining objects. Many such workloads can be modeled using Zipfian access distributions [3, 5, 6, 67]; recent work has shown that some real workloads exhibit unprecedented skew levels (e.g., Zipf distributions with $\alpha > 1$) [10, 67]. Additionally, the set of popular objects changes dynamically: in some cases, the average hot object loses its popularity within 10 minutes [5].

Storage systems typically partition objects among multiple storage servers for scalability and load distribution. The implication of high skew in workloads is that load across storage servers is also uneven: the few servers that store the most popular objects will receive disproportionately more traffic than the others. The access skew is often high enough that the load for an object can exceed the processing capacity of a single server, leading to server overload. To reduce performance penalties, the system needs to be over-provisioned, which significantly increases overall cost.

Skewed workloads are diverse. Read-heavy workloads have been the focus of many recent studies, and many systems optimize heavily for them (e.g., assuming $> 95\%$ of requests are reads) [21, 29, 41, 45]. While many workloads do fall into this category, mixed or write-heavy workloads are also common [67]. Object sizes also vary widely, even within one provider. Systems may store small values (a few bytes), larger values (kilobytes to megabytes), or a combination of the two [1, 3, 5, 67]. An ideal solution to workload skew should be able to handle all of these cases.

2.1 Existing Approaches

How should a storage system handle skewed workloads, where the request load for a particularly popular object might exceed the processing capability of an individual server? Two existing approaches have proven effective here: caching popular objects in a faster tier, and replicating objects to increase aggregate load capacity.

Caching Caching has long served as the standard approach for accelerating database-backed web applications. Recent work has demonstrated, both theoretically and practically, the effectiveness of a caching approach: only a small number of keys need to be cached in order to achieve provable load balancing guarantees [17, 29, 41].

There are, however, two limitations with the caching approach. First, the effectiveness of caching hinges on the ability to build a cache that can handle orders of magnitude more

requests than the storage servers. Once an easily met goal, this has become a formidable challenge as storage systems themselves employ in-memory storage [50, 53, 58], clever data structures [42, 46], new NVM technologies [25, 68], and faster network stacks [38, 42, 48]. Recent efforts to build faster caches out of programmable switches [29, 45] address this, but hardware constraints impose significant limitations, e.g., an inability to support values greater than 128 bytes. Secondly, caching solutions only benefit read-heavy workloads, as cached copies must be invalidated until writes are processed by the storage servers.

Selective Replication Replication is another common solution to load imbalance caused by skewed workloads. By selectively replicating popular objects [2, 9, 13, 50], requests to these objects can be sent to any of the replicas, effectively distributing load across servers.

Existing selective replication approaches, however, face two challenges. First, clients must be able to identify the replicated objects and their locations – which may change as object popularity changes. This could be done using a centralized directory service, or by replicating the directory to the clients. Both pose scalability limitations: a centralized directory service can easily become a bottleneck, and keeping a directory synchronized among potentially hundreds of thousands of clients is not easy.

Providing consistency for replicated objects is the second major challenge – a sufficiently complex one that existing systems do not attempt to address it. They either replicate only read-only objects, or require users to explicitly manage inconsistencies resulting from replication [2, 9]. The solutions required to achieve strongly consistent replication (e.g., consensus protocols [35]) are notoriously complex, and incur significant coordination overhead [39], particularly when objects are modified frequently.

2.2 Pegasus Goals

The goal of our work is to provide an effective load balancing solution for the aforementioned classes of challenging workloads. Concretely, we require our system to 1) provide good load balancing for dynamic workloads with high skew, 2) work with fast in-memory storage systems, 3) handle arbitrary object sizes, 4) guarantee linearizability [24], and 5) be equally effective for read-heavy, write-heavy, and mixed read/write workloads. As listed in Table 1, existing systems make explicit trade-offs and none of them simultaneously satisfy all five properties. In this paper, we will introduce a new distributed storage load balancing approach that makes no compromises, using an *in-network coherence directory*.

3 System Model

Pegasus is a design for rack-scale storage systems consisting of a number of storage servers connected via a single top-of-rack (ToR) switch, as shown in Figure 1. Pegasus combines in-switch load balancing logic with a new storage system. The

	Highly Skewed Workload	Fast In-Memory Store	All Object Sizes	Strong Consistency	Any Read-Write Ratio
Consistent Hashing [30]	✗	✓	✓	✗	—
Slicer [2]	✓	✗	✓	✗	—

SwitchKV [41]	✓	✗	✓	✓	✗
NetCache [29]	✓	✓	✗	✓	✗
Pegasus	✓	✓	✓	✓	✓

Table 1: A comparison of existing load balancing systems vs. Pegasus. In the "Any Read-Write Ratio" column, we only consider systems that provide strong consistency.

Figure 1: Pegasus system model. Pegasus is a rack-scale storage system. It augments the top-of-rack switch with an in-network coherence directory to balance load across storage servers in the rack. Servers store data in memory for fast and predictable performance.

Pegasus system provides a key-value store with a read/write interface. It does not support read-modify-write or atomic cross-key operations. Pegasus ensures strong data consistency (specifically, linearizability [24]). It uses in-memory storage to offer fast and predictable performance.

The Pegasus architecture is a co-design of in-switch processing and an application-level protocol. This is made possible by leveraging the capabilities of newly available switches with programmable dataplanes, such as the Barefoot Tofino, Cavium XPlaint, or Broadcom Trident3 families. Broadly speaking, these chips offer reconfigurability in three relevant areas: (1) programmable parsing of application-specific headers; (2) flexible packet processing pipelines, usually consisting of 10–20 pipeline stages each capable of a match lookup and one or more ALU operations; and (3) general-purpose memory, on the order of 10 MB. Importantly, all of these features are on the switch dataplane, meaning that they can be used while processing packets at full line rate – a total capacity today measured in terabits per second.

Pegasus provides load balancing at the rack level, i.e., 32–256 servers connected by a single switch. It does not provide fault tolerance guarantees within the rack. Larger-scale, re-

silient systems can be built out of multiple Pegasus racks. For these systems, Pegasus ensures availability using a chain replication protocol to replicate objects across multiple racks for fault tolerance.

4 A Case for In-Network Directories

As we have discussed in §2, selectively replicating popular objects can offer good load balancing for highly skewed workloads, and it avoids certain drawbacks of a caching approach. Existing selective replication solutions, however, fall short in providing efficient directory services and strong consistency for the dynamic set of replicated objects. Our key observation is that in a rack-scale storage system (§3), the ToR switch serves as a *central point* of the system and is on the path of every client request and server reply. This enables us to implement a *coherence directory* abstraction in the ToR switch that addresses both challenges at the same time. It can track the location of every replicated object in the system and forward requests to servers with available capacity, and even change the number or location of replicas by determining where to send WRITE requests. Leveraging this in-network coherence directory, we co-design a *version-based coherence protocol* which guarantees linearizability and is highly efficient at processing object updates, enabling us to provide good load balancing even for write-intensive workloads.

4.1 Coherence Directory for Replicated Data

How do we design an efficient selective replication scheme that provides strong consistency? At a high level, the system needs to address the following challenges: first, it needs to track the replicated items and their locations with the latest value (i.e., the replica set). Second, read requests for a replicated object must be forwarded to a server in the current replica set. Third, after a write request is completed, all subsequent read requests must return the updated value.

The standard distributed systems approaches to this problem do not work well in this environment. One might try to have clients contact any server in the system, which then forwards the query to an appropriate replica for the data, as in distributed hash tables [14, 59, 60]. However, for in-memory storage systems, receiving and forwarding a request imposes

nearly as much load as executing it entirely. Nor is it feasible for clients to directly track the location of each object (e.g., using a configuration service [8, 27]), as there may be hundreds of thousands or millions of clients throughout the datacenter, and it is a costly proposition to update each of them as new objects become popular or an object's replica set is updated.

In Pegasus, we take a different approach. We note that these are the same set of challenges faced by CPU cache coherence and distributed shared memory systems. To address the above issues, these systems commonly run a cache coherence protocol using a coherence directory [4, 19, 22, 31, 34, 36, 37, 40]. For each data block, the coherence directory stores an entry that contains the set of processors that have a shared or exclusive copy. The directory is kept up to date as processors read and write blocks – invalidating old copies as necessary – and can always point a processor to the latest version.

A coherence directory can be applied to selective replication. It can track the set of replicated objects and forward read requests to the right servers, and it can ensure data consistency by removing stale replicas from the replica set. However, to use a coherence directory for a distributed storage system requires the directory to handle all client requests. Implemented on a conventional server, it will quickly become a source of latency and a throughput bottleneck.

4.2 Implementing Coherence Directory in the Network

Where should we implement a coherence directory that processes all client requests while not becoming a performance bottleneck? The ToR switch, as shown in Figure 1, provides a viable option for our targeted rack-scale storage systems. Switch ASICs are optimized for packet I/O: current generation switches can support packet processing at more than 10 Tb/s aggregate bandwidth and several billion packets per second [64, 65]. The programmable switches we target have a fixed-length reconfigurable pipeline, so any logic that fits within the pipeline can run at the switch's full line rate. Thus, implementing the coherence directory in the ToR switch for a rack-scale storage system will not become the bottleneck nor add significant latency, as it already processes all network traffic for the rack.

But can we implement a coherence directory efficiently in the ToR switch? To do so, two challenges have to be addressed. First, we need to implement all data structures and functional logic of a coherence directory in the switch *data plane*. We show that this is indeed possible with recent programmable switches: we store the replicated keys and their replica sets in the switch's memory, match and forward based on custom packet header fields (e.g. keys and operation types), and apply directory updating rules for the coherence protocol. We give a detailed description of our switch implementation in §8.

Second, the switch data plane has limited resources and many are already consumed by bread-and-butter switch functionality [56]. As the coherence directory tracks the replica set for each replicated object, the switch can only support a

limited number of objects to be replicated. Our design meets this challenge. Interestingly, it is possible to achieve provable load balancing guarantees if we only replicate the most popular $O(n \log n)$ objects to all servers, where n is the *number of servers* (not keys) in the system (we give a more detailed analysis of this result in §4.5). Moreover, the coherence directory only stores small metadata such as key hashes and server IDs. For a rack-scale system with 32–256 servers, the size of the coherence directory is a small fraction of the available switch resources.

4.3 A Coherence Protocol for the Network

Designing a coherence protocol using an in-network coherence directory raises several new challenges. Traditional CPU cache coherence protocols can rely on an ordered and reliable interconnection network, and they commonly block processor requests during a coherence update. Switch ASICs have limited buffer space and therefore cannot hold packets indefinitely. Network links between ToR switches and servers are also unreliable: packets can be arbitrarily dropped, re-ordered, or duplicated. Many protocols for implementing ordered and reliable communication require complex logic and large buffering space that are unavailable on a switch.

We design a new *version-based, non-blocking* coherence protocol to address these challenges. The switch assigns a monotonically increasing version number to each write request and inserts it in the packet header. Servers store these version numbers alongside each object, and attach the version number in each read and write reply. The switch additionally stores a *completed* version number for each replicated object in the coherence directory. When receiving read or write replies (for replicated objects), the switch compares the version in the reply with the *completed* version in the directory. If the version number in the reply is higher, the switch updates the *completed* version number and resets the replica set to include only the source server. Subsequent read requests are then forwarded to the server with the new value. When more than one server has the latest value of the object, the version number in the reply can be equal to the *completed* version. In that case, we add the source server (if not already present) to the replica set so that subsequent read requests can be distributed among up-to-date replicas.

This protocol – which we detail in §6 – guarantees linearizability [24]. It leverages two key insights. First, all storage system requests and replies have to traverse the ToR switch. We therefore only need to update the in-network coherence directory to guarantee data consistency. This allows us to avoid expensive invalidation traffic or inter-server coordination overhead. Second, we use version numbers, applied by the switch to packet headers, to handle network asynchrony.

4.4 Load-Aware Scheduling

When forwarding read requests, the switch can pick any of the servers currently in the replica set. The simplest policy is to

select a random server from the set and rely on statistical load balancing among the servers. However, this approach falls short when the processing capacity is uneven on the storage servers (e.g. due to background tasks or different hardware specifications). To handle this issue, we also implement a weighted round-robin policy: storage servers periodically report their system load to the controller. The controller assigns weights for each server based on these load information and installs them on the switch. The switch then forwards requests to servers in the replica set proportional to their weights. Note that our in-network directory approach provides the mechanism for performing server selection. A full discussion of all scheduling policies is beyond the scope of this paper.

Surprisingly, these mechanisms can also be used for write requests. At first glance, it appears necessary to broadcast new writes to all servers in the replica set – potentially creating significant load and overloading some of the servers. However, the switch can choose a *new* replica set for the object on *each* write. It can forward write requests to one or more of the servers, and the coherence directory ensures data consistency, no matter which server the switch selects. The ability to move data frequently allows a switch to use load-aware scheduling *for both read and write requests*. This is key to Pegasus’s ability to improve performance for both read- and write-intensive workloads.

4.5 Feasibility of An In-Network Coherence Directory

Pegasus makes efficient use of switch resources because it only tracks object metadata (vs. full object contents [29]), and only for a small number of objects. We claimed in §4.2 that Pegasus only needs to replicate the most popular $O(n \log n)$ objects (where n is the number of servers) to achieve strong load balancing guarantees. This result is an extension of previous work [17] which showed that *caching* the $O(n \log n)$ most frequently accessed objects is sufficient to achieve provable load balancing. That is, if we exclude these objects, the remaining load on each server exceeds the average load by at most a slack factor α , which depends on the constant factors but is generally quite small; see §9.5. Intuitively, most of the load in a highly-skewed workload is (by definition) concentrated in a few keys, so eliminating that load rebalances the system.

Our approach, rather than absorbing that load with a cache, is to redistribute it among the storage servers. A consequence of the previous result is that if the total request handling capacity of the system exceeds the request load by a factor of α , then there exists a way to redistribute the requests of the top $O(n \log n)$ keys such that no server exceeds its capacity. For read-only workloads, a simple way to achieve this is to replicate these keys to all servers, then route request to any server with excess capacity, e.g., by routing a request for a replicated key to the least-loaded server in the system.

Writes complicate the situation because they must be processed by all servers storing the object. As described in §4.4,

Figure 2: Pegasus packet format. The Pegasus application-layer header is embedded in the UDP payload. OP is the request or reply type. KEYHASH contains the hash value of the key. VER is an object version number. SERVERID contains a unique server identifier.

Pegasus can pick a new replica set, and a new replication factor, for an object on each write. Pegasus accommodates write-intensive workloads by tracking the write fraction for each object and setting the replication factor proportional to the expected number of reads per write, yielding constant overhead. Strictly speaking, our initial analysis (for read-only workloads) may not apply in this case, as it is no longer possible to send a read to *any* server. However, since Pegasus can re-balance the replica set on every write and dynamically adjusts the replication factor, it remains effective at load balancing for any read-write ratio. Intuitively, a read-mostly workload has many replicas, so Pegasus has a high degree of freedom for choosing a server for each read, whereas a write-mostly workload has fewer replicas but constantly rebalances them to be on the least-loaded servers.

5 Pegasus Overview

We implement an in-network coherence directory in a new rack-scale storage system, Pegasus. Figure 1 shows the high level architecture of a Pegasus deployment. All storage servers reside within a single rack. The top-of-rack (ToR) switch that connects all servers implements Pegasus’s coherence directory for replicated objects.

Switch. The ToR switch maintains the coherence directory: it stores the set of replicated keys, and for each key, a list of servers with a valid copy of the data. To reduce switch resource overhead and to support arbitrary key sizes, the directory identifies keys by a small fixed-sized hash.

Pegasus defines an application-layer packet header embedded in the L4 payload, as shown in Figure 2. Pegasus reserves a special UDP port for the switch to match Pegasus packets. The application-layer header contains an OP field, either READ, WRITE, READ-REPLY, or WRITE-REPLY. KEYHASH is an application-generated, fixed-size hash value of the key. VER is an object version number assigned by the switch. SERVERID contains a unique identification of the server and is filled by servers on replies. If at-most-once semantics is required (§6.4), the header will additionally contain REQID, a globally unique ID for the request (assigned by the client). Non-Pegasus packets are forwarded using standard L2/L3 routing, keeping the switch fully compatible with existing network protocols.

To keep space usage low, the Pegasus switch keeps directory entries only for the small set of replicated objects. Read and write requests for replicated keys are forwarded according to the Pegasus load balancing and coherence protocol. The

Switch States:

- `ver_next`: next version number
- `rkeys`: set of replicated keys
- `rset`: map of replicated keys \rightarrow set of servers with a valid copy
- `ver_completed`: map of replicated keys \rightarrow version number of the latest completed WRITE

Figure 3: Switch states

other keys are mapped to a *home server* using a fixed algorithm, e.g., consistent hashing [30]. Although this algorithm could be implemented in the switch, we avoid the need to do so by having clients address their packets to the appropriate server; for non-replicated keys, the Pegasus switch simply forwards them according to standard L2/L3 forwarding policies.

Controller. The Pegasus control plane decides *which* keys should be replicated. It is responsible for updating the coherence directory with the most popular $O(n \log n)$ keys. To do so, the switch implements a request statistics engine that tracks the access rate of each key using both the data plane and the switch CPU. The controller – which can be run on the switch CPU, or a remote server – reads access statistics from the engine to find the most popular keys. The controller keeps only soft state, and can be immediately replaced if it fails.

6 Pegasus Protocol

To simplify exposition, we begin by describing the core Pegasus protocol (§6.2), under the assumption that the set of popular keys is fixed, and show that it provides linearizability. We then show how to handle changes in which keys are popular (§6.3), and how to provide exactly-once semantics (§6.4). Finally, we discuss server selection policies (§6.5) and other protocol details (§6.6).

Additionally, a TLA+ specification of the protocol which we have model checked for safety is available in our public repository [55].

6.1 Switch State

To implement an in-network coherence directory, Pegasus maintains a small amount of metadata in the switch dataplane, as listed in Figure 3. A counter `ver_next` keeps the next version number to be assigned. A lookup table `rkeys` stores the $O(n \log n)$ replicated hot keys, using `KEYHASH` in the packet header as the lookup key. For each replicated key, the switch maintains the set of servers with a valid copy in `rset`, and the version number of the latest completed WRITE in `ver_completed`. In §8, we elaborate how we store this state and implement this functionality in the switch dataplane.

6.2 Core Protocol: Request and Reply Processing

The core Pegasus protocol balances load by tracking the replica set of popular objects. It can load balance READ operations by choosing an existing replica to handle the request, and can change the replica set for an object by choosing which replicas process WRITE operations. Providing this load balancing while ensuring linearizability requires making sure that

Algorithm 1 HandleRequestPacket(pkt)

```

1: if pkt.op = WRITE then
2:   pkt.ver ← ver_next++
3: end if
4: if rkeys.contains(pkt.keyhash) then
5:   if pkt.op = READ then
6:     pkt.dst ← select replica from rset[pkt.keyhash]
7:   else if pkt.op = WRITE then
8:     pkt.dst ← select from all servers
9:   end if
10: end if
11: Forward packet

```

Algorithm 2 HandleReplyPacket(pkt)

```

1: if rkeys.contains(pkt.keyhash) then
2:   if pkt.ver > ver_completed[pkt.keyhash] then
3:     ver_completed[pkt.keyhash] ← pkt.ver
4:     rset[pkt.keyhash] ← set(pkt.serverid)
5:   else if pkt.ver = ver_completed[pkt.keyhash] then
6:     rset[pkt.keyhash].add(pkt.serverid)
7:   end if
8: end if
9: Forward packet

```

the in-network directory tracks the location of the *latest successfully written value* for each replicated key. Pegasus does this by assigning version numbers to incoming requests and monitoring outgoing replies to detect when a new version has been written.

6.2.1 Handling Client Requests

The Pegasus switch assigns a version number to every WRITE request, by writing `ver_next` into its header and incrementing `ver_next` (Algorithm 1 line 1-3). It determines how to forward a request by matching the request’s key hash with the `rkeys` table. If the key is not replicated, the switch simply forwards the request to the original destination – the home server of the key. For replicated keys, it forwards READ requests by choosing one server from the key’s `rset`. For replicated WRITES, it chooses one or more destinations from the set of all servers. In both cases, this choice is made according to the server selection policy (§6.5).

Storage servers maintain a version number for each key alongside its value. When processing a WRITE request, the server compares `VER` in the header with the version in the store, and updates both the value and the version number *only if* the packet has a *higher* `VER`. It also includes the version number read or written in the header of READ-REPLY and WRITE-REPLY messages.

6.2.2 Handling Server Replies

When the switch receives a READ-REPLY or a WRITE-REPLY, it looks up the reply’s key hash in the switch `rkeys` table.

If the key is replicated, the switch compares `VER` in the packet header with the latest completed version of the key in `ver_completed`. If the reply has a higher version number, the switch updates `ver_completed` and resets the key's replica set to include only the source server (Algorithm 2 line 1-4). If the two version numbers are equal, the switch adds the source server to the key's replica set (Algorithm 2 line 5-7).

The effect of this algorithm is that write requests are sent to a new replica set which may or may not overlap with the previous one. As soon as one server completes and acknowledges the write, the switch directs all future read requests to it – which is sufficient to ensure linearizability. As other replicas also acknowledge the same version of the write, they begin to receive a share of the read request load.

6.2.3 Correctness

Pegasus provides linearizability [24]. The intuition behind this is that the Pegasus directory monitors all traffic, and tracks where the latest observed version of a key is located. As soon as any client sees a new version of the object – as indicated by a `READ-REPLY` or `WRITE-REPLY` containing a higher version number – the switch updates the directory to send future read requests to the server holding that version.

The critical invariant is that the Pegasus directory contains at least one address of a replica storing a copy of the latest write to be *externalized*, as well as a version number of that write. A write is externalized when its value can be observed outside the Pegasus system, which can happen in two ways. The way a write is usually externalized is when a `WRITE-REPLY` is sent, indicating that the write has been completed. It is also possible, if the previous and current replica set overlap, that a server will respond to a concurrent `READ` with the new version before the `WRITE-REPLY` is delivered. Pegasus detects both cases by monitoring both `WRITE-REPLY` and `READ-REPLY` messages, and updating the directory if `VER` exceeds the latest known compatible version number.

This invariant, combined with Pegasus's policy of forwarding reads to a server from the directory's replica set, is sufficient to ensure linearizability:

- `WRITE` operations can be ordered by their version numbers.
- If a `READ` operation r is submitted after a `WRITE` operation w completes, then r comes after w in the apparent order of operations because it is either forwarded to a replica with the version written by w or a replica with a higher version number.
- If a `READ` operation r_2 is submitted after another `READ` r_1 completes, then it comes after r_1 in the apparent order of operations, because it will either be forwarded to a replica with the version r_1 saw or a replica with a newer version.

6.3 Adding and Removing Replicated Keys

Key popularities change constantly. The Pegasus controller continually monitors access frequencies and updates the coherence directory with the most popular $O(n \log n)$ keys. We

elaborate how access statistics are maintained in §8.

When a new key becomes popular, Pegasus must create a directory entry for it. The Pegasus controller does this by adding the key's home server to `rset`. It also adds a mapping for the key in `ver_completed`, associating it with `ver_next - 1`, the largest version number that could have been assigned to a write to that key at the key's home server. Finally, the controller adds the key to `rkeys`. This process does not immediately move or replicate the object. However, later `WRITE` requests will be sent to a new (and potentially larger) replica set, with a version number necessarily larger than the one added to the directory. Once these newly written values are externalized, they will be added to the directory as normal.

Transitioning a key from the replicated to unreplicated state is similarly straight-forward. The controller simply marks the switch's directory entry for transition. The next `WRITE` for that key is sent to its home server; once the matching `WRITE-REPLY` is received, the key is removed from the directory.

Read-only objects and virtual writes. The protocol above only moves an object to a new replica set (or back to its home node) on the next write. While this simplifies design, it poses a problem for objects that are read-only or modified infrequently. Conceptually, Pegasus addresses this by performing a write that does not change the object's value when an object needs to be moved. More precisely, the controller can force replication by issuing a *virtual write* to the key's home server, instructing it to increment its stored version number to the one in `ver_completed` and to forward that value to other replicas so that they can be added to `rset` and assist in serving reads.

6.4 Avoiding Duplicate Requests

At-most-once semantics, where duplicated or retried write requests are not reexecuted, are desirable. There is some debate about whether these semantics are required by linearizability or an orthogonal property [18, 28], and many key-value stores do not have this property. Pegasus accommodates both camps by optionally supporting at-most-once semantics.

Pegasus uses the classic mechanism of maintaining a table of the most recent request from each client [43] to detect duplicate requests. This requires that the same server process the original and the retried request, a requirement akin to "stickiness" in classic load balancers. A simple way to achieve this would be to send each write request initially to the object's home server. However, this sacrifices load balancing of writes.

We instead provide duplicate detection without sacrificing load balancing by noticing that it is not necessary for one server to see all requests for an object – only that a retried request goes to the same server that previously processed it. Thus, Pegasus forwards a request initially to a single *detector node* – a server deterministically chosen by the *request's* unique `REQID`, rather than the key's hash. It also writes into a packet header the other replicas, if any, that the request should be sent to. The detector node determines if the request is a duplicate; if not, it processes it and forwards the request to the

other selected servers.

Some additional care is required to migrate client table state when a key transitions from being unpopular to popular and vice versa. We can achieve this by pausing WRITES to the key during transitions. When a new key becomes popular, the controller retrieves existing client table entries from the home server and propagates them to all servers. When a popular key becomes unpopular, it queries all servers to obtain their client tables, and sends their aggregation (taking the latest entry for each client) to the home server. Once this is complete, the system can resume processing WRITES for that key.

6.5 Server Selection Policy

Which replica should be chosen for a request? This is a policy question whose answer does not impact correctness (i.e., linearizability) but determines how effective Pegasus is at load balancing. As described in §4.4, we currently implement two such policies. The first policy is to simply pick a random replica and rely on statistical load balancing. A more sophisticated policy is to use weighted round-robin: the controller assigns weights to each server based on load statistics it collects from the servers, and instructs the switch to select replicas with frequency proportional to the weights.

Write replication policy. Read operations are sent to exactly one replica. Write requests can be sent to one or more servers, whether they are in the current replica set or not. Larger replica set sizes improve load balancing by offering more options for future read requests, but increase the cost of write operations. For write-heavy workloads, increasing the write cost can easily negate any load balancing benefit.

As discussed in §4.5, the switch tracks the average READS per WRITE for each replicated object. By choosing a replication factor to be proportional to this ratio, Pegasus can bound the overhead regardless of the write fraction.

6.6 Additional Protocol Details

Hash collisions. The Pegasus coherence directory acts on small key hashes, rather than full keys. Should there be a hash collision involving a replicated key and a non-replicated key, requests for the non-replicated key may be incorrectly forwarded to a server that is not its home server. To deal with this issue, each server tracks the set of all currently replicated keys (kept up to date by the controller per §6.3). Armed with this information, a server can forward the improperly forwarded request to the correct home server. This request chaining approach has little performance impact: it only affects hash collisions *involving the small set of replicated keys*. Moreover, we only forward requests for the unreplicated keys which have low access rate. In the extremely rare case of a hash collision involving two of the $O(n \log n)$ most popular keys, Pegasus only replicates one of them to guarantee correctness.

Version number overflow. Version numbers must increase monotonically. Pegasus uses 64-bit version numbers, which

makes overflow unlikely: it would require processing transactions at the full line rate of our switch for over 100 years. Extremely long-lived systems, or ones that prefer shorter version numbers, can use standard techniques for version number wraparound.

Garbage collection. When handling WRITES for replicated keys, Pegasus does not explicitly invalidate or remove the old version. Although this does not impact correctness – the coherence directory forwards all requests to the latest version – retaining obsolete copies forever wastes storage space on servers. We handle this issue through garbage collection. The Pegasus controller already notifies servers about which keys are replicated, and periodically reports the last-completed version number. Each server, then, can detect and safely remove a key if it has an obsolete version, or if the key is no longer replicated (and the server is not the home node for that key).

7 Beyond a Single Rack

Thus far, we have discussed single-rack, single-switch Pegasus deployments. Of course, larger systems need to scale beyond a single rack. Moreover, the single-rack architecture provides no availability guarantees when servers or racks fail: while Pegasus replicates popular objects, the majority of objects still have just one copy. This choice is intentional, as entire-rack failures are common enough to make replicating objects within a rack insufficient for real fault tolerance.

We address both issues with a multi-rack deployment model where each rack of storage servers and its ToR switch runs a separate Pegasus instance. The workload is partitioned across different racks, and chain replication [66] is used to replicate objects to multiple racks. Object placement is done using two layers of consistent hashing. A global configuration service [8, 27] maps each range of the keyspace to a *chain* of Pegasus racks. Within each rack, these keys are mapped to servers as in §5. In effect, each key is mapped to a chain of servers, each server residing in a different rack.

We advocate this deployment model because it uses in-switch processing only in the ToR switches in each rack. The remainder of the datacenter network remains unmodified, and in particular it does not require any further changes to packet routing, which has been identified as a barrier to adoption for network operators [56]. A consequence is that it cannot load balance popular keys across different racks. Our simulations, however, indicate that this effect is negligible at all but the highest workload skew levels: individual servers are easily overloaded, but rack-level overload is less common.

Replication Protocol. As in the original chain replication, clients send WRITES to the head server in the chain. Each server forwards the request to the next in the chain, until reaching the tail server, which then replies to the client. Clients send READS to the tail of the chain; that server responds directly to the client. In each case, if the object is a popular one in that rack, the Pegasus switch can redirect or replicate it.

Figure 4: Switch data plane design for the Pegasus coherence directory

Pegasus differs from the original chain replication protocol in that it cannot assume reliable FIFO channels between servers. To deal with network asynchrony, it reuses the version numbers provided by the Pegasus switches to ensure consistency. Specifically, we augment Algorithm 1 in the following way: when a Pegasus switch receives a WRITE request, it only stamps `ver_next` into the request if `VER` in the packet header is not null; otherwise, it leaves the version number in the request unmodified and sets its `ver_next` to be one greater than that value (if it isn't already). The effect of this modification is that WRITE requests only carry version numbers from the head server's ToR switch; and the number does not change when propagating along the chain. This ensures that all replicas apply WRITES in the same order.
