- **All components are replicated:** Consider schedulers for example: replicas of a scheduler shard sit in different DCs and elect a leader to process requests. If the leader fails or its network is partitioned from other DCs, a follower in another DC becomes the new leader.
- **Tasks keep running:** Even if all Twine components fail, existing tasks continue to run. New jobs cannot be created and existing tasks cannot be updated until Twine recovers. If a DC is partitioned from the scheduler, existing tasks in the DC continue to run.
- **Rate-limit destructive operations:** It is possible that a bug or fault might cause Twine to perform a large number of destructive operations quickly, e.g., shuffling tasks across machines at a fast pace. We protect against this failure by ensuring all components have fail-safe mechanisms to rate-limit destructive operations.
- **Network redundancy:** Fabric Aggregator connects our data centers in a region and can “suffer many simultaneous failures without compromising the overall performance of the network [14].” We did not experience within-region network partitioning as a major challenge.

Operational principles. In addition to the design principles listed above, we observe several operational principles.

- **Twine manages itself:** To avoid developing yet another cluster management tool to manage Twine installations, all Twine components, except for the agent, run as Twine jobs. We developed automation to bootstrap the Twine ecosystem starting from scratch. The Twine agent has no dependencies on other Twine components and our bootstrapping mechanism directly sends commands to agents to start other Twine components as Twine tasks.

- **Twine manages its dependencies:** As we built confidence in Twine’s bootstrapping automation, we ran all systems that Twine depends on as normal Twine jobs, including ZooKeeper, Delos [4], Configurator [35], and a few other systems for storage, security, and continuous delivery. Twine managing itself and its dependencies improves reliability by eliminating the risk associated with maintaining specialized cluster management tools [8].
- **Gradual but frequent software release:** A new release progresses gradually across regions and shards so that a bug does not hit the entire fleet instantaneously. All components are released weekly or more frequently to lower the risk associated with large changesets.
- **Recurring large-scale failure test [38]:** This happens regularly in production to verify Twine’s reliability.

These principles help us run Twine reliably. We share one anecdote where rate-limiting mitigated the risk caused by the complex interplay of four concurrent events: 1) shifting traffic from region *X* to region *Y*, 2) performing a load test in region *Y*, 3) adding new server racks to region *Y* before removing old racks, and 4) software upgrade for the web tier. The first three events led to increased power consumption in region *Y* and power capping on many machines. The scheduler rate-limited the number of tasks moving away from power-capped machines. This rate-limiting halted the web tier’s software upgrade and protected against further loss of capacity. In this incident, rate-limiting provided a safety net before we debugged the incident.

5 Evaluation

Our evaluation answers the following questions:

1. How does TaskControl deal with complex scenarios that impact an application’s availability?
2. How effective is autoscaling for production use?
3. How effective are host profiles in improving performance? What is the overhead of switching host profiles?
4. How cost effective are small machines in replacing big machines?

5.1 TaskControl

Figure 14 demonstrates how TaskControl handles the complex situation of a software release and machine failures happening concurrently. This experiment uses a caching service managed by Shard Manager (§2.7). The cache’s data are partitioned into 15,000 shards, and each shard runs three replicas. The 45,000 shard replicas are hosted by 1,000 Twine tasks. Shard Manager’s TaskController helps minimize the risk of a shard losing more than one replica, i.e., driving Figure 14b’s 2 replicas down curve towards zero.

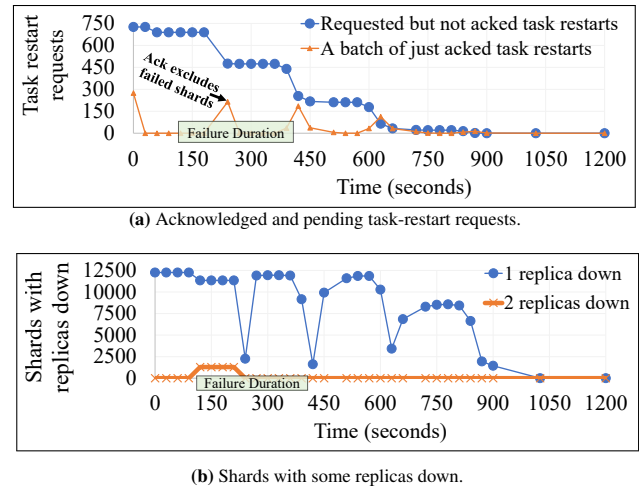

Figure 14: TaskControl helps a stateful service uphold its availability in the event of a concurrent software release and hardware failures.

Let T_x denote the moment of x seconds into the experiment. At T_0 , the user initiates a rolling update of the service. In Figure 14a, at T_0 , the TaskController allows 274 tasks to update concurrently (the bottom curve). It does not allow any of the other 726 tasks to update (the top curve) because that would cause some shards to lose their second replicas. In Figure 14b, at T_0 , 12,264 shards lose one replica (the top curve) because they are hosted by the 274 tasks undergoing update. No shard loses its second replica (the bottom curve) because of the TaskController’s precise shard availability calculation.

During the `Failure Duration` in the figures (between T_{120} and T_{415}), we inject the failure of one MSB that kills 50 tasks causing 1,292 shards to lose their second replicas, because those shards are also hosted by the 274 tasks undergoing update. The spike in Figure 14b’s bottom curve reflects the impact on the 1,292 shards.

By T_{240} , the 274 tasks are updated and become healthy. As a result, even if the 50 tasks in the failed MSB are still down, shards with 2 replicas down drop to zero (the bottom curve in Figure 14b). At T_{240} , the TaskController carefully selects the second batch of 214 tasks to update, ensuring no overlap between the shards hosted by the 214 tasks and the shards hosted by the 50 tasks in the failed MSB (see `Ack excludes failed shards` in Figure 14a). This careful task selection keeps Figure 14b’s 2 replicas down curve at zero throughout the rest of the experiment.

5.2 Autoscaling

Currently, we autoscale ≈ 800 services. Figure 15 shows the efficacy of autoscaling on our web tier, which is our largest service. Autoscaling frees up to 25% of the web tier’s machines during off-peak hours. The bottom curve represents the web tier’s CPU utilization. The middle curve represents the web tier’s real job size, i.e., the number tasks in the job.

Figure 15: Autoscaling the web tier. The CPU spikes are caused by the continuous-delivery process restarting tasks.

The top curve represents autoscaling’s recommendation for the job’s ideal size. The CPU utilization closely follows the recommended job size, demonstrating the prediction’s accuracy. Usually, the real job size also closely follows the recommended job size, but we intentionally choose a week when they diverged during peak hours.

During the week of March 12, 2020, our online products experienced a drastic traffic growth [19] related to COVID-19, causing a temporary capacity shortage. As a result, the real job size could not grow to follow the recommended job size during peak hours. The web tier’s TaskController adapted to this unexpected situation without any manual intervention. During peak hours, it advanced the continuous-delivery software releases more slowly, bringing down fewer tasks concurrently to limit temporary capacity losses. During non-peak hours, it advanced software releases at a normal pace.

5.3 Host Profiles

Figure 16: Host profiles improve the throughput of memcache.

Host profile’s impact on application performance. We use memcache as an example to demonstrate how host profiles help improve application performance. We deploy a highly optimized version of memcache [30] on tens of thousands of machines. Figure 16 compares three host profiles versus the default settings. The baseline achieves 930K lookups per second on an 18-core/36-hyperthread machine. This extremely high throughput drives the need for host customization.

The CPU `affinity` host profile improves the throughput by dedicating 12 hyperthreads to handling NIC IRQs, one hyperthread to memcache’s busy-loop thread, and 23 hyperthreads to memcache’s worker threads. This separation avoids unnecessary interrupts and context switches. `add'l BPF cfg` further reduces the overhead of certain BPF programs by

lowering the packet sampling rate and disabling certain packet marking. `add'l sysctl` further tunes 17 CPU scheduling and network settings, where improvements in reliability are more important than the mild performance gains. For example, based on lessons from past incidents, we tuned `net.ipv4.tcp_mem` to alleviate TCP’s memory pressure under high loads in order to prevent cascading failures.

Overhead of switching host profiles. Figure 17 shows the host profile switching time. We discuss both ends of the performance spectrum. The P90 for enabling CPU Turbo takes 3.0 seconds. The P90 for enabling HugePages takes 244 seconds, as memory fragmentation sometimes causes the Linux kernel to fail to allocate hugepages and a machine reboot may be needed to finish the operation. To alleviate the problem, we recently developed a kernel improvement [33] that achieves above 95% success rate for hugepage allocation; we are still in the process of deploying it to production.

Figure 17: P90 host profile switching time for different host profiles.

On average, a machine changes its host profile once every two days; hence the overall overhead is negligible. Figure 18 depicts how autoscaling impacts host profile changes.

Figure 18: Autoscaling is the biggest driver for host profile changes. The load of an active last minute (ALM) tracking service is proportional to the number of people using our online products. In response to our products’ changing load, Twine moves machines to entitlements running ALM-tracking services during hour 3 to 8 and to entitlements running non-ALM-tracking services during hour 13 to 20, respectively.

5.4 Power-efficient Small Machines

The total cost of ownership (TCO) of a machine includes the hardware cost, power consumption, and operating expense. We compare the TCO of small machines vs. big machines using the following metrics:

- *B*: The TCO of a big machine (dual CPUs and 256GB RAM) is *B* times that of a small machine (one CPU and 64GB RAM).

- S : A service needs S number of small machines to replace a big machine and achieve the same performance.
- $\frac{S}{B}$: Relative TCO (RTCO) of a service running on small machines vs. on big machines.

Figure 19 shows the RTCO of 22 fleet-wide representative services. One service has worse than 100% RTCO, seven use the maximum prescribed 100% RTCO, and a majority of services are able to achieve a better RTCO.

Figure 19: The relative total cost of ownership of services running on small machines vs. on big machines. Smaller numbers mean bigger savings.

The first service in Figure 19 achieves a low 33% RTCO by adopting Shard Manager (§2.7). The service is sharded; its biggest shard has 20x higher load than its smallest shard and the load varies. The service’s previous static-sharding solution did not work well, whereas Shard Manager is able to balance the load via shard migration. After switching to small machines, the service better utilizes the overall higher CPU count of small machines under the same TCO.

The second service achieves a 48% RTCO by moving from an in-memory data store to an external flash-based database. Its 48% RTCO includes the cost of the database, which is only a small part of the total TCO.

The service with 76% RTCO is TAO [7], our social graph cache. CacheLib [5] provides transparent tiered memory on top of 64GB RAM and TBs of local flash to replace 256GB RAM (§2.8). Its 76% RTCO includes the cost of flash.

One outlier service has 110% RTCO, meaning it costs 10% more to run on small machines. The memory is used to store certain data indices and ML models that rank the indices. We are improving the service to target 90% RTCO, e.g., by leveraging CacheLib [5] to provide tiered memory.

Across all services in our fleet beyond the examples in Figure 19, we achieved an average 83% RTCO, i.e., 17% fleet-wide TCO savings. This also includes 18% power savings. Overall, we have been successful at using small machines.

6 Experience with Shared Infrastructure

As described in §1, Twine has allowed us to grow *twshared*, our shared compute pool, from $\approx 15\%$ in 2019 to $\approx 56\%$ in 2020. We share our experience with growing *twshared*.

6.1 Economies of Scale in *twshared*

Shared infrastructure provides economies of scale by reducing hardware, development, and operational costs. Examples:

- **Capacity buffer consolidation.** As services migrated into *twshared*, we consolidated siloed buffers for software releases, maintenance, fault tolerance, and growth into centralized buffers, improving utilization by $\approx 3\%$.
- **Turbo Boost.** We aggressively enabled Turbo on processor cores and relied on ReBalancer to mitigate power hotspots, improving utilization by $\approx 2\%$ in 2020.
- **Autoscaling.** Autoscaling freed up over-provisioned capacity, reclaiming $\approx 2\%$ of capacity in 2020.

As shown in Figure 20, as of October 2020, *twshared*’s average memory and CPU utilization are $\approx 40\%$ and $\approx 30\%$, respectively. For comparison, the figure also shows utilization for *private pools*, our legacy pools of customized machines dedicated to individual workloads. We plan to improve utilization through multiple approaches, such as the one described below. Our fleet is dominated by user-facing services that provision capacity for peak load. Autoscaling frees some of this over-provisioned capacity during off-peak hours and provides it as opportunistic capacity for other workloads to use. Unfortunately, we do not yet provide service-level objectives (SLOs) on the availability of opportunistic capacity, which is limiting adoption and usage of all available capacity. As we establish SLOs for opportunistic capacity, improve stacking, and consolidate capacity buffers, we expect *twshared*’s utilization to increase.

Figure 20: Daily average CPU and memory utilization of *twshared* and private pools circa October 2020.

6.2 Path to Shared Infrastructure

We had broad conversations with colleagues in industry and learned that while partial consolidation of workloads is common, no large company has achieved near 100% shared infrastructure consolidation. Further, we learned that cultural challenges are as significant as technical challenges. Below, we describe our strategy and major milestones towards migrating *all* non-storage workloads into *twshared*.

Make Twine capable of supporting a large shared pool. Scalability, entitlements, host profiles, and TaskControl are Twine’s important features that enabled workload consolidation. The flexibility offered by host profiles and TaskControl ensures that *twshared* can support both 1) the general needs of thousands of services, and 2) the specialized needs of a smaller set of services that consume the majority of capacity.

Figure 21: Breakdown of machines in our fleet as of **August 2018**. Each small rectangle inside a category represents a private pool, and its size is proportional to the number of machines in the private pool. There were hundreds of private pools, many of which were small in size. The percentages at the top reflect the number of machines in each category relative to all machines globally. From August 2018 to **October 2020**, the breakdown evolved from [8%, 14%, 65%, 13%] to [13%, 5%, 26%, 56%], where the numbers match the left-to-right categories in the figure.

Publicize the growth and health of twshared. We developed a tool to show the realtime breakdown of our fleet and the growth of twshared. A snapshot is shown in Figure 21. We consolidated the fragmented mechanisms of measuring machine health into the Health Check Service. Continuous improvements have resulted in twshared running healthier than private pools, 99.6% vs. 98.3%.

Set a strong example for others to follow. Early on, we targeted the web tier, our largest private pool. It directly serves external users of our company’s products and any outage would be immediately noticeable. We finished migrating the web tier into twshared mid-2019. As the web tier team is highly respected in the company, their testimony motivated others to follow.

Make migration mandatory. After the web tier migration, we gained company-wide support for mandatory migration. Further, we established that all new compute capacity will land only in twshared. This mandate, along with Twine’s flexibility of supporting customization through TaskControl and host profiles, has made twshared our ubiquitous compute pool.

6.3 Case Study of twshared Migration

PG_x is a large product group that runs hundreds of diverse services on hundreds of thousands of machines. Their services vary in size from a few machines to tens of thousands, and in complexity from computationally intensive ML training to latency-sensitive ad delivery. Previously, their fleet was fragmented into tens of private pools per region. The first PG_x service migrated into twshared in January 2020; as of September 2020, more than 70% of PG_x machines run in twshared. Given the size and diversity of their services, we expect the migration to finish in late 2021.

PG_x services use hundreds of twshared entitlements; if a service runs in multiple regions, it needs one entitlement per

Figure 22: CDF of PG_x entitlement size. The distribution is highly skewed. The largest 54 entitlements account for 70% of PG_x capacity in twshared.

region. Figure 22 shows the size distribution with the biggest entitlement running $\approx 2K$ jobs on $\approx 15K$ machines.

Accommodating workload-specific requirements helps onboard PG_x services onto twshared. For instance, many PG_x services run A/B tests in production, e.g., to evaluate the effectiveness of a new model—these services need to explicitly configure the processor generation for their tasks to prevent performance variations between hardware types from polluting their test results.

The capacity guaranteed by entitlements and private pools account for 55% of PG_x machines. The remaining 45% are from opportunistic sources including capacity buffers, machines freed up by autoscaling, and unused portions of other teams’ entitlements. *Optimus* is an application-level scheduler that runs atop Twine to manage opportunistic capacity. When opportunistic capacity is not available, some services gracefully degrade their quality of service.

Jobs with a TaskController consume 36% of PG_x capacity in twshared; in total these jobs use three different TaskControllers, including the one from Shard Manager [16]. About 95% of PG_x capacity is consumed by entitlements that use some combination of these three host profile settings:

1. If a service does frequent flash writes, it prefers the flash drive to expose only a fraction of the flash capacity in order to reduce write amplification and burn rate.
2. If a service can fully utilize a whole machine and does not stack with other services, we disable the cgroup2 CPU controller to eliminate its overhead.
3. Because our data centers are power constrained and CPU Turbo consumes extra power, we enable Turbo only for services that can benefit significantly from Turbo and are running in selected data centers with sufficient power.

Overall, our experience with PG_x indicates that, despite the significant upfront effort needed for migration, even large and varied services are motivated to adopt shared infrastructure that reduces their operational burden. PG_x’ success in using opportunistic capacity at a large scale has spurred us to develop SLO guarantees and drive broader adoption (§6.1). Entitlements, TaskControl, and host profiles enable customization in a shared pool and were the features that enabled the migration. On the other hand, PG_x services have grown to hundreds of entitlements within 9 months, motivating us to address entitlement fragmentation (§7.1).

7 Lessons Learned

Evolving Twine and growing twshared has taught us several lessons. We share some highlights and lowlights below.

7.1 Entitlement Fragmentation

We overloaded entitlements with two responsibilities: fleet partitioning and quota management. Entitlements partition millions of machines into smaller units that can be effectively managed by scheduler shards. Twine jobs can only stack within the same entitlement, implying that an entitlement be sized at a few thousand machines, similar to a Borg [39] cell.

On the other hand, leveraging entitlements for quota management results in small entitlements. For example, an important service may wish for an entitlement with 10 tasks rather than a larger entitlement shared with other services to protect against the risk that a rogue service grows unexpectedly and uses up the entitlement quota.

We are in the process of splitting an entitlement's responsibility into two new abstractions: a *materialization* for fleet partitioning and a stackable *reservation* for quota management. A *materialization* functions as a pseudo cluster, has a host profile associated with it, and is always large enough to enable job stacking across thousands of machines.

7.2 Controlled Customization

Our goal is ubiquitous shared infrastructure. A difficult lesson we learned from the first six years of operating twshared was that customization is key to migrating services over. For instance, without host profiles, our web tier and memcache services would not run in twshared as their performance would regress by 11% and 10.2% respectively. TaskControl has provided a path for stateful services such as TAO [7] and MySQL to deprecate their custom cluster management tooling and adopt Twine and shared infrastructure.

We prioritize maintainability when deciding what customization to permit. Currently, we offer 17 host profiles and 16 TaskControllers to support thousands of services. Our recent migration of $\approx 70\%$ of a large product group's services into twshared (§6.3) leveraged existing host profiles and TaskControllers.

In hindsight, we permitted some customizations that appeared useful initially, but later became barriers for fleet-wide optimizations. For example, a job's tasks are identical by default, but we provided the ability to customize individual tasks, including the executables to run, command line options, environment variables, and restart policies. Developers abused this customization to implement simple sharding so that each task does different work. Autoscaling changes the number of tasks in a job and breaks the job's task customization. As we enable autoscaling for all ALM-tracking services, we are removing task customization and migrating these services to use Shard Manager [16] instead.

7.3 Supporting Global Services

Many developers wish to run a global service without worrying about operational challenges: which regions to deploy to, how much capacity is needed in each region, and how to handle regional failures. We currently operate multiple global Twine deployments that spread a global job's tasks across regions, similar to how a regional Twine deployment spreads a regional job's tasks across data centers in a region. Currently, global jobs account for 8% of all our jobs.

We have learned over time that global Twine deployments did not provide the right abstraction for managing global services. Machines in a region are largely fungible due to the high network bandwidth and low latency within a region, but this is not true for machines distributed across regions. Hence, it is better to explicitly decompose a service's global capacity needs into capacity needs for specific regions, as opposed to global allocators making ad hoc decisions on which regions to get machines from. We are replacing global Twine deployments with a new Federation system built atop regional Twine deployments to provide stronger capacity guarantees and more holistic support for a global-service abstraction.

7.4 Challenges with Small Machines

Our decision to leverage small machines brings with it numerous trade-offs. The effort to rearchitect and reimplement memory-capacity-bound services was higher than we anticipated. On the other hand, we leveraged this opportunity to holistically modernize our legacy services, e.g., moving from static sharding to dynamic sharding for better load balancing. As small machines run contrary to the industry practice of favoring big machines; we need to work closely with hardware vendors to optimize machines for our internal workloads, e.g., removing unneeded NUMA components.

That said, the 18% power efficiency win (§5.4) from small machines has been worth the above trade-offs. We intend to continue using small machines in the coming years, but are also prepared to evolve our hardware strategy as needed. Two factors lead to our decision of adopting small machines: 1) our legacy large services were optimized for utilizing entire machines running in private pools, and 2) our stacking technology needed to mature and improve support for performance isolation [42]. As our services undergo architectural changes to run effectively in twshared, and we improve our stacking technology, we may revisit our hardware strategy.

8 Related Work

Scalability and scheduling performance. Kubernetes [25] and Hydra [9] scale out through federation, whereas Twine scales out through sharding. Figure 13 compares the two approaches. A large body of work [6, 15, 20, 31] focuses on improving batch scheduling throughput and latency. Twine

delegates the handling of short-lived batch jobs to application-level batch schedulers. This separation of concerns helps Twine scale, as discussed in §3.2.

Entitlements. Twine has some similarity to the two-level schedulers (Mesos [17], YARN [37], Apollo [6], and Fuxi [44]), with Twine entitlements as resource offers and Twine scheduler shards as Application Masters (or *frameworks* in Mesos). However, the bottom-level Resource Manager (or *Master* in Mesos) is designed for the scale of a single cluster. In contrast to the single-master two-level architecture, we propose a three-level architecture with sharding so our design scales out: Resource Broker manages machines, Twine scheduler manages containers, and Application-level schedulers manage workloads such as batch and ML.

Kubernetes' cluster autoscaler [24] can respond to workload growth by provisioning VMs in a public cloud and adding them to a node pool. Kubernetes' resizable node pool corresponds to Twine's entitlement, and a public cloud's available resources correspond to Twine's shared free machine pool maintained by Resource Broker. Decoupling Kubernetes and cloud makes the setup flexible, but also misses optimization opportunities compared with Twine's integrated ecosystem. Multiple Kubernetes clusters run independently without coordination, whereas Twine's ReBalancer performs global optimization across entitlements, and an entitlement can be migrated across scheduler shards.

TaskControl. The two-level schedulers (Mesos [17], YARN [37], Apollo [6], and Fuxi [44]) allow their applications to provide custom Application Masters. The interface with Application Masters is for negotiating resource allocation, e.g., "*requesting N containers with X CPU and Y memory*," whereas the TaskControl API is for negotiating lifecycle management, e.g., "*delaying restarting task T* ."

Kubernetes [23]'s custom controllers provide a universal extension framework that can be used to implement various custom functions like autoscaling and injecting sidecars for traffic routing. In contrast, TaskControl exclusively focuses on allowing or delaying task lifecycle operations. This narrow interface strikes a balance between standardization and customization (§7.2) and prevents proliferation of customizing all aspects of the Twine control plane. We are unaware of any Kubernetes custom controller that specifically offers extension points to allow or delay task lifecycle operations.

Azure supports update domains and fault domains [3] and the example stateful service in Figure 2 can improve availability by spreading its data shards' replicas across those domains. However, in the event of a machine failure, Azure may still proceed with a rolling update that can lead to unavailable shards because it does not know precisely how the shard replicas are spread across fault domains and update domains.

Host profiles. Paragon [12] schedules a job on machines that are beneficial to the job's performance, but it does not reconfigure a machine.

Some systems statically partition machines in a cluster and preconfigure their hardware and OS settings to suit different workloads. Others dynamically adjust predetermined settings (e.g., Turbo [40]) based on runtime profiling, while disallowing other customizations (e.g., btrfs vs. ext4). We believe that Twine is the first system that 1) allows workloads to provide customized hardware and OS settings to run in a shared machine pool and 2) dynamically reconfigures a machine just-in-time as the workload is scheduled onto the machine. On average, Twine reconfigures a machine once every two days, primarily due to Autoscaling (see Figure 18).

Power-efficient hardware. A large body of work studies power-efficient computing [1, 10, 27]. Our infrastructure is unique in 1) using power-efficient small machines as a universal computing platform, and 2) consolidating towards a single compute machine type (one CPU and 64GB RAM), as opposed to offering a variety of high-memory or high-CPU machine types. Both approaches required our workloads to make software architectural changes that would be challenging in a public cloud with external customer workloads.

Overcommitment and autoscaling. Past work overcommits CPU and memory by colocating batch jobs and online services [11, 22, 39, 43]. Twine does not overcommit CPU or memory by default, although a job owner can explicitly configure their job to do so. On the other hand, we overcommit power by default [41], as power is our most constrained resource. Twine helps mitigate power hotspots by relocating tasks across data centers. Twine's SRM uses historical data to predictably adjust the number of tasks in a job. Borg's Autopilot [34] adjusts the CPU and memory allocated to each task—this is an area of future work for Twine.

9 Conclusion

We identify existing cluster management systems' limitations in supporting large-scale shared infrastructure. We describe our novel solution that allowed us to scale Twine to manage one million machines in a region, move jobs across physical clusters, collaborate with applications to manage their lifecycle, support host customization in a shared pool, use power-efficient small machines to achieve higher performance per watt, and employ autoscaling to improve machine utilization. We share our experience with twshared and our strategy towards ubiquitous shared infrastructure.

Acknowledgments

This paper presents the engineering work of several teams at Facebook that have built Twine and its ecosystem over the past decade. We thank Niket Agarwal, Marius Eriksen, Tianyin Xu, Murray Stokely, Seth Hettich, and the OSDI reviewers for their insightful feedback.

Abstract

User-facing latency-sensitive web services include numerous distributed, intercommunicating microservices that promise to simplify software development and operation. However, multiplexing of compute resources across microservices is still challenging in production because contention for shared resources can cause latency spikes that violate the service-level objectives (SLOs) of user requests. This paper presents *FIRM*, an intelligent fine-grained resource management framework for predictable sharing of resources across microservices to drive up overall utilization. *FIRM* leverages online telemetry data and machine-learning methods to adaptively (a) detect/localize microservices that cause SLO violations, (b) identify low-level resources in contention, and (c) take actions to mitigate SLO violations via dynamic reprovisioning. Experiments across four microservice benchmarks demonstrate that *FIRM* reduces SLO violations by up to $16\times$ while reducing the overall requested CPU limit by up to 62%. Moreover, *FIRM* improves performance predictability by reducing tail latencies by up to $11\times$.

1 Introduction

User-facing latency-sensitive web services, like those at Netflix [68], Google [77], and Amazon [89], are increasingly built as microservices that execute on shared/multi-tenant compute resources either as virtual machines (VMs) or as containers (with containers gaining significant popularity of late). These microservices must handle diverse load characteristics while efficiently multiplexing shared resources in order to maintain service-level objectives (SLOs) like end-to-end latency. SLO violations occur when one or more “critical” microservice instances (defined in §2) experience load spikes (due to diurnal or unpredictable workload patterns) or shared-resource contention, both of which lead to longer than expected times to process requests, i.e., latency spikes [4, 11, 22, 30, 35, 44, 53, 69, 98, 99]. Thus, it is critical to efficiently multiplex shared resources among microservices to reduce SLO violations.

Figure 1: Latency spikes on microservices due to low-level resource contention.

Traditional approaches (e.g., overprovisioning [36, 87], recurrent provisioning [54, 66], and autoscaling [39, 56, 65, 81, 84, 88, 127]) reduce SLO violations by allocating more CPUs and memory to microservice instances by using performance models, handcrafted heuristics (i.e., static policies), or machine-learning algorithms.

Unfortunately, these approaches suffer from two main problems. First, they fail to efficiently multiplex resources, such as caches, memory, I/O channels, and network links, at fine granularity, and thus may not reduce SLO violations. For example, in Fig. 1, the Kubernetes container-orchestration system [20] is unable to reduce the tail latency spikes arising from contention for a shared resource like memory bandwidth, as its autoscaling algorithms were built using heuristics that only monitor CPU utilization, which does not change much during the latency spike. Second, significant human-effort and training are needed to build high-fidelity performance models (and related scheduling heuristics) of large-scale microservice deployments (e.g., queuing systems [27, 39]) that can capture low-level resource contention. Further, frequent microservice updates and migrations can lead to recurring human-expert-driven engineering effort for model reconstruction.

FIRM Framework. This paper addresses the above prob-

lems by presenting *FIRM*, a multilevel machine learning (ML) based resource management (RM) framework to manage shared resources among microservices at finer granularity to reduce resource contention and thus increase performance isolation and resource utilization. As shown in Fig. 1, *FIRM* performs better than a default Kubernetes autoscaler because *FIRM* adaptively scales up the microservice (by adding local cores) to increase the aggregate memory bandwidth allocation, thereby effectively maintaining the per-core allocation. *FIRM* leverages online telemetry data (such as request-tracing data and hardware counters) to capture the system state, and ML models for resource contention estimation and mitigation. Online telemetry data and ML models enable *FIRM* to adapt to workload changes and alleviate the need for brittle, hand-crafted heuristics. In particular, *FIRM* uses the following ML models:

- *Support vector machine (SVM) driven detection and localization of SLO violations to individual microservice instances.* *FIRM* first identifies the “critical paths,” and then uses per-critical-path and per-microservice-instance performance variability metrics (e.g., sojourn time [1]) to output a binary decision on whether or not a microservice instance is responsible for SLO violations.
- *Reinforcement learning (RL) driven mitigation of SLO violations that reduces contention on shared resources.* *FIRM* then uses resource utilization, workload characteristics, and performance metrics to make dynamic reprovisioning decisions, which include (a) increasing or reducing the partition portion or limit for a resource type, (b) scaling up/down, i.e., adding or reducing the amount of resources attached to a container, and (c) scaling out/in, i.e., scaling the number of replicas for services. By continuing to learn mitigation policies through reinforcement, *FIRM* can optimize for dynamic workload-specific characteristics.

Online Training for *FIRM*. We developed a *performance anomaly injection framework* that can artificially create resource scarcity situations in order to both train and assess the proposed framework. The injector is capable of injecting resource contention problems at a fine granularity (such as last-level cache and network devices) to trigger SLO violations. To enable rapid (re)training of the proposed system as the underlying systems [67] and workloads [40,42,96,98] change in datacenter environments, *FIRM* uses *transfer learning*. That is, *FIRM* leverages transfer learning to train microservice-specific RL agents based on previous RL experience.

Contributions. To the best of our knowledge, this is the first work to provide an SLO violation mitigation framework for microservices by using fine-grained resource management in an application-architecture-agnostic way with multilevel ML models. Our main contributions are:

1. *SVM-based SLO Violation Localization:* We present (in §3.2 and §3.3) an efficient way of localizing the microservice instances responsible for SLO violations by extracting critical paths and detecting anomaly instances in near-real

time using telemetry data.

2. *RL-based SLO Violation Mitigation:* We present (in §3.4) an RL-based resource contention mitigation mechanism that (a) addresses the large state space problem and (b) is capable of tuning tailored RL agents for individual microservice instances by using transfer learning.
3. *Online Training & Performance Anomaly Injection:* We propose (in §3.6) a comprehensive performance anomaly injection framework to artificially create resource contention situations, thereby generating the ground-truth data required for training the aforementioned ML models.
4. *Implementation & Evaluation:* We provide an open-source implementation of *FIRM* for the Kubernetes container-orchestration system [20]. We demonstrate and validate this implementation on four real-world microservice benchmarks [34, 116] (in §4).

Results. *FIRM* significantly outperforms state-of-the-art RM frameworks like Kubernetes autoscaling [20, 55] and additive increase multiplicative decrease (AIMD) based methods [38, 101].

- It reduces overall SLO violations by up to $16\times$ compared with Kubernetes autoscaling, and $9\times$ compared with the AIMD-based method, while reducing the overall requested CPU by as much as 62%.
- It outperforms the AIMD-based method by up to $9\times$ and Kubernetes autoscaling by up to $30\times$ in terms of the time to mitigate SLO violations.
- It improves overall performance predictability by reducing the average tail latencies up to $11\times$.
- It successfully localizes SLO violation root-cause microservice instances with 93% accuracy on average.

FIRM mitigates SLO violations without overprovisioning because of two main features. First, it models the dependency between low-level resources and application performance in an RL-based feedback loop to deal with uncertainty and noisy measurements. Second, it takes a two-level approach in which the online critical path analysis and the SVM model filter only those microservices that need to be considered to mitigate SLO violations, thus making the framework application-architecture-agnostic as well as enabling the RL agent to be trained faster.

2 Background & Characterization

The advent of *microservices* has led to the development and deployment of many web services that are composed of “micro,” loosely coupled, intercommunicating services, instead of large, monolithic designs. This increased popularity of service-oriented architectures (SOA) of web services has been made possible by the rise of containerization [21, 70, 92, 108] and container-orchestration frameworks [19, 20, 90, 119] that enable modular, low-overhead, low-cost, elastic, and high-efficiency development and production deployment of SOA microservices [8, 9, 33, 34, 46, 68, 77, 89, 104]. A deployment of

Table 1: CP changes in Fig. 2(b) under performance anomaly injection. Each case is represented by a $\langle \text{service}, \text{CP} \rangle$ pair. N, V, U, I, T , and C are microservices from Fig. 2.

Case	Average Individual Latency (ms)						Total (ms)
	N	V	U	I	T	C	
$\langle V, \text{CP1} \rangle$	13	603	166	33	71	68	614 ± 106
$\langle U, \text{CP2} \rangle$	14	237	537	39	62	89	580 ± 113
$\langle T, \text{CP3} \rangle$	13	243	180	35	414	80	507 ± 75

Figure 4: Improvement of end-to-end latency by scaling “highest-variance” and “highest-median” microservices.

anomaly injections.¹ Table 1 lists the changes observed in the latencies of individual microservices, as well as end-to-end latency. We observe as much as $1.2\text{--}2\times$ variation in end-to-end latency across the three CPs. Such dynamic behavior exists across all our benchmark microservices. Fig. 3 illustrates the latency distributions of CPs with minimum and maximum latency in each microservice benchmark, where we observe as much as $1.6\times$ difference in median latency and $2.5\times$ difference in 99th percentile tail latency across these CPs.

Recent approaches (e.g., [3, 47]) have explored static identification of CPs based on historic data (profiling) and have built heuristics (e.g., application placement, level of parallelism) to enable autoscaling to minimize CP latency. However, our experiment shows that this by itself is not sufficient. The requirement is to *adaptively capture changes in the CPs*, in addition to changing resource allocations to microservice instances on the identified CPs to mitigate tail latency spikes.

Insight 2: Microservices with Larger Latency Are Not Necessarily Root Causes of SLO Violations. It is important to find the microservices responsible for SLO violations to mitigate them. While it is clear that such microservices will always lie on the CP, it is less clear which individual service on the CP is the culprit. A common heuristic is to pick the one with the highest latency. However, we find that that rarely leads to the optimal solution. Consider Fig. 4. The left side shows the CDF of the latencies of two services (i.e., `composePost` and `text`) on the CP of the `post-compose` request in the Social Network benchmark. The `composePost` service has a higher median/mean latency while the `text` service has a higher variance. Now, although the `composePost`

¹ *Performance anomaly injections* (§3.6) are used to trigger SLO violations by generating fine-grained resource contention with configurable resource types, intensity, duration, timing, and patterns, which helps with both our characterization (§2) and ML model training (§3.4).

Figure 5: Dynamic behavior of mitigation strategies: *Social Network* (top); *Train-Ticket Booking* (bottom). Error bars show 95% confidence intervals on median latencies.

service contributes a larger portion of the total latency, it does not benefit from scaling (i.e., getting more resources), as it does not have resource contention. That phenomenon is shown on the right side of Fig. 4, which shows the end-to-end latency for the original configuration (labeled “Before”) and after the two microservices were scaled from a single to two containers each (labeled “Text” and “Compose”). Hence, scaling microservices with higher variances provides better performance gain.

Insight 3: Mitigation Policies Vary with User Load and Resource in Contention. The only way to mitigate the effects of dynamically changing CPs, which in turn cause dynamically changing latencies and tail behaviors, is to efficiently identify microservice instances on the CP that are resource-starved or contending for resources and then provide them with more of the resources. Two common ways of doing so are (a) to *scale out* by spinning up a new instance of the container on another node of the compute cluster, or (b) to *scale up* by providing more resources to the container via either explicitly partitioning resources (e.g., in the case of memory bandwidth or last-level cache) or granting more resources to an already deployed container of the microservice (e.g., in the case of CPU cores).

As described before, recent approaches [23, 38, 39, 56, 65, 84, 94, 101, 127]) address the problem by building static policies (e.g., AIMD for controlling resource limits [38, 101], and rule/heuristics-based scaling relying on profiling of historic data about a workload [23, 94]), or modeling performance [39, 56]. However, we found in our experiments with the four microservice benchmarks that such static policies are not well-suited for dealing with latency-critical workloads because the optimal policy must incorporate dynamic contextual information. That is, information about the type of user requests, and load (in requests per second), as well as the critical resource bottlenecks (i.e., the resource being contended for), must be jointly analyzed to make optimal decisions. For example, in Fig. 5 (top), we observe that the trade-off between

scale-up and scale-out changes based not only on the user load but also on the resource type. At 500 req/s, scale-up has a better payoff (i.e., lower latency) than scale-out for both memory- and CPU-bound workloads. However, at 1500 req/s, scale-out dominates for CPU, and scale-up dominates for memory. This behavior is also application-dependent because the trade-off curve inflection points change across applications, as illustrated in Fig. 5 (bottom).

3 The FIRM Framework

In this section, we describe the overall architecture of the FIRM framework and its implementation.

1. Based on the insight that resource contention manifests as dynamically evolving CPs, FIRM first detects CP changes and extracts critical microservice instances from them. It does so using the *Tracing Coordinator*, which is marked as ① in Fig. 6.² The tracing coordinator collects tracing and telemetry data from every microservice instance and stores them in a centralized graph database for processing. It is described in §3.1.
2. The *Extractor* detects SLO violations and queries the Tracing Coordinator with collected real-time data (a) to extract CPs (marked as ② and described in §3.2) and (b) to localize critical microservice instances that are likely causes of SLO violations (marked as ③ and described in §3.3).
3. Using the telemetry data collected in ① and the critical instances identified in ③, FIRM makes mitigation decisions to scale and reprovision resources for the critical instances (marked as ④). The policy used to make such decisions is automatically generated using RL. The RL agent jointly analyzes contextual information about resource utilization (i.e., low-level performance counter data collected from the CPU, LLC, memory, I/O, and network), performance metrics (i.e., per-microservice and end-to-end latency distributions), and workload characteristics (i.e., request arrival rate and composition) and makes mitigation decisions. The RL model and setup are described in §3.4.
4. Finally, actions are validated and executed on the underlying Kubernetes cluster through the deployment module (marked as ⑤ and described in §3.5).
5. In order to train the ML models in the Extractor as well as the RL agent (i.e., to span the exploration-exploitation trade-off space), FIRM includes a performance anomaly injection framework that triggers SLO violations by generating resource contention with configurable intensity and timing. This is marked as ⑥ and described in §3.6.

3.1 Tracing Coordinator

Distributed tracing is a method used to profile and monitor microservice-based applications to pinpoint causes of poor

²Unless otherwise specified, ① refers to annotations in Fig. 6.

Figure 6: FIRM architecture overview.

performance [111–115]. A *trace* captures the work done by each service along request execution paths, i.e., it follows the execution “route” of a request across microservice instances and records time, local profiling information, and RPC calls (e.g., source and destination services). The execution paths are combined to form the *execution history graph* (see §2). The time spent by a single request in a microservice instance is called its *span*. The span is calculated based on the time when a request arrives at a microservice and when its response is sent back to the caller. Each span is the most basic single unit of work done by a microservice.

The FIRM tracing module’s design is heavily inspired by Dapper [95] and its open-source implementations, e.g., Jaeger [112] and Zipkin [115]. Each microservice instance is coupled with an OpenTracing-compliant [75] *tracing agent* that measures spans. As a result, any new OpenTracing-compliant microservice can be integrated naturally into the FIRM tracing architecture. The Tracing Coordinator, i.e., ①, is a stateless, replicable data-processing component that collects the spans of different requests from each tracing agent, combines them, and stores them in a graph database [72] as the execution history graph. The graph database allows us to easily store complex caller-callee relationships among microservices depending on request types, as well as to efficiently query the graph for critical path/component extraction (see §3.2 and §3.3). Distributed clock drift and time shifting are handled using the Jaeger framework. In addition, the Tracing Coordinator collects telemetry data from the systems running the microservices. The data collected in our experiments is listed in Table 2. The distributed tracing and telemetry collection overhead is indiscernible, i.e., we observed a <0.4% loss in throughput and a <0.15% loss in latency. FIRM had a

Table 2: Collected telemetry data and sources.

cAdvisor [13] & Prometheus [82]

offcore_response.*.llc_hit/miss.local_DRAM, offcore_response.*.llc_hit/miss.remote_DRAM

maximum CPU overhead of 4.6% for all loads running in our experiments on the four benchmarks [34, 116]. With FIRM, the network in/out traffic without sampling traces increased by 3.4%/10.9% (in bytes); the increase could be less in production environments with larger message sizes [63].

3.2 Critical Path Extractor

The first goal of the FIRM framework is to quickly and accurately identify the CP based on the tracing and telemetry data described in the previous section. Recall from Def. 2.3 in §2 that a CP is the longest path in the request’s execution history graph. Hence, changes in the end-to-end latency of an application are often determined by the slowest execution of one or more microservices on its CP.

We identify the CP in an execution history graph by using Alg. 1, which is a weighted longest path algorithm proposed to retrieve CPs in the microservices context. The algorithm needs to take into account the major communication and computation patterns in microservice architectures: (a) *parallel*, (b) *sequential*, and (c) *background* workflows.

- *Parallel workflows* are the most common way of processing requests in microservices. They are characterized by child spans of the same parent span that overlap with each other in the execution history graph, e.g., U , V , and T in Fig. 2(b). Formally, for two child spans i with start time st_i and end time et_i , and j with st_j, et_j of the same parent span p , they are called *parallel* if $(st_j < st_i < et_j) \vee (st_i < st_j < et_i)$.
- *Sequential workflows* are characterized by one or more child spans of a parent span that are processed in a serialized manner, e.g., U and I in Fig. 2(b). For two of p ’s child-spans i and j to be in a sequential workflow, the time $t_{i \rightarrow p} \leq t_{p \rightarrow j}$, i.e., i completes and sends its result to p before j does. Such sequential relationships are usually indicative of a *happens-before* relationship. However, it is impossible to ascertain the relationships merely by observing traces from the system. If, across a sufficient number of request executions, there is a violation of that inequality, then the services are not sequential.
- *Background workflows* are those that do not return values to their parent spans, e.g., W in Fig. 2(b). Background workflows are not part of CPs since no other span depends on their execution, but they may be considered responsible for SLO violations when FIRM’s Extractor is localizing

Algorithm 1 Critical Path Extraction

Require: Microservice execution history graph G

Attributes: *childNodes*, *lastReturnedChild*

```

1: procedure LONGESTPATH( $G$ , currentNode)
2:    $path \leftarrow \emptyset$ 
3:    $path.add(currentNode)$ 
4:   if currentNode.childNodes == None then
5:     Return  $path$ 
6:   end if
7:    $lrc \leftarrow currentNode.lastReturnedChild$ 
8:    $path.extend(LONGESTPATH(G, lrc))$ 
9:   for each  $cn$  in currentNode.childNodes do
10:    if  $cn.happensBefore(lrc)$  then
11:       $path.extend(LONGESTPATH(G, cn))$ 
12:    end if
13:  end for
14:  Return  $path$ 
15: end procedure

```

Algorithm 2 Critical Component Extraction

Require: Critical Path CP , Request Latencies T

```

1: procedure CRITICALCOMPONENT( $G$ ,  $T$ )
2:    $candidates \leftarrow \emptyset$ 
3:    $T_{CP} \leftarrow T.getTotalLatency()$   $\triangleright$  Vector of CP latencies
4:   for  $i \in CP$  do
5:      $T_i \leftarrow T.getLatency(i)$ 
6:      $T_{99} \leftarrow T_i.percentile(99)$ 
7:      $T_{50} \leftarrow T_i.percentile(50)$ 
8:      $RI \leftarrow PCC(T_i, T_{CP})$   $\triangleright$  Relative Importance
9:      $CI \leftarrow T_{99}/T_{50}$   $\triangleright$  Congestion Intensity
10:    if  $SVM.classify(RI, CI) == True$  then
11:       $candidates.append(i)$ 
12:    end if
13:  end for
14:  Return  $candidates$ 
15: end procedure

```

critical components (see §3.3). That is because background workflows may also contribute to the contention of underlying shared resource.

3.3 Critical Component Extractor

In each extracted CP, FIRM then uses an adaptive, data-driven approach to determine critical components (i.e., microservice instances). The overall procedure is shown in Alg. 2. The extraction algorithm first calculates per-CP and per-instance “features,” which represent the performance variability and level of request congestion. Variability represents the single largest opportunity to reduce tail latency. The two features are then fed into an incremental SVM classifier to get binary decisions, i.e., on whether that instance should have its resources

re-provisioned or not. The approach is a dynamic selection policy that is in contrast to static policies, as it can classify critical and noncritical components adapting to dynamically changing workload and variation patterns.

In order to extract those microservice instances that are potential candidates for SLO violations, we argue that it is critical to know both the variability of the end-to-end latency (i.e., per-CP variability) and the variability caused by congestion in the service queues of each individual microservice instances (i.e., per-instance variability).

Per-CP Variability: Relative Importance. Relative importance [62, 110, 122] is a metric that quantifies the strength of the relationship between two variables. For each critical path CP , its end-to-end latency is given by $T_{CP} = \sum_{i \in CP} T_i$, where T_i is the latency of microservice i . Our goal is to determine the contribution that the variance of each variable T_i makes toward explaining the total variance of T_{CP} . To do so, we use the Pearson correlation coefficient [12] (also called zero-order correlation), i.e., $PCC(T_i, T_{CP})$, as the measurement, and hence the resulting statistic is known as the variance explained [31]. The sum of $PCC(T_i, T_{CP})$ over all microservice instances along the CP is 1, and the relative importance values of microservices can be ordered by $PCC(T_i, T_{CP})$. The larger the value is, the more variability it contributes to the end-to-end CP variability.

Per-Instance Variability: Congestion Intensity. For each microservice instance in a CP, congestion intensity is defined as the ratio of the 99th percentile latency to the median latency. Here, we chose the 99th percentile instead of the 70th or 80th percentile to target the tail latency behavior. The chosen ratio explains per-instance variability by capturing the congestion level of the request queue so that it can be used to determine whether it is necessary to scale. For example, a higher ratio means that the microservice could handle only a subset of the requests, but the requests at the tail are suffering from congestion issues in the queue. On the other hand, microservices with lower ratios handle most requests normally, so scaling does not help with performance gain. Consequently, microservice instances with higher ratios have a greater opportunity to achieve performance gains in terms of tail latency by taking scale-out or reprovisioning actions.

Implementation. The logic of critical path extraction is incorporated into the construction of spans, i.e., as the algorithm proceeds (Alg. 1), the order of tracing construction is also from the root node to child nodes recursively along paths in the execution history graph. Sequential, parallel, and background workflows are inferred from the parent-child relationships of spans. Then, for each CP, we calculate feature statistics and feed them into an incremental SVM classifier [29, 58] implemented using stochastic gradient descent optimization and RBF kernel approximation by `scikit-learn` libraries [91]. Triggered by detected SLO violations, both critical path extraction and critical component extraction are stateless and multithreaded; thus, the workload scales with

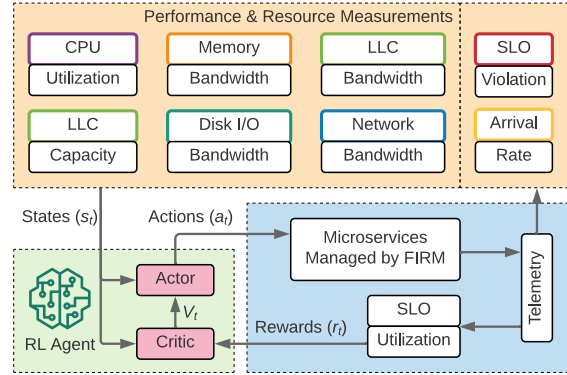

Figure 7: Model-free actor-critic RL framework for estimating resources in a microservice instance.

the size of the microservice application and the cluster. They together constitute FIRM’s extractor (i.e., ② and ③). Experiments (§4.2) show that it reports SLO violation candidates with feasible accuracy and achieves completeness with §3.4 by choosing a threshold with a reasonable false-positive rate.

3.4 SLO Violation Mitigation Using RL

Given the list of critical service instances, FIRM’s Resource Estimator, i.e., ④, is designed to analyze resource contention and provide reprovisioning actions for the cluster manager to take. FIRM estimates and controls a fine-grained set of resources, including CPU time, memory bandwidth, LLC capacity, disk I/O bandwidth, and network bandwidth. It makes decisions on scaling each type of resource or the number of containers by using measurements of tracing and telemetry data (see Table 2) collected from the Tracing Coordinator. When jointly analyzed, such data provides information about (a) shared-resource interference, (b) workload rate variation, and (c) request type composition.

FIRM leverages reinforcement learning (RL) to optimize resource management policies for long-term reward in dynamic microservice environments. We next give a brief RL primer before presenting FIRM’s RL model.

RL Primer. An RL agent solves a *sequential decision-making problem* (modeled as a Markov decision process) by interacting with an environment. At each discrete time step t , the agent observes a *state of the environment* $s_t \in S$, and performs an *action* $a_t \in A$ based on its *policy* $\pi_\theta(s)$ (parameterized by θ), which maps *state space* S to *action space* A . At the following time step $t + 1$, the agent observes an *immediate reward* $r_t \in R$ given by a reward function $r(s_t, a_t)$; the immediate reward represents the loss/gain in transitioning from s_t to s_{t+1} because of action a_t . The tuple (s_t, a_t, r_t, s_{t+1}) is called one *transition*. The agent’s goal is to optimize the policy π_θ so as to maximize the expected *cumulative discounted reward* (also called the value function) from the start distribution $J = \mathbb{E}[G_1]$, where the return from a state G_t is defined

to be $\sum_{k=0}^T \gamma^k r_{t+k}$. The discount factor $\gamma \in (0, 1]$ penalizes the predicted future rewards.

Two main categories of approaches are proposed for policy learning: value-based methods and policy based methods [5]. In value-based methods, the agent learns an estimate of the optimal value function and approaches the optimal policy by maximizing it. In policy-based methods, the agent directly tries to approximate the optimal policy.

Why RL? Existing performance-modeling-based [23, 38, 39, 56, 94, 101, 127] or heuristic-based approaches [6, 7, 37, 65, 84] suffer from model reconstruction and retraining problems because they do not address dynamic system status. Moreover, they require expert knowledge, and it takes significant effort to devise, implement, and validate their understanding of the microservice workloads as well as the underlying infrastructure. RL, on the other hand, is well-suited for learning resource reprovisioning policies, as it provides a tight feedback loop for exploring the action space and generating optimal policies without relying on inaccurate assumptions (i.e., heuristics or rules). It allows direct learning from actual workload and operating conditions to understand how adjusting low-level resources affects application performance. In particular, FIRM utilizes the deep deterministic policy gradient (DDPG) algorithm [59], which is a *model-free, actor-critic* RL framework (shown in Fig. 7). Further, FIRM's RL formulation provides two distinct advantages:

1. Model-free RL does not need the ergodic distribution of states or the environment dynamics (i.e., transitions between states), which are difficult to model precisely. When microservices are updated, the simulations of state transitions used in model-based RL are no longer valid.
2. The Actor-critic framework combines policy-based and value-based methods (i.e., consisting of an actor-net and a critic-net as shown in Fig. 8), and that is suitable for continuous stochastic environments, converges faster, and has lower variance [41].

Learning the Optimal Policy. DDPG's policy learning is an actor-critic approach. Here the "critic" estimates the *value function* (i.e., the expected value of cumulative discounted reward under a given policy), and the "actor" updates the policy in the direction suggested by the critic. The critic's estimation of the expected return allows the actor to update with gradients that have lower variance, thus speeding up the learning process (i.e., achieving convergence). We further assume that the actor and critic are represented as deep neural networks. DDPG also solves the issue of dependency between samples and makes use of hardware optimizations by introducing a *replay buffer*, which is a finite-sized cache \mathcal{D} that stores transitions (s_t, a_t, r_t, s_{t+1}) . Parameter updates are based on a mini-batch of size N sampled from the replay buffer. The pseudocode of the training algorithm is shown in Algorithm 3. RL training proceeds in episodes and each episode consists of T time steps. At each time step, both actor and critic neural nets are updated once.

Algorithm 3 DDPG Training

```

1: Randomly init  $Q_w(s, a)$  and  $\pi_\theta(a|s)$  with weights  $w$  &  $\theta$ .
2: Init target network  $Q'$  and  $\pi'$  with  $w' \leftarrow w$  &  $\theta' \leftarrow \theta$ 
3: Init replay buffer  $\mathcal{D} \leftarrow \emptyset$ 
4: for episode = 1,  $M$  do
5:   Initialize a random process  $\mathcal{N}$  for action exploration
6:   Receive initial observation state  $s_1$ 
7:   for  $t = 1, T$  do
8:     Select and execute action  $a_t = \pi_\theta(s_t) + \mathcal{N}_\epsilon$ 
9:     Observe reward  $r_t$  and new state  $s_{t+1}$ 
10:    Store transition  $(s_t, a_t, r_t, s_{t+1})$  in  $\mathcal{D}$ 
11:    Sample  $N$  transitions  $(s_i, a_i, r_i, s_{i+1})$  from  $\mathcal{D}$ 
12:    Update critic by minimizing the loss  $\mathcal{L}(w)$ 
13:    Update actor by sampled policy gradient  $\nabla_\theta J$ 
14:     $w' \leftarrow \gamma w + (1 - \gamma)w'$ 
15:     $\theta' \leftarrow \gamma \theta + (1 - \gamma)\theta'$ 
16:   end for
17: end for

```

In the critic, the value function $Q_w(s_t, a_t)$ with parameter w and its corresponding loss function are defined as:

$$Q_w(s_t, a_t) = \mathbb{E}[r(s_t, a_t) + \gamma Q_w(s_{t+1}, \pi(s_{t+1}))]$$

$$\mathcal{L}(w) = \frac{1}{N} \sum_i (r_i + \gamma Q'_{w'}(s_{i+1}, \pi'_{\theta'}(s_{i+1})) - Q_w(s_i, a_i))^2.$$

The target networks $Q'_{w'}(s, a)$ and $\pi'_{\theta'}(s)$ are introduced in DDPG to mitigate the problem of instability and divergence when one is directly implementing deep RL agents. In the actor component, DDPG maintains a parametrized actor function $\pi_\theta(s)$, which specifies the current policy by deterministically mapping states to a specific action. The actor is updated as follows:

$$\nabla_\theta J = \frac{1}{N} \sum_i \nabla_a Q_w(s = s_i, a = \pi(s_i)) \nabla_\theta \pi_\theta(s = s_i).$$

Problem Formulation. To estimate resources for a microservice instance, we formulate a sequential decision-making problem which can be solved by the above RL framework. Each microservice instance is deployed in a separate container with a tuple of resource limits $RLT = (RLT_{cpu}, RLT_{mem}, RLT_{llc}, RLT_{io}, RLT_{net})$, since we are considering CPU utilization, memory bandwidth, LLC capacity, disk I/O bandwidth, and network bandwidth as our resource model.³ This limit for each type of resource is predetermined (usually overprovisioned) before the microservices are deployed in the cluster and later controlled by FIRM.

At each time step t , utilization RU_t for each type of resource is retrieved using performance counters as telemetry data in ①. In addition, FIRM's Extractor also collects current

³The resource limit for the CPU utilization of a container is the smaller of \hat{R}_i and the number of threads $\times 100$.

Figure 8: Architecture of actor-critic nets.

latency, request arrival rate, and request type composition (i.e., percentages of each type of request). Based on these measurements, the RL agent calculates the states listed in Table 3 and described below.

- *SLO maintenance ratio* (SM_t) is defined as $SLO_latency / current_latency$ if the microservice instance is determined to be the culprit. If no message arrives, it is assumed that there is no SLO violation ($SM_t = 1$).
- *Workload changes* (WC_t) is defined as the ratio of the arrival rates at the current and previous time steps.
- *Request composition* (RC_t) is defined as a unique value encoded from an array of request percentages by using `numpy.ravel_multi_index()` [74].

For each type of resources i , there is a predefined resource upper limit \hat{R}_i and a lower limit \hat{R}_i (e.g., the CPU time limit cannot be set to 0). The actions available to the RL-agent is to set $RLT_i \in [\hat{R}_i, \hat{R}_i]$. If the amount of resource reaches the total available amount, then a scale-out operation is needed. Similarly, if the resource limit is below the lower bound, a scale-in operation is needed. The CPU resources serve as one exception to the above procedure: it would not improve the performance if the CPU utilization limit were higher than the number of threads created for the service.

The goal of the RL agent is, given a time duration t , to determine an optimal policy π_t that results in as few SLO violations as possible (i.e., $\min_{\pi_t} SM_t$) while keeping the resource utilization/limit as high as possible (i.e., $\max_{\pi_t} RU_t / RLT_t$). Based on both objectives, the reward function is then defined as $r_t = \alpha \cdot SM_t \cdot |\mathcal{R}| + (1 - \alpha) \cdot \sum_i^{|\mathcal{R}|} RU_i / RLT_i$, where \mathcal{R} is the set of resources.

Transfer Learning. Using a tailored RL agent for every microservice instead of using the shared RL agent should improve resource reprovisioning efficiency, as the model would be more sensitive to application characteristics and features. However, such an approach is hard to justify in practice (i.e., for deployment) because of the time required to train such tailored models for user workloads, which might have significant churn. FIRM addresses the problem of rapid model training by using transfer learning in the domain of RL [14, 105, 106], whereby agents for SLO violation mitigation can be trained for either the general case (i.e., any microservices) or the

specialized case (i.e., “transferred” to the behavior of individualized microservices). The pre-trained model used in the specialized case is called the base model or the source model. That approach is possible because prior understanding of a problem structure helps one solve similar problems quickly, with the remaining task being to understand the behavior of updated microservice instances. Related work on base model selection and task similarity can be found in [105, 106], but the base model that FIRM uses for transfer learning is always the RL model learned in the general case because it has been shown in evaluation to be comparable with specialized models. We demonstrate the efficacy of transfer learning in our evaluation described in §4. The RL model that FIRM uses is designed to scale since both the state space and the action space are independent of the size of the application or the cluster. In addition to having the general case RL agent, the FIRM framework also allows for the deployment of specialized per-microservice RL agents.

Implementation Details. We implemented the DDPG training algorithm and the actor-critic networks using PyTorch [83]. The critic net contains two fully connected hidden layers with 40 hidden units, all using ReLU activation function. The first two hidden layers of the actor net are fully connected and both use ReLU as the activation function while the last layer uses Tanh as the activation function. The actor network has 8 inputs and 5 outputs, while the critic network has 23 inputs and 1 output. The actor and critic networks are shown in Fig. 8, and their inputs and outputs are listed in Table 3. We chose that setup because adding more layers and hidden units does not increase performance in our experiments with selected microservice benchmarks; instead, it slows down training speed significantly. Hyperparameters of the RL model are listed in Table 4. We set the time step for training the model to be 1 second, which is sufficient for action execution (see Table 6). The latencies of each RL train-

ing update and inference step are 73 ± 10.9 ms and 1.2 ± 0.4 ms, respectively. The average CPU and memory usage of the Kubernetes pod during the training stage are 210 millicores and 192 Mi, respectively.

3.5 Action Execution

FIRM’s Deployment Module, i.e., ⑤, verifies the actions generated by the RL agent and executes them accordingly. Each action on scaling a specific type of resource is limited by the total amount of the resource available on that physical machine. FIRM assumes that machine resources are unlimited and thus does not have admission control or throttling. If an action leads to oversubscribing of a resource, then it is replaced by a scale-out operation.

- **CPU Actions:** Actions on scaling CPU utilization are executed through modification of `cpu.cfs_period_us` and `cpu.cfs_quota_us` in the `cgroups` CPU subsystem.
- **Memory Actions:** We use Intel MBA [49] and Intel CAT [48] technologies to control the memory bandwidth and LLC capacity of containers, respectively.⁴
- **I/O Actions:** For I/O bandwidth, we use the `blkio` subsystem in `cgroups` to control input/output access to disks.
- **Network Actions:** For network bandwidth, we use the Hierarchical Token Bucket (HTB) [45] queueing discipline in Linux Traffic Control. Egress `qdiscs` can be directly shaped by using HTB. Ingress `qdiscs` are redirected to the virtual device `ifb` interface and then shaped through the application of egress rules.

3.6 Performance Anomaly Injector

We accelerate the training of the machine learning models in FIRM’s Extractor and the RL agent through performance anomaly injections. The injection provides the ground truth data for the SVM model, as the injection targets are controlled and known from the campaign files. It also allows the RL agent to quickly span the space of adverse resource contention behavior (i.e., the exploration-exploitation trade-off

⁴Our evaluation on IBM Power systems (see §4) did not use these actions because of a lack of hardware support. OS support or software partitioning mechanisms [60, 85] can be applied; we leave that to future work.

in RL). That is important, as real-world workloads might not experience all adverse situations within a short training time. We implemented a performance anomaly injector, i.e., ⑥, in which the injection targets, type of anomaly, injection time, duration, patterns, and intensity are configurable. The injector is designed to be bundled into the microservice containers as a file-system layer; the binaries incorporated into the container can then be triggered remotely during the training process. The injection campaigns (i.e., how the injector is configured and used) for the injector will be discussed in §4. The injector comprises seven types of performance anomalies that can cause SLO violations. They are listed in Table 5 and described below.

Workload Variation. We use an HTTP benchmarking tool `wrk2` as the workload generator. It performs multithreaded, multiconnection HTTP request generation to simulate client-microservice interaction. The request arrival rate and distribution can be adjusted to break the predefined SLOs.

Network Delay. We use Linux traffic control (`tc`) to add simulated delay to network packets. Given the mean and standard deviation of the network delay latency, each network packet is delayed following a normal distribution.

CPU Utilization. We implement the CPU stressor based on `iBench` and `stress-ng` to exhaust a specified level of CPU utilization on a set of cores by exercising floating point, integer, bit manipulation and control flows.

LLC Bandwidth & Capacity. We use `iBench` and `pmbw` to inject interference on the Last Level Cache (LLC). For bandwidth, the injector performs streaming accesses in which the size of the accessed data is tuned to the parameters of the LLC. For capacity, it adjusts intensity based on the size and associativity of the LLC to issue random accesses that cover the LLC capacity.

Memory Bandwidth. We use `iBench` and `pmbw` to generate memory bandwidth contention. It performs serial memory accesses (of configurable intensity) to a small fraction of the address space. Accesses occur in a relatively small fraction of memory in order to decouple the effects of contention in memory bandwidth from contention in memory capacity.

I/O Bandwidth. We use `Sysbench` to implement the file I/O workload generator. It first creates test files that are larger than the size of system RAM. Then it adjusts the number of threads, read/write ratio, and sleeping/working ratio to meet a specified level of I/O bandwidth. We also use `Trickle` for limiting the upload/download rate of a specific microservice instance.

Network Bandwidth. We use Linux traffic control (`tc`) to limit egress network bandwidth. For ingress network bandwidth, an intermediate function block (`ifb`) pseudo interface is set up, and inbound traffic is directed through that. In that way, the inbound traffic then becomes schedulable by the egress `qdisc` on the `ifb` interface, so the same rules for egress can be applied directly to ingress.

4 Evaluation

4.1 Experimental Setup

Benchmark Applications. We evaluated FIRM on a set of end-to-end interactive and responsive real-world microservice benchmarks: (i) DeathStarBench [34], consisting of *Social Network*, *Media Service*, and *Hotel Reservation* microservice applications, and (ii) Train-Ticket [128], consisting of the *Train-Ticket Booking Service*. *Social Network* implements a broadcast-style social network with unidirectional follow relationships whereby users can publish, read, and react to social media posts. *Media Service* provides functionalities such as reviewing, rating, renting, and streaming movies. *Hotel Reservation* is an online hotel reservation site for browsing hotel information and making reservations. *Train-Ticket Booking Service* provides typical train-ticket booking functionalities, such as ticket inquiry, reservation, payment, change, and user notification. These benchmarks contain 36, 38, 15, and 41 unique microservices, respectively; cover all workflow patterns (see §3.2); and use various programming languages including Java, Python, Node.js, Go, C/C++, Scala, PHP, and Ruby. All microservices are deployed in separate Docker containers.

System Setup. We validated our design by implementing a prototype of FIRM that used Kubernetes [20] as the underlying container orchestration framework. We deployed the four microservice benchmarks with FIRM separately on a Kubernetes cluster of 15 two-socket physical nodes without specifying any anti-colocation rules. Each server consists of 56–192 CPU cores and RAM that varies from 500 GB to 1000 GB. Nine of the servers use Intel x86 Xeon E5s and E7s processors, while the remaining ones use IBM ppc64 Power8 and Power9 processors. All machines run Ubuntu 18.04.3 LTS with Linux kernel version 4.15.

Load Generation. We drove the services with various open-loop asynchronous workload generators [123] to represent an active production environment [17, 97, 118]. We uniformly generated workloads for every request type across all microservice benchmarks. The parameters for the workload generators were the same as those for DeathStarBench (which we applied to Train-Ticket as well), and varied from predictable constant, diurnal, distributions such as Poisson, to unpredictable loads with spikes in user demand. The workload generators and the microservice benchmark applications were never co-located (i.e., they executed on different nodes in the cluster). To control the variability in our experiments, we disabled all other user workloads on the cluster.

Injection and Comparison Baselines. We used our performance anomaly injector (see §3.6) to inject various types of performance anomalies into containers uniformly at random with configurable injection timing and intensity. Following the common way to study resource interference, our experiments on SLO violation mitigation with anomalies were designed to

be comprehensive by covering the worst-case scenarios, given the random and nondeterministic nature of shared-resource interference in production environments [22, 78]. Unless otherwise specified, (i) the anomaly injection time interval was in an exponential distribution with $\lambda = 0.33s^{-1}$, and (ii) the anomaly type and intensity were selected uniformly at random. We implemented two baseline approaches: (a) the Kubernetes autoscaling mechanism [55] and (b) an AIMD-based method [38, 101] to manage resources for each container. Both approaches are rule-based autoscaling techniques.

4.2 Critical Component Localization

Here, we use the techniques presented in §3.2 and §3.3 to study the effectiveness of FIRM in identifying the microservices that are most likely to cause SLO violations.

Single anomaly localization. We first evaluated how well FIRM localizes the microservice instances that are responsible for SLO violations under different types of single-anomaly injections. For each type of performance anomaly and each type of request, we gradually increased the intensity of injected resource interference and recorded end-to-end latencies. The intensity parameter was chosen uniformly at random between [start-point, end-point], where the start-point is the intensity that starts to trigger SLO violations, and the end-point is the intensity when either the anomaly injector has consumed all possible resources or over 80% of user requests have been dropped or returned time. Fig. 9(a) shows the receiver operating characteristic (ROC) curve of root cause localization. The ROC curve captures the relationship between the false-positive rate (x-axis) and the true-positive rate (y-axis). The closer to the upper-left corner the curve is, the better the performance. We observe that the localization accuracy of FIRM, when subject to different types of anomalies, does not vary significantly. In particular, FIRM’s Extractor module achieved near 100% true-positive rate, when the false-positive rate was between [0.12, 0.16].

Multi-anomaly localization. There is no guarantee that only one resource contention will happen at a time under dynamic datacenter workloads [40, 42, 96, 98] and therefore we also studied the container localization performance under multi-anomaly injections and compared machines with two different processor ISAs (x86 and ppc64). An example of the intensity distributions of all the anomaly types used in this experiment are shown in Fig. 9(c). The experiment was divided into time windows of 10 s, i.e., T_i from Fig. 9(c)). At each time window, we picked the injection intensity of each anomaly type uniformly at random with range [0, 1]. Our observations are reported in Fig. 9(b). The average accuracy for localizing critical components in each application ranged from 92% to 94%. The overall average localization accuracy was 93% across four microservice benchmarks. Overall, we observe that the accuracy of the Extractor did not differ between the two sets of processors.

Figure 10: Learning curve showing total reward during training and SLO mitigation performance.

4.3 RL Training & SLO Violation Mitigation

To understand the convergence behavior of FIRM’s RL agent, we trained three RL models that were subjected to the same sequence of performance anomaly injections (described in §4.1). The three RL models are: (i) a common RL agent for all microservices (one-for-all), (ii) a tailored RL agent for a particular microservice (one-for-each), and (iii) a transfer-learning-based RL agent. RL training proceeds in episodes (iterations). We set the number of time steps in a training episode to be 300 (see Table 4), but for the initial stages, we terminate the RL exploration early so that the agent could reset and try again from the initial state. We did so because the initial policies of the RL agent are unable to mitigate SLO violations. Continuously injecting performance anomalies causes user requests to drop, and thus only a few request traces were generated to feed the agent. As the training progressed, the agent improved its resource estimation policy and could mitigate SLO violations in less time. At that point (around 1000 episodes), we linearly increased the number of time steps to let the RL agent interact with the environment longer before terminating the RL exploration and entering the next iteration.

We trained the abovementioned three RL models on the Train-Ticket benchmark. We studied the generalization of the RL model by evaluating the end-to-end performance of FIRM on the DeathStarBench benchmarks. Thus, we used DeathStarBench as a validation set in our experiments. Fig. 10(a) shows that as the training proceeded, the agent was getting

better at mitigation, and thus the moving average of episode rewards was increasing. The initial steep increase benefits from early termination of episodes and parameter exploration. Transfer-learning-based RL converged even faster (around 2000 iterations⁵) because of parameter sharing. The one-for-all RL required more iterations to converge (around 15000 iterations) and had a slightly lower total reward (6% lower compared with one-for-each RL) during training.

In addition, higher rewards, for which the learning algorithm explicitly optimizes, correlate with improvements in SLO violation mitigation (see Fig. 10(b)). For models trained in every 200 episodes, we saved the checkpoint of parameters in the RL model. Using the parameter, we evaluated the model snapshot by injecting performance anomalies (described in §4.1) continuously for one minute and observed when SLO violations were mitigated. Fig. 10(b) shows that FIRM with either a single-RL agent (one-for-all) or a multi-RL agent (one-for-each) improved with each episode in terms of the SLO violation mitigation time. The starting policy at iteration 0–900 was no better than the Kubernetes autoscaling approach, but after around 2500 iterations, both agents were better than either Kubernetes autoscaling or the AIMD-based method. Upon convergence, FIRM with a single-RL agent achieved a mitigation time of 1.7 s on average, which outperformed the AIMD-based method by up to 9× and Kubernetes autoscaling by up to 30× in terms of the time to mitigate SLO violations.

4.4 End-to-End Performance

Here, we show the end-to-end performance of FIRM and its generalization by further evaluating it on DeathStarBench benchmarks based on the hyperparameter tuned during training with the Train-Ticket benchmark. To understand the 10–30× improvement demonstrated above, we measured the 99th percentile end-to-end latency when the microservices were being managed by the two baseline approaches and by FIRM. Fig. 11(a) shows the cumulative distribution of the end-to-end

⁵ 1000 iterations correspond to roughly 30 minutes with each iteration consisting of 300 time steps.

Figure 11: Performance comparisons (CDFs) of end-to-end latency, requested CPU limit, and the number of dropped requests.

latency. We observed that the AIMD-based method, albeit simple, outperforms the Kubernetes autoscaling approach by $1.7\times$ on average and by $1.6\times$ in the worst case. In contrast, FIRM:

1. Outperformed both baselines by up to $6\times$ and $11\times$, which leads to $9\times$ and $16\times$ fewer SLO violations;
2. Lowered the overall requested CPU limit by 29–62%, as shown in Fig. 11(b), and increased the average cluster-level CPU utilization by up to 33%; and
3. Reduced the number of dropped or timed out user requests by up to $8\times$ as shown in Fig. 11(c).

FIRM can provide these benefits because it detects SLO violations accurately and addresses resource contention before SLO violations can propagate. By interacting with dynamic microservice environments under complicated loads and resource allocation scenarios, FIRM’s RL agent dynamically learns the policy, and hence outperforms heuristics-based approaches.

5 Discussion

Necessity and Challenges of Modeling Low-level Resources. Recall from §2 that modeling of resources at a fine granularity is necessary, as it allows for better performance without overprovisioning. It is difficult to model the dependence between low-level resource requirements and quantifiable performance gain while dealing with uncertain and noisy measurements [76, 120]. FIRM addresses the issue by modeling that dependency in an RL-based feedback loop, which automatically explores the action space to generate optimal policies without human intervention.

Why a Multilevel ML Framework? A model of the states of all microservices that is fed as the input to a single large ML model [81, 126] leads to (i) state-action space explosion issues that grow with the number of microservices, thus increasing the training time; and (ii) dependence between the microservice architecture and the ML-model, which sacrifices the generality. FIRM addresses those problems by incorporating a two-level ML framework. The first level ML model uses SVM to filter the microservice instances responsible for SLO violations, thereby reducing the number of microservices that need to be considered in mitigating SLO violations. That en-

Table 6: Avg. latency for resource management operations.

Operation	Partition (Scale Up/Down)					Container Start	
	CPU	Mem	LLC	I/O	Net	Warm	Cold
Mean (ms)	2.1	42.4	39.8	2.3	12.3	45.7	2050.8
Std Dev (ms)	0.3	11.0	9.2	0.4	1.1	6.9	291.4

ables the second level ML model, the RL agent, to be trained faster and removes dependence on the application architecture. That, in turn, helps avoid RL model reconstruction/retraining.

Lower Bounds on Manageable SLO Violation Duration for FIRM. As shown in Table 6, the operations to scale resources for microservice instances take 2.1–45.7 ms. Thus, that is the minimum duration of latency spikes that any RM approach can handle. For transient SLO violations, which last shorter than the minimum duration, the action generated by FIRM will always miss the mitigation deadline and can potentially harm overall system performance. Worse, it may lead to oscillations between scaling operations. Predicting the spikes before they happen, and proactively taking mitigation actions can be a solution. However, it is a generally-acknowledged difficult problem, as microservices are dynamically evolving, in terms of both load and architectural design, which is subject to our future work.

Limitations. FIRM has several limitations that we plan to address in future work. First, FIRM currently focuses on resource interference caused by real workload demands. However, FIRM lacks the ability to detect application bugs or misconfigurations, which may lead to failures such as memory leak. Allocating more resources to such microservice instances may harm the overall resource efficiency. Other sources of SLO violations, including global resource sharing (e.g., network switches or global file systems) and hardware causes (e.g., power-saving energy management), are also beyond FIRM’s scope. Second, the scalability of FIRM is limited by the maximum scalability of the centralized graph database, and the boundary caused by the network traffic telemetry overhead. (Recall the lower bound on the SLO violation duration.) Third, we plan to implement FIRM’s tracing module based on side-car proxies (i.e., service meshes) [15] that minimizes application instrumentation and has wider support of programming languages.

6 Related Work

SLO violations in cloud applications and microservices are a popular and well-researched topic. We categorize prior work into two buckets: root cause analyzers and autoscalers. Both rely heavily on the collection of tracing and telemetry data.

Tracing and Probing for Microservices. Tracing for large-scale microservices (essentially distributed systems) helps understand the path of a request as it propagates through the components of a distributed system. Tracing requires either application-level instrumentation [18,32,57,95,111–115] or middleware/OS-level instrumentation [10,16,63,109] (e.g., Sieve [109] utilizes a kernel module *sysdig* [103] which provides system calls as an event stream containing tracing information about the monitored process to a user application).

Root Cause Analysis. A large body of work [16,35,50,52,61,63,93,109,121,124] provides promising evidence that data-driven diagnostics help detect performance anomalies and analyze root causes. For example, Sieve [109] leverages Granger causality to correlate performance anomaly data series with particular metrics as potential root causes. Pinpoint [16] runs clustering analysis on Jaccard similarity coefficient to determine the components that are mostly correlated with the failure. Microscope [61] and MicroRCA [124] are both designed to identify abnormal services by constructing service causal graphs that model anomaly propagation and by inferring causes using graph traversal or ranking algorithms [51]. Seer [35] uses deep learning to learn spatial and temporal patterns that translate to SLO violations. However, none of these approaches addresses the dynamic nature of microservice environments (i.e., frequent microservice updates and deployment changes), which require costly model reconstruction or retraining.

Autoscaling Cloud Applications. Current techniques for autoscaling cloud applications can be categorized into four groups [65,84]: (a) rule-based (commonly offered by cloud providers [6,7,37]), (b) time series analysis (regression on resource utilization, performance, and workloads), (c) model-based (e.g., queueing networks), or (d) RL-based. Some approaches combine several techniques. For instance, Auto-pilot [88] combines time series analysis and RL algorithms to scale the number of containers and associated CPU/RAM. Unfortunately, when applied to microservices with large scale and complex dependencies, independent scaling of each microservice instance results in suboptimal solutions (because of critical path intersection and insight 2 in §2), and it is difficult to define sub-SLOs for individual instances. Approaches for autoscaling microservices or distributed dataflows [39,56,81,126,127] make scaling decisions on the number of replicas and/or container size without considering low-level shared-resource interference. ATOM [39] and Microscaler [127] do so by using a combination of queueing network- and heuristic-based approximations. ASFM [81] uses recurrent neural network activity to predict workloads

and translates application performance to resources by using linear regression. Streaming and data-processing scalers like DS2 [56] and MIRAS [126] leverage explicit application-level modeling and apply RL to represent the resource-performance mapping of operators and their dependencies.

Cluster Management. The emergence of cloud computing motivates the prevalence of cloud management platforms that provide services such as monitoring, security, fault tolerance, and performance predictability. Examples include Borg [119], Mesos [43], Tarcil [28], Paragon [25], Quasar [26], Morpheus [54], DeepDive [73], and Q-clouds [71]. In this paper, we do not address the problem of cluster orchestration. FIRM can work in conjunction with those cluster management tools to reduce SLO violations.

7 Conclusion

We propose *FIRM*, an ML-based, fine-grained resource management framework that addresses SLO violations and resource underutilization in microservices. FIRM uses a two-level ML model, one for identifying microservices responsible for SLO violations, and the other for mitigation. The combined ML model reduces SLO violations up to 16× while reducing the overall CPU limit by up to 62%. Overall, FIRM enables fast mitigation of SLOs by using efficient resource provisioning, which benefits both cloud service providers and microservice owners. FIRM is open-sourced at <https://gitlab.engr.illinois.edu/DEPEND/firm.git>.

A Artifact Appendix

A.1 Abstract

FIRM is publicly available at <https://gitlab.engr.illinois.edu/DEPEND/firm.git>. We provide implementations for FIRM’s SVM-based critical component extraction, RL-based SLO violation mitigation, and the performance anomaly injection. In addition, we provide a tracing data set of the four microservice benchmarks deployed on our dedicated Kubernetes cluster of 15 physical nodes. The data set was generated by running open-loop workload generation and performance anomaly injection.

A.2 Artifact Check-list

- **Algorithm:** FIRM’s critical component extraction includes an algorithm to find the weighted longest path (i.e., critical path analysis) from the execution history graph of microservices.
- **Model:** FIRM’s two-level machine learning architecture includes an SVM-based critical component extraction model and an RL-based SLO violation mitigation model. The latter one is designed based on deep deterministic policy gradient (DDPG).
- **Data set:** The artifact includes a tracing data set collected by running four microservice benchmarks [34, 116] in a 15-node Kubernetes cluster. The microservice benchmarks are driven by workload generation and performance anomaly injection.
- **Hardware:** Experiments can run on a cluster of physical nodes with Intel Cache Allocation Technology (CAT) [48] and Intel Memory Bandwidth Allocation (MBA) [49] enabled.
- **Required disk space:** Neo4j [72] requires 10 GB minimum block storage, and the storage size depends on the size of the database.
- **Set-up instructions:** Set-up instructions are available at the `README.md` file in the repository.
- **Public link:** <https://gitlab.engr.illinois.edu/DEPEND/firm.git>
- **Code licenses:** Apache License Version 2.0
- **Data licenses:** CC0 License

A.3 Description

A.3.1 How to Access

The artifact is publicly available at <https://gitlab.engr.illinois.edu/DEPEND/firm.git>.

A.3.2 Hardware Dependencies

Experiments can be run on a cluster of physical nodes with processors that have Intel CAT and MBA technologies enabled. They are required for last-level cache partitioning and memory bandwidth partitioning respectively.

A.3.3 Software Dependencies

Software dependencies are specified at the `README.md` file, which includes Kubernetes, Docker-Compose, and Docker.

A.3.4 Data Sets

The tracing data sets of four microservice benchmarks deployed on our dedicated Kubernetes cluster consisting of 15 heterogeneous nodes are also available. The data sets are not sampled and are from selected types of requests in each benchmark, i.e., compose-posts in the social network application, compose-reviews in the media service application, book-rooms in the hotel reservation application, and reserve-tickets in the train ticket booking application. A detailed description is available at `data/README.md`.

A.4 Installation

Installation instructions are specified at the `README.md` file in the repository.

A.5 Experiment Workflow

Experiments on physical clusters start from deploying the Kubernetes with FIRM. Microservice applications instrumented with the OpenTracing [75] standard are then deployed in the Kubernetes cluster. One can also use the instrumented microservice benchmarks in the repository for experiments. To drive the experiments, workload generators and performance anomaly injectors should be configured and installed accordingly. Then the training of FIRM’s ML models is divided into two phases. In the first phase, the workflow stops at the SLO violation localization. The SVM model is trained with the feature data retrieved from the tracing coordinator and the label data from the performance anomaly injection campaign. In the second phase, the workflow continues and FIRM’s RL agent is trained by interacting with the environment.

A.6 Experiment Customization

FIRM’s multilevel ML modeling provides the flexibility of customizing the algorithms for both SLO violation localization and mitigation. The SVM model can be replaced by other supervised learning models or other heuristics-based methods. The DDPG algorithm used by the RL agent can also be replaced by other RL algorithms. The repository consists of the implementations of other alternative RL models such as proximal policy optimization (PPO) and policy gradient.

In addition, different types of resources in control are also configurable in the RL agent and the performance anomaly injector. That pluggability allows one to add or remove resources, and to change the actions associated with each type of resource.

Abstract

Cluster managers like Kubernetes and OpenStack are notoriously hard to develop, given that they routinely grapple with hard combinatorial optimization problems like load balancing, placement, scheduling, and configuration. Today, cluster manager developers tackle these problems by developing system-specific best effort heuristics, which achieve scalability by significantly sacrificing the cluster manager’s decision quality, feature set, and extensibility over time. This is proving untenable, as solutions for cluster management problems are routinely developed from scratch in the industry to solve largely similar problems across different settings.

We propose DCM, a radically different architecture where developers specify the cluster manager’s behavior declaratively, using SQL queries over cluster state stored in a relational database. From the SQL specification, the DCM compiler synthesizes a program that, at runtime, can be invoked to compute policy-compliant cluster management decisions given the latest cluster state. Under the covers, the generated program efficiently encodes the cluster state as an optimization problem that can be solved using off-the-shelf solvers, freeing developers from having to design ad-hoc heuristics.

We show that DCM significantly lowers the barrier to building scalable and extensible cluster managers. We validate our claim by powering three production-grade systems with it: a Kubernetes scheduler, a virtual machine management solution, and a distributed transactional datastore.

1 Introduction

Today’s data centers are powered by a variety of cluster managers like Kubernetes [10], DRS [47], Openstack [15], and OpenShift [14]. These systems configure large-scale clusters and allocate resources to jobs. Whether juggling containers, virtual machines, micro-services, virtual network appliances, or serverless functions, these systems must enforce numerous cluster management *policies*. Some policies represent *hard constraints*, which must hold in any valid system configuration; e.g., “each container must obtain its minimal requested amount of disk space”. Others are *soft constraints*, which reflect preferences and quality metrics; e.g., “prefer to scatter replicas across as many racks as possible”. A cluster manager therefore solves a challenging combinatorial optimization problem of finding configurations that satisfy hard constraints while minimizing violations of soft constraints.

Despite the complexity of the largely similar algorithmic problems involved, cluster managers in various contexts tackle the configuration problem using custom, system-specific best-effort heuristics—an *approach that often leads to a software engineering dead-end* (§2). As new types of policies are introduced, developers are overwhelmed by having to write code to solve arbitrary combinations of increasingly complex constraints. This is unsurprising given that most cluster management problems involve *NP-hard combinatorial optimization* that cannot be efficiently solved via naive heuristics. Besides the algorithmic complexity, the lack of separation between the cluster state, the constraints, and the constraint-solving algorithm leads to high code complexity and maintainability challenges, and hinders re-use of cluster manager code across different settings (§2). In practice, even at a large software vendor we find policy-level feature additions to cluster managers *take months* to develop.

Our contribution This paper presents *Declarative Cluster Managers* (DCM), a radically different approach to building cluster managers, wherein the implementation to compute policy-compliant configurations is *synthesized* by a compiler from a high-level specification.

Specifically, developers using DCM maintain cluster state in a relational database, and *declaratively* specify the constraints that the cluster manager should enforce using SQL. Given this specification, DCM’s compiler synthesizes a program that, at runtime, can be invoked to pull the latest cluster state from the database and compute a set of policy-compliant changes to make to that state (e.g., compute optimal placement decisions for newly launched virtual machines). The generated program – an *encoder* – encodes the cluster state and constraints into an optimization model that is then solved using a constraint solver.

In doing so, DCM significantly lowers the barrier to building cluster managers that achieve all three of *scalability*, *high decision quality*, and *extensibility* to add new features and policies. In contrast, today’s cluster managers use custom heuristics that heavily sacrifice both decision quality and extensibility to meet scalability goals (§2).

For scalability, our compiler generates implementations that construct highly efficient constraint solver encodings that scale to problem sizes in large clusters (e.g., 53% improved p99 placement latency in a 500 node cluster over the heavily optimized Kubernetes scheduler, §6.1).

For high decision quality, the use of constraint solvers under-the-covers guarantees optimal solutions for the specified problems, with the freedom to relax the solution quality if needed (e.g., $4\times$ better load balancing in a commercial virtual machine resource manager, §6.2).

For extensibility, DCM enforces a strict separation between the a) cluster state, b) the modular and concise representation of constraints in SQL, and c) the solving logic. This makes it easy to add new constraints and non-trivial features (e.g., making a Kubernetes scheduler place both pods and virtual machines in a custom Kubernetes distribution, §6.3).

Several research systems [46, 53, 57, 78, 92] propose to use constraint solvers for cluster management tasks. These systems all involve a significant amount of effort from optimization experts to handcraft an encoder for specific problems with simple, well-defined constraints – let alone encode the full complexity and feature sets of production-grade cluster managers (e.g., Kubernetes has 30 policies for driving initial placement alone). Even simple encoders are challenging to scale to large problem sizes and are not extensible even when they do scale (§8). In fact, for these reasons, *constraint solvers remain rarely used* within production-grade cluster managers in the industry-at-large: none of the open-source cluster managers use solvers and, anecdotally, nor do widely used enterprise offerings in this space.

Instead, with DCM, developers need not handcraft heuristics nor solver encodings to tackle challenging cluster management problems.

Providing a capability like DCM is fraught with challenges. First, cluster managers operate in a variety of modes and timescales: from incrementally placing new workloads at millisecond timescales, to periodically performing global reconfiguration (like load balancing or descheduling); we design a programming model that is flexible enough to accommodate these various use cases within a single system (§3). Second, constraint solvers are not a panacea and are notoriously hard to scale to large problem sizes. DCM’s compiler uses carefully designed optimization passes that bridge the wide chasm between a high-level SQL specification of a cluster management problem and an efficient, low-level representation of an optimization model – doing so leverages the strengths of the constraint solver while avoiding its weaknesses (§4).

Summary of results We report in-depth about our experience building and extending a Kubernetes Scheduler using DCM. We implement existing policies in Kubernetes in under 20 lines of SQL each. On a 500 node Kubernetes cluster on AWS, DCM improves 95th percentile pod placement latencies by up to $2\times$, is $10\times$ more likely to find feasible placements in constrained scenarios, and correctly preempts pods $2\times$ faster than the baseline scheduler. We also report simulation results with up to 10K node clusters and experiment with non-trivial extensions to the scheduler, like placing both pods and VMs within a custom Kubernetes distribution. We also use DCM

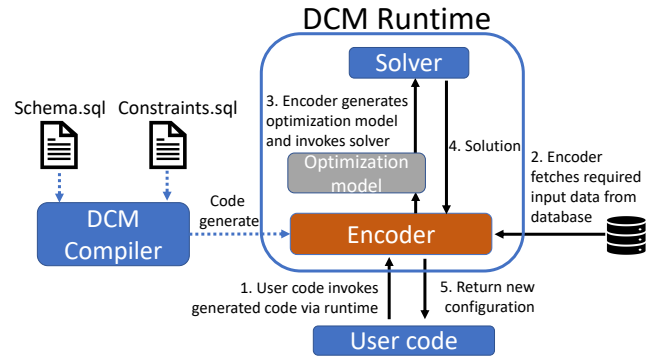

Figure 1: DCM architecture. Dotted lines show the compilation flow. Solid lines show runtime interactions between the DCM runtime, user code and the cluster state DB.

to power a commercial virtual machine management solution where we improved load balancing quality by $4\times$. Lastly, we briefly discuss a distributed transactional datastore where we implemented several features with a few lines of SQL.

2 Motivation

Our motivating concern is that ad-hoc solutions for cluster management problems are regularly built from scratch in the industry, due to the wide range of specialized data-center environments and workloads that organizations have, for which off-the-shelf solutions do not suffice. Even beyond dedicated cluster managers like Kubernetes [10], OpenStack [15], and Nomad [50], similar capabilities are routinely embedded within enterprise-grade distributed systems like databases and storage systems: e.g., for policy-based configuration, data replication, or load-balancing across machines, all of which are combinatorial optimization problems.

Today, developers handcraft heuristics to solve these cluster management problems that incur significant engineering overhead. First, the heuristics are hard to scale to clusters with hundreds to thousands of nodes; they often require purpose-built and inflexible pre-computing and caching optimizations to remain tractable [40, 95]. Even then, the heuristics are challenging to get right as developers have to account for arbitrary combinations of constraints. Second, the heuristics sacrifice decision quality to scale (e.g., load balancing quality), which is not surprising given that combinatorial optimization problems cannot be solved efficiently via naive heuristics. Third, they lead to complex code that makes it hard to extend and evolve the cluster manager over time; it is not uncommon for policy-level feature additions to take multiple months’ worth of effort to deliver.

We illustrate the above challenges using Kubernetes as a representative example.

Kubernetes example The Kubernetes Scheduler is responsible for assigning groups of containers, called *pods*, to cluster

Policy	Description
H1-4	Avoid nodes with resource overload, unavailability or errors
H5	Resource capacity constraints: pods scheduled on a node must not exceed node's CPU, memory, and disk capacity
H6	Ensure network ports on host machine requested by pod are available
H7	Respect requests by a pod for specific nodes
H8	If pod is already assigned to a node, do not reassign
H9	Ensure pod is in the same zone as its requested volumes
H10-11	If a node has a 'taint' label, ensure pods on that node are configured to tolerate those taints
H12-13	Node affinity/anti-affinity: pods are affine/anti-affine to nodes according to configured labels
H14	Inter-pod affinity/anti-affinity: pods are affine/anti-affine to each other according to configured labels
H15	Pods of the same service must be in the same failure-domain
H16-20	Volume constraints specific to GCE, AWS, Azure.
S1	Spread pods from the same group across nodes
S2-5	Load balance pods according to CPU/Memory load on nodes
S6	Prefer nodes that have matching labels
S7	Inter-pod affinity/anti-affinity by labels
S8	Prefer to not exceed node resource limits
S9	Prefer nodes where container images are already available

Figure 2: Policies from the baseline Kubernetes scheduler, showing both hard (H) constraints and soft (S) constraints.

nodes (physical or virtual machines). Each pod has a number of user-supplied attributes describing its resource demand (CPU, memory, storage, and custom resources) and placement preferences (the pod's affinity or anti-affinity to other pods or nodes). These attributes represent hard constraints that must be satisfied for the pod to be placed on a node (H1–H20 in Table 2). Kubernetes also supports soft versions of placement constraints, with a violation cost assigned to each constraint (S1–S9 in Table 2). Like other task-by-task schedulers [15, 94, 95], the Kubernetes default scheduler uses a greedy, best-effort heuristic to place one task (pod) at a time, drawn from a queue. For each pod, the scheduler tries to find feasible nodes according to the hard constraints, score them according to the soft constraints, and pick the best-scored node. Feasibility and scoring are parallelized for speed.

Decision quality: not guaranteed to find feasible, let alone optimal, placements Pod scheduling is a variant of the multidimensional bin packing problem [18, 21], which is NP-hard and cannot, in the general case, be solved efficiently with greedy algorithms. This is especially the case when the scheduling problem is *tight* due to workload consolidation and users increasingly relying on affinity constraints for performance and availability.

To remain performant, the Kubernetes scheduler only considers a random subset of nodes when scheduling a pod, which might miss feasible nodes [93]. Furthermore, the scheduler may commit to placing a pod and deny feasible choices from pods that are already pending in the scheduler's queue (a common weakness among task-by-task schedulers [40]).

Feature limitations: best-effort scheduling does not support global reconfiguration Many scenarios require the scheduler to simultaneously reconfigure arbitrary groups of pods

Figure 3: An anti-affinity constraint prevents Pod 1 and Pod 2 from being in the same zone, pod 1 is affine to node 1, and pod 2 has a lower priority than pod 1. Placing pod 1 on node 1 requires evicting pod 2 on node 2.

and nodes. For instance, Figure 3 shows a scenario where a high priority pod (pod 1) can only be placed on node 1, but to do so, the scheduler has to preempt a lower priority pod on node 2. Computing this rearrangement requires simultaneous reasoning about resource and affinity constraints spanning multiple pods and nodes, which cannot be achieved in the current architecture. Thus, although such global reconfiguration is in high demand among users, it is unsupported in Kubernetes [60, 64].

Extensibility: Best-effort scheduling leads to complex code Similar to Borg [40, 95], Kubernetes needs careful engineering to keep scheduling tractable at scale. Several policies like inter-pod affinity (Table 2-H14) and service affinities (Table 2-H15) are compute intensive because they require reasoning over groups of pods. These policies are kept tractable using carefully designed caching and pre-computing optimizations that are fragile in the face of evolving requirements. For example, it is hard to extend inter-pod affinity policies to specify the number of pods per node [58, 59, 61–63], and there are discussions among developers to restrict these policies to make the code efficient [60]. For similar reasons, there are discussions among developers to remove the service affinity policy due to accumulating technical debt around its pre-computing optimizations [69]. Such complexity accumulates to make entire classes of policies requested by users difficult to implement in the scheduler [60, 64, 73].

Beyond policy-level extensions, the tight coupling between the cluster state representation in the scheduler's data-structures and the scheduling logic makes it near impossible to introduce changes to the underlying abstractions (e.g., extending the scheduler to also place tasks other than pods, like virtual machines [71]) without a complete rewrite [66].

3 Declarative Programming with DCM

Our position is that developers should specify cluster management policies using a high-level declarative language, and let an automated tool like DCM generate the logic that efficiently computes policy-compliant decisions. Architecturally,

it allows the behavior of the cluster manager to be described and evolved independently of the implementation details.

We use SQL as the declarative language for specifying policies for multiple reasons. First, it allows us to consistently describe and manipulate both the cluster state and the constraints on that state. Second, it is a battle-tested and widely known language, which aids adoption. Third, it is sufficiently expressive that we have not felt the need for designing yet another DSL (§4.1.1).

We now demonstrate DCM’s capabilities and programming model with a simplified guide to building a Kubernetes scheduler with it. Our scheduler operates as a drop-in replacement for the default scheduler (§2), supporting all of its capabilities and adding new ones.

The workflow in a DCM-powered scheduler consists of three steps (Figure 1). First, the scheduler stores the cluster state in an SQL database based on an SQL schema designed by the developer. Second, the developer extends the schema with scheduling constraints, also written in SQL. The compiler generates an encoder based on the constraints and schema. Third, at runtime, the scheduler invokes the generated encoder via the DCM library as new pods are added to the system. The generated encoder pulls the required cluster state from the database, produces and solves an optimization model that is parameterized by that state, and outputs the required scheduling decisions.

Cluster state database Kubernetes stores all state (of nodes and pods) in an etcd [36] cluster. The default scheduler maintains a cache of relevant parts of this state locally using in-memory data structures. In DCM, we replace this cache with an in-memory embedded SQL database (H2 [4]) and specify an SQL schema (tables and views) to represent the cluster state. Currently, the schema uses 18 tables and 12 views to describe the set of pods, nodes, volumes, container images, pod labels, node labels, and other cluster state. The developer annotates some columns in the schema as *decision variables*, i.e., variables to be assigned automatically by DCM. For example, a placement decision of a pod on a node is represented by the table in Figure 4 with decision variables (*node_name*) annotated as `@variable_columns` and other *input variables* supplied by the database.

Constraints Next, the developer specifies constraints against the cluster state as a collection of SQL views. DCM supports both hard and soft constraints, encompassing *all* the cluster management *policies* that the system must enforce.

Hard constraints are specified as SQL views with the annotation `@hard_constraint`. For example, consider the constraint in Figure 5, which states that pod *P* can be scheduled on node *N* if *N* has not been marked unschedulable by the operator, is not under resource pressure, and reports as being ready to accept new pods. We implement this by declaring a view, `constraint_node_predicates`, with a `check` clause

```
-- @variable_columns (node_name)
create table pods_to_assign
(
    pod_name varchar(100) not null primary key,
    status varchar(10) not null,
    namespace varchar(100) not null,
    node_name varchar(100),
    ... -- more columns
);
```

Figure 4: A table describing pods waiting to be scheduled. The `@variable_columns` annotation indicates that the `node_name` column should be treated as a set of decision variables. Other columns are input variables, whose values are supplied by the database.

```
create view valid_nodes as
select node_name from node_info
where unschedulable = false and memory_pressure = false
    and out_of_disk = false and disk_pressure = false
    and pid_pressure = false and network_unavailable = false
    and ready = true;

-- @hard_constraint
create view constraint_node_predicates as
select * from pods_to_assign
check (node_name in (select node_name from valid_nodes));
```

Figure 5: A hard constraint to ensure pods that are pending placement are never assigned to nodes that are marked unschedulable by the operator, are under resource pressure, or do not self-report as being ready to accept new pod requests.

that asserts that all pods must be assigned to nodes from the `valid_nodes` view computed in the database.

Soft constraints are also specified as SQL views with annotation `@soft_constraint` and contain a single record storing an integer value. DCM ensures that the computed solution *maximizes* the sum of all soft constraints. For example, consider CPU utilization load balancing policy across nodes in a cluster (Figure 6). We first write a convenience view (`spare_capacity_per_node`) that computes the spare CPU capacity after pod placement. We then describe a soft constraint view (`constraint_load_balance_cpu`) on the minimum spare capacity in the cluster. This forces DCM to compute solutions that maximize the minimum CPU utilization of nodes, thereby spreading pods across the cluster.

Compiler and runtime The DCM interface for programmers is shown in (Figure 8). The first step is invoking the DCM compiler using the schema and constraints as input. This generates a program (e.g., a Java program – §4.1.2) that pulls the required tables from the database, constructs an optimization model, and solves it using a constraint solver. The generated program is compiled using the relevant toolchain (e.g., `javac` – §4.1.2) and loaded into memory. The compiler returns a `Model` object that wraps the loaded program.

When pods are added to the system, the scheduler updates the relevant tables (like `pods_to_assign`). The scheduler

```

create view spare_capacity_per_node as
select (node.available_cpu_capacity
       - sum(pods_to_assign.cpu_request)) as cpu_spare
from node join pods_to_assign
on pods_to_assign.node_name = node.name
group by node.name;

-- @soft_constraint
create view constraint_load_balance_cpu as
select min(cpu_spare) from spare_capacity_per_node;

```

Figure 6: A soft constraint that maximizes the minimum spare CPU capacity in the cluster for load balancing.

```

-- @hard_constraint
create view constraint_node_affinity as
select * from pods_to_assign
check (pods_to_assign.has_requested_node_affinity = false
or pods_to_assign.node_name in
(select node_name
 from candidate_nodes_for_pods
 where pods_to_assign.pod_name =
       candidate_nodes_for_pods.pod_name));

```

Figure 7: A membership constraint to describe node affinity (the pod must only be assigned to nodes it is affine to, as computed in another view `candidate_nodes_for_pods`)

then invokes `model.solve()` (Figure 8) to find an optimal placement for these pods by assigning values to `pods_to_assign.node_name` according to the specified constraints. The call returns a copy of the `pods_to_assign` table with the `node_name` column reflecting the computed optimal placement. The scheduler then uses this data to issue placement commands for each pod via the Kubernetes scheduling API (the same API used by the default scheduler).

Note that DCM treats the state database as the input to every call to `model.solve()`. It does not (and cannot) assume the cluster configuration changes based on the computed solution, because the caller may choose not to apply the solution, there may be errors during reconfiguration or numerous other external events. This is in sharp contrast to prior art that uses handcrafted solver encodings for specific cluster management tasks, where all the cluster state is duplicated within the solver’s memory [40, 53, 57, 92] (§8).

Supporting diverse cluster management tasks and tunable search scopes DCM enables developers to arbitrarily tune the search space of a problem by controlling the data within the input tables and views. For example, consider the set of pods in the `pods_to_assign` table. For fast incremental initial placement, we can populate the table with a fixed size batch of newly created pods only, and compute placement decisions for the entire batch at a time. For a pod preemption model (a kind of global reconfiguration), we populate the same table with previously placed pods and specify additional constraints that assign a bounded number of pods to a “null node” (representing preemption). Similarly, the

Operation	Description
<code>model = DCM.compile(schema)</code>	Invoke DCM compiler to synthesize an encoder from the SQL schema and constraints
<code>model.connect(db)</code>	Establish JDBC connection to the state DB
<code>model.solve(timeout)</code>	Solve constraints and return a set of tables

Figure 8: DCM interface

scheduler may dynamically sample the subset of nodes to be considered for placement in a given iteration.

In this manner, DCM allows developers to easily instantiate models that solve different sub-problems within a cluster manager. We implemented three models in our Kubernetes scheduler: one for fast initial placement, a slower timescale pre-emption model, and an admin-triggered tool for de-scheduling [68] which can be used to recover capacity from highly utilized nodes by terminating pods.

4 DCM Design

As we show in §3, DCM enables programmers to specify cluster management policies using a high-level declarative language familiar to most programmers, and code generate the logic that efficiently computes policy-compliant decisions. However, we have to address several key challenges to realize such a capability.

First, given the amount of expertise that is typically required to handcraft efficient optimization models and encodings, it is non-trivial to bridge the gap between the SQL representation of a problem and the generation of a corresponding encoder that interacts with solvers via their respective low-level APIs. We discuss how the DCM compiler synthesizes efficient encoders in §4.1.

Second, given that programmers need systematic ways to test and debug the policies that they write, we describe how we leverage a common solver capability of finding *unsatisfiable cores* to aid in debugging (§4.2).

4.1 DCM compiler

The DCM compiler generates an encoder that produces optimization models according to the database schema and the constraints specified by the developer.

4.1.1 Syntax and expressiveness

The compiler accepts input SQL tables with variable columns of type integer, boolean, and string (floating point is supported if the backend solver supports it, like Gecode [2]). The compiler supports a subset of the SQL query language for constraint specification, including most commonly used constructs (inner join, anti-join, group by, aggregate queries, sub-queries, correlated sub-queries as seen in Figures 5 and 6, ARRAY columns), arithmetic and logical expressions (standard Boolean operators, linear arithmetic, comparisons over integers, and equality checks over strings), standard SQL aggre-

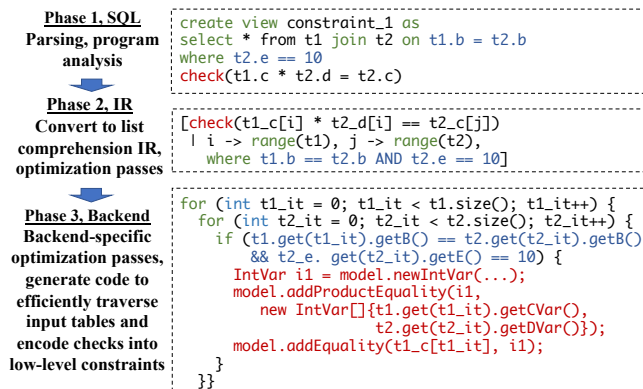

Figure 9: System compiler workflow, showing a simple SQL query, its representation in the IR as a list comprehension, and a simplified version of the corresponding generated code by our or-tools backend.

gate functions (sum, min, max, count), and additional aggregates that help in constraint modeling (e.g., the `all_different` aggregate which enforces pair-wise inequalities among a set of variables (§4.1.3)). The compiler is extensible, allowing user-defined aggregates to be added with a few lines of code. We also take special care in dealing with SQL nulls, depending on the backend.

Both SQL tables and views computed in the database can be used as input relations for hard and soft constraints (Figures 5 and 6). This allows developers to efficiently construct inputs for a DCM model by exploiting the full extent of the SQL syntax and capabilities supported by the database. For example, the database can efficiently process joins to compute the required inputs for a model.

Using this syntax, we were able to compactly specify all hard and soft constraints encountered in our case studies, including resource capacity, affinity, anti-affinity, and load balancing constraints along various axes. SQL is significantly more concise than the low-level interfaces supported by solvers, with an SQL view compiling down to many low-level constraints.

4.1.2 Compiler workflow

Figure 9 shows the compiler’s workflow in generating an encoder from the high-level SQL. The example shown is simplified Java generated by our OR-tools backend.

Phase 1, SQL Internally, the SQL parser first extracts all table and view definitions from the supplied database schema, and produces syntax trees for all the hard and soft constraints. It then performs a series of passes over the queries to infer whether parts of the constraints can be evaluated in the database. For example, 1) simple sub-queries that do not involve variables are better evaluated in the database rather than

in the generated encoder or the solver, 2) some backends (like Minizinc) cannot efficiently compute the groups produced by an SQL group by because they cannot represent tuples – we can compute these groups in the database as well.

Phase 2, Intermediate representation Next, the compiler converts the query to an intermediate representation (IR) based on list-comprehension syntax [37]. In Figure 9, the SQL query is simplified in the IR as nested for loops and a filtering condition (instead of tables and predicates *across* various clauses of the SQL query). In general, the list comprehension syntax makes it easy to apply standard query optimization algorithms (like unnesting subqueries). It has been well-studied in the database community [23, 24, 37, 45, 55, 56].

Phase 3, Backend The compiler backend generates a program that produces an optimization model by interacting with the interfaces exposed by specific solver toolkits, e.g., setting up linear inequalities for an ILP solver. The IR facilitates support for multiple backends, allowing systems to benefit from different types of solvers. Regardless of the backend, the generated encoders prepare optimization models where variables and constraints are parameterized by the content of the cluster state database. At runtime, the encoder binds these variables to values extracted from the database before dispatching the optimization model to the solver.

OR-tools CP-SAT: Our ‘flagship’ backend generates encoders for the Google OR-tools CP-SAT solver [3]. It generates Java code to pull cluster state from the database at runtime and iterate over the state to encode constraints efficiently using the CP-SAT solver APIs. It translates joins into hash-table based accesses when feasible (e.g., equality-based joins using primary keys, unique columns specified via the use of SQL `distinct`), or into nested for loops otherwise (Figure 9). We generate several utility classes to aid the encoding (like type-safe tuple classes to refer to records from different tables). The backend performs common sub-expression elimination within the generated code fragments (e.g., when computing a complex expression within `if` or `for` blocks).

MiniZinc: Our initial DCM prototype interacted with the MiniZinc toolkit [80], which exposes a high-level constraint modeling language, and thereby supports integration with a variety of solvers. However, despite our best efforts, we could not scale it to clusters larger than 50-100 nodes due to the limited control we have over Minizinc encodings. However, we use it to interface with tools for debugging models §4.2.

4.1.3 Generating scalable encodings

We now discuss details of our backend for the Google OR-tools CP-SAT solver [3]. A CP-solver encoding specifies different constraints over input variables. For example, to encode a simple intermediate expression $a = (b < 10)$, we need to introduce a constraint $b < 10$, and link the truth value

<pre>// Unfixed arity sum([1 i -> range(t1) where t1.c1[i] = 10])</pre>	<pre>// Fixed arity sum([(t1.c1[i] = 10) i -> range(t1)])</pre>
-----------------------------------------------------------------------------------	---------------------------------------------------------------------------

Figure 10: Two equivalent IR expressions to compute the sum over a subset of a variable column (`t1.c1`).

Figure 11: Effect of different optimizations in our or-tools backend on the runtime of a benchmark model (Figure 6). Not shown are option types, where runtimes exceed a minute.

of that constraint to a by introducing two more constraints $a \rightarrow (b < 10)$ and $\neg a \rightarrow (b \geq 10)$ (a process called *full reification*). At a high-level, CP-solvers find feasible solutions via a combination of search and *propagation*: at each node of the search tree, the solver iteratively changes the domain of a variable, causing constraints linked to that variable to update other variables they are linked to, and so on until a fixed point is reached. Therefore, every additional constraint and auxiliary variable we introduce impacts solver performance.

In short, like any constraint solver, the CP-SAT solver’s performance is highly sensitive to the encoding (two equivalent encodings often result in vastly different solver runtimes). Hence, we employ various optimizations in DCM compiler based on structural information extracted from the SQL program and IR, to generate encoders that produce efficient models.

The key takeaway is that a literal translation of SQL queries into an encoding is *not scalable*, we therefore have to find smarter encodings. We do so by using re-writing rules that mimic what an optimization expert would otherwise handcraft into an encoder. We describe the impact of these rules using a benchmark that is bottlenecked by the `spare_capacity_per_node` view in Figure 6.

Re-writing to use fixed arity Consider the two expressions in our IR shown in Figure 10. Both these statements correspond to a high-level SQL operation to compute the number of elements in a variable column with values equal to 10. In the first case, we cannot statically determine the size of the filtered list in our encoder, because the values of the variables (and therefore the arity of the list to sum) are not *fixed yet*. The general way to encode such an expression is to use *option types* [75], where a variable might be ‘absent’. However, several auxiliary variables and constraints need to be introduced to encode such an expression using option types. This problem is exacerbated by the join in `spare_capacity_per_node`

view, and where we do not know the arity of the produced *table*. An option type encoding for 1000 nodes and 50 pods for this view produces roughly *200K auxiliary variables and 400K constraints*, and makes our benchmark take more than a minute to complete.

Another approach is to avoid option types, and instead, compute a *sum of predicates* (Figure 10), which achieves the same result because the predicates evaluate to 0 or 1. Doing so keeps the number of auxiliary variables proportional to the number of predicates to evaluate, and brings the benchmark’s runtime from minutes to 6.2s (Figure 11). The same encoding in MiniZinc takes 24s to solve, representing the inefficiencies introduced by high-level modeling frameworks.

Re-writing to use scalar products Re-writing to use fixed arity introduces $O(|pods| * |nodes|)$ reified boolean variables and constraints to encode whether a particular combination of rows from both tables appear in the final result set, which is then used to compute the sums required to specify hard constraints (like capacity bounds) and soft constraints (like load balancing requirements). Rather than naively iterate row by row to create several auxiliary variables that are summed to compute the load, our compiler infers that we are effectively computing a scalar product between two vectors, which can be expressed more efficiently with fewer auxiliary variables, which improves runtime by 20% (Figure 11). However, this does not still eliminate the $O(|pods| * |nodes|)$ boolean variables and is still prohibitively slow for large clusters.

Re-writing to use global constraints Global constraints are constraints over *groups* of variables for which solvers implement specialized and efficient propagator algorithms that dramatically reduce the search space of the problem. Encoding a problem using global constraints is key to scaling optimization models to large problem sizes because they typically avoid the need to generate too many auxiliary variables and constraints that burden the solver.

The join discussed above can be further optimized by using global constraints. Observe that we compute the load so that we can specify a capacity constraint on it (the load should be less than a constant). We can therefore detect this possibility and generate code to encode the join and the capacity constraint together as an *interval packing problem*: given a set of interval variables $I_1, I_2 \dots I_n$ of lengths $S_1, S_2 \dots S_n$, with demands $D_1, D_2 \dots D_n$ pack them onto a timeline represented by the intervals, such that the total demand at any given instant of time is less than a capacity C (here, each interval variable represents a cell on the variable column, whereas the timeline represents rows on the column being joined to). This allows us to use a well known global constraint, *cumulative*. Crucially, this non-trivial encoding only introduces $O(|pods| + |nodes|)$ auxiliary variables (instead of $O(|pods| * |nodes|)$), that allows us to scale that SQL query to large cluster sizes, leading to a 96% reduction in runtime over the previous optimization in our benchmark (Figure 11).

Another example of a global constraint is the `all_different` constraint that ensures a group of variables take different values (a common pattern in various anti-affinity policies). We also leverage membership global constraints where possible to encode the SQL `IN` operator.

As we mention in §4.1.1, we provide a suite of custom aggregate functions that developers may use in their models: these functions take advantage of the above global constraints under the covers.

Full- versus half-reification We already mentioned full reification (e.g., $a \leftrightarrow (b < 10)$). In several cases, it is both correct and more efficient to only introduce *half reified* constraints of the form $a \rightarrow (b < 10)$, because it introduces only half the constraints. Doing so is particularly effective to encode soft constraints for placement preferences in the following form: $b \rightarrow (var = A \vee var = B \dots)$ (the solver tries to maximize b , which coaxes var to draw from a pool of preferred values). Again, using structural information from the IR, we can statically determine when we only need half-reified expressions. In our benchmark, this further yields a 43% improvement in performance (Figure 11).

4.2 Testing and debugging models

An important concern in using DCM is understanding *why* the cluster manager failed in finding a valid solution (e.g., a pod placement decision). Did the cluster run out of resources? Did the user mistakenly specify mutually contradicting constraints, e.g., affinity and anti-affinity over the same group of pods? Or was there a bug in the developer’s constraint specification? DCM improves debuggability by taking advantage of a common solver capability: identifying *unsatisfiable cores* [72]. An unsatisfiable core is a minimal subset of model constraints and inputs that suffices to make the overall problem unsatisfiable (e.g., a single input variable that cannot simultaneously satisfy two contradicting constraints).

We leverage this capability by providing a translation layer that extracts an unsatisfiable core from the solver and identifies corresponding SQL constraints and records in the tables that lead to a contradiction. We found this invaluable when debugging complex scenarios involving affinity and anti-affinity constraints. For example, a common pattern we experienced when adding and testing new affinity policies was that the new policy *tightened the problem*, and therefore triggered a violation of some other constraint in the system (such as resource capacity constraints). Rather than suspect a bug in our specification of the new policy, the unsatisfiable core rightfully points us to the contradiction between the capacity constraint and the affinity requirement.

4.3 Implementation

Our DCM implementation is 6.1K LoC in Java for the library and an additional 2.7K LoC for tests. Of this, the OR-tools

and MiniZinc backends take up roughly 2K and 1K LOC, respectively. We use the JOOQ library [8] to conveniently interface with different SQL databases. All our experiments use the OR-Tools backend, given that MiniZinc simply does not scale to large cluster sizes. Our implementation is available as an open-source project [17].

5 Experience using DCM

We now describe the three case studies we applied DCM to, and qualitatively assess the development effort to do so. The case studies are presented in the reverse chronological order in which we applied DCM; we found that the overall design and SQL-based programming model were stable throughout the process, even though we did harden DCM along the way. DCM’s ability to compute unsatisfiable cores (§4.2) were invaluable in all these efforts.

Kubernetes scheduler This use case is both our most recent and most comprehensive application of DCM. Like the Kubernetes default scheduler, our scheduler also runs as a pod within Kubernetes and uses the same REST APIs and hooks to consume and actuate upon the Kubernetes’ cluster state. Our scheduler consumes the same cluster metadata (information about nodes, pods, labels, and other input information) as the default scheduler to make scheduling decisions. Our scheduler uses an embedded in-memory SQL database (H2) as a cache of the cluster state, which is used to serve inputs to `model.solve()` (§3). It computes scheduling decisions for a batch of pods at a time.

Our scheduler is implemented in ~1.5K lines of Java code, with 1.8K lines of code for tests. Roughly half the scheduler’s code is boilerplate to subscribe to Kubernetes’ state and store it in an in-memory SQL database (H2 [4]). All the tables, views, and policies amount to ~550 lines of SQL. We implemented all policies in Table 2, except H16-20, as they were specific to volume management on GCE, AWS, and Azure.

Of the 550 lines of SQL, roughly two-thirds describe input tables and views that are executed entirely in the database, whereas the rest were used to describe constraints. We were able to handle heavy and complex joins in the database (e.g. computing groups of pods that repel each other due to inter pod anti-affinity). Support for SQL ARRAY columns was critical to bounding the size of inputs to DCM.

We spent the vast majority of our effort trying to understand Kubernetes’ semantics. Particularly, Kubernetes’ *match expression* logic, a DSL used to filter objects based on *labels*, was widely used within several policies supported by the scheduler (taints, tolerations, node/pod (anti) affinities, etc.). Its semantics differed arbitrarily across policies (multiple affinity requirements for nodes were treated as a logical OR, whereas the equivalent for pods was treated as a logical AND [11, 12, 90]). Once we understood the semantics, translating the requirements into SQL was straightforward: it took

a few hours per policy to design and code (i) the schema and constraints, (ii) the logic to write Kubernetes' state into the database, and (iii) the required unit and integration tests.

Most of the time and effort in performance engineering the scheduler went into ensuring that the views executed by the database used the right indexes. While these views could all be expressed concisely in SQL (<20 LOC), the most concise SQL was sometimes not the most performant. For example, an OR in some join predicates caused H2 to not use indexes and revert to scans. We had to split these queries into two and UNION the results together to meet our performance needs [6]. In another case, we used triggers to simulate materialized views [5], to incrementally update resource reservation counters on each node as pods were placed (rather than compute these statistics each time using a join during pod placement).

VM load balancing utility We built a tool for suggesting VM migrations in a commercial data-center management solution. The system has a resource manager that makes VM placement decisions at various timescales. At slower timescales (e.g., every five minutes), the system introspects the state of the entire cluster and identifies a series of VM migrations to make, with the objective of reducing the overall standard deviation of node resource utilization (along multiple resource dimensions). We apply DCM to improve load balancing in §6.2. The load balancing and capacity constraints we introduced were structurally similar to the ones we specified in our Kubernetes use case.

Distributed transactional datastore We implemented a management plane from scratch for a distributed transactional data platform used in a commercial product. Nodes in the system assume one or more 'roles', such as being a serial-izer (as in Megastore [20], Omid [25]), a backup serial-izer, data nodes (that host data shards and replicas), or management nodes. We apply DCM to the management node logic, supporting several requirements provided by engineers. We replicated existing failure handling policies and added new capabilities like distributing roles across nodes, and rack-aware placement of data shards. All policies used <10 lines of SQL, as the system was simple compared to our other use cases.

6 Evaluation

The premise of our work is that DCM is a viable approach to building cluster managers that can (Q1) scale, (Q2) compute high-quality decisions, and (Q3) be easily extended. We answer these questions as follows:

Q1: For scalability: we study the Kubernetes scheduler we built using DCM and evaluate it on a 500 node cluster on Amazon EC2 using workload characteristics from Azure [77]. We use simulations to study scalability up to 10K nodes.

Q2: For decision quality: we study scenarios involving our

Kubernetes scheduler as well as the load balancer we built for the commercial virtual machine management platform.

Q3: For extensibility: we were able to express all cluster management policies in our three use cases using SQL. In addition, we discuss a non-trivial extension we built for our Kubernetes scheduler using DCM.

6.1 Q1: Scalability evaluation

We set up a 500 node Kubernetes cluster running on AWS.¹ We use t3.2xlarge instances (8 vCPUs, 32 GB RAM) for the Kubernetes master node and t3.small instances for worker nodes, given that in these experiments, the focus is on the schedulers running on the master node.

Workload We use a publicly available trace from Azure [77], that describes a month's worth of workload information for two million VMs in 2019². It gives us a trace of replicas that were launched, with their corresponding CPU and memory reservations. We replay 14 hours worth of traces and speed them up by 20× to achieve arrival rates seen in Borg clusters at Google [95] (median/peak of 100/500 pod creations per second). We then replay three variants of the workload, each with a fraction F of replica groups configured with inter-pod anti affinities within the group; $F = 100\%$ is a Kubernetes best practice for availability reasons [1], and users even run automated tools like kube-score [9] to prevent pods from being deployed without anti-affinities configured. The anti-affinity policy is a challenging constraint because it requires reasoning across groups of pods and uses several handcrafted performance optimizations in the Kubernetes default scheduler (§2). In addition, the workload also exercises most hard and soft constraints shown in Table 2.

End-to-end latency results Figure 12 shows the end-to-end latency for bringing up pods on the AWS cluster, for different values of F . The latency is measured from when the workload generator issues a pod creation command to when the pod first changes its status to Running. The default scheduler's end-to-end latency degrades as more pods are configured with anti-affinity constraints, with its 95th percentile latency degrading from 4.14s at $F = 0$ to 12.45s at $F = 100$. On the other hand, DCM incurs a higher latency than the default scheduler at $F = 0$ due to the added latency in its critical path from the database and solver (p95 of 5.33s). However, DCM's end-to-end latency characteristics are insensitive to the fraction of pods configured with constraints (ECDFs for DCM are identical across all F , Figure 12). At $F = 100$, DCM improves the 95th percentile end-to-end latency over the default scheduler by 53% (5.9s vs 12.45s).

¹Kubernetes requires careful configuration and tuning to scale beyond 500 nodes. Even at this size, we had to overcome several issues around networking, kubelet failures, and API throttling to stabilize the cluster [27,70]. We defer to simulations to stress DCM beyond 500 nodes.

²Our results are qualitatively similar when using the 2017 trace.

Figure 12: End-to-end pod creation latency on a 500 node AWS cluster, using workload characteristics from the Azure 2019 trace [77] (trace sped up by $20\times$). F is the percentage of pods configured with anti-affinity constraints.

Note that our scheduler evaluates all nodes per scheduling decision, whereas the default scheduler only evaluates half the nodes in the cluster for scalability reasons (the number of nodes sampled depends on the total cluster size [93]). When we configured the Kubernetes scheduler to evaluate all nodes, its average latency **doubled** over DCM. Furthermore, the default scheduler incurs a significant amount of engineering complexity in the form of caching and pre-computing optimizations for the sole purpose of speeding up anti-affinity predicates. In contrast, DCM only required a simple SQL specification of the same constraints using 4 SQL views.

Per-pod scheduling latency Figure 13 shows the per-pod scheduling latency for DCM versus the baseline. For DCM, we measure the amortized latency over a batch of pods (maximum batch size of 50 pods), which includes the time taken for querying data from the database, creating a model based on the input data, running the solver, and returning results to the calling code. For Kubernetes, to be conservative, we only measure the time taken to execute all predicates and priorities for a pod once that pod is pulled from the scheduler’s work queue. DCM’s scheduling latency is competitive with the baseline at $F = 0$: DCM experiences a median (p95) pod scheduling latency of 3.11ms (14.46ms) versus 2.55ms (6.19ms) for the default scheduler. However, DCM’s per-pod scheduling latency is similar across all tested values of F , whereas the default scheduler’s latency increases significantly with F . At $F = 100$, DCM improves average latency by $1.6\times$ (5.13ms versus 8.04ms). The p95 latency for DCM to schedule a batch of pods stayed under 250ms in all cases. DCM’s ability to schedule a batch of pods at a time is what leads to larger absolute savings in end-to-end latency (Figure 12) versus the per-pod scheduling latency.

Figure 13: Per-pod scheduling latency at $20\times$ trace speed up (log-scale). Despite our use of a full-featured SQL database and a constraint solver in the critical path, DCM improves per-pod scheduling latency at higher values of F .

#Nodes	N=500	N=5K	N=10K
#Variables	5524	45983	91010

Table 1: Average number of model variables before the OR-tools presolve phase.

DCM scheduling latency breakdown Figure 14 breaks down the scheduling latency in DCM by its various phases: the time to fetch inputs from the database (database), to encode the inputs into an optimization model (modelCreation), and to run the solver (orToolsTotal). We also plot the time spent within the or-tools *presolve* phase (presolve), where the solver applies several complex optimizations to simplify the supplied encoding. dcmSolve subsumes modelCreation and orToolsTotal. The sum of dcmSolve and database equals the total scheduling latency.

At a cluster size of 500 and $F = 0$, fetching the required inputs from the database is inexpensive (mean 0.58ms per-pod) compared to invoking the solver (2.8ms per-pod) (Figure 14). DCM’s generated code is highly efficient at model creation, contributing an average latency of 450 μ s per-pod. Similarly, presolve times are also low, staying around 2.5ms for 95% of cases. As we increase F , the database’s latency gradually increases (mean 0.88ms) due to the views computed in the database for finding groups of pods that repel each other, but the increase remains small relative to the overall latency. Importantly, solver latency is largely unaffected by the more complex constraints.

Effect of increased cluster sizes To study the impact of cluster size and scale on DCM, we turn to simulations. This is straightforward to do in our scheduler implementation: we simply mock the Kubernetes API, mimicking cluster sizes of 500, 5000, and 10000 nodes. It allows us to replay the same Azure traces against an identical DCM scheduler, but subject the system to a variety of scales and loads. To stress DCM,

Figure 14: Scheduling latency breakdown between time spent fetching input data from the database (database), our generated code creating an optimization model (modelCreation), the ‘pre-solve’ phase in or-tools (presolve), and the total solve time in or-tools (orToolsTotal).

we speed up the trace by $100\times$ and set $F = 100\%$.

We observe the scheduling latency breakdowns again in Figure 15. At 5K node scale, the per-pod scheduling latency is under 13ms (and 690ms per batch) 99% of the time. At 10K node scale, however, the p99 per-pod scheduling latency is 30ms and 1.6s per batch, which is high. To dig deeper, note that the relative contributions of the database and the constraint solver to the overall latency widen with increasing cluster size. As we mentioned before, our scheduler considers **all** nodes when placing pods, which shifts more of the burden to the solver as cluster sizes increase. We note that the presolve phase is the primary contributor to the overall latency. This is because of an API limitation in OR-tools around creating interval variables (§4.1.3).

In particular, there are steps within the solver’s presolve pass that we could perform efficiently during model creation, but the OR-tools API is not rich enough to permit. This forces our generated code to construct models with redundant variables (proportional to the number of nodes) that the solver internally tidies up into a more compact encoding (specifically, when encoding our capacity constraints). Table 1 shows the average model sizes generated by our encoder – the presolve phase trims these models down by an order of magnitude. The added cost of repeatedly performing this step on every scheduling decision is acceptable at cluster sizes of up to 5000 nodes ($< 1\text{ms}$ at $N = 500$ and $< 8\text{ms}$ at $N = 5K$, Figure 15). We are reaching out to the or-tools developers to see if the API can be augmented to avoid this cost.

6.2 Q2: Decision quality evaluation

Kubernetes packing efficiency for higher consolidation

We now evaluate a common enterprise data center scenario,

Figure 15: Simulation: scheduling latency breakdown at different cluster sizes. Per-pod scheduling latencies stay under 30ms even at 10K node scale. At 5K and 10K node scales, the presolve phase of the solver dominates.

where cluster sizes are typically small (under fifty nodes), but consolidation rates need to be kept high. In such scenarios, it is imperative for schedulers to find feasible and dense packings. We use a common pod affinity/anti-affinity pattern seen in production workloads [67], where nginx [13] servers in a web application need to be co-located on the same machine as an in-memory Redis cache [84]. We create 30 such applications, each with 10 pods, with pod CPU and memory requirements following an exponential distribution. We generate 35 such workloads, which leads to a different arrival sequence of resource demands per experiment.

We find that DCM places 100% of pods in 29 out of 35 experiments, and in the worst case, places at least 93% of pods across all runs. In contrast, the baseline scheduler packs all pods only in 3 out of 35 instances. This highlights DCM’s effectiveness at placing *groups* of pods. Instead, the baseline myopically places one pod at a time, causing it to make decisions that prevent future pods from being placed. Note, if the pods appear well spaced apart in time, or DCM uses smaller batching sizes, its performance will approach that of the baseline.

Kubernetes placement convergence time for preemptions

We now test DCM’s effectiveness in making global reconfiguration decisions. We replay a workload used to test Kubernetes’ preemption logic [65], that creates 3 sets of pods with different priorities. The resource demands are set to accommodate *only* the highest priority pods on the cluster, and the lower priority pods should either not be placed or be preempted. The default scheduler invokes its preemption logic on a pod-by-pod basis and uses a set of heuristics to determine when to retry pods it could not place (e.g according to a backoff policy, and retrying when nodes report status

Figure 16: VM load balancing use case: memory load distribution across hosts with and without DCM.

Figure 17: Load distribution before and after using DCM. The X-axis represents hosts, the Y-axis represents the memory utilization per host. Hosts have different capacities, and boxes in each bar represent VM sizes, scaled to the host's capacity.

updates). In doing so, the baseline scheduler takes almost 100 seconds to place all high priority pods. Instead, DCM initially places low priority pods and systematically replaces them with higher priority pods in phases as new pod requests arrive, by invoking its preemption model to look at the state of all nodes (§3). In doing so, the scheduler converges to placing all high priority pods in just under 50 seconds, twice as fast as the baseline scheduler.

VM load balancing quality evaluation We test our VM load balancing tool (§4.3) using a trace from a bug report submitted by a customer. This production cluster has 16 hosts with heterogeneous CPU and memory capacities, and 524 VMs with a range of CPU and memory sizes. The baseline system's heuristic-based load balancer could not identify VM migrations to improve the load distribution of the cluster, which led to the bug report. Figure 16 (baseline) shows the memory utilization of every host as per the trace (we only

show memory utilization because there were no CPU resource reservations by the VMs). Figure 17 shows the VM sizes, scaled according to each host's capacity.

With DCM, we specified the necessary hard constraints (capacity and affinity requirements) and a soft constraint that minimizes the load difference between the most and least utilized node. We then asked the tool to identify twenty VM migrations, which significantly improved the load distribution (Figure 16). With the baseline, the most loaded and least loaded nodes were at 85% and 39% utilization, whereas DCM found moves to spread utilization between 52% and 67%. DCM took a second to make its decision, whereas the baseline heuristic takes roughly five seconds.

6.3 Q3: Extensibility

We validate our hypothesis that DCM enables building *extensible* cluster managers. §5 discusses the ease with which we added policies to all three case studies, taking only a few hours per policy to design, implement, and test. In this section, we focus on a more challenging test of extensibility by discussing a non-trivial modification to our Kubernetes scheduler.

Our case study involves a custom Kubernetes distribution where the Kubernetes control plane deploys both pods and VMs (the nodes run both pods and VMs). A challenge here is that the default scheduler's implementation is intricately coupled to the Kubernetes data-structures that represent pods (for example, every predicate and priority implementation expects a pod object). VMs, as a Kubernetes object that can also be placed on nodes, is beyond the Kubernetes scheduler's resource management model. This scheduling inflexibility is a known pain point in the Kubernetes community [66]. The only option today is for the Kubernetes scheduler to coordinate with another scheduler that can deploy VMs. This is, therefore, a good case study to validate DCM's extensibility goal.

We extend the Kubernetes scheduler we built using DCM to jointly reason about pods and VMs. From a placement standpoint, pods and VMs are simply *tasks* that need to be assigned to nodes, and only represent a slightly different set of constraints (for example, VMs can be migrated but pods cannot, because most of the Kubernetes ecosystem does not assume pods can be migrated).

Most of our effort went into the Java code and boilerplate required to subscribe to the Kubernetes API to learn about new VM creations (specifically, a Kubernetes Custom Resource [85]) and writing these obtained objects into our database. On the SQL side, however, these capabilities only involved minimal changes to the DCM-based Kubernetes scheduler: we added four constraints in total and made a cosmetic change to the SQL schema for readability (replacing instances of `pods_to_assign` with `tasks_to_assign`). The minimal effort here was possible only because DCM enforces a declarative approach to specifying the cluster state and the constraints on it.

7 Discussion and future work opportunities

Solver Scalability Cluster sizes in enterprises are typically modest and well within Kubernetes’ scalability targets. This is a scale that we are confident DCM excels at (§6.1).

Pushing DCM to hyperscale needs, however, is an interesting area for future work. While the techniques described in §4.1.3 are required for scalability, there will inevitably be a point where it is better to *partition a problem*, something that DCM cannot perform automatically for the developer. For example, in a cluster with 100K nodes, it is likely overkill to evaluate every single node in the cluster for an optimal placement decision. Instead, the 100K nodes can be partitioned into 10 or 20 groups that are somewhat similar in composition (analogous to Borg cells [95] or sub-clusters in Hydra [29]). A DCM model (or a custom heuristic) could pick a group to place a workload in, followed by another model that places the workload within the selected group (the second model, in this case, would use as input, a table/view with only nodes from the selected group). Another approach would be to evaluate multiple such groups in parallel and pick the result with the best objective function. We explicitly designed DCM’s programming model for such flexibility.

There are several further opportunities for improving performance that we have not yet explored. For example, solvers can be configured to return good-enough (as opposed to optimal) results, when the current best solution is within a certain bound, to improve performance.

Database scalability In-memory, incremental view maintenance is key to scaling the database side. For now, we had to simulate materialized views using triggers in H2 (§5). H2’s simplicity also meant that its optimizer did not perform several natural query transformations that more mature engines do, which required us to write more complex SQL than was required (§5). This is additional work that would not be required with an incremental engine. We are currently integrating DCM with the Differential Datalog (ddlog) engine [86].

Expressiveness of SQL So far, across all use cases (§5), we are yet to find a policy we could not express using this model. We are confident of SQL’s expressive power for several reasons.

SQL shines at concisely cross-referencing state across different tables, a capability that has been useful in a broad range of contexts (e.g., SQCK [48]). We simply leverage that strength of SQL to both represent complex cluster state and concisely specify constraints spanning several tables; the actual check clauses and objective function expressions within these constraint queries are typically comparable to what is shown in Figures 5, 6, and 7.

The more complex SQL we have written are for views executed in the database, which become inputs for the generated code (§4.1.1, §5). There is a lot of expressive power here;

for example, developers may use a database’s user-defined functions for specific input transformations if required, but we have not yet needed to do so (even for handling Kubernetes’s match expression DSL, §5).

At the same time, DCM does require expressing policies in terms of *intent*, rather than the exact steps of an algorithm. We anticipate that this will pose a learning curve for some developers.

Generality of optimizations DCM cannot prevent users from writing SQL that generates inefficient code, a common challenge for declarative programming models (SQL databases provide tools for users to inspect query plans for this reason, like the EXPLAIN query). For now, our compiler warns developers when it emits inefficient code (e.g., cross products across tables without indexes), and exposes detailed diagnostics to understand runtime performance (e.g., Figure 14 and Table 1).

We provide a suite of aggregate functions (like `all_different`) that we encourage developers to use because it leads to clearer policies and makes it straightforward to generate efficient code that uses global constraints (§4.1.1). So far, we only added functions if they were useful across several use cases. It is similar with rewrite rules: we only add ones that have broad utility (e.g., we find the fixed-arity rule applying to most uses of SUM/COUNT).

8 Related work

Use of solvers for resource management A large body of work has used solvers for resource management, including CP solvers [51] to pack and migrate VMs; flow network solvers [40, 53] and MIPs [38, 42–44, 91, 92] for job scheduling, and ILPs for traffic engineering [30]. These systems use handcrafted encoders written by optimization experts for specific problems. Even in the industry, we find that the few organizations that use solvers for such tasks typically have dedicated teams of optimization experts. In contrast, we generate scalable encoders from a declarative specification written using SQL. Our programming model significantly lowers the barrier to powering systems with constraint solvers – developers express policies directly against the cluster state, without having to translate them into the low-level mathematical formalisms of solver encodings.

We sketched out the initial idea for DCM in a workshop paper [89]. In this paper, we extend this preliminary work with a detailed design and implementation, and a comprehensive evaluation using three case studies.

Quincy [53] and Firmament [40] use flow network solvers for scheduling, which yield quick solve times (sub-second, even for topologies with thousands of nodes), but cannot model many classes of constraints, including inter-task constraints like affinity/anti-affinity [41]. Compared to DCM,

they involve a high degree of modeling complexity: developers need to map scheduling constraints to flow network constructs like vertices, arcs, and flows, which make it challenging to apply to general systems like Kubernetes. For example, the experimental Poseidon Kubernetes scheduler [88] is based on Firmament, but the developers found constraints like inter-pod affinity both hard to implement [87] and scale [16] (up to $3\times$ slower than the default scheduler *evaluating all nodes*).

Wrasse [82] uses a DSL based on a balls and bins abstraction to specify resource allocation constraints and a GPU-based solver to find solutions. Its low-level modeling language makes it hard to express complex constraints; it supports resource capacity constraints, but not other important classes of constraints like affinities and load balancing.

Some production systems use meta-heuristic search for resource management. VMware DRS [47] uses a greedy hill-climbing search, and Service Fabric [76] uses simulated annealing. Several systems employ a variety of heuristics for resource management [26, 28, 29, 32, 33, 39, 54]. These works neither use declarative programming techniques nor benefit from solver-based optimal solutions to enforce policies.

Simplifying systems using relational languages Several works have used the strengths of relational languages to simplify systems programming. Boom Analytics [19] uses the Overlog language to build an HDFS/Hadoop clone with comparable performance. P2 [74] also uses Overlog, but to declaratively specify peer-to-peer overlays. Ravel [96] is an SDN controller that uses SQL databases to abstract and manipulate network state. SQCK [48] simplifies filesystem checker implementations by using declarative queries to validate complex filesystem images instead of writing low-level C code. DCM builds on the above ideas and not only uses a relational database to store and manipulate cluster state but also code generates logic to search for new configurations based on constraints written in SQL.

Network configuration synthesis Network configuration synthesis from high-level specification [22, 34, 35] for BGP and OSPF is orthogonal to dynamic cluster management with constraint specification by DCM. ConfigAssure [79] and Alloy [78] use model finding to identify configurations that satisfy a specification given by an administrator (or detect errors in existing ones). Alloy uses a DSL for specification, whereas ConfigAssure uses the Prolog language. DCM, on the other hand, works on top of standard SQL databases and is capable of supporting optimization goals as well. The tested use cases for ConfigAssure and Alloy are well within scope for DCM.

DSLs for infrastructure automation Many configuration management tools use custom DSLs. Hewson et al. [52] propose an object-oriented DSL to specify a configuration for a data-center, which is enforced by a constraint solver. PoDIM [31] does not use a solver but uses an SQL-like DSL to

specify requirements for a configuration. Configuration management tools like Puppet [81], Ansible [83], Terraform [49], and Helm [7] all use custom DSLs to configure and deploy infrastructure repeatably. These systems target a different use case than DCM: they are not designed to solve optimization tasks within a dynamic distributed system at short timescales but instead target infrastructure deployment, which runs at much slower timescales.

9 Conclusion

Cluster management logic is notoriously hard to develop, given that they routinely involve combinatorial optimization tasks that cannot be efficiently solved using best-effort heuristics. With DCM, we propose building cluster managers where the implementation to compute policy-compliant decisions is synthesized by a compiler from a high-level specification. DCM significantly lowers the barrier to building cluster managers that scale, compute high-quality decisions, and are easy to evolve with new features over time. We validate our thesis by applying DCM to three production use cases: we built a Kubernetes scheduler that is faster and more flexible than the heavily optimized default scheduler, improved load balancing quality in a virtual machine management solution, and easily added features to a distributed transactional data store.

Microsoft Azure and Microsoft Research

Abstract

We describe the design and implementation of Protean – the Microsoft Azure service responsible for allocating Virtual Machines (VMs) to millions of servers around the globe. A single instance of Protean serves an entire availability zone (10-100k machines), facilitating seamless failover and scale-out to customers. The design has proven robust, enabling a substantial expansion of VM offerings and features with minimal changes to the core infrastructure. In particular, Protean preserves a clear separation between *policy* and *mechanisms*. From a policy perspective, a flexible rule-based Allocation Agent (AA) allows Protean to efficiently address multiple constraints and performance criteria, and adapt to different conditions. On the system side, a multi-layer caching mechanism expedites the allocation process, achieving turnaround times of few milliseconds. A slight compromise on allocation quality enables multiple AAs to run concurrently on the same inventory, resulting in increased throughput with negligible conflict rate. Our results from both simulations and production demonstrate that Protean achieves high throughput and utilization (85-90% on a key utilization metric), while satisfying user-specific requirements. We also demonstrate how Protean is adapted to handle capacity crunch conditions, by zooming in on spikes caused by COVID-19.

1 Introduction

The Cloud has revolutionized the way computing resources are consumed. Providers allow end-users easy access to secure, elastic and state-of-the-art resources, while applying efficient management techniques in order to optimize their return on investment. In particular, resource *virtualization* is used to maximize the utilization of the underlying hardware. Consequently, one of the most crucial components in the cloud stack is the Virtual Machine (VM) *allocator*, which assigns VM requests to the physical hardware. Indeed, sub-optimal placement decisions can result in fragmentation (and in turn, unnecessary over-provisioning of physical resources), performance impact and service delays, and even rejection of incoming requests and customer impacting allocation failures.

In this paper, we describe in detail the VM allocator for Azure – one of the leading cloud service providers in the

world. Azure provides and manages infrastructure for SAAS, PAAS and IAAS workloads. Its fleet consists of millions of physical machines spanning more than a hundred countries. Azure offers more than 500 different VM types tailored to a vast array of application requirements reflected in the virtual resource specification of each VM. VMs serve as the primary units of (multi-dimensional) resource allocation, and the means through which customers are able to leverage the rich array of computing services offered by Azure; see §2 for an analysis of Azure workloads.

The rapid growth of Azure both in terms of its feature set and massive geo-scale mandated that its core VM allocator be designed in a *robust* manner. First, the allocator logic must be *extensible* – to efficiently facilitate new features, constraints and offerings over time. Second, close attention was given to *flexibility* – in our context, the ability to configure the allocator to different working conditions and scenarios. Third, the core algorithms had to be highly *optimized*: Given Azure’s scale, even 1% in fragmentation reduction can lead to cost savings in the order of \$100M per year.

From an operational perspective, the total demand in Azure is in the order of millions of VMs per day. Such large scale leads to a complicated system challenge – satisfying this high request rate while maintaining fast response times and high resource utilization. In principle, an allocation service needs to control a sufficiently large inventory of underlying capacity (or domain), so that new requests assigned to the domain can be accommodated, and customers within the domain can scale-out (namely, get additional VMs upon request). However, controlling a large inventory inherently impacts the *latency* of an allocation. To avoid unacceptable delays, a design must include efficient mechanisms for determining the physical placement of the VM. In addition, to achieve adequate *throughput*, the system architecture may incorporate multiple allocation processes [43]. Parallelizing the allocation logic introduces new challenges, such as sustaining high resource utilization while keeping conflicts to a minimum.

While some of these challenges have been discussed in similar contexts [17, 38, 43, 48], most previous works either do not provide full details on the design and implementation, or resort to simulation studies (or small size implementations) without providing comprehensive evaluation from a global-scale production deployment. In this paper, we describe the

*O.H, L.M, I.M and A.P contributed equally to this paper.

design, implementation and evaluation of Protean, the core allocation service governing all VM placement and resource allocation in Azure. An instance of Protean operates at the granularity of an availability zone (typically 10-100 thousands of machines), which allows for high acceptance rates and seamless scale-out capabilities.

To achieve the desired robustness while controlling such large inventories, Protean’s design provides a clear separation between *policy* and system *mechanisms*. Policy is expressed through a flexible rule-based Allocation Agent (AA), which addresses multiple constraints and performance criteria for allocating VMs. AA’s logic is inherently *extensible*; rules can be refined and added with minimal disruption to the system. Crucially, the rule-based semantics foster *explainability*, and force clear and conscious trade-offs between the numerous metrics and optimization criteria. On the system side, a multi-layer caching infrastructure keeps track of previous allocation outcomes through efficient update mechanisms, resulting in an order of magnitude reduction in turnaround time compared to a system without this caching layer. Notably, the memory footprint of the cache is manageable (e.g., around 1GB for 10k machines), and scales sublinearly with the number of machines. By slightly compromising on the allocation quality, we enable multiple AAs to run concurrently, resulting in increased throughput with negligible conflict rate. The number of AAs, as well as key rule parameters, are tuned at a slow time-scale using production data.

Our results from real production measurements and a variety of simulations demonstrate that Protean achieves low latency (typically 20ms per VM), while satisfying user-specific requirements and values of 85-90% for a key utilization metric. Importantly, Protean can easily satisfy the peak demands observed in production (up to 2000 requests per second), and may sustain much higher throughput if needed, as demonstrated in simulations §6.2. In addition, we show how Protean adapts to different conditions, by focusing on recent capacity challenges during the COVID-19 crisis. In particular, we discuss how Protean seamlessly allowed critical control-plane policy changes that were required to support the sudden increase in demand. In summary, our main contributions are:

- We provide a detailed analysis of the workload and inventory of Azure. Our analysis (§2) reveals key characteristics, which motivate Protean’s design.
- We design a flexible rule-based allocation agent (§3), which allows operators to incorporate new logic and *explain* allocation outcomes to customers.
- To our knowledge, we provide the first detailed account of the allocation logic and key implementation details of a core VM allocator in a leading public cloud provider. Our implementation includes a novel caching infrastructure tailored to expedite the VM allocation process (§5).
- We evaluate Protean using extensive measurements from geo-scale production, and augment these evaluations with

Figure 1: Azure Cloud Topology: Regions consist of availability zones, each of which comprise several datacenters that house racks of servers.

low and high fidelity simulators where necessary (§6). Our results show that Protean achieves low latency and high throughput while sustaining high utilization under diverse operating conditions.

2 Background and Motivation

2.1 Azure – A Global-Scale Public Cloud

The inventory. The global Azure inventory is arranged in a hierarchy of *regions* and *availability zones*, exposed directly to the customer. A region can have up to three zones, each in turn consisting of one or more *datacenters* (see Fig. 1). Each datacenter is divided into *clusters* and *racks*. There is no strict upper bound on the size of a zone or a datacenter. Our larger zones have over a hundred thousand machines, spread over more than a hundred clusters, with each cluster having around a thousand machines. The smaller zones have only around a thousand machines.

The inventory within a zone is typically heterogeneous, with machines ranging across multiple hardware generations and Stock Keeping Unit (SKU) configurations, including special servers for HPC, GPUs, etc. Table 1 summarizes the distribution of the different hardware generations for one of the zones. In this case, the bulk of the inventory belongs to two generations, while the others represent a generation that is being decommissioned, and a new generation that is in early-stage deployment. In contrast to zone heterogeneity, a cluster is a *homogeneous* set of machines (e.g., identical SKUs and configurations) spanning multiple racks; each cluster supports most VM types. In §3.2 we discuss how we exploit cluster homogeneity to improve request latency.

The workload. As mentioned, Azure exposes numerous options for renting VMs. Users specify their requirements in

Gen	Cores Per Machine	# Machines
3	10	7295
4	24	34208
5	40	18016
6	48	2064

Table 1: Distribution of hardware generations for a zone. Individual similar SKUs are aggregated within each generation.

the form of an *service request*. Each zone may accommodate millions of requests per day. A service request consists of one or more *VM requests*, grouped as a *tenant*. The tenant service model expresses the relationships and constraints imposed on these VMs. An allocation succeeds only if all the requested VMs within a tenant are successfully allocated (gang-scheduling). A service model specifies the type of each VM (which in turn determines the core, memory, disk, or network requirements for the VM), fault domain requirements, and priority of the service. By default, the tenant VMs can be spread across the entire zone. However, a tenant can request all its VMs to be co-located within specific inventory boundaries such as a datacenter or a row, or conversely, can forbid too many of its VMs from being placed on the same machine or rack. A tenant can even specify that no VMs from any other tenant be placed on the machine that hosts its VMs.

A customer can resize (scale in/out) or delete an existing tenant, or create a new tenant. Platform initiated requests due to unexpected machine failures, planned maintenance, or decommissioning of machines can lead to reallocation of some or all tenant VMs. Note that higher-level services can stitch together multiple tenants to expose alternative grouping semantics to customers, such as jobs with tasks that can be incrementally scheduled, or auto-scaled group of identical VMs (e.g., virtual machine scale sets [4]). These services are responsible for breaking the groups of VMs into tenants before sending service requests to Protean.

Protean – a zone allocation service. Azure operates an allocation service for each zone, termed Protean.¹ Requests are assigned to each zone either directly by the customer, or by a higher-level service. The main role of Protean is to find a physical placement (machine) for each VM in an allocation request, subject to explicit requirements and constraints specified in the underlying service model, as well as other internal operational considerations. To cope with large request loads, Protean employs multiple *Allocation Agents (AAs)*, which run in parallel. Similar to [43], each agent is aware of the entire inventory and can choose any eligible machine from the inventory to host a VM. The authoritative state of the inventory is maintained in a persistent store. Each AA maintains its own view of the inventory, which is updated periodically and in response to allocation or inventory related events.

¹Protean means able to change frequently, versatile.

2.2 Workload Analysis

We next analyze some properties of our workload, with a focus on characteristics that have influenced Protean’s design.

Demand is heterogeneous. Our zones exhibit workloads which are fairly diverse in nature. We observe a large number of different VM types, see Table 2. The distribution is generally nonuniform – some VM types may account for up to 50% of the workload, while others are rare. To give more insight into the challenge pertaining to packing the VMs, Table 3 shows the distribution of CPU requirements, measured in number of cores. We observe that most VMs require a small number of cores, but some require half or even an entire server.

VM Type	Zone1 (%)	Zone2 (%)
A	4.6	0.1
B	3.5	3.6
C	6.5	12.9
D	0.7	8.4
E	1.9	3.7
F	3.2	4.4
G	0.6	3.1
H	0.8	2.2
I	2.4	7.4
J	23.7	31.6
K	21.3	2.1
L	3.5	0.4
M	0.0	2.2

Table 2: Distribution of VM types for selected zones. VM types having < 2% in both zones are excluded. We avoid using real VM type names to preserve confidentiality.

Subsequent requests are similar. While our system supports many VM types, we observe that subsequent requests are fairly “similar”. For example, Fig. 2 shows the *reuse distance*, which for each request of VM type v , measures the number of unique VM types requested since the last time that v was requested. We observe that more than 80% of requests have zero reuse distance, while the majority has distance less than five. This behavior can be attributed to a combination of factors, such as large service requests that ask for the same type of VM, and having a relatively small set of popular VM

VM Cores	Zone1 (%)	Zone2 (%)
1	17.1	27.0
2	37.4	52.4
4	32.0	10.5
8	8.9	4.5
≥ 10	4.3	2.6
≥ 20	0.3	3.1

Table 3: Distribution of VM resources for selected zones.

Figure 2: Reuse distance for VM requests in a zone for an entire day.

Figure 3: Number of VM requests for a zone. Counted over each hour, and averaged over day-of-week for five weeks (shaded area is standard deviation).

Figure 4: Requests per second for a zone on a single day, with max over 5 min intervals.

types (see Table 2). This “locality” property plays a key role in our design for the allocation agent.

VM lifetime varies substantially. We observe that most VM lifetimes are short, in the order of several minutes. However, some VMs can stay in the system “forever” – for weeks and months. See Figure 5 for empirical lifetime distributions across representative zones.

Figure 5: Zone-based VM lifetime distributions. The data represents VMs that were alive during a ten-day period in March 2020. The lifetime of VMs that remained alive when the data was collected (June 2020) may be longer than reported.

Demand has spikes and diurnal pattern. Fig. 3 shows the request count over a week in one of our busier zones, averaged over day-of-week for 5 weeks. We observe some diurnal patterns, e.g., typically less usage overnight. Demand can also have large spikes throughout the day, as seen in Fig. 4. Note that the demand reaches above 2k requests per second. This behavior forces us to provision for the peak by employing multiple AAs for each Protean instance (see §4). At the same time, we exploit the off-peak periods to better prepare the AAs for future allocations (see §5.2).

Tenants sizes are typically small, but can be huge. Our analysis on two large zones indicates that 94% of requests are for a single VM. 99% of requests are for five or less VMs. We also observe a few requests for hundreds of VMs; naturally, such requests would pose additional challenges (e.g., spreading the VMs across different fault domains).

2.3 Takeaways

Scale and uncertainty. Our analysis demonstrates that the incoming demand is highly variable. Because Protean latency and throughput requirements cannot be compromised, our design has to account for extreme demand conditions. Furthermore, Protean has to accommodate small and large regions, which requires flexible configurations (for example, the number of AAs).

Opportunity for caching. We have provided evidence that subsequent requests are similar over time. This motivates the “caching” of placement evaluation logic, and reuse across multiple requests – this idea is central in our design and facilitates scaling to large zones and regions.

The packing challenge. Our workload is highly diverse – numerous VM types of different sizes, high variability in lifetimes (which are unknown in advance). This poses a substantial challenge in adequately “packing” the VM in physical servers. Algorithmically, a simplified version of our packing problem already maps to dynamic bin packing [11], which is an NP-hard problem in the offline setting (i.e., assuming all VM arrivals are known), with quite bad competitive ratio in the online setting [6]. In our practical setting, we have other elements that make the problem even more challenging (multiple priorities, fault domain requirements, etc.). Supplementary to this paper, we release a new trace that can be used by the research community to design and test different packing algorithms [3].

3 Rule-Based Allocation Agent

In this section, we describe the main design principles of Protean’s allocation agent.

3.1 Metrics and Constraints

Metrics. Protean targets several metrics related to both performance and quality of the allocation. The key metrics are:

- **Latency.** A single VM allocation should be satisfied promptly, typically within 20 ms.
- **Throughput.** Protean should be able to handle peak demands without delaying or throttling requests.

- *Acceptance.* Protean should minimize the rejection rate. A rejection occurs when a VM request cannot be satisfied.

We note that latency is not important in isolation (although might become excessive for large tenants). Nonetheless, lower latency facilitates higher throughput. Intuitively, when latency is lower, requests can be processed by fewer AAs, resulting in fewer conflicts and likely higher throughput. Furthermore, lower latency decreases the probability that an individual AA drifts from the true state of the inventory, which improves allocation quality. Naturally, the three metrics above depend on the size of the inventory. Latency and throughput become more challenging with larger inventories, but accepting requests becomes easier. We are also interested in efficient usage of compute resources; we will formally define utilization-related metrics in §6.

Requirements and constraints.

Addressing multiple considerations. First and foremost, Protean must make *correct* assignments; for example, an allocation cannot violate the capacity of a machine. Additionally, the request may include certain constraints that the allocation must satisfy. For example, certain VMs may require a specific type of hardware (e.g., GPUs). Furthermore, a service request for multiple VMs may require that the VMs are spread across multiple fault domains (typically across different racks).

Tenant experience. Protean should avoid allocations on machines that are not in a “ready” state; have not been updated with the latest host environment; or are likely to fail in the near future. If a machine fails, then its hosted VMs *must* be allocated to other machines. Low priority VMs are used by Azure offerings, such as Batch [1] and Spot Virtual Machines [2]. While these VMs are allowed to be preempted, Protean still aims to minimize their eviction rates.

Adaptability. Protean must allow for an easy configuration of allocation logic, and adjust for different conditions.

Extensibility and interpretability. Protean should be easily and safely extendable, in order to enable engineers to incorporate new allocation logic. Accordingly, the allocation logic should allow for incremental changes, and performing A/B testing in production. Moreover, Protean should enable operators to interpret the allocation decisions (e.g., “why did the request fail?”, “why was machine x chosen for VM request v ?”); explaining allocation outcomes is regarded as one of the main challenges in large-scale cloud scheduling [46].

3.2 Allocation Rules

As discussed above, Protean has to account for multiple considerations simultaneously. First, strict placement constraints need to be enforced (e.g., a VM has to be allocated to a specific hardware type); other placement considerations can be viewed as “preferred”, for example, it is better to place the VM on a server that is perceived as healthy, has certain disk configuration, etc. On top of that, Protean targets “high-quality”

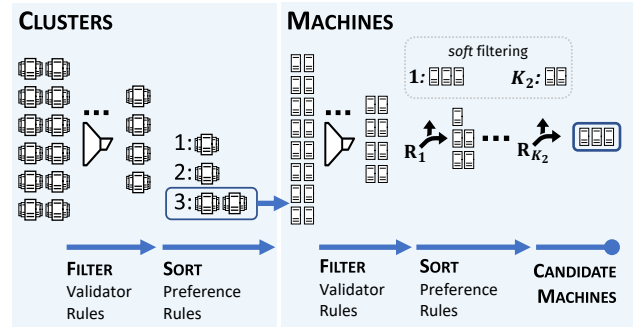

Figure 6: Rule based selection.

allocations; for example, packing the servers efficiently by minimizing fragmentation, balancing allocations across racks, avoiding lower-priority VMs evictions, etc. Due to the numerous dimensions involved, Protean’s allocation logic is organized as a set of *rules*. The rules determine which machine will be assigned for each individual VM. A service request for k VMs will invoke the rule logic k times.

Rules are classified into either *validator* or *preference* rules. A validator rule accounts for hard constraints, whereas a preference rule can be viewed as a soft constraint. The rules are arranged in a two-level hierarchy – cluster selection rules followed by machine selection rules (Fig. 6). In total, there are currently around one hundred rules.

Cluster and machine selection rules. Cluster selection rules effectively reduce the time complexity of the selection process by limiting the scope of the machine selection rules to a small number of clusters in a zone. Because clusters are homogeneous (see §2), we implement several cluster validator rules which filter out clusters that are not relevant for the VM request (e.g., a VM that requires a GPU machine can be hosted only on a cluster with GPU machines). In addition, a few cluster preference rules are used to sort the valid clusters (e.g., we prefer emptier clusters to balance the available capacity across clusters). Based on that, Protean chooses the k highest-quality clusters, where $k \in [8, 16]$ is a configurable parameter; the inventory for the machine selection rules will in turn consist of the machines in these clusters. The parameter k is set based on a tradeoff between exposing a large set of machines for making high-quality decisions and sustaining adequate latency.

In turn, machine selection rules again consist of validator rules that exclude specific machines from being considered, followed by preference rules which eventually select a small number of machines that are the best match for the particular VM. A randomized tie-breaking rule picks one of these machines for the physical assignment of the VM. In what follows we provide a more formal description of rule semantics, as well as some examples.

Validator rules. Each validator rule implements the Boolean method $\text{IsValid}(x, v)$ to indicate whether an object x is a valid candidate for placing VM v ; an object can be either a cluster or

a machine, depending on the rule. Validator rules are used to prune the set of objects in the inventory to a subset of objects that are valid candidates for placing the VM. **Examples:** (1) `AreNodeResourcesValid(x, v)` checks whether machine x has enough available capacity to accommodate VM v . The method returns *true* if all resource dimensions can be fulfilled (CPU, memory, disk, etc.). (2) `IsTypeSupported(x, v)` checks whether cluster x is compatible with the VM type corresponding to v .

Preference rules. A preference rule quantifies the extent to which each candidate object x (either a cluster or a machine, depending on the rule) is a good fit for the VM. Each preference rule r accounts for a specific consideration (e.g., packing quality, balancing, cluster/machine quality, etc.) through a numeric *score* $S_r(x, v)$. We use the convention that a lower score is better. **Examples:** (1) `BestFit(x, v)` assigns a score $\sum_i w_i(a_i(x) - d_i(v))$, where $a_i(x)$ is the availability of “resource” i (e.g., CPU cores, memory, SSD)² in machine x , $d_i(v)$ is the requirement of the VM for that resource, and w_i is the weight of the resource which quantifies its scarcity (intuitively, the higher w_i the scarcer the resource). A lower score here implies that the machine is a better fit for that VM, since it is closer to being fully packed; we note that similar packing heuristics have been proposed in [39]. (2) `PreferNonEmptyMachines(x, v)` This rule prefers to use machines that are non empty, primarily in order to improve packing quality. (3) `PreferEmptyClusters(x, v)` This rule quantifies how many empty cores cluster x has. The idea here is to balance the available capacity among clusters. This is done to minimize the probability that the cluster capacity is exhausted, which is important from several perspectives. For example, some customers require affinity within the cluster, and would not be able to scale out if the cluster is completely full.

3.3 Accounting for Multiple Rules

As illustrated in Fig. 6, the sequence of validator rules filters out objects (clusters, machines) that are not eligible for the particular VM. One of the main challenges in the design of Protean was: how to account for multiple preference rules? The inherent issue here is that different rules represent different and hard-to-compare preferences. We describe below the principles of our approach.

Compare method. Each preference rule r implements the `Compare(x, y | v)` method to compare two objects x and y based on their scores; the method returns 0 if scores are equal, 1 if $S_r(x, v) < S_r(y, v)$, or -1 otherwise.

Comparisons and sorting. Each preference rule expresses its relative importance using a *weight* (or gain value). Two objects are compared according to an aggregate score com-

puted as the sum of products of the compare value returned by each rule compare method and its weight. Using the pairwise comparisons, Protean computes a sorted list of the entire set of objects based on their aggregate preference scores.

Weight assignment. While our system allows to set any positive value for the rule weights, we have chosen to set the weights in a way that imposes strict ordering between the preference rules. The rules are assigned weights according to an order-preserving encoding (i.e., weights are exponentially apart from each other), such that, effectively, any rule can only express a preference among objects that have been preferred by the previous rule. Accordingly, the entire set of rules (including validator rules) can be regarded as a *filtering* process in which the set of preferred objects is narrowed as more rules are considered; see §3.4 for discussion.

Quantization. Having a strict prioritization among the preference rules, requires “smoothing” the preference rules, so that all rules can contribute. We do so by quantizing the score of some rules into a small number of buckets (e.g., rules with a continuous score, such as `BestFit`). For example, we may apply the transformation $\lceil S \cdot N \rceil$, where $S \in [0, 1]$ is the original (continuous) score and N is the number of buckets. The rule ordering and the specific quantization values entail domain knowledge and understanding of business needs and preferences. Their setting is based on trial and error, building on simulation results as well as production telemetry.

3.4 Discussion

We conclude this section by discussing how the rule-based allocator helps us achieve our design goals.

Addressing multiple considerations. Having multiple rules allows us to address multiple hard constraints, and explicitly influence the quality of the allocation through designated rules (e.g., best-fit for packing). The fundamental requirement of making “correct” allocations will manifest itself in certain system mechanisms; for example, ensuring that decisions are made based on the true state of the zone (§5).

User experience. By design, Protean will *not* fail a VM request if there exists a feasible assignment for that VM. This holds because (i) Protean chooses clusters that contain feasible nodes; (ii) Protean considers all nodes in the selected clusters. In addition, Protean has rules that target better user experience (e.g., prefer “healthier” machines).

Adaptability. The rules themselves can be customized and refined as needed. For example, if a specific rule is too “aggressive”, a simple configuration change can make it softer, e.g., by making the quantization coarser. As a concrete example, we describe in §6 how Protean has been adapted to tackle a capacity crunch during the Covid-19 crisis.

Extensibility and robustness. Our rule-based allocator is inherently extensible and robust. It is not too difficult to insert a new rule, or to modify or delete an existing one; two main design choices enable that: (i) rather than using a general

²Protean currently does not account for power. Power budgets are defined for different aggregations of servers: chassis, racks, rows, etc. A separate power-capping system [31] ensures that power usage does not exceed the budget; since power consumption falls within the budget at high percentiles, capping engages rarely.

Figure 7: Protean System Architecture

weighted score function, Protean maintains a ranking of the rules, and auto-generates weights that maintain the exponential distance property; (ii) the internal rule scores are not factored in the sorting of the machines, which makes the design or modification of rules more robust. This is enabled by using the rule compare method as a building block.

Interpretability. Strict ordering allows for better interpretability. For example, we can infer why a certain machine was not chosen for a particular VM request. More broadly, we can aggregate statistics to determine how aggressive each rule is (e.g., what fraction of objects it “filters on average”). This evaluation helps us adjust the quantization of rules and their ordering if needed; see §6 for an example.

4 Architecture

In this section, we provide a high-level overview of Protean, and describe how the AA handles a service request.

Protean operation. Fig. 7 describes the high-level system architecture of Protean. Protean employs multiple Allocation Agents (AAs) that operate concurrently, following an optimistic concurrency model. The AAs are organized to run in multiple machines. Each machine hosts a single process, which in turn creates multiple worker threads, one thread per AA. Allocation requests from clients are routed to these processes through a load-balancer. Within a process, the requests are stored in a shared work-queue until they are picked up and processed by a free AA. The number of AAs is determined according to the peak instantaneous demand in the zone, while the number of AAs per machine depends on the memory footprint of each AA. Each AA makes allocation decisions based on its own (possibly stale) view of the inventory, and after processing a request successfully, tries to commit the result to a replicated store. The replicated store performs conflict detection, and serializes the commits to the same node (commits to different nodes are handled in parallel). Further, it stores all inventory information that is modified by the VM placement

Algorithm 1: Service allocation algorithm

```

1 def ALLOCATE_SERVICE ( $v_1, \dots, v_n, \text{retries}$ ):

decisions from AAs. The replicated store functions as the authoritative source for the latest placement-related inventory state, and publishes all changes through a publish-subscribe (pub/sub) service.

Changes in the inventory that are not influenced by placement decisions, such as changes in machine health or capabilities, are also published via the pub/sub service. The AAs learn about inventory changes primarily through the updates produced by the pub/sub service. Additionally, on commit failures due to conflicts, they learn about the latest placement-related information for the conflicting machines as part of the failure notification.

Service allocation workflow. A service request may consist of multiple VM requests that are processed sequentially by a single AA. Algorithm 1 summarizes how Protean handles a service request. ORDER determines the order in which the VM requests will be processed. The goal of the ordering is to minimize the risk that a request is rejected due to fault domain considerations. ASSIGN_MACHINE_TO_VM attempts to assign a machine to a single VM by applying the rule logic; it is applied sequentially for each of the requested VMs (see §5 for implementation details). If the AA succeeds in assigning machines for all of the requested VMs, COMMIT tries to commit the service allocation result to the authoritative store. The commit fails if any of the VM-Machine assignments is invalidated because of a conflicting assignment made by another AA. On commit failures, the allocator state is rolled back and the entire request is re-queued for retry. The number of retries is configurable. We allow for a relatively high number of retries (more than 10) to avoid unnecessary allocation failures; however this has a negligible effect in production (e.g., the 99.9-percentile allocations succeed after three retries). The commit stage is pipelined with the previous stages, so that the AA is free to process the next request while a commit is in flight.

5 Protean Implementation

In this section, we describe our caching framework, which substantially expedites the ASSIGN_MACHINE_TO_VM pro-

cedure (§5.1–5.2). We also discuss our flexible conflict detection and reduction mechanisms (§5.3).

5.1 Preliminaries

To make high quality assignments, the AA initially considers the entire set of machines in the inventory as candidates.

Cluster selection. As discussed in §3.2, the AA starts the selection process by filtering and sorting clusters instead of machines. Since a zone has at most a few hundred clusters today, filtering and sorting the clusters is very fast (a couple of milliseconds at most). Accordingly, the cluster selection phase does not require any additional enhancements (such as caching past selection decisions). The output of this phase is the best 8 to 16 clusters; their machines (typically 10-15k) are the candidates for the machine selection process.

Machine selection – basic complexity. Recall that the machine-selection logic first trims the set of candidate machines to the set of valid machines by evaluating all validator rules for each machine. Then, it builds a comparison-based total ordering of the machines in the valid set, based on the suitability of each machine in hosting the VM (§3.3). Finally, a machine is randomly selected from the set of best machines. Building an *evaluation result* – the ordered list of valid machines – incurs a runtime complexity of $N \sum_{i=1}^{K_1} T_v(i) + N \log N (\sum_{i=1}^{K_2} T_p(i))$, where N is the number of candidate machines, K_1 the number of validator rules, K_2 the number of preference rules, $T_v(i)$ the time to compute IsValid for the i^{th} validator rule, and $T_p(i)$ the time to compute Compare for the i^{th} preference rule. If the AA attempted to build this evaluation result from scratch for every request, it would exceed the required latency bounds for anything more than just a couple of thousand machines.

Motivation for caching. First, we observe “*Locality in requests*”. Each VM request is characterized by a vector of *trait* values. Example traits include: VM-Type, priority, and RequireIsolation (i.e., the VM should be on a machine of its own). There are tens of traits, each of which can take several values (including a “don’t care” or empty option). In Sec. §2.2 we show that requests exhibit “locality” when zooming in on a single dimension (VM type). We note that this phenomenon carries over to the entire vector: there are a few value vectors commonly used across multiple requests, especially if they are chronologically close. The second observation is that the *inventory state changes slowly*. The state of a machine can change because of allocation-related events (addition, suspension, or deletion of VMs), or because of changes in health or other conditions of a VM or a machine. However, allocation-related events are the dominant reason for such changes. Hence the machines that change between consecutive executions of the AA are primarily the machines whose states were altered as a result of allocation decisions made by other AAs running in parallel. Since the number of parallel AAs is relatively small, there are typically not many such

changes. These characteristics would allow us to drastically reduce the amount of computation performed in an execution of the machine selection logic by caching and reusing an evaluation “state” from previous executions. Intuitively, the only computation that is required is to update the state to incorporate the impact of inventory changes since the previous run. We next discuss the details of our caching approach.

5.2 Caching for Efficient Machine Selection

Each AA maintains a collection of cached objects, which together hold the information required for machine selection.

5.2.1 Caching Rule State

Caching internal rule state for efficient execution. Rules are the basic building blocks of the selection process. So, first and foremost, we use caching to improve the execution time for IsValid and Compare methods of the rules ($T_v(i)$ and $T_p(i)$ respectively). Specifically, every *rule type* implements these methods. The instantiations of each rule type, termed *rule objects*, are cached for reuse. A newly created rule object computes and stores all the information that it requires to execute the IsValid or Compare method in constant time. Usually this information is stored on a per machine basis. For example, the PreferNonEmptyMachines rule (see §3.2) stores a $\langle \text{MachineID}, \text{Boolean} \rangle$ dictionary that tracks whether each machine is empty or not.

Just-in-time updates of rule state. Every time a cached rule object is used, its internal state has to be brought up-to-date before its IsValid or Compare method can be called. To that end, along with the IsValid or Compare method, each rule implements the $\text{Update}(x_1, \dots, x_m)$ method in order to update its stored state. The *Update* method is called immediately before the rule object is used. Its argument, (x_1, \dots, x_m) , represents the latest state for machines that have *changed* from the last time the object was updated. Every rule can execute its IsValid or Compare function in constant time once it has updated its state with the latest changes.

Splitting rule state into multiple objects. The stored state of a rule object may depend on one or more request traits. For example, the AreNodeResourcesValid rule depends on the requested VM-Type, and hence must cache the Boolean whether the machine has enough capacity for each $\langle \text{Machine}, \text{VM-Type} \rangle$ pair. We observe, however, that to process a particular VM request, the rule object only needs the information for the VM-Type value of that request. Updating the state for every other VM-Type value would increase the just-in-time update time, and in turn the request processing time. Hence, instead of creating a single rule object for all requests, a rule object is created on demand for every VM-Type value. A rule object for a particular VM-Type value is used for all requests asking for that value. In effect, requests are divided into *equivalence classes* based on the relevant trait value, and

Time	Request	Cached Objects	Hits	Misses (Create New)
T1	$req(x_1, y_1)$	None	None	$Eval(x_1, y_1)$ $R_1(x_1, y_1)$ $R_2(x_1)$
T2	$req(x_1, y_2)$	$Eval(x_1, y_1)$ $R_1(x_1, y_1)$ $R_2(x_1)$	$R_2(x_1)$	$Eval(x_1, y_2)$ $R_1(x_1, y_2)$
T3	$req(x_1, y_1)$	$Eval(x_1, y_1)$ $Eval(x_1, y_2)$ $R_1(x_1, y_1)$ $R_2(x_1)$ $R_1(x_1, y_2)$	$Eval(x_1, y_1)^*$	None

Table 4: Example cache timeline. *If $Eval(x_1, y_1)$ needs to be updated then $R_1(x_1, y_1)$ and $R_2(x_1)$ would also be requested (and have cache hits).

Figure 8: Cache hierarchy for the example in Table 4.

a single rule object handles all requests belonging to a class. For rules depending on multiple request traits, each unique combination of the trait values define a new equivalence class of requests for that rule. For the special case where a rule does not depend on any request trait (e.g., `PreferNonEmptyMachine`), a single rule object is used for all requests. This rule object specialization technique substantially reduces processing latency, and further decreases the effective memory size needed for caching.

Caching rule objects. Rule object references are stored in a constant size pool. The size is determined through trial-and-error based on memory footprint and hit-rate considerations. A rule object is identified by its type and the request trait value combination that it is associated with. Rule objects are evicted from the pool either if it is full (following a standard LRU eviction policy), or if they reach a certain age. Age-based eviction allows us to reduce the memory footprint during periods of low load.

5.2.2 Caching Rule Evaluation State

Caching the rule objects helps in substantially reducing $T_v(i)$ and $T_p(i)$. However, without any additional enhancements, we would still pay the sorting complexity of $N \log N$. Hence, we introduce additional objects termed *RuleEvaluation* objects. A rule evaluation object essentially holds the complete state of the evaluation, for a specific vector of trait values (see §5.1). The state includes the evaluation result (sorted list of machines) and references to relevant rule objects whose trait values match the respective values in the entire vector of trait values. A *RuleEvaluation* object is created after computing the evaluation result for a new vector of trait values, which serves as the identifier for the object). The object will then be reused for all requests that map to this identifier.

Updating the RuleEvaluation object. Similar to the rule objects, a cached *RuleEvaluation* object is brought up-to-date before it is used. However, unlike rule objects, *RuleEvaluation* objects use a common *Update* method, whose goal is to update the evaluation result with the changed machines. The method proceeds as follows: (1) the cached rule objects are brought up-to-date by calling their *Update* methods; (2) the modified machines are removed from the evaluation result; (3) the validator rules are run for each of these machines to

determine which machines are valid; (4) valid machines are inserted back into the ordered list with an updated position. Because each insertion takes $\log N$ time, the *Update* method has runtime complexity of $M \log N$, where M is the number of machines with modified state. This is a substantial reduction in complexity, because $M \ll N$ (M is in the order of tens). *RuleEvaluation* objects are cached in another constant size memory pool, with an LRU eviction policy.

Example. Consider an example scenario where each request can have two traits $X \in \{x_1, x_2\}$ and $Y \in \{y_1, y_2\}$; and the allocation logic is expressed through two rules: R_1 , which depends on traits X and Y , and R_2 , which depends on X . Figure 8 shows the various rule and *RuleEvaluation* objects that are created and reused as the allocation engine serves incoming requests with different trait values. The accompanying Table 4 shows the hierarchy of objects that are created and cached as a consequence of processing the requests. The first request at time T1 has trait values $X = x_1$ and $Y = y_1$, and accordingly two new rule objects $R_1(x_1, y_1)$ and $R_2(x_1)$, and an evaluation object $Eval(x_1, y_1)$ are created. The second request at time T2 uses a different value y_2 for trait Y , and hence cannot reuse $Eval(x_1, y_1)$ or $R_1(x_1, y_1)$ objects. It reuses $R_2(x_1)$ since the trait value for X does not change, and creates new objects $R_1(x_1, y_2)$ and $Eval(x_1, y_2)$. The third request at time T3 uses the same trait values as the first, and hence is able to reuse all three objects that were created during the processing of the first request. Overall, two *RuleEvaluation* objects are created, corresponding to the two trait value vectors $\{x_1, y_1\}$ and $\{x_1, y_2\}$. They share a single object for rule R_2 , but use two separate objects for rule R_1 .

5.2.3 Additional Cache Hierarchies

Multiple rules often depend on the same part of the state. For example, multiple rules need to track whether machines are empty (e.g., `BestFit` and a rule that attempts to balance capacity across racks). For such cases, we encapsulate the shared part of the state in a *Shared-Cache* type, which multiple rules can refer to. Just like a *Rule*, a *Shared-Cache* implements the *Update* method, and declares any request traits it depends on. *Shared-Caches* play a huge role in reducing memory usage. These objects are cached in their own constant size memory pool. As mentioned, a cached object may depend on other

cached objects. The rule selection engine thus ensures that all dependencies are updated before the object is updated. Our cache hierarchy embeds desirable properties. For example, when a new RuleEvaluation object is created, it may often rely on existing rule and shared-cache objects.

5.2.4 Efficiently Updating the Cache

Tracking and updating mechanisms. Recall that each AA maintains its own private caches. Since each cached object can in principle be updated just before it is used, objects can exist at different levels of staleness. To facilitate seamless updates, each AA has a *journal* that keeps track of changes to any machine in the inventory. The journal maintains a global revision number which is incremented upon every update. In addition, the journal stores only the latest machine state for every machine. Every cached object stores the highest revision number it has seen, which corresponds the latest inventory update it has consumed. An object brings itself up to date by reading only the journal records with higher revision numbers. Consequently, the update operation has runtime complexity at the order of the number of machines that were *modified*, rather than the entire inventory. The AA updates the journal during an ongoing evaluation to record each VM placement decision that it is making. In addition, the AA updates the journal between evaluations by processing enqueued incoming changes from the pub/sub service or the placement store.

Background updates. An up-to-date cache can handle a request in few ms by simply extracting the best machine(s). However, when this is not the case, just-in-time cache update times can be a significant part of the total VM request latency. Nonetheless, because the system has multiple AAs that are provisioned to handle the rare periods of peak load, they remain inactive for most of the time. Hence, when an AA has no requests to process, it is used to opportunistically update the caches (starting with RuleEvaluation cache objects and proceeding recursively).

5.2.5 Discussion

Design advantages. One clear advantage of our caching approach over other alternatives (e.g., node sampling or strict partitioning the inventory) is that Protean can sustain low latency and high throughput without giving up on allocation opportunities. Another appealing property of our implementation is that the complexity of creating, reusing, and updating a rule object is almost completely hidden from the creator of a rule. A rule only has to implement the *IsValid* (or *Compare*) and *Update* methods and declare the request traits it depends on. The rest is handled by the machine selection engine within the AA. This clear separation between the rules and the evaluation engine has been instrumental in the extensibility and adaptability of Protean.

Global rules. There are a few machine selection rules that do not express preference for individual machines, but rather among groups of machines (e.g., prefer the least used rack). We refer to such rules as *global* rules. Most global rules reason about clusters and hence are part of cluster selection. However, a few rules also reason about racks, and hence are part of the machine selection stage. Global rules require us to adjust our caching methodology. To understand the issue, observe that for such rules, a change in a single machine within the group might impact the value of all other machines in that group (e.g., an allocation to a single machine in a rack might make the rack less attractive than another rack). Hence, a single machine change makes *all* machines in the group ‘dirty’, and the cached objects would require updating all the machines in the group. To still benefit from our caching infrastructure, we use a divide and conquer approach: in a nutshell, we divide the machine inventory into *cells*. Each cell consists of a subset of machines who are considered identical from the perspective of all the global rules. We apply our caching mechanisms separately for each cell; that means that we maintain a sorted list of valid machines (the filtering and sorting is done based on all non-global rules). To obtain the actual evaluation result, we pick the best machine from each cell, and do the required comparisons and sorting based on all rules. While these comparisons slow the evaluation time, we note that the original complexity term of $N \log N$ reduces to $N_c \log N_c$, where N_c is the number of cells. In our current setting, cells correspond to racks. The number of racks after cluster selection is in the order of a hundred, hence $N_c \ll N$.

5.3 Conflict Detection and Reduction

Occasional spikes of thousands of requests push all AAs to work at full tilt. Naturally, chances of commit failures due to conflicts increase considerably during such periods. Conflicts reduce the effective throughput and increase outright failures; as a request fails after a fixed number of retries. We employ the following strategies to reduce such failures.

Fine-grained conflict detection. We built a conflict-detection mechanism which allows commits to succeed even when the AA makes a placement decision based on an out-dated view of a machine. The logic verifies that the new placement decision does not over-commit the machine resources or violate other anti-colocation constraints (such as placing a new VM on a machine that already hosts a VM requiring isolation). If so, it merges the new placement decision with the current state of the machine as part of the commit. This mechanism has led to 25% drop in conflicts in one of our busiest zones, compared to the simpler strategy of rejecting all out-dated placement decisions.

Trading allocation quality for conflict reduction. Conflicts increase during high-load periods, not only because of rapid inventory changes, but also because AAs apply the same logic; AAs are likely to identify highly overlapping sets of best ma-

chines if their respective requests are similar. The number of machines in this set might be very small, so that even a random selection from it may lead to a conflict with high probability. To address this challenge, the AA employs an hybrid strategy for selecting a machine in its final step. In periods with no conflicts, it selects from the set of best machines. Alternatively, it may use a more permissive *conflict-avoidance* scheme; this scheme randomly selects a machine from the top N_0 machines, where N_0 is a configurable parameter (note that the top N_0 machines may differ in their desirability). The conflict-avoidance scheme is enabled with a probability proportional to the ratio of conflict failures to total commit attempts, measured using a rolling window of the most recent commit attempts. The conflict-avoidance scheme is instrumental in satisfying demand at high-load periods; since such periods are infrequent, it has little effect on allocation quality.

6 Evaluation

6.1 Methodology

Production measurements. Since Protean is fully deployed across all regions of Azure, it is natural to evaluate it using measurements from production. Our infrastructure collects numerous diagnostic metrics and structured logs, which are used for monitoring and evaluation. These metrics and logs are aggregated into a central and easily accessible source, which allows custom queries for specific data extraction. Production measurements is the default method in our evaluation; we will mention explicitly when we use simulations.

Simulations. Simulations are incredibly useful for evaluating what-if scenarios, such as the effect of different inventory sizes, different rule configurations, etc. Our simulations use real traces and configurations as input, and can be considered a reasonably accurate representation of reality. In particular, the simulated workload includes both traces from production, as well as realistic probabilistic models of VM requests, derived from historical traces. We built two types of simulators. The *high-fidelity* simulator uses the actual production code of Protean to perform the allocations, and outputs large amounts of data for debugging purposes. Our *low-fidelity* simulator includes a lightweight emulation of the allocator (e.g., supports a subset of the rules). This simulator still provides an excellent approximation of the system, is orders-of-magnitude faster, and especially useful for large scale evaluations.

6.2 Performance and Scale

Here we evaluate key mechanisms and design choices that help Protean scale. We focus on the caching mechanism and the effect of multiple AAs.

Cache evaluation: Hit-rate, latency and update overhead. As discussed in §2, the nature of our workload motivates the

Figure 9: Cache-hit ratio over time for some caches. The frequency of requests for each cache is shown on the right.

Figure 10: Latency in a large zone; average (+standard deviation) per hour per day, over two months.

use of caching. Our first goal is to understand the effectiveness of the hierarchical cache architecture. Towards that end, Fig. 9 shows typical hit-ratio patterns in one of our zones, focusing on four different cacheable classes over a day period (taking into account all cached objects for each class). The *FdEmptyNodes* and *BestFit* are cached rules; *NodeResources* is a Shared-Cache; and *RuleEvaluation* corresponds to the *RuleEvaluation* class. The stacked bar to the right of the figure shows the frequency of cache requests as a percentage of allocation requests (*NodeResources* cache is requested only in 0.16% of allocations, hence barely noticed). Lower-level caches are only requested when higher-level caches miss, so to interpret the results, both the request frequency and hit-ratio should be considered. For example, the *NodeResources* cache has a hit-ratio around 20%, but is less frequently accessed – compared to *RuleEvaluation*, which has a much higher hit-ratio and is accessed on every request.

The resulting benefit of our cache and high hit-rates for evaluation caches is improved latency. This can be clearly seen from Fig. 10, which depicts the effect of a cache hit/miss for the *RuleEvaluation* cache. Given our high hit-rate, the overall average latency is close to 20 ms per allocation. A cache-miss still uses many lower-level caches so that the latency is typically 70-80ms. We note that Protean’s latency is affected by additional functionality beyond the allocation process itself, such as tracking and outputting debug information about every allocation.

To gain further insights into the cache operation and resulting latencies, we track the average number of machines updated per allocation in one of our zones (~30k machines), over an entire day. Cache hits/misses have a significant impact on the number of updated machines: approximately 50 for a

Figure 11: Median latency vs inventory size over one-month. Baseline results are based on high-fidelity simulation.

Figure 12: Memory used per AA vs inventory size. Average (+standard deviation) over a month over all zones.

hit verses 2000 for a miss. A hit thus translates to less overhead in the allocation process and in turn, to lower latency. Notably, the number of updates is relatively small even in case of a miss (6.6% of the machines). This can be attributed to two main factors. First, the cluster selection process filters out a large part of the inventory. In particular, we observe through simulations that cluster selection rules filter out up to 20% of the inventory for zones of 10k machines or more. Second, a substantial part of inventory updates occur asynchronously via background resolve. Indeed, our production measurements indicate that 80-96% of machine updates are done by that mechanism.

Scaling with inventory. Fig. 11 shows the inventory size effect on latency under three different scenarios. The first two scenarios correspond to cache hit or miss for RuleEvaluation cache, where the results represent production measurements of zones with different sizes. To further examine the effectiveness of mechanisms, we include a third scenario (“baseline”) where the caching and cluster selection are disabled; because we would rather not disable these mechanisms in production, we use our high-fidelity simulator to obtain the results; observe that the median latency reaches around 1000 ms for larger zones. In addition to latency performance, it is also important to examine the cache’s memory footprint. Fig. 12 shows the memory required per AA, as a function of inventory size. The fitted line, obtained via regression, shows that the growth of our the memory footprint is sublinear ($\sim x^{0.73}$), which helps keep memory sizes manageable at scale.

Multiple allocation agents. Multiple allocators influence important metrics, such as the number of conflicts, delay and

Figure 13: [Simulation] Throughput (allocations per second) over a selected time horizon, for various number of AAs. The bars represent the requests, and the curves represent their processing. A shorter x-axis “span” means better performance.

Figure 14: [Simulation] 99th percentile of conflicts per second and corresponding throughput. Uses production trace as input.

throughput. Since the number of AAs in production is fixed, we use our low-fidelity simulator for the experiments: we emulate an heterogeneous inventory of one of our zones with nearly 25k machines. We replay an actual request trace of an entire day. We use the same conflict-avoidance (see §5.3) parameters (100 machines allowed for final random selection, rolling window size of 50 commits) and number of retries before rejection (20) as in production. To expedite the low-fidelity simulations, the actual cache infrastructure is not integrated in the simulator. To mimic the cache, we use a realistic statistical model, derived from production measurements of the same zone over a month period. A cache hit/miss is determined using a Bernoulli random variable, with an average hit-ratio ($p = 0.9$) obtained from production; a hit results in 14ms latency, whereas a miss incurs a higher latency of 88ms.

Our first experiment examines how different number of AAs handle a spike in demand (see Fig. 13). The key takeaway here is that a single allocator struggles to satisfy the load in a reasonable time, causing excess delays to requests. With five AAs, the requests are handled in more than 3x less time (adding more AAs yields similar results). Our second experiment (Fig. 14) replays another trace from the same zone; the figure depicts the 99th percentile for the conflicts per second, as well as the throughput observed during the same time. Our collision-avoidance strategy provides clear gains: note that throughput increases substantially with the number of AAs with little effect on conflicts.

Figure 15: [Simulation] Scale test. 99th percentile of conflicts per second with corresponding throughput and rejection rate.

Our system easily handles the request volume currently seen in production. It is of natural interest to study (via simulations) the possible performance trends at higher scale. Towards that end, we take an existing request trace and speed up time by factors of up to 1000x. Fig. 15 shows throughput, conflicts and rejection rates as we scale up the demand, verses the number of AAs handling the requests; the simulations use our standard avoidance scheme. We observe that although throughput reaches over 10k requests per second, this comes at the expense of significant conflicts which in turn affect the rejection rate. The throughput eventually plateaus, likely due to a combination of fixed inventory size and increasing conflicts. In a production setting, we would have several options to deal with increased demand (e.g., tune the avoidance scheme, or longer-term increase of inventory size).

6.3 Allocation Quality

Quality vs. performance tradeoff. There are different criteria for quantifying quality; for example, balancing allocations across multiple fault domains is important for satisfying large service requests. In this section, we zoom in on a key efficiency metric – *packing density* – which measures the average number of allocated cores on non-empty machines (certain machines must be kept empty, e.g., for failover of large VMs). Formally, the packing density at time t is the ratio between the number of allocated cores, and the number of non-empty machines times the number of cores in each machine. We note that packing density can be defined similarly for other resources, such as memory; we focus on CPU because it is typically the bottleneck resource. Table 5 summarizes a set of experiments in one of our zones, using the low-fidelity simulator on a 5 month trace. The different rows correspond to different parameter configurations of the BestFit rule; in particular, the configurations differ by the number of buckets (see §3.2), where ∞ means no quantization. Recall that the more buckets we use the finer is the quantization of the score, which allows for better discrimination of machines by the packing quality. On the flip side, a finer quantization means that downstream rules are left with fewer candidate machines. The results demonstrate some interesting trends. As expected, the packing density (denoted PD %) increases with the num-

Buckets	PD (%)	Post-BestFit (%)	P ₉₉ Conflicts / min
1	83.5	27.6	13.4
2	84.3	25.0	13.5
3	86.3	21.0	11.6
4	87.3	16.5	12.0
5	87.8	13.7	10.7
∞	89.1	2.3	18.0

Table 5: [Simulation] The trade-off between packing and robust allocations. PD (%) is the packing density averaged over five months.

ber of buckets; note that the most significant increase is from two to three buckets. More buckets increases the packing density by a little, however at the cost of filtering out a substantial percent of candidate machines (Post-BestFit). The effect is magnified at the extreme of no quantization, where very few candidate machines are left. As a consequence, not only downstream rules become meaningless, but also the conflict rate increases. This is because different allocators are more likely to pick the same machine for allocation. In view of the above analysis, we currently use three buckets in production.

Adapting to COVID-19 capacity crunch. As a consequence of the COVID-19 pandemic, Azure observed a sharp increase in demand. As an immediate response, we increased the utilization limits in each cluster by 1%. These limits are used to leave enough buffers for in-cluster scale-outs as well as to account for failures. The increase was done easily by modifying configurable threshold values in a cluster validator rule `IsClusterBelowLimit(x,v)`. This limit change slightly increased the risk for scale-outs and fail-overs. To mitigate the risk, we used Protean to identify fragmented machines, and recommend migration targets that would improve packing (what-if analysis). A supplementary VM migration mechanism used these recommendations to live-migrate some VMs (targeting first-party VMs only), resulting in improved packing density. Fig. 16 shows both the average utilization (i.e., ratio between number of allocated cores and total number of cores in Azure) and the packing density over our entire fleet. The dashed lines indicates the point of time at which the above changes were made. The net effect of Protean adaptation was a sizeable increase in utilization, facilitated by a significant improvement in packing density. We also depict in the same figure the relative trends for the overall capacity fulfillment rate (CFR) – the fraction of allocations that are successfully deployed. CFR dipped slightly in mid-March, but went up again exceeding its target of four nines by mid-April.

7 Related Work

Resource management for large compute clusters. Numerous systems have been implemented for various domains, including batch scheduling for HPC applications

[25, 44, 45], big-data analytics [7, 20, 23, 28, 38, 40, 47, 52], stream-processing [34], AI [36], etc. More related to our context is the work on hyper-scale cloud computing clusters, see [8, 12, 15–17, 43, 48] and references therein. Our cloud workload analysis adds to a body of work on this topic, e.g., [5, 10, 12, 18, 26, 30, 35, 42, 46, 50].

Scheduler types. One useful way to classify large-scale schedulers is based on how they process work items (jobs, tasks, VMs, etc.). *Centralized monolithic* schedulers [21, 24, 52] use a single agent to process requests. They avoid concurrency issues, yet are harder to scale. A subset of these schedulers, optimizes placement decisions by *batch-processing* multiple jobs together [19, 21, 24]. Our demanding latency and throughput requirements preclude using these approaches. To cope with scale and management complexities, *two-level* schedulers [23, 47] perform coarse-grained resource management, while leaving the fine-grained scheduling to application frameworks. Similarly, *distributed schedulers* [36, 38, 41] decentralize the scheduling logic by employing sophisticated queue management strategies at the target machines (see also works on *hybrid schedulers* [13, 14, 29]). Two-level or various distributed approaches are less applicable for VM scheduling, which is inherently IaaS-centric. Our AA is centralized, while target machines create their assigned VMs according to a simple FCFS policy.

Concurrent schedulers. Similar to Sparrow [38], Apollo [7] and Omega [43], Protean is a concurrent scheduler which employs multiple agents over a shared inventory. Omega handles conflicts immediately as part of scheduling, whereas Apollo and Mercury allow conflicting scheduling decisions to queue on target nodes while deferring conflict resolution. As in [43], we use multiple concurrent allocation agents and a conflict resolution model. Indeed, our customers prefer VM requests to fail early rather than waiting longer in hope for success; this allows higher level services to quickly try other alternatives, such as using another zone or modifying some request properties.

Allocation scope. Cluster selection and caching allow Protean to make resource assignment decisions based on the entire inventory, similar to [7, 15]. Alternatively, schedulers can statically partition the inventory [49], or use random

sampling to make a decision using a subset of the inventory [17, 38, 48]. Protean shares similarities with Google’s Borg [48]. Borg employs other optimizations for scalability, such as caching node preference scores until the node changes, and avoiding duplicate work by evaluating decisions for only a single task within a group of identical tasks. Protean caches not only node-centric data, but also rule and evaluation outcomes that can be used across different requests. In addition, Borg introduces the notion of equivalent classes, where feasibility and scoring is determined only for a single task out of identical tasks in a job. Protean extends this idea by considering requests across tenants to be equivalent if they share the same trait values. Finally, unlike Borg, we do not employ sampling (termed “relaxed randomization”), but rather use other techniques to help with scale (multi-layer caching and cluster selection).

Resource efficiency. Cloud schedulers attempt to increase actual resource usage through a variety of techniques, e.g., reclaiming unused resources, harvesting, profiling, heterogeneity and interference awareness [9, 12, 15, 16, 22, 27, 32, 33, 37, 48, 51, 53]. Protean’s flexible rule-based logic facilitates dynamic resource adjustment and interference mitigation strategies; their description is outside the scope of this paper.

8 Conclusion

We describe Protean, the VM allocation service of Azure. Our design separates policy from mechanisms, which has allowed us to successfully expand our VM offerings over the years. A flexible rule-based allocator facilitates refining the allocation logic and explaining it to customers. VM requests are processed in milliseconds, due to a hierarchical caching framework. Results from production demonstrate that Protean sustains adequate trade-offs between performance and quality.

Acknowledgements

We are grateful to our shepherd, John Wilkes, and the anonymous reviewers for their detailed and thoughtful feedback. We would like to acknowledge the contributions of the engineers who have been involved in the design, implementation, and maintenance of Protean over the years - Jason Chu, Chris Cowdery, Dustin Dobransky, Eric Hao, Ryan Hidalgo, Valentina Li, John Miller, Mukund Nigam, Jason Seo, Kanishk Thareja, Karel Trueba, Yiran Wei and Brian Yan. We also thank Saurabh Agarwal, Girish Bablani, Ricardo Bianchini, Íñigo Goiri, Marcus Fontoura and Saad Syed for helpful discussions.

Abstract

High-performance tensor programs are crucial to guarantee efficient execution of deep neural networks. However, obtaining performant tensor programs for different operators on various hardware platforms is notoriously challenging. Currently, deep learning systems rely on vendor-provided kernel libraries or various search strategies to get performant tensor programs. These approaches either require significant engineering effort to develop platform-specific optimization code or fall short of finding high-performance programs due to restricted search space and ineffective exploration strategy.

We present Ansor, a tensor program generation framework for deep learning applications. Compared with existing search strategies, Ansor explores many more optimization combinations by sampling programs from a hierarchical representation of the search space. Ansor then fine-tunes the sampled programs with evolutionary search and a learned cost model to identify the best programs. Ansor can find high-performance programs that are outside the search space of existing state-of-the-art approaches. In addition, Ansor utilizes a task scheduler to simultaneously optimize multiple subgraphs in deep neural networks. We show that Ansor improves the execution performance of deep neural networks relative to the state-of-the-art on the Intel CPU, ARM CPU, and NVIDIA GPU by up to $3.8\times$, $2.6\times$, and $1.7\times$, respectively.

1 Introduction

Low-latency execution of deep neural networks (DNN) plays a critical role in autonomous driving [14], augmented reality [3], language translation [15], and other applications of AI. DNNs can be expressed as a directed acyclic computational graph (DAG), in which nodes represent the operators (*e.g.*, convolution, matrix multiplication) and directed edges represent the dependencies between operators. Existing deep learning frameworks (*e.g.*, Tensorflow [1], PyTorch [39], MXNet [10]) map the operators in DNNs to vendor-provided kernel libraries (*e.g.*, cuDNN [13], MKL-DNN [27]) to

achieve high performance. However, these kernel libraries require significant engineering effort to manually tune for each hardware platform and operator. The significant manual effort required to produce efficient operator implementations for each target accelerator limits the development and innovation of new operators [7] and specialized accelerators [35].

Given the importance of DNNs' performance, researchers and industry practitioners have turned to search-based compilation [2, 11, 32, 49, 59] for automated generation of *tensor programs*, *i.e.*, low-level implementations of tensor operators. For an operator or a (sub-)graph of multiple operators, users define the computation in a high-level declarative language (§2), and the compiler then searches for programs tailored towards different hardware platforms.

To find performant tensor programs, it is necessary for a search-based approach to explore a large enough search space to cover all the useful tensor program optimizations. However, existing approaches fail to capture many effective optimization combinations, because they rely on either predefined manually-written templates (*e.g.*, TVM [12], FlexTensor [59]) or aggressive pruning by evaluating incomplete programs (*e.g.*, Halide auto-scheduler [2]), which prevents them from covering a comprehensive search space (§2). The rules they use to construct the search space are also limited.

In this paper, we explore a novel search strategy for generating high-performance tensor programs. It can automatically generate a large search space with comprehensive coverage of optimizations and gives every tensor program in the space a chance to be chosen. It thus enables to find high-performance programs that existing approaches miss.

Realizing this goal faces multiple challenges. First, it requires automatically constructing a large search space to cover as many tensor programs as possible for a given computation definition. Second, we need to search efficiently without comparing incomplete programs in the large search space that can be orders of magnitude larger than what existing templates can cover. Finally, when optimizing an entire DNN with many subgraphs, we should recognize and prioritize the subgraphs that are critical to the end-to-end performance.

To this end, we design and implement *Ansor*, a framework for automated tensor program generation. Ansor utilizes a hierarchical representation to cover a large search space. This representation decouples high-level structures and low-level details, enabling flexible enumeration of high-level structures and efficient sampling of low-level details. The space is constructed automatically for a given computation definition. Ansor then samples complete programs from the search space and fine-tunes these programs with evolutionary search and a learned cost model. To optimize the performance of DNNs with multiple subgraphs, Ansor dynamically prioritizes subgraphs of the DNNs that are more likely to improve the end-to-end performance.

We evaluate Ansor on both standard deep learning benchmarks and emerging new workloads against manual libraries and state-of-the-art search-based frameworks. Experiment results show that Ansor improves the execution performance of DNNs on the Intel CPU, ARM CPU, and NVIDIA GPU by up to $3.8\times$, $2.6\times$, and $1.7\times$, respectively. For most computation definitions, the best program found by Ansor is outside the search space of existing search-based approaches. The results also show that, compared with existing search-based approaches, Ansor searches more efficiently, generating higher-performance programs in a shorter time, despite its larger search space. Ansor can match the performance of a state-of-the-art framework with an order of magnitude less search time. Besides, Ansor enables automatic extension to new operators by only requiring their mathematical definitions without manual templates.

In summary, this paper makes the following contributions:

- A mechanism to generate a large hierarchical search space of tensor programs for a computational graph.
- An evolutionary strategy with a learned cost model to fine-tune the performance of tensor programs.
- A scheduling algorithm based on gradient descent to prioritize important subgraphs when optimizing the end-to-end performance of DNNs.
- An implementation and comprehensive evaluation of the Ansor system demonstrating that the above techniques outperform state-of-the-art systems on a variety of DNNs and hardware platforms.

2 Background

The deep learning ecosystem is embracing a rapidly growing diversity of hardware platforms including CPUs, GPUs, FPGAs, and ASICs. In order to deploy DNNs on these platforms, high-performance tensor programs are needed for the operators used in DNNs. The required operator set typically contains a mixture of standard operators (*e.g.*, `matmul`, `conv2d`) and novel operators invented by machine learning researchers (*e.g.*, `capsule conv2d` [23], `dilated conv2d` [57]).

```
Matrix Multiplication  $C_{i,j} = \sum_k A_{i,k} B_{k,j}$ 
C = compute((N, M), lambda i, j: sum(A[i, k]*B[k, j], [k]))
```

Figure 1: The computation definition of matrix multiplication.

To deliver portable performance of these operators on a wide range of hardware platforms in a productive way, multiple compiler techniques have been introduced (*e.g.*, TVM [11], Halide [41], Tensor Comprehensions [49]). Users define the computation in a form similar to mathematical expressions using a high-level declarative language, and the compiler generates optimized tensor programs according to the definition. Figure 1 shows the computation definition of matrix multiplication in the TVM tensor expression language. Users mainly need to define the shapes of the tensors and how each element in the output tensor is computed.

However, automatically generating high-performance tensor programs from a high-level definition is extremely difficult. Depending on the architecture of the target platform, the compiler needs to search in an extremely large and complicated space containing combinatorial choices of optimizations (*e.g.*, tile structure, tile size, vectorization, parallelization). Finding high-performance programs requires the search strategy to cover a comprehensive space and explore it efficiently. We describe two recent and effective approaches in this section and other related work in §8.

Template-guided search. In template-guided search, the search space is defined by manual templates. As shown in Figure 2a, the compiler (*e.g.*, TVM) requires the user to manually write a template for a computation definition. The template defines the structure of the tensor programs with some tunable parameters (*e.g.*, tile size and unrolling factor). The compiler then searches for the best values of these parameters for a specific input shape configuration and a specific hardware target. This approach has achieved good performance on common deep learning operators. However, developing templates requires substantial effort. For example, the code repository of TVM already contains more than 15K lines of code for these templates. This number continues to grow as new operators and new hardware platforms emerge. Besides, constructing a quality template requires expertise in both tensor operators and hardware. It takes non-trivial research effort [32, 55, 59] to develop quality templates. Despite the complexity of template design, manual templates only cover limited program structures because manually enumerating all optimization choices for all operators is prohibitive. This approach typically requires defining one template for each operator. FlexTensor [59] proposes a general template to cover multiple operators, but its template is still designed for single operator granularity, which fails to include optimizations involving multiple operators (*e.g.*, operator fusion). The search space of optimizing a computational graph with multiple operators should contain different ways to compose the operators. A template-based approach fails to achieve this because it cannot break down their fixed templates and re-compose them

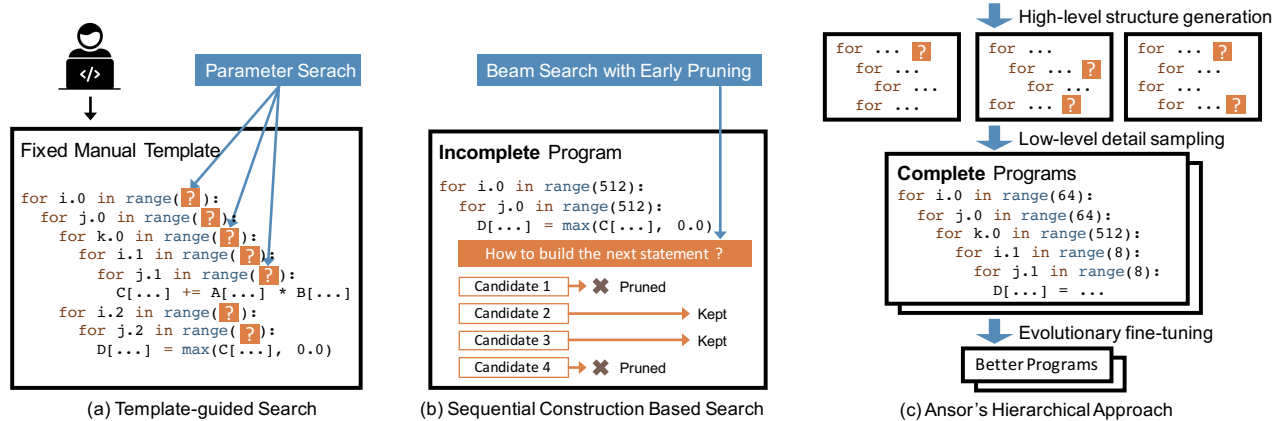

Figure 2: Search strategy comparison. The pseudo-code shows tensor programs with loop nests. The question marks in orange background denote low-level parameters.

during the search.

Sequential construction based search. This approach defines the search space by decomposing the program construction into a fixed sequence of decisions. The compiler then uses an algorithm such as beam search [34] to search for good decisions (e.g., Halide auto-scheduler [2]). In this approach, the compiler constructs a tensor program by sequentially unfolding all nodes in the computational graph. For each node, the compiler makes a few decisions on how to transform it into low-level tensor programs (i.e., deciding computation location, storage location, tile size, etc.). When all nodes are unfolded, a complete tensor program is constructed. This approach uses a set of general unfolding rules for every node, so it can search automatically without requiring manual templates. Because the number of possible choices of each decision is large, to make the sequential process feasible, this approach keeps only top- k candidate programs after every decision. The compiler estimates and compares the performance of candidate programs with a learned cost model to select the top- k candidates; while other candidates are pruned. During the search, the candidate programs are incomplete because only part of the computational graph is unfolded or only some of the decisions are made. Figure 2b shows this process.

However, estimating the final performance of incomplete programs is difficult in several respects: (1) the cost model trained on complete programs cannot accurately predict the final performance of incomplete programs. The cost model can only be trained on complete programs because we need to compile programs and measure their execution time to get the labels for training. Directly using this model to compare the final performance of incomplete programs will result in poor accuracy. As a case study, we train our cost model (§5.2) on 20,000 random complete programs from our search space and use the model to predict the final performance of incomplete programs. The incomplete programs are obtained by only applying a fraction of loop transformations of the complete programs. We use two ranking metrics for evaluation: the accuracy of pairwise comparison and the recall@ k

Figure 3: Pairwise comparison accuracy and top- k recall curve on random partial programs. In both subfigures, higher values are better.

score of top- k programs ¹ ($k = 10$). As shown in Figure 3, the two curves start from 50% and 0% respectively, meaning that random guess with zero information gives 50% pairwise comparison accuracy and 0% top- k recall. The two curves increase quickly as the programs become complete, which means the cost model performs very well for complete programs but fails to accurately predict the final performance of incomplete programs. (2) The fixed order of sequential decisions limits the design of the search space. For example, some optimization needs to add new nodes to the computational graph (e.g., adding cache nodes, using `rfactor` [46]). The number of decisions for different programs becomes different. It is hard to align the incomplete programs for a fair comparison. (3) Sequential construction based search is not scalable. Enlarging the search space needs to add more sequential construction steps, which, however, leads to a worse accumulated error.

Ansor's hierarchical approach As shown in Figure 2c, Ansor is backed by a hierarchical search space that decouples high-level structures and low-level details. Ansor constructs the search space for a computational graph automatically, eliminating the need to manually develop templates. Ansor then samples complete programs from the space and performs fine-tuning on complete programs, avoiding the inaccurate estimation of incomplete programs. Figure 2 shows the key dif-

¹ recall@ k of top- $k = \frac{|G \cap P|}{k}$, where G is the set of top- k programs according to the ground truth and P is the set of top- k programs predicted by the model.

ference between Ansor’s approach and existing approaches.

3 Design Overview

Ansor is an automated tensor program generation framework. Figure 4 shows the overall architecture of Ansor. The input of Ansor is a set of to be optimized DNNs. Ansor uses the operator fusion algorithm from Relay [42] to convert DNNs from popular model formats (e.g., ONNX [6], TensorFlow PB) to partitioned small subgraphs. Ansor then generates tensor programs for these subgraphs. Ansor has three major components: (1) a program sampler that constructs a large search space and samples diverse programs from it; (2) a performance tuner that fine-tunes the performance of sampled programs; (3) a task scheduler that allocates time resources for optimizing multiple subgraphs in the DNNs.

Program sampler. One key challenge Ansor has to address is generating a large search space for a given computational graph. To cover diverse tensor programs with various high-level structures and low-level details, Ansor utilizes a hierarchical representation of the search space with two levels: *sketch* and *annotation* (§4). Ansor defines the high-level structures of programs as sketches and leaves billions of low-level choices (e.g., tile size, parallel, unroll annotations) as annotations. This representation allows Ansor to enumerate high-level structures flexibly and sample low-level details efficiently. Ansor includes a program sampler that randomly samples programs from the space to provide comprehensive coverage of the search space.

Performance tuner. The performance of randomly sampled programs is not necessarily good. The next challenge is to fine-tune them. Ansor employs evolutionary search and a learned cost model to perform fine-tuning iteratively (§5). At each iteration, Ansor uses re-sampled new programs as well as good programs from previous iterations as the initial population to start the evolutionary search. Evolutionary search fine-tunes programs by mutation and crossover which perform out-of-order rewrite and address the limitation of sequential construction. Querying the learned cost model is orders of magnitude faster than actual measurement, so we can evaluate thousands of programs in seconds.

Task scheduler. Using program sampling and performance fine-tuning allows Ansor to find high-performance tensor programs for a computational graph. Intuitively, treating a whole DNN as a single computational graph and generating a full tensor program for it could potentially achieve the optimal performance. This, however, is inefficient because it has to deal with the unnecessary exponential explosion of the search space. Typically, the compiler partitions the large computational graph of a DNN into several small subgraphs [11, 42]. This partition has a negligible effect on the performance thanks to the layer-by-layer construction nature of DNNs. This brings the final challenge of Ansor: how to allocate time resources when generating programs for multiple subgraphs.

Figure 4: System Overview. The gray arrows show the flow of extracting subgraphs from deep learning models and generating optimized programs for them. The green arrows mean the measurer returns profiling data to update the status of all components in the system.

The task scheduler (§6) in Ansor uses a scheduling algorithm based on gradient descent to allocate resources to the subgraphs that are more likely to improve the end-to-end DNN performance.

4 Program Sampling

The search space an algorithm explores determines the best programs it can find. The considered search spaces in existing approaches are limited by the following factors: (1) Manual enumeration (e.g., TVM [12]). It is impractical to manually enumerate all possible choices by templates, so existing manual templates only cover a limited search space heuristically. (2) Aggressive early pruning (e.g., Halide auto-scheduler [2]). Aggressive early pruning based on evaluating incomplete programs prevents the search algorithm from exploring certain regions in the space.

In this section, we introduce techniques to push the boundary of the considered search space by addressing the above limitations. To solve (1), we automatically expand the search space by recursively applying a set of flexible derivation rules. To avoid (2), we randomly sample complete programs in the search space. Since random sampling gives an equal chance to every point to be sampled, our search algorithm can potentially explore every program in the considered space. We do not rely on random sampling to find the optimal program, because every sampled program is later fine-tuned (§5).

To sample programs that can cover a large search space, we define a hierarchical search space with two levels: *sketch* and *annotation*. We define the high-level structures of programs as sketches and leave billions of low-level choices (e.g., tile

No	Rule Name	Condition	Application
1	Skip	$\neg \text{IsStrictInlinable}(S, i)$	$S' = S; i' = i - 1$
2	Always Inline	$\text{IsStrictInlinable}(S, i)$	$S' = \text{Inline}(S, i); i' = i - 1$
3	Multi-level Tiling	$\text{HasDataReuse}(S, i)$	$S' = \text{MultiLevelTiling}(S, i); i' = i - 1$
4	Multi-level Tiling with Fusion	$\text{HasDataReuse}(S, i) \wedge \text{HasFusibleConsumer}(S, i)$	$S' = \text{FuseConsumer}(\text{MultiLevelTiling}(S, i), i); i' = i - 1$
5	Add Cache Stage	$\text{HasDataReuse}(S, i) \wedge \neg \text{HasFusibleConsumer}(S, i)$	$S' = \text{AddCacheWrite}(S, i); i = i'$
6	Reduction Factorization	$\text{HasMoreReductionParallel}(S, i)$	$S' = \text{AddRfactor}(S, i); i' = i - 1$
...	User Defined Rule

Table 1: Derivation rules used to generate sketches. The condition runs on the current state $\sigma = (S, i)$. The application derives the next state $\sigma' = (S', i')$ from the current state σ . Note that some function (e.g., *AddRfactor*, *FuseConsumer*) can return multiple possible values of S' . In this case we collect all possible S' , and return multiple next states σ' for a single input state σ .

size, parallel, unroll annotations) as annotations. At the top level, we generate sketches by recursively applying a few derivation rules. At the bottom level, we randomly annotate these sketches to get complete programs. This representation summarizes a few basic structures from billions of low-level choices, enabling the flexible enumeration of high-level structures and efficient sampling of low-level details.

While Ansor supports both CPU and GPU, we explain the sampling process for CPUs in §4.1 and §4.2 as an example. We then discuss how the process is different for GPU in §4.3.

4.1 Sketch Generation

As shown in Figure 4, the program sampler accepts partitioned subgraphs as input. The first column in Figure 5 shows two examples of the input. The input has three equivalent forms: the mathematical expression, the corresponding naive program obtained by directly expanding the loop indices, and the corresponding computational graph (directed acyclic graph, or DAG).

To generate sketches for a DAG with multiple nodes, we visit all the nodes in a topological order and build the structure iteratively. For computation nodes that are compute-intensive and have a lot of data reuse opportunities (e.g., conv2d, matmul), we build basic tile and fusion structures for them as the sketch. For simple element-wise nodes (e.g., ReLU, element-wise add), we can safely inline them. Note that new nodes (e.g., caching nodes, layout transform nodes) may also be introduced to the DAG during the sketch generation.

We propose a derivation-based enumeration approach to generate all possible sketches by recursively applying several basic rules. This process takes a DAG as an input and returns a list of sketches. We define the State $\sigma = (S, i)$, where S is the current partially generated sketch for the DAG, and i is the index of the current working node. The nodes in a DAG are sorted in a topological order from output to input. The derivation begins from the initial naive program and the last node, or the initial state $\sigma = (\text{naive program}, \text{index of the last node})$. Then we try to apply all derivation rules to the states recursively. For each rule, if the current state satisfies the application condition, we apply the rule to $\sigma = (S, i)$ and get $\sigma' = (S', i')$ where $i' \leq i$. This way the index i (working node)

decreases monotonically. A state becomes a terminal state when $i = 0$. During enumeration, multiple rules can be applied to one state to generate multiple succeeding states. One rule can also generate multiple possible succeeding states. So we maintain a queue to store all intermediate states. The process ends when the queue is empty. All $\sigma.S$ in terminal states form a sketch list at the end of the sketch generation. The number of sketches is less than 10 for a typical subgraph.

Derivation rules. Table 1 lists derivation rules we used for the CPU. We first provide the definition of the used predicates and then describe the functionality of each rule. *IsStrictInlinable*(S, i) indicates if the node i in S is a simple element-wise operator that can always be inlined (e.g., element-wise add, ReLU). *HasDataReuse*(S, i) indicates if the node i in S is a compute-intensive operator and has plentiful intra-operator data reuse opportunity (e.g., matmul, conv2d). *HasFusibleConsumer*(S, i) indicates if the node i in S has only one consumer j and node j can be fused into node i (e.g., matmul + bias_add, conv2d + relu). *HasMoreReductionParallel*(S, i) indicates if the node i in S has little parallelism in space dimensions but has ample parallelism opportunity in reduction dimensions. (e.g., computing 2-norm of a matrix, matmul $C_{2 \times 2} = A_{2 \times 512} \cdot B_{512 \times 2}$). We perform static analysis on the computation definitions to get the values for these predicates. The analysis is done automatically by parsing the read/write pattern in the mathematical expressions. Next, we introduce the functionality of each derivation rule.

Rule 1 just simply skips a node if it is not strictly inlinable. Rule 2 always inlines strictly inlinable nodes. Since the conditions of rule 1 and rule 2 are mutually exclusive, a state with $i > 1$ can always satisfy one of them and continue to derive.

Rules 3, 4, and 5 deal with the multi-level tiling and fusion for nodes that have data reuse. Rule 3 performs multi-level tiling for data reusable nodes. For CPU, we use a “SSRSRS” tile structure, where “S” stands for one tile level of space loops and “R” stands for one tile level of reduction loops. For example, in the matmul $C(i, j) = \sum_k A[i, k] \times B[k, j]$, i and j are space loops and k is a reduction loop. The “SSRSRS” tile structure for matmul expands the original 3-level loop (i, j, k) into a 10-level loop $(i_0, j_0, i_1, j_1, k_0, i_2, j_2, k_1, i_3, j_3)$. Although we do not permute the loop order, this multi-level

tiling can also cover some cases of reordering. For example, the above 10-level loop can be specialized to just a simple reorder (k_0, j_2, i_3) by setting the length of other loops to one. The "SSRSRS" tile structure is general for compute-intensive dense operators (e.g., matmul, conv2d, conv3d) in deep learning, because they all consist of space loops and reduction loops.

Rule 4 performs multi-level tiling and also fuses the fusible consumers. For example, we fuse the element-wise nodes (e.g., ReLU, bias add) into the tiled nodes (e.g., conv2d, matmul). Rule 5 adds a caching node if the current data-reusable node does not have a fusible consumer. For example, the final output node in a DAG does not have any consumer, so it directly writes results into main memory by default and this is inefficient due to the high latency of memory accesses. By adding a cache node, we introduce a new fusible consumer into the DAG, then rule 4 can be applied to fuse this newly added cache node into the final output node. With the cache node fused, now the final output node writes its results into a cache block, and the cache block will be written to the main memory at once when all data in the block is computed.

Rule 6 can use `rfactor` [46] to factorize a reduction loop into a space loop to bring more parallelism.

Examples. Figure 5 shows three examples of the generated sketches. The sketches are different from the manual templates in TVM, because the manual templates specify both high-level structures and low-level details while sketches only define high-level structures. For the example input 1, the sorted order of the four nodes in the DAG is (A, B, C, D) . To derive the sketches for the DAG, we start from output node $D(i = 4)$ and apply rules to the nodes one by one. Specifically, the derivation for generated sketch 1 is:

$$\begin{aligned} \text{Input 1} &\rightarrow \sigma(S_0, i = 4) \xrightarrow{\text{Rule 1}} \sigma(S_1, i = 3) \xrightarrow{\text{Rule 4}} \\ &\sigma(S_2, i = 2) \xrightarrow{\text{Rule 1}} \sigma(S_3, i = 1) \xrightarrow{\text{Rule 1}} \text{Sketch 1} \end{aligned}$$

For the example input 2, the sorted order of the five nodes is (A, B, C, D, E) . Similarly, we start from the output node $E(i = 5)$ and apply rules recursively. The generated sketch 2 is derived by:

$$\begin{aligned} \text{Input 2} &\rightarrow \sigma(S_0, i = 5) \xrightarrow{\text{Rule 5}} \sigma(S_1, i = 5) \xrightarrow{\text{Rule 4}} \\ &\sigma(S_2, i = 4) \xrightarrow{\text{Rule 1}} \sigma(S_3, i = 3) \xrightarrow{\text{Rule 1}} \\ &\sigma(S_4, i = 2) \xrightarrow{\text{Rule 2}} \sigma(S_5, i = 1) \xrightarrow{\text{Rule 1}} \text{Sketch 2} \end{aligned}$$

Similarly, the generated sketch 3 is derived by:

$$\begin{aligned} \text{Input 2} &\rightarrow \sigma(S_0, i = 5) \xrightarrow{\text{Rule 6}} \sigma(S_1, i = 4) \xrightarrow{\text{Rule 1}} \\ &\sigma(S_2, i = 3) \xrightarrow{\text{Rule 1}} \sigma(S_3, i = 2) \xrightarrow{\text{Rule 2}} \\ &\sigma(S_4, i = 1) \xrightarrow{\text{Rule 1}} \text{Sketch 3} \end{aligned}$$

Customization. While the presented rules are practical enough to cover the structures for most operators, there are always exceptions. For example, some special algorithms (e.g.,

Winograd convolution [30]) and accelerator intrinsics (e.g., TensorCore [37]) require special tile structures to be effective. Although the template-guided search approach (in TVM) can craft a new template for every new case, it needs a great amount of design effort. On the other hand, the derivation-based sketch generation in Ansor is flexible enough to generate the required structures for emerging algorithms and hardware, as we allow users to register new derivation rules and integrate them seamlessly with existing rules.

4.2 Random Annotation

The sketches generated by the previous subsection are incomplete programs because they only have tile structures without specific tile sizes and loop annotations, such as parallel, unroll, and vectorization. In this subsection, we annotate sketches to make them complete programs for fine-tuning and evaluation.

Given a list of generated sketches, we randomly pick one sketch, randomly fill out tile sizes, parallelize some outer loops, vectorize some inner loops, and unroll a few inner loops. We also randomly change the computation location of some nodes in the program to make a slight tweak to the tile structure. All “random” in this subsection means a uniform distribution over all valid values. If some special algorithms require custom annotations to be effective (e.g., special unrolling), we allow users to give simple hints in the computation definition to adjust the annotation policy. Finally, since changing the layout of constant tensors can be done in compilation time and brings no runtime overhead, we rewrite the layouts of the constant tensors according to the multi-level tile structure to make them as cache-friendly as possible. This optimization is effective because the weight tensors of convolution or dense layers are constants for inference applications.

Examples of random sampling are shown in Figure 5. The sampled program might have fewer loops than the sketch because the loops with length one are simplified.

4.3 GPU Support

For GPU, we change the multi-level tiling structure from "SSRSRS" to "SSRRRSRS" to match the architecture of GPU. The loops in the first three space tiles are bound to BlockIdx, virtual thread (for reducing bank conflicts), and ThreadIdx, respectively. We add two sketch derivation rules, one for utilizing shared memory by inserting a caching node (similar to Rule 5) and the other for cross-thread reduction (similar to Rule 6).

5 Performance Fine-tuning

The programs sampled by the program sampler have good coverage of the search space, but their qualities are not guaranteed. This is because the optimization choices, such as tile structure and loop annotations, are all randomly sampled. In this

Figure 5: Examples of generated sketches and sampled programs. This figure shows two example inputs, three generated sketches and four sampled programs. The code example is pseudo code in a python-like syntax.

section, we introduce the performance tuner that fine-tunes the performance of the sampled programs via evolutionary search and a learned cost model.

The fine-tuning is performed iteratively. At each iteration, we first use evolutionary search to find a small batch of promising programs according to a learned cost model. We then measure these programs on hardware to get the actual execution time cost. Finally, the profiling data got from measurement is used to re-train the cost model to make it more accurate.

The evolutionary search uses randomly sampled programs as well as high-quality programs from the previous measurement as the initial population and applies mutation and crossover to generate the next generation. The learned cost model is used to predict the *fitness* of each program, which is the throughput of one program in our case. We run evolution for a fixed number of generations and pick the best programs found during the search. We leverage a learned cost model because the cost model can give relatively accurate estimations of the fitness of programs while being orders of magnitudes

faster than the actual measurement. It allows us to compare tens of thousands of programs in the search space in seconds, and pick the promising ones to do actual measurements.

5.1 Evolutionary Search

Evolutionary search [54] is a generic meta-heuristic algorithm inspired by biological evolution. By iteratively mutating high-quality programs, we can generate new programs with potentially higher quality. The evolution starts from the sampled initial generation. To generate the next generation, we first select some programs from the current generation according to certain probabilities. The probability of selecting a program is proportional to its fitness predicted by the learned cost model (§5.2), meaning that the program with a higher performance score has a higher probability to be selected. For the selected programs, we randomly apply one of the evolution operations to generate a new program. Basically, for decisions we made during sampling (§4.2), we design corresponding evolution

operations to rewrite and fine-tune them.

Tile size mutation. This operation scans the program and randomly selects a tiled loop. For this tiled loop, it divides a tile size of one tile level by a random factor and multiplies this factor to another level. Since this operation keeps the product of tile sizes equal to the original loop length, the mutated program is always valid.

Parallel mutation. This operation scans the program and randomly selects a loop that has been annotated with parallel. For this loop, this operation changes the parallel granularity by either fusing its adjacent loop levels or splitting it by a factor.

Pragma mutation. Some optimizations in a program are specified by compiler-specific pragma. This operation scans the program and randomly selects a pragma. For this pragma, this operation randomly mutates it into another valid value. For example, our underlying code generator supports auto unrolling with a maximum number of steps by providing an `auto_unroll_max_step=N` pragma. We randomly tweak the number N .

Computation location mutation. This operation scans the program and randomly selects a flexible node that is not multi-level tiled (e.g., a padding node in the convolution layer). For this node, the operation randomly changes its computation location to another valid attach point.

Node-based crossover. Crossover is an operation to generate new offspring by combining the genes from two or more parents. The genes of a program in Ansor are its rewriting steps. Every program generated by Ansor is rewritten from its initial naive implementation. Ansor preserves a complete rewriting history for each program during sketch generation and random annotation. We can treat rewriting steps as the genes of a program because they describe how this program is formed from the initial naive one. Based on this, we can generate a new program by combining the rewriting steps of two existing programs. However, arbitrarily combining rewriting steps from two programs might break the dependencies in steps and create an invalid program. As a result, the granularity of crossover operation in Ansor is based on nodes in the DAG, because the rewriting steps across different nodes usually have less dependency. Ansor randomly selects one parent for each node and merges the rewriting steps of selected nodes. When there are dependencies between nodes, Ansor tries to analyze and adjust the steps with simple heuristics. Ansor further verifies the merged programs to guarantee the functional correctness. The verification is simple because Ansor only uses a small set of loop transformation rewriting steps, and the underlying code generator can check the correctness by dependency analysis.

The evolutionary search leverages mutation and crossover to generate a new set of candidates repeatedly for several rounds and outputs a small set of programs with the highest scores. These programs will be compiled and measured on the target hardware to obtain the real running time cost. The col-

lected measurement data is then used to update the cost model. In this way, the accuracy of the learned cost model is gradually improved to match the target hardware. Consequently, the evolutionary search gradually generates higher-quality programs for the target hardware platform.

Unlike the search algorithms in TVM and FlexTensor that can only work in a fixed grid-like parameter space, the evolutionary operations in Ansor are specifically designed for tensor programs. They can be applied to general tensor programs and can handle a search space with complicated dependency. Unlike the unfolding rules in Halide auto-scheduler, these operations can perform out-of-order modifications to programs, addressing the sequential limitations.

5.2 Learned Cost Model

A cost model is necessary for estimating the performance of programs quickly during the search. We adopt a learned cost model similar to related works [2, 12] with newly designed program features. A system based on learned cost models has great portability because a single model design can be reused for different hardware backends by feeding in different training data.

Since our target programs are mainly data parallel tensor programs, which are made by multiple interleaved loop nests with several assignment statements as the innermost statements, we train the cost model to predict the score of one innermost non-loop statement in a loop nest. For a full program, we make predictions for each innermost non-loop statement and add the predictions up as the score. We build the feature vector for an innermost non-loop statement by extracting features in the context of a full program. The extracted features include arithmetic features and memory access features. A detailed list of extracted features is in an appendix of the extended version of this paper [58].

We use weighted squared error as the loss function. Because we mostly care about identifying the well-performing programs from the search space, we put more weight on the programs that run faster. Specifically, the loss function of the model f on a program P with throughput y is $loss(f, P, y) = w_P (\sum_{s \in S(P)} f(s) - y)^2 = y (\sum_{s \in S(P)} f(s) - y)^2$ where $S(P)$ is the set of innermost non-loop statements in P . We directly use the throughput y as weight. We train a gradient boosting decision tree [9] as the underlying model f . A single model is trained for all tensor programs coming from all DAGs, and we normalize the throughput of all programs coming from the same DAG to be in the range of $[0, 1]$. When optimizing a DNN, the number of measured programs are typically less than 30,000. Training a gradient boosting decision tree is very fast on such a small data sets, so we train a new model every time instead of doing incremental updates.

6 Task Scheduler

A DNN can be partitioned into many independent subgraphs (*e.g.*, conv2d + relu). For some subgraphs, spending time in tuning them does not improve the end-to-end DNN performance significantly. This is due to two reasons: either (1) the subgraph is not a performance bottleneck, or (2) tuning brings only minimal improvement in the subgraph's performance.

To avoid wasting time on tuning unimportant subgraphs, Ansor dynamically allocates different amounts of time resources to different subgraphs. Take ResNet-50 for example, it has 29 unique subgraphs after the graph partitioning. Most of these subgraphs are convolution layers with different shapes configurations (input size, kernel size, stride, etc). We need to generate different programs for different convolution layers because the best tensor program depends on these shape configurations. In reality, users may have multiple DNNs for all their applications. This leads to more subgraphs as well as more opportunities to reduce the total tuning time, because we can share and reuse knowledge between subgraphs. A subgraph can also appear multiple times in a DNN or across different DNNs.

We define a task as a process performed to generate high-performance programs for a subgraph. It means that optimizing a single DNN requires finishing dozens of tasks (*e.g.*, 29 tasks for ResNet-50). Ansor's task scheduler allocates time resources to tasks in an iterative manner. At each iteration, Ansor selects a task, generates a batch of promising programs for the subgraph, and measures the program on hardware. We define such an iteration as one unit of time resources. When we allocate one unit of time resources to a task, the task obtains an opportunity to generate and measure new programs, which also means the chance to find better programs. We next present the formulation of the scheduling problem and our solution.

6.1 Problem Formulation

When tuning a DNN or a set of DNNs, a user can have various types of goals, for example, reducing a DNN's latency, meeting latency requirements for a set of DNNs, or minimizing tuning time when tuning no longer improves DNN performance significantly. We thus provide users a set of objective functions to express their goals. Users can also provide their own objective functions.

Suppose there are n tasks in total. Let $t \in \mathbf{Z}^n$ be the allocation vector, where t_i is the number of time units spent on task i . Let the minimum subgraph latency task i achieves be a function of the allocation vector $g_i(t)$. Let the end-to-end cost of the DNNs be a function of the latency of the subgraphs $f(g_1(t), g_2(t), \dots, g_3(t))$. Our objective is to minimize the end-to-end cost:

$$\text{minimize } f(g_1(t), g_2(t), \dots, g_3(t))$$

$$\begin{aligned} f_1 &= \sum_{j=1}^m \sum_{i \in S(j)} w_i \times g_i(t) \\ f_2 &= \sum_{j=1}^m \max(\sum_{i \in S(j)} w_i \times g_i(t), L_j) \\ f_3 &= -(\prod_{j=1}^m \frac{B_j}{\sum_{i \in S(j)} w_i \times g_i(t)})^{\frac{1}{m}} \\ f_4 &= \sum_{j=1}^m \sum_{i \in S(j)} w_i \times \max(g_i(t), ES(g_i, t)) \end{aligned}$$

Table 2: Examples of objective functions for multiple neural networks

To minimize the end-to-end latency of a single DNN, we can define $f(g_1, g_2, \dots, g_n) = \sum_{i=1}^n w_i \times g_i$, where w_i is the number of appearances of task i in the DNN. This formulation is straightforward because f is an approximation of the end-to-end DNN latency.

When tuning a set of DNNs, there are several options. Table 2 shows a number of example objective functions for tuning multiple DNNs. Let m be the number of DNNs, $S(j)$ is the set of tasks that belong to DNN j . f_1 adds up the latency of every DNN, which means to optimize the cost of a pipeline that sequentially runs all DNNs once. In f_2 , we define L_j as the latency requirement of DNN j , meaning that we do not want to spend time on a DNN if its latency has already met the requirement. In f_3 , we define B_j as the reference latency of a DNN j . As a result, our goal is to maximize the geometric mean of speedup against the given reference latency. Finally in f_4 , we define a function $ES(g_i, t)$ that returns an early stopping value by looking at the history of latency of task i . It can achieve the effect of per-task early stopping.

6.2 Optimizing with Gradient Descent

We propose a scheduling algorithm based on gradient descent to efficiently optimize the objective function. Given the current allocation t , the idea is to approximate the gradient of the objective function $\frac{\partial f}{\partial t_i}$ in order to choose the task i such that $i = \text{argmax}_i |\frac{\partial f}{\partial t_i}|$. We approximate the gradient by making an optimistic guess and considering the similarity between tasks. The derivation is in an appendix of the extended version of this paper [58]. We approximate the gradient by

$$\begin{aligned} \frac{\partial f}{\partial t_i} &\approx \frac{\partial f}{\partial g_i} (\alpha \frac{g_i(t_i) - g_i(t_i - \Delta t)}{\Delta t} + \\ &\quad (1 - \alpha) (\min(-\frac{g_i(t_i)}{t_i}, \beta \frac{C_i}{\max_{k \in N(i)} V_k} - g_i(t_i))) \end{aligned}$$

where Δt is a small backward window size, $g_i(t_i)$ and $g_i(t_i - \Delta t)$ are known from the history of allocations. $N(i)$ is the set of similar tasks of i , C_i is the number of floating point operation in task i and V_k is the number of floating point operation per second we can achieve in task k . The parameter α and β control the weight to trust some predictions.

To run the algorithm, Ansor starts from $t = \mathbf{0}$ and warms up with a round of round-robin to get an initial allocation vector $t = (1, 1, \dots, 1)$. After the warm-up, at each iteration, we

compute the gradient of each task and pick $\arg\max_i |\frac{\partial f}{\partial t_i}|$. Then we allocate the resource unit to task i and update the allocation vector $t_i = t_i + 1$. The optimization process continues until we run out of the time budget. To encourage exploration, we adopt a ϵ -greedy strategy [47], which preserves a probability of ϵ to randomly select a task.

Taking the case of optimizing for a single DNN’s end-to-end latency for example, Ansor prioritizes a subgraph that has a high initial latency because our optimistic guess says we can reduce its latency quickly. Later, if Ansor spends many iterations on it without observing a decrease in its latency, Ansor leaves the subgraph because its $|\frac{\partial f}{\partial t_i}|$ decreases.

7 Evaluation

The core of Ansor is implemented in C++ with about 12K lines of code (3K for the search policy and 9K for other infrastructure). Ansor generates programs in its own intermediate representation (IR). These programs are then lowered to TVM IR for code generation targeting various hardware platforms. Ansor only utilizes TVM as a deterministic code generator.

We evaluate the performance of generated programs on three levels: single operator, subgraph, and entire neural network. For each level of evaluation, we compare Ansor against the state-of-the-art search frameworks and hardware-specific manual libraries. We also evaluate the search efficiency and the effectiveness of each component in Ansor.

The generated tensor programs are benchmarked on three hardware platforms: an Intel CPU (18-core Platinum 8124M@3.0 GHz), an NVIDIA GPU (V100), and an ARM CPU (4-core Cortex-A53@1.4GHz on the Raspberry Pi 3b+). We use float32 as the data type for all evaluations.

7.1 Single Operator Benchmark

Workloads. We first evaluate Ansor on a set of common deep learning operators, including 1D, 2D, and 3D convolution (C1D, C2D, and C3D respectively), matrix multiplication (GMM), group convolution (GRP), dilated convolution (DIL) [57], depth-wise convolution (DEP) [24], transposed 2D convolution (T2D) [40], capsule 2D convolution (CAP) [23], and matrix 2-norm (NRM). For each operator, we select 4 common shape configurations and evaluate them with two batch sizes (1 and 16). In total, there are 10 operators \times 4 shape configurations \times 2 batch size = 80 test cases. The shape configurations used can be found in an appendix of the extended version of this paper [58]. We run these test cases on the Intel CPU.

Baselines. We include PyTorch (v1.5) [39], Halide auto-scheduler (commit: 1f875b0) [2], FlexTensor (commit: 7ac302c) [59], and AutoTVM (commit: 69313a7) [12] as baselines. PyTorch is backed by the vendor-provided kernel library MKL-DNN [27]. Halide auto-scheduler is a sequential construction based search framework for Halide. AutoTVM

and FlexTensor are template-guided search frameworks based on TVM. Since Halide auto-scheduler does not have a pre-trained cost model for AVX-512, we disabled AVX-512 for the evaluation in §7.1 and §7.2. For every operator, we use the best layout available in each framework, but the input and output tensors must not be packed.

Search settings. We let search frameworks (*i.e.*, Halide auto-scheduler, FlexTensor, AutoTVM, and Ansor) to run search or auto-tuning with up to 1,000 measurement trials per test case. This means each framework can measure at most $80 \times 1,000$ programs for auto-tuning in this evaluation. Using the same number of measurement trials makes it a fair comparison without involving implementation details. In addition, using 1,000 measurement trials per test case is typically enough for the search to converge in these frameworks.

Normalization. Figure 6 shows the normalized performance. For each test case, we normalize the throughputs to the best performing framework. We then plot the geometric mean of the four shapes of each operator. The geometric mean is also normalized to the best performing framework, so the best framework has a normalized performance of 1 in the figure. The error bar denotes the standard deviation of the normalized throughput of four shapes of each operator.

Results. As shown in the Figure 6, Ansor performs the best or equally the best in all operator and batch size settings. Ansor outperforms existing search frameworks by $1.1 - 22.5\times$. The performance improvements of Ansor come from both its large search space and effective exploration strategy. For most operators, we found the best program generated by Ansor is outside the search space of existing search frameworks because Ansor is able to explore more optimization combinations. For example, the significant speedup on NRM is because Ansor can parallelize reduction loops, while other frameworks do not. The large speedup on T2D is because Ansor can use correct tile structures and unrolling strategies to let the code generator simplify the multiplication of zeros in strided transposed convolution. In contrast, other frameworks fail to capture many effective optimizations in their search space, making them unable to find the programs that Ansor does. For example, the unfolding rules in Halide do not split the reduction loop in GMM and do not split reduction loops in C2D when padding is computed outside of reduction loops. The templates in AutoTVM have limited tile structures, as they cannot cover the structure of “Generated Sketch 1” in Figure 5. The template in FlexTensor does not change the computation location of padding. The template in FlexTensor fails to run for reduction operators like NRM.

Ablation study. We run four variants of Ansor on a convolution operator and report the performance curve. We pick the last convolution operator in ResNet-50 with batch size=16 as the test case, because its search space is sufficiently large to evaluate the search algorithms. Other operators share a similar pattern. In Figure 7, each curve is the median of 5 runs. “Ansor (ours)” uses all our introduced techniques. “Beam

Figure 6: Single operator performance benchmark on a 20-core Intel-Platinum-8269CY. The y-axis is the throughput normalized to the best throughput for each operator.

Figure 7: Ablation study of four variants of Ansor on a convolution operator. The y-axis is the throughput relative to the throughput of the best program.

Search” means we prune incomplete programs with the cost model during the sampling process and do not use fine-tuning. “No fine-tuning” is based on “Ansor (ours)” but disables fine-tuning and only relies on random sampling. “Limited space” is also based on “Ansor (ours)” but limits the search space to make it similar to the space in existing manual templates (*e.g.*, limit tiling level, innermost tile sizes, and computation location). As demonstrated by Figure 7, dropping either the large search space or efficient fine-tuning decreases the final performance significantly. The aggressive early pruning in “Beam search” throws away incomplete programs with good final performance due to inaccurate estimation.

7.2 Subgraph Benchmark

We perform the subgraph benchmark on two common subgraphs in DNNs. The “ConvLayer” is a subgraph consisting of 2D convolution, batch normalization [28], and ReLU activation, which is a common pattern in convolutional neural networks. The “TBS” is a subgraph consisting of two matrix transposes, one batch matrix multiplication, and a softmax, which is a pattern in the multi-head attention [51] in language models. Similar to the single operator benchmark (§7.1), we select four different shape configurations and two batch sizes, run auto-tuning with up to 1,000 measurement trails per test case, and report the normalized performance. We use the

Figure 8: Subgraph performance benchmark on a 20-core Intel-Platinum-8269CY and an NVIDIA V100. “@C” denotes CPU results and “@G” denotes GPU results. The y-axis is the throughput normalized to the best throughput for each subgraph.

same set of baseline frameworks and run the benchmark on the Intel CPU and the NVIDIA GPU. We do not report the performance of Halide auto-scheduler on GPU because as of writing the paper its GPU support is still in an experimental stage. FlexTensor fails to run on complicated subgraphs like “TBS”.

Figure 8 shows that Ansor outperforms manual libraries and other search frameworks by 1.1 – 14.2 \times . Ansor can generate high-performance programs consistently for these subgraphs on both platforms. FlexTensor performs well for single operators but shows less advantage for subgraphs because it lacks the support of operator fusion.

7.3 End-to-End Network Benchmark

Workloads. We benchmark the end-to-end inference execution time of several DNNs, which include ResNet-50 [22] and MobileNet-V2 [43] for image classification, 3D-ResNet-18 [21] for action recognition, DCGAN [40] generator for image generation, and BERT [15] for language understanding. We benchmark these DNNs on three hardware platforms. For the server-class Intel CPU and NVIDIA GPU, we report the results for batch size 1 and batch size 16. For the ARM CPU in the edge device, real-time feedback is typically desired, so we only report the results for batch size 1.

Baselines and Settings. We include PyTorch (v1.5 with torch script), TensorFlow (v2.0 with graph mode), TensorRT (v6.0 with TensorFlow integration) [38], TensorFlow Lite (V2.0), and AutoTVM as baseline frameworks. We do not include Halide auto-scheduler or FlexTensor because they lack the support of widely-used deep learning model formats (*e.g.*, ONNX, TensorFlow PB) and high-level graph optimizations. As a result, we expect that the end-to-end execution time they can achieve will be the sum of the latency of all subgraphs in a DNN. In contrast, AutoTVM can optimize a whole DNN with its manual templates and various graph-level optimizations (*e.g.*, graph-level layout search [32], graph-level constant

Figure 9: Network inference performance benchmark on three hardware platforms. The y-axis is the throughput relative to the best throughput for each network.

folding [42]) which improve the performance significantly. Anso also performs layout rewrite as described in §4.2. We let both AutoTVM and Anso run auto-tuning until they use to $1000 \times n$ measurement trials on each DNN, where n is the number of subgraphs in the DNN. This is typically enough for them to converge. We set the objective of the task scheduler as minimizing the total latency of one DNN and generate programs for these networks one by one. On the other hand, PyTorch, TensorFlow, TensorRT, and TensorFlow Lite are all backed by static kernel libraries (MKL-DNN on Intel CPU, CuDNN on NVIDIA GPU, and Eigen on ARM CPU) and do not need auto-tuning. We enable AVX-512 for all frameworks on the Intel CPU in this network benchmark.

Results. Figure 9 shows the results on the Intel CPU,

Figure 10: Network performance auto-tuning curve. The y-axis is the speedup relative to AutoTVM.

NVIDIA GPU and ARM CPU². Overall, Anso performs the best or equally the best in all cases. Compared with search-based AutoTVM, Anso matches or outperforms it in all cases with $1.0 - 21.8\times$ speedup. Compared with the best alternative, Anso improves the execution performance of DNNs on the Intel CPU, ARM CPU, and NVIDIA GPU by up to $3.8\times$, $2.6\times$, and $1.7\times$, respectively. The reason for the significant speedup on DCGAN is that DCGAN mainly consists of transposed 2D convolution (T2D), which can be well optimized by Anso, as shown and explained in the single operator benchmark (§7.1). AutoTVM performs very well for ResNet-50 on the Intel CPU thanks to its highly-optimized templates for 2D convolution and global layout search [32]. Anso does not run a global layout search but does rewrite the layout of weight tensors as described in §4.2. Anso uses more levels of tiling so it packs weight tensors into more levels. The layout rewrite brings about 40% improvement to ResNet-50 in Anso. Compared with vendor-specific static libraries, Anso has more advantages on uncommon shapes and small batch sizes, because it is not easy to manually optimize for these cases.

Ablation study. We run variants of Anso on two test cases in Figure 10. In the left figure, we run four variants of Anso to generate programs for a single mobilenet-V2. In the right figure, we run these variants for both mobilenet-V2 and ResNet-50. We set the objective function of the task scheduler to be the geometric mean of speedup against AutoTVM. As shown in Figure 10, “No task scheduler” means we use a round-robin strategy to allocate equal time resources to all subgraphs. “Limited space” is based on “Anso (ours)” but limits the search space. “No fine-tuning” is also based on “Anso (ours)” but disables fine-tuning and relies on random sampling only. As can be seen in Figure 10, “Limited space” performs the worst in terms of the final achieved performance, proving that the best programs are not included in the limited space. The final achieved performance can be improved by enlarging the search space, as depicted in “No fine-tuning”. However, in the right figure, randomly assigning tile sizes and annotations

²3D-ResNet and DCGAN are not yet supported by TensorFlow Lite on the ARM CPU.

still cannot beat AutoTVM in the given time budget. After enabling fine-tuning, “No task scheduler” outperforms AutoTVM in both cases. Finally, “Ansor (ours)” employs the task scheduler to prioritize performance bottlenecks (*e.g.*, subgraphs contain 3x3 convolution), so it performs the best in both search efficiency and the final achieved performance.

7.4 Search Time

Ansor searches efficiently and can outperform or match AutoTVM with less search time. Ansor slices the time and utilizes the task scheduler to simultaneously optimize all subgraphs together. In contrast, AutoTVM and other systems do not have a task scheduler, so they generate programs for all subgraphs one by one with a predefined budget of measurement trials for each subgraph. Ansor saves the search time by prioritizing important subgraphs, while AutoTVM spends predefined time budget on every subgraph, which may be a waste on the unimportant subgraphs.

Table 3 shows the search time required for Ansor to match the performance of AutoTVM on the Intel CPU network benchmark (§7.3). We list the search time in two metrics: number of measurements and wall-clock time. “Number of measurements” is a metric agnostic to the implementation of measurement and the overhead of search algorithm, while “Wall-clock time” takes these factors into account. As shown in the table, Ansor can match the performance of AutoTVM with an order of magnitude less search time. In Table 3a the saving in search time comes from the task scheduler, efficient fine-tuning, and comprehensive coverage of effective optimizations. In Table 3b, Ansor shows more time-saving in wall-clock time. This is because Ansor does not introduce much search overhead and has a better implementation of the measurement (on the Intel CPU, Ansor can get accurate measurement results with fewer repetitions by explicitly flushing the cache for some tensors). On other backends, Ansor can match the performance of AutoTVM with a similar saving in search time.

Typically, it takes several hours for Ansor to generate fully-optimized programs for a DNN on a single machine. This is acceptable for inference applications because it is a one-shot effort before deployment. In addition, the whole architecture of Ansor can be parallelized very easily.

7.5 Cost Model Evaluation

In this subsection, we evaluate the prediction quality of the learned cost model. We use 25,000 programs measured during tuning ResNet-50 on the Intel CPU as the data set. We randomly pick 20,000 programs as the training set and use the remaining 5,000 programs as the test set. We train the cost model and let it make predictions for the test set.

Figure 11 plots the predicted throughputs vs. measured throughputs. The measured throughputs are normalized to

	AutoTVM	Ansor	Time-saving
ResNet-50	21,220	6,403	3.3 ×
Mobilenet-V2	31,272	1,892	16.5 ×
3D-ResNet	5,158	1,927	2.7 ×
DCGAN	3,003	298	10.1 ×
BERT	6,220	496	12.5 ×

(a) The number of measurements.

	AutoTVM	Ansor	Time-saving
ResNet-50	39,250	4,540	8.6 ×
Mobilenet-V2	58,468	660	88.6 ×
3D-ResNet	7,594	2,296	3.3 ×
DCGAN	4,914	420	11.7 ×
BERT	12,007	266	45.1 ×

(b) Wall-clock time (seconds)

Table 3: The number of measurements and wall-clock time used for Ansor to match the performance of AutoTVM on the Intel CPU (batch size=1).

Figure 11: Measured throughputs vs. predicted throughputs.

the best performing programs in the test set. The predicted throughputs are the output of the model, so they can be negative. In Figure 11a, the points scatter around the diagonal line, meaning that the model makes accurate predictions. The distribution is not uniform because the data set is collected during the search. Good programs have a higher probability to be chosen for measurements, so most of the programs are in the top right corner. The points with measured throughput 0.0 are programs that are invalid or killed due to timeout during measurements. In Figure 11b, we sort the 5000 points according to the predictions from the slowest to the fastest, and use the relative ranking as x-axis. So the points are distributed uniformly over x-axis. It shows the distribution of performance of the explored programs better.

The model archives 0.079 RMSE, 0.958 R^2 correlation, 0.851 pairwise comparison accuracy, and 0.624 recall@30 of top-30 programs (see the definition at footnote 1) on the test set.

8 Related Work

Automatic tensor program generation based on scheduling languages. Halide [41] introduces a scheduling language

that can describe loop optimization primitives. This language is suitable for both manual optimization and automatic search. Halide has three versions of auto-scheduler based on different techniques [2, 31, 36]. The latest one with beam search and learned cost model performs the best among them, which is also used in our evaluation. TVM [11] utilizes a similar scheduling language and includes a template-guided search framework AutoTVM [12]. FlexTensor [59] proposes general templates that can target a set of operators, but its templates are designed for single operators. It is hard to use these templates for optimizations involving multiple operators (e.g., operator fusion). A concurrent work ProTuner [19] uses Monte Carlo tree search to solve the inaccurate estimation problem in Halide auto-scheduler. ProTuner mainly targets image processing workloads, while Ansor targets deep learning workloads and introduces new search space and other optimizations.

Polyhedral compilation models. The polyhedral compilation model [8, 52, 53] formulates the optimization of programs as an integer linear programming (ILP) problem. It optimizes a program with affine loop transformation that minimizes the data reuse distance between dependent statements. Tiramisu [5] and TensorComprehensions [49] are two polyhedral compilers that also target the deep learning domain. Tiramisu provides a scheduling language similar to the Halide language, and it needs manual scheduling. TensorComprehensions can search for GPU code automatically, but it is not yet meant to be used for compute-bounded problems [11]. It cannot outperform TVM on operators like conv2d and matmul [11, 48]. This is because of the lack of certain optimizations [50] and the inaccurate implicit cost model in the polyhedral formulation.

Graph-level optimization for deep learning. Graph-level optimizations treat an operator in the computational graph as a basic unit and perform optimization at graph level without changing the internal implementations of operators. The common optimizations at graph level include layout optimizations [32], operator fusion [11, 38, 60], constant folding [42], auto-batching [33], automatic generation of graph substitution [29] and so forth. The graph-level optimizations are typically complementary to operator-level optimizations. Graph-level optimizations can also benefit from high-performance implementations of operators. For example, general operator fusion relies on the code generation ability of Ansor. We leave the joint optimization of Ansor and more graph-level optimization as future work.

Search-based compilation and auto-tuning. Search based compilation and auto-tuning have already shown their effectiveness in domains other than deep learning. Stock [44] is a super-optimizer based on random search. Stock searches for loop-free hardware instruction sequences, while Ansor generates tensor programs with nests of loops. OpenTuner [4] is a general framework for program auto-tuning based on multi-armed bandit approaches. OpenTuner relies on user-specified search space, while Ansor constructs the

search space automatically. Traditional high-performance libraries such as ATLAS [56] and FFTW [16] also utilize auto-tuning. More recent works NeuroVectorizer [18] and AutoPhase [20, 26] use deep reinforcement learning to automatically vectorize programs and optimize the compiler phase ordering.

9 Limitations and Future work

One of Ansor’s limitations is that Ansor cannot optimize graphs with dynamic shapes [45]. Ansor requires the shapes in the computational graph to be static and known in advance to do analysis, construct the search space, and perform measurements. How to generate programs for symbolic or dynamic shape is an interesting future direction. Another limitation is that Ansor only supports dense operators. To support sparse operators (e.g., SpMM) that are commonly used in sparse neural networks [17] and graph neural networks [25], we expect that a large portion of Ansor can still be reused, but we need to redesign the search space. Lastly, Ansor only performs program optimizations at a high level but relies on other code generators (e.g., LLVM and NVCC) to do platform-dependent optimizations (e.g., instruction selection). Ansor comes short of utilizing the special instructions, such as Intel VNNI, NVIDIA Tensor Core, and ARM Dot for mixed-precision and low-precision operators, which are not handled well by the off-the-shelf code generators currently.

10 Conclusion

We propose Ansor, an automated search framework that generates high-performance tensor programs for deep neural networks. By efficiently exploring a large search space and prioritizing performance bottlenecks, Ansor finds high-performance programs that are outside the search space of existing approaches. Ansor outperforms existing manual libraries and search-based frameworks on a diverse set of neural networks and hardware platforms by up to $3.8\times$. By automatically searching for better programs, we hope that Ansor will help bridge the gap between the increasing demand in computing power and limited hardware performance. Ansor is integrated into the Apache TVM open-source project³.

Abstract

Performing Deep Neural Network (DNN) computation on hardware accelerators efficiently is challenging. Existing DNN frameworks and compilers often treat the DNN operators in a data flow graph (DFG) as opaque library functions and schedule them onto accelerators to be executed individually. They rely on another layer of scheduler, often implemented in hardware, to exploit the parallelism available in the operators. Such a two-layered approach incurs significant scheduling overhead and often cannot fully utilize the available hardware resources. In this paper, we propose RAMMER, a DNN compiler design that optimizes the execution of DNN workloads on massively parallel accelerators. RAMMER generates an efficient static spatio-temporal schedule for a DNN at compile time to minimize scheduling overhead. It maximizes hardware utilization by holistically exploiting parallelism through inter- and intra- operator co-scheduling. RAMMER achieves this by proposing several novel, hardware neutral, and clean abstractions for the computation tasks and the hardware accelerators. These abstractions expose a much richer scheduling space to RAMMER, which employs several heuristics to explore this space and finds efficient schedules. We implement RAMMER for multiple hardware backends such as NVIDIA GPUs, AMD GPUs, and Graphcore IPU. Experiments show RAMMER significantly outperforms state-of-the-art compilers such as TensorFlow XLA and TVM by up to $20.1\times$. It also outperforms TensorRT, a vendor optimized proprietary DNN inference library from NVIDIA, by up to $3.1\times$.

1 Introduction

Deep neural network (DNN) is now a widely adopted approach for image classification, natural language processing, and many other AI tasks. Due to its importance, many computational devices, such as CPU, GPU, FPGA, and specially designed DNN accelerators have been leveraged to

perform DNN computation. Efficient DNN computation on these devices is an important topic that has attracted much research attention in recent years [23, 28, 32, 40, 52]. One of the key factors that affect the efficiency of DNN computation is scheduling, i.e. deciding the order to perform various pieces of computation on the target hardware. The importance of scheduling in general is well known and has been thoroughly studied [20, 39]. However, there is little work discussing scheduling for DNN computation on hardware devices specifically.

The computational pattern of a deep neural network is usually modeled as a data flow graph (DFG), where each node corresponds to an operator, which represents a unit of computation such as matrix multiplication, while an edge depicts the dependency between operators. This representation naturally contains two levels of parallelism. The first level is the inter-operator parallelism, where operators that do not have dependencies in the DFG may run in parallel. The second level is the intra-operator parallelism, where an operator such as matrix multiplication has inherent internal data parallelism and can leverage hardware accelerators that can perform parallel computation, such as a GPU.

To exploit the two levels of parallelism, current practice adopts a two-layered scheduling approach. An inter-operator DFG layer scheduler takes the data flow graph and emits operators that are ready to be executed based on the dependencies. In addition, an intra-operator scheduler takes an operator and maps it to the parallel execution units in the accelerator. This layering design has a fundamental impact on the system architectures of the existing DNN tool sets. For example, the DFG layer scheduler is typically implemented in deep learning frameworks such as TensorFlow [18] or ONNX Runtime [14]. The operator layer scheduler, on the other hand, is often hidden behind the operator libraries such as cuDNN [12] and MKL-DNN [9], and sometimes implemented directly in hardware, as is the case for GPUs.

While widely adopted by existing frameworks and accelerators, such a two-layer scheduling approach incurs fundamental performance limitations. The approach works well only

^{*}Both authors contributed equally.

when the overhead of emitting operators is largely negligible compared to the execution time of operators, and when there is sufficient intra-operator parallelism to saturate all processing units in an accelerator. This unfortunately is often not the case in practice. DNN accelerators keep on increasing performance at a much faster pace than CPUs, thus making the operator emitting overhead more and more pronounced. This is exacerbated for DNN inference workloads when the batch size is small, which limits the intra-operator parallelism. Moreover, the two-layer scheduling approach overlooks the subtle interplay between the upper and lower layers: to optimize the overall performance, a system could reduce the degree of intra-operator parallelism in order to increase the level of inter-operator parallelism (§ 2).

To mitigate these limitations, we present RAMMER, a deep learning compiler that takes a holistic approach to manage the parallelism available in the DNN computation for scheduling. It unifies the inter- and intra-operator scheduling through a novel abstraction called *rTask*. *rTask* enables the scheduler to break the operator boundary and allows fine-grained scheduling of computation onto devices. Instead of the existing design that breaks scheduling into two pieces managed by software and hardware separately, RAMMER is a unified software-only solution, which makes it less dependent on underlying hardware and thus can be adopted by diverse DNN accelerators. In RAMMER, we make the following design decisions.

First, to exploit the intra-operator parallelism through a software compiler, RAMMER redefines a DNN operator as an *rTask*-operator or *rOperator*. An *rOperator* consists of multiple independent, homogeneous *rTasks*, each is a minimum schedulable unit runs on a single execution unit of an accelerator (e.g., a streaming multiprocessor SM in a GPU). Thus, *rTask* as the fine-grained intra-operator information is exposed to the RAMMER scheduler. RAMMER treats a DNN as a data flow graph of *rOperator* nodes, hence it can still see the coarse-grained inter-operator (DFG) dependencies.

Unfortunately, certain modern accelerators such as GPU do not expose interfaces for intra-operator (i.e., *rTask*) scheduling. To address this challenge, as a second design decision RAMMER abstracts a hardware accelerator as a *virtualized parallel device* (*vDevice*), which contains multiple virtualized execution units (*vEU*). The *vDevice* allows several *rTasks*, even from different operators, to run on a specified *vEU* in a desired order. Moreover, a *vEU* can run a *barrier rTask* that waits for the completion of a specified set of *rTasks*, thus ensuring the correct execution of *rTasks* from dependent operators. The *vDevice* maps a *vEU* to one of the physical execution units in an accelerator to perform the actual computation of *rTasks*.

Finally, fine-grained scheduling could incur significant runtime overheads, even more so than the operator scheduling overhead discussed previously. To address this issue, RAMMER moves the scheduling decision from runtime to compile time. This is driven by the observation that most DNN's DFG

is available at the compile time, and the operators usually exhibit deterministic performance characteristics. Therefore, the runtime performance can be obtained through compile time profiling [45]. This not only avoids unnecessary runtime overheads, but also allows a more costly scheduling policy to fully exploit the inter- and intra- operator parallelism together.

RAMMER is compatible with optimizations developed in existing DNN compilers. RAMMER can import a data-flow graph from other frameworks like TensorFlow. Such a DFG can be optimized with techniques employed by a traditional graph optimizer such as [18]. An *rOperator* can also be optimized by an existing kernel tuner [23]. Our experience shows that, on top of existing optimizations, RAMMER can provide significant additional performance improvement, especially for DNN inference workloads.

RAMMER is hardware neutral. The abstractions proposed, such as *rTask*, *rOperator* and *vEU* are applicable to any massively parallel computational devices with homogeneous execution units. This includes almost all the computational devices proposed for DNN workloads. In this paper, in addition to describe in detail how RAMMER is implemented on NVIDIA GPUs, we will also discuss our experience retargeting RAMMER for several alternative computing devices.

We have implemented RAMMER with 52k lines of C++ code and open-sourced the code¹. Our evaluation on 6 DNN models shows that RAMMER significantly outperforms state-of-the-art compilers like XLA and TVM on both NVIDIA and AMD GPUs, with up to $20.1\times$ speedup. RAMMER even outperforms TensorRT [13], a vendor optimized DNN inference library from NVIDIA, with up to $3.1\times$ gain.

Our experience on RAMMER strongly suggests that the current industry-prevalent practice of vendor supplying highly optimized DNN operator implementations in a library form (such as cuDNN and MKL-DNN) is sub-optimal. This practice will incur significant efficiency cost for DNN workloads. The situation will become even worse in the coming years as modern accelerators keep on increasing the available hardware parallelism while new DNN architectures strive to save computation by replacing larger operators with many smaller ones [49, 54]. We recommend vendors to supply optimized implementations in other forms, such as our proposed *rOperator* and *vEU* abstractions, in order to enable holistic optimization that can fully utilize hardware resources.

2 Motivation

In this section, we highlight some results to illustrate the limitation of the two-layer design of existing deep learning frameworks. Without loss of generality, we experiment with TensorFlow [18], a state-of-the-art DNN framework, on an NVIDIA GPU, using the same settings as in §5.

¹<https://github.com/microsoft/nnfusion>

Figure 1: The average GPU utilization on different DNN model with different batch size (BS). The utilization only accounts for kernel execution, excluding other stages like operator emitting.

Figure 2: The average kernel time and end-to-end execution time on different DNN model with different batch size (BS).

Hardware-managed intra-operator scheduling leads to low GPU utilization. The two-layer design delegates the intra-operator scheduling to the hardware scheduler in an accelerator like GPU. Figure 1 shows that such an approach could lead to low GPU utilization across different DNN models. When the batch size is 1, the GPU utilization could be as low as 2% for Seq2Seq model. Even when the batch size is increased to 16, the average GPU utilization across the 6 models is merely 40%². To improve the scheduling efficiency, modern GPUs support the multi-streaming mechanism that allows independent operators to run concurrently. However, our measurement in §5 shows that multi-streaming often hurts rather than improves the overall performance.

High inter-operator scheduling overheads. The two-layer approach also incurs a higher inter-operator scheduling overheads. Here, we regard the time not spent doing actual computation in the GPU as the overhead for inter-operator scheduling. This overhead includes various operations to support operator emitting, including kernel launching, context initialization, communication between host and GPU, and so on. The percentage shown above each bar in Figure 2 depicts how much time the DNN model is *not* spent in the actual GPU computation. From the figure it is clear that the overhead of inter-operator scheduling is quite significant. When batch size is 1, the average overhead is 55% across the 6 DNN

²Note that the LSTM’s GPU utilization is slightly higher when batch size is 1 compared to that when batch size is 16, because TensorFlow uses different kernel implementations of GEMM for different batch sizes.

Figure 3: An illustration of (a) the inefficiency scheduling in existing approach; and (b) an optimized scheduling plan.

Figure 4: The profiled kernel time of all the operators in ResNeXt model. Each data point ran 1,000 times

models. Increasing the batch size to 16 slightly improves the situation, while the overhead is still not negligible (between 16% and 55%). Modern DNN compilers, including the one in TensorFlow, employs a technique called kernel fusion [17, 23], which merges several DNN operators into a single one when allowed. However, our results in §5 show that this technique cannot reduce the overhead significantly.

Interplay between inter- and intra-operator scheduling. Separating scheduling into two layers ignores the subtle interplay between inter-operator and intra-operator scheduling, which may lead to suboptimal performance. For example, Figure 3(a) shows two independent operators being scheduled to a GPU. For operator 0, to maximize its performance, the system may choose the fastest implementation with a high degree of parallelism. Thus operator 0 could greedily span all the parallel execution units (EUs) of an accelerator (in this case the streaming multiprocessors of the GPU), while each EU may not be fully utilized. Since operator 0 occupies all the EUs, operator 1 has to wait for available resource. A better scheduler could reduce the degree of parallelism of operator 0 to increase the level of inter-operator parallelism, by mapping operator 1 alongside operator 0, as illustrated by Figure 3(b). We will discuss more details of this issue in §3.3 and §5.

Opportunities. Given the fundamental limitations of the two-layer design observed above, it is desirable to manage the scheduling of inter and intra-operator together. However, a naive implementation of this approach may incur even higher overheads than the already significant inter-operator scheduling overheads. Fortunately, most DNN’s DFG is available at

Figure 5: System overview of DNN computation in (a) existing DNN frameworks, and (b) RAMMER, where each node in a DFG is an *rOperator* that explicitly exposes the intra-operator parallelism through *rTask*; Rather than dynamically scheduling each *rOperator*, RAMMER compiles the DFG into a static execution plan called *rProgram* (composed of *rTasks*) and maps it to hardware by a software device abstraction called *vDevice*.

the compile time, and the operators often exhibit deterministic performance, therefore, their execution times can be obtained through compile time profiling [45]. For example, Figure 4 shows the averaged GPU kernel time and the variance of all the operators in the ResNeXt [49] model. The kernel run-time weighted average of standard deviations among all operators is only 7%. This allows us to move the scheduling from run-time to compile-time, by generating an offline schedule plan to reduce runtime overhead.

3 RAMMER’s Design

The observations in §2 motivate RAMMER, a DNN compiler framework that manages both inter and intra-operator scheduling. Figure 5 shows the key differences between an existing deep learning framework and RAMMER. First, the input to RAMMER is a data-flow graph where a node is an *rOperator*, rather than a traditional operator. An *rOperator* explicitly exposes *rTask*, a fine-grained computation unit that could run on a parallel execution unit in an accelerator. We discuss details of *rTask* in §3.1. Second, instead of separating the two-layer scheduling between software and hardware, RAMMER introduces *rTask-aware DFG compiler* to manage the inter and intra-operator scheduling in one place. The *rTask-aware DFG compiler* will generate a static execution plan for runtime execution. Often, it is not efficient or not possible to pack the entire DNN computation in a single accelerator device invocation. Therefore, the execution plan is breaking into

```

1 interface Operator { void compute(); };
2 interface rOperator {
3     void compute_rtask(size_t rtask_id);
4     size_t get_total_rtask_num();
5 };

```

Figure 6: The execution interfaces of traditional operator and *rOperator*. More details in §4.

multiple *rPrograms*, each contains a piece of computation to be carried out on the hardware. Instead of emitting one operator at a time for an accelerator, RAMMER emits an *rProgram* at a time. The details of the *rTask-aware DFG compiler* will be discussed in §3.3. To carry out the execution plan, RAMMER abstracts a hardware accelerator as a *virtualized parallel device* (*vDevice*), which includes multiple virtualized execution units (*vEUs*). The *vDevice* provides the scheduling and synchronization capabilities at the *rTask* level so that the *rProgram* can be mapped to the corresponding *vEUs* at compile time. The *vEUs*, together with the *vDevice* will be mapped to the hardware at runtime. We introduce virtualized device in §3.2.

3.1 *rOperator*

An *rOperator* is defined as a group of independent, homogeneous *rTasks* (short for RAMMER task), where an *rTask* is the minimum computation unit in an operator to be executed on a processing element of the accelerator device. The concept of *rTask* naturally aligns with the parallel architecture of DNN accelerators, e.g., the SIMD architecture of GPU. To maximize efficiency, the computation on such an accelerator needs to be divided into multiple parallel (homogeneous) tasks. Each of these parallel tasks can be represented by an *rTask*, thereby exposing the intra-operator parallelism not only to the underlying hardware, but to the RAMMER compiler. Given that an *rTask* is logically identical to a parallel task, RAMMER relies on external tools to partition an *rOperator* into *rTasks* (e.g., TVM [23]). In another word, RAMMER uses external heuristics to decide a reasonable granularity of *rTask*.

As a concrete example, a matrix multiplication operator can be divided into multiple homogeneous *rTasks*, each computes a tile of the output matrix, while the tiling strategy is assumed to be given. If a complicated DNN operator can hardly be divided into independent homogeneous *rTasks* (e.g., SeparableConv2D [7]), it can be represented as multiple dependent *rOperators*, each can be partitioned into *rTasks*.

An *rTask* is indexed by a logical *rtask_id*. The *rTasks* in an *rOperator* are numbered continuously. To execute an *rTask*, the parallel execution unit could call the `compute_rtask()` interface (line 3 Figure 6). To generate an *rProgram*, RAMMER needs to know the total number of *rTasks* in an operator. This is available through the interface `get_total_rtask_num()`. In contrast, a traditional opera-

tor has only one interface `compute()` (line 1 Figure 6). The implementation of an *rOperator* is called *rKernel*, which realizes the concrete *rTask* computation logics and decides the total number of *rTasks*. One *rOperator* might have multiple versions of *rKernels* based on different tiling strategies, e.g., trading off between resource efficiency and overall execution time.

The *rOperator* abstraction allows RAMMER to expose both inter- and intra-operator parallelisms. This opens up a new space to optimize DNN computation holistically.

3.2 Virtualized Parallel Device

Modern accelerators do not provide interfaces to map an *rTask* to a desired execution unit directly. For example, a GPU only allows to execute one operator (in the form of a kernel) at a time. To address this challenge, RAMMER abstracts a hardware accelerator as a software-managed virtual device called *virtualized parallel device* (*vDevice*). A *vDevice* further presents multiple parallel *virtual execution units* (*vEUs*), each of them can execute *rTasks* independently.

With *vDevice*, RAMMER organizes the computation of *rTask*-aware DFG as an *rProgram* on a *vDevice*. An *rProgram* is represented as two dimensional array of *rTask* `prog[vEU_id][order]`, where `vEU_id` denotes the *vEU* the *rTask* is assigned to, and `order` denotes the execution order of the *rTask* in this *vEU*. For example, `prog[0][0]` denotes the first *rTask* to be executed in *vEU* 0. To ensure the correct execution of dependent *rTasks* in a plan, RAMMER introduces **barrier-*rTask***. A barrier-*rTask* takes the argument of a list of pairs `<vEU_id, order>`. The barrier-*rTask* will wait until the completion of all *rTasks* indexed by each pair. The barrier-*rTask* provides a fine-grained synchronization mechanism to enable *rTask* schedule plan execution.

For the execution of DNN computation, a *vDevice* needs to be mapped to a physical accelerator at runtime. We will discuss how RAMMER implements the mapping of *vDevice* to different hardware accelerators in §4.

3.3 *rTask*-aware DFG Compiler

The *rTask* abstraction and the fine-grained *rTask* execution capability exposed by the *vDevice* open up a large optimization space. RAMMER aims to generate a high-quality schedule in this space, represented as a sequence of *rPrograms*. To this end, the *rTask*-aware DFG compiler separates the scheduling mechanism from its policy. On the mechanism side, it provides two capabilities: (1) Two scheduling interfaces for a policy to generate an execution plan. (2) A profiler to supply profiling information requested by a scheduling policy.

Scheduling interfaces. RAMMER's *rTask*-aware DFG compiler introduces two scheduling interfaces, `Append` and `Wait`. `Append(task_uid, vEU_id)` assigns an *rTask* from

Algorithm 1: Wavefront Scheduling Policy

Data: *G*: DFG of *rOperator*, *D*: *vDevice*
Result: Plans: *rPrograms*

```

1 Function Schedule(G, D):
2   Pcurr = {};
3   for W = Wavefront(G) do
4     P1 = ScheduleWave(W, Pcurr, D);
5     P2 = ScheduleWave(W, {}, D);
6     if time(P1) ≤ time(Pcurr) + time(P2) then
7       Pcurr = P1;
8     else
9       Plans.push_back(Pcurr);
10      Pcurr = P2;
11   return Plans;
12 Function ScheduleWave(W, P, D):
13   SelectRKernels(W, P);
14   for op ∈ W do
15     for r ∈ op.rTasks do
16       vEU = SelectvEU(op, P, D);
17       P.Wait(r, Predecessor(op).rTasks);
18       P.Append(r, vEU);
19   return P;

```

an operator to the specified *vEU* in a sequential order. Here `task_uid` is a global identifier for an *rTask*, which is essentially the operator `id` combined with the `rtask_id` within the operator. The second API, namely `Wait(wtask_uid, list<task_uid>)`, allows an *rTask* specified by `wtask_uid` to wait for *rTasks* in `list<task_uid>`. The `Wait` interface will implicitly `Append` a **barrier-*rTask*** (discussed in §3.2) right before the *rTask* `wtask_uid`. As an optimization, when waiting for multiple consecutive *rTasks* r_1, r_2, \dots, r_n sequentially appended to the same *vEU*, the *rTask* only need to include the last one, i.e., r_n , in the waiting list.

Compile-time profiling. RAMMER profiler provides the following three types of information: 1) individual *rTask* execution time on a *vEU*; 2) resource usage of an *rTask* such as the local memory or registers used and 3) the overall execution time of an *rProgram*. This profiling information can guide a policy to generate an efficient scheduling plan.

Scheduling policy. Algorithm 1 illustrates how to use the above scheduling interfaces and the profiler to implement a scheduling policy to exploit both inter- and intra-operator parallelisms. This policy takes an *rTask*-aware DFG and schedules operators in *waves* [37]. The operators in a wave are the fringe nodes of a breadth-first-search on the DFG. The policy will include a wave's operators in the current *rProgram* if the profiling results (denoted by `time()`) suggest it will reduce the total execution time. Otherwise, the policy will create a separate *rProgram* (line 2-10).

First of all, we assume that each *rOperator* has one or more implementations called *rKernels*, each *rKernel* is a way to break the operator into *rTasks* with different resource and run-time trade-offs. Among the *rKernels* of a particular *rOperator*,

Figure 7: Overall workflow of RAMMER.

there is the *fastest* one with the smallest runtime, and there is the most *efficient* one with the smallest product of runtime and the total number of *rTasks*.

For each wave, the policy selects the implementations of the operators through `SelectRKernels()` (line 13), with the following heuristics: If combine all the *rTasks* in the wave with the *fastest* operator implementations still cannot occupy all the parallel execution units in the accelerator, the policy will just select them. Otherwise, the policy will find the most *efficient rKernels* and then perform a profiling. The policy will choose these *rKernels* if the profiling results show better execution time, otherwise it will stick with the fastest *rKernels*. This heuristic considers the interplay between the inter- and intra-operator scheduling by evaluating the *rOperators* (and their *rTasks*) in a wave, instead of individually. After the *rKernel* selection, the policy calls `SelectvEU()` to decide which vEU an *rTask* should be scheduled to (line 16). Given the current *rProgram* *P*, `SelectvEU()` chooses the vEU that can execute the *rTask* at the earliest, based on the profiled execution time of each *rTask* in *P*. Finally, the policy calls `Wait()` to ensure *rTask* level dependency (derived from the DFG) and `Append()` to assign the *rTask* to the selected vEU (line 17-18). The policy in Algorithm 1 demonstrates how RAMMER separates the scheduling mechanism from scheduling policy. As shown in §5, this simple policy can already outperform the state-of-the-art, sometimes significantly. We envision the proposed scheduling mechanism could enable future research on more advanced scheduling policies to further explore the optimization space.

4 Implementation

We implement RAMMER with 52k lines of C++ code, including 3k lines of code for the core compiler and scheduling function. The input of RAMMER is a DNN model in either TensorFlow [18] frozen graph, TorchScript [16] or ONNX [14] format. RAMMER first converts the input model into a DFG of *rOperators*. Since the input model is often not optimized, like other compilers, we also implemented common graph optimizations such as constant folding, common sub-expression elimination, pattern-based kernel fusion, etc. For each *rOperator* from an optimized DFG, RAMMER loads one or multiple versions of *rKernel* implementations from dif-

```

1  __device__ void matmul_rTask(float *A, float *B,
2  float *C, size_t rtask_id) {
3  size_t tile_x = rtask_id / (M/32);
4  size_t tile_y = rtask_id % (N/32);
5  size_t i = threadIdx.x/32 + tile_x*32;
6  size_t j = threadIdx.x%32 + tile_y*32;
7  C[i][j] = 0;
8  for (size_t k = 0; k < K; k++)
9      C[i][j] += A[i][k] * B[k][j];
10 }
11
12 class MatmulROperator {
13 __device__ void compute_rtask(size_t rtask_id){
14     matmul_rTask(input0, input1, output0, rtask_id);
15     size_t get_total_rtask_num(){return M/32*N/32;};
16 };

```

Figure 8: A CUDA implementation of a naive matrix multiplication with the *rOperator* abstraction.

ferent sources, e.g., auto-kernel generators [23], hand-tuned kernels, or converted from existing operators in other frameworks. RAMMER compiler will then partition the DFG into sub-graphs (e.g., based on the policy in Algorithm 1) and compile each of them as an *rProgram*. As an output, each *rProgram* is further generated as a device code (e.g., GPU kernels) that runs on the accelerator. Figure 7 summarizes the overall workflow of RAMMER.

In the rest of this section, we describe the details about RAMMER’s implementation for CUDA GPU. We focus on NVIDIA GPUs and the CUDA eco-system because they are the most widely used accelerators for DNN. To demonstrate that the vDevice abstraction enables RAMMER compiler to support different accelerators with an uniform interface, we will also briefly describe our experience with other DNN accelerators, including AMD GPUs and Graphcore IPU, at the end of this section.

4.1 RAMMER on NVIDIA CUDA GPUs

An NVIDIA GPU usually consists of tens to hundreds of *streaming multiprocessors (SM)*, each containing tens of cores. Computation on SM follows the Single Instruction Multiple Thread (SIMT) model. In this paper we assume the readers are familiar with the basic concepts of CUDA [4], the programming paradigm introduced by NVIDIA to program their GPUs. A single CUDA program (often referred to as a CUDA kernel) groups multiple threads into *blocks*, each thread-block is assigned to run on an SM, where the scheduling is performed by GPU hardware. RAMMER naturally maps each vEU to an SM and implements an *rTask* as a thread-block.

4.1.1 *rOperator* in CUDA

Figure 8 shows a naive CUDA implementation of an *rOperator* that multiplies a $M \times K$ matrix *A* by a $K \times N$ matrix *B*. For simplicity, we assume *M* and *N* are evenly divisible

by 32. In the code, each *rTask* computes a 32×32 tile of the output matrix *C*. Line 1-10 in Figure 8 shows the computation of one thread in one *rTask*. The thread uses *rtask_id*, a RAMMER assigned id to identify the tile to be computed by this *rTask* (line 3-4), and uses *threadIdx*, a CUDA built-in thread index to identify the data element to be computed (line 5-6) by this thread. The identified element is then computed in line 7-9. Line 13 shows the interface exposed by this *rOperator*, which will be called by a vEU's parallel thread. The total *rTasks* needed in this operator is determined by the matrix dimension *M* and *N*, and can be obtained through the *get_total_rtask_num* interface (line 16). The key difference between code in Figure 8 and a traditional CUDA code is that an *rTask* uses *rtask_id*, a logical index controlled by RAMMER, instead of *blockIdx*, a built-in thread-block index controlled by the GPU's hardware scheduler. This enables RAMMER to map an *rTask* to a desired vEU by executing *compute_rtask()* with a proper *rtask_id*. Note that the code shown in Figure 8 is for illustrative purpose. The evaluation shown in §5 uses a more complicated tiled version of matrix multiplication *rOperator*, which further improves the performance through carefully exploiting GPU memory hierarchy, e.g., shared memory and registers [36, 41].

4.1.2 vDevice and vEU on CUDA GPU

On a CUDA GPU, the intra-operator scheduling is usually managed by the GPU's built-in scheduler. To bypass the built-in scheduler, RAMMER leverages a persistent thread-block (PTB) [29] to implement a vEU in a vDevice. PTB is a thread-block containing a group of continuously running threads, where RAMMER is able to “pin” the PTB to the desired SM. Given an *rProgram*, each thread in the PTB (and hence the vEU) executes the *compute_rtask()* according to the sequence specified by the *rProgram*. To execute the *compute_rtask()* from multiple *rTasks* continuously in a PTB, a function qualifier *__device__* is required by CUDA for *compute_rtask()* and any sub functions executed therein (e.g., line 1 and 13 in Figure 8).

Figure 9 illustrates the CUDA code for a vDevice with two vEUs, i.e., a CUDA kernel function with two PTBs. This vDevice executes an *rProgram* compiled from a DFG with three *rOperators*: a *Matmul*, a *Relu*, and a *Conv*. Specified by the execution plan, the vDevice executes two *rTasks* of the *Matmul* operator on vEU 0, and in parallel it also runs four *rTasks* of the *Relu* operator on vEU 1. Then a global barrier is inserted to the two vEUs, each runs a barrier-*rTask*: vEU 0 waits for the 4th *rTask* on vEU 1, and vEU 1 waits for the 2nd *rTask* on vEU 0. Finally, the vDevice executes two *rTasks* of the *Conv* operator on the two vEUs respectively. On each vEU, RAMMER runs the *rTasks* sequentially in a code branch, executed only if the current vEU Id matches the one generated by the *rProgram*.

Before a lengthy DNN computation, RAMMER dispatches

```

1 // config: <<<(vEU_size,1,1), (vEU#,1,1)>>>
2 __global__ void vdevice_run() {
3     if (Get_vEU_Id() == 0) { // vEU 0
4         MatmulTaskOp.compute_rtask(0);
5         MatmulTaskOp.compute_rtask(1);
6         // wait the rTask on vEU 1 with order=3
7         BarrierTask({<1, 3>}).compute_rtask();
8         Conv2DrTaskOp.compute_rtask(0);
9     }
10    else if (Get_vEU_Id() == 1) { // vEU 1
11        for (auto i : 4)
12            RelurTaskOp.compute_rtask(i);
13        // wait the rTask on vEU 0 with order=1
14        BarrierTask({<0, 1>}).compute_rtask();
15        Conv2DrTaskOp.compute_rtask(1);
16    }
17 }

```

Figure 9: The CUDA code for a vDevice with two vEUs.

each vEU (implemented by a PTB) to a desired SM through the GPU scheduler [48]. To improve hardware utilization, an SM can run multiple vEUs (PTBs) concurrently. Since CUDA uses a SIMT model, all vEU are homogeneous, the number of vEUs an SM can support depends on the most demanding *rTask* across all the vEUs, i.e., the *rTask* that requires the most thread number, register number, shared memory size, etc. In practice, we set the number of vEUs on each SM according to the maximum active PTB number provided by the CUDA compiler *nvcc* [5]. With the vDevice abstraction, the optimizations in RAMMER become hardware agnostic.

4.1.3 Executing *rTask* on vEU in CUDA

Executing heterogeneous *rTasks*. In a CUDA kernel, the number of threads in a thread block is fixed in the entire execution lifecycle. This force RAMMER to require that all the *rTasks* on a vEU to run on with the same number of persistent threads. In practice, different *rOperators* may use different number of threads to balance parallelism and per-thread resource usage. To address this problem, RAMMER sets the number of threads of a vEU to be the maximum number of threads used by an *rTask* in the vEU. For an *rTask* with less threads, RAMMER inserts early-exit logic in the extra threads to skip the unnecessary (and invalid) execution. However, early-exit may lead to dead-lock: a global barrier might never return because early-exit logic may skip the barrier. To avoid this issue, RAMMER can leverage the CUDA cooperative group primitives [3], which explicitly controls the scope of threads during a synchronization.

Implementing barrier-*rTask*. To implement an efficient barrier-*rTask*, RAMMER introduces a step array, where each element is an integer tracking the number of finished *rTasks* in each vEU. When finished, an *rTask* will use its first thread to increase the corresponding element in the step array by 1. When waiting for a list of *rTasks* on *N* vEUs, a barrier-

r Task uses its first N threads to poll on the corresponding elements in the step array until the steps are larger than the orders of those r Tasks. After that, the barrier- r Task calls `__syncthreads` to ensure all threads in this vEU are ready to run the next r Task.

4.1.4 Transforming Legacy CUDA Operators

Many operators for DNN are already available as CUDA kernel code. To reduce development efforts, RAMMER introduces a source-to-source converter to transform a legacy CUDA operator into an r Operator. The key insight of the converter lies on the facts that to exploit the intra-operator parallelism, legacy CUDA operators are also implemented as thread-blocks, although they use `blockIdx` and let CUDA GPU hardware control the intra-operator scheduling directly. r Operator can just compute the desired `blockIdx` from `rtask_id` without changing computation logic in the legacy kernel.

One challenge in this transformation is that the thread-blocks in existing operator could be laid out in 1, 2, or 3-dimensional shape, while in a vEU threads are laid out in a 1-dimensional shape. This means our vEU needs to support r Task with different threads shapes. For example, Figure 10 illustrates a vEU executing two r Tasks with the thread shapes of $[2 \times 2]$ and $[2 \times 3]$ respectively. Our solution is to stick to a 1-D persistent thread shape for a vEU, and apply a thread index remapping to compute the desired `threadIdx` in the legacy kernel with the vEU's 1-D `threadIdx`. Notice that, as discussed before, the number of threads of a vEU is the maximum number of threads of all r Task in the vEU, so that such a remapping is always possible. For example, in Figure 10 we configure the vEU with $[1 \times 6]$ persistent threads. When executing r Task 0 with a legacy $[2 \times 2]$ thread shape, RAMMER remaps the $[2 \times 2]$ shape to the vEU's $[1 \times 6]$ thread.

In summary, to convert a legacy DNN operator to an r Operator, one needs to remap thread and block index, implement the early-exit logic, and use CUDA cooperative group primitive to support local barrier on the active (i.e. not early-exited) threads. RAMMER implements these changes by inserting a compiler-generated code segment at the entry point of the legacy operator kernel code. With these modifications, RAMMER can preserve the legacy operator implementation, and reuse it as an r Task operator. In RAMMER, we have transformed and implemented total 150 r Kernels for 70 r Operators.

4.2 RAMMER on Other Accelerators

The design of RAMMER is not limited to CUDA and NVIDIA GPUs. In fact, our r Task, r Operator and vEU abstractions are applicable to any massively parallel computational devices with homogeneous execution units, including most of the devices that used for DNN computation. In this section, we discuss how to port RAMMER to support other devices.

Figure 10: Executing two heterogeneous r Tasks on a vEU.

4.2.1 RAMMER on AMD GPUs

AMD GPUs are similar to NVIDIA GPUs, which also consist of many parallel execution units called *compute units* (CU). AMD GPU has a HIP programming model [8], which is similar to CUDA. AMD provides a `hipify` tool that can convert a CUDA kernel to a HIP kernel. `hipify` can help convert most CUDA r Operators to the HIP version. Some CUDA kernel configurations, such as the number of threads per thread-block and size of local memory, are not optimized for AMD GPUs due to the minor architecture differences. We re-implemented 41 r Kernels for AMD GPUs for better performance. `hipify` can also convert the CUDA implementation of vDevice (i.e., PTBs) to the HIP version. The only exception is that AMD GPUs do not support cooperative group primitives. To address this issue, we introduce a new API in r Operator to provide the number of (block-wise) synchronizations S (i.e. calls to `__syncthreads`). For early-exit threads, instead of exit immediately, RAMMER will insert code to call the `__syncthreads` primitive S times.

4.2.2 RAMMER on Graphcore IPU

The Graphcore IPU (Intelligence Processing Unit) [10] is a state-of-the-art DNN accelerator with an architecture quite different from GPUs. IPU is a massively parallel MIMD processor with a bulk-synchronous-parallel (BSP) communication model. Each IPU contains 1,216 parallel processing units called *tiles*; a tile consists of a hyper-threaded computing core plus 256 KB of local memory. DNN computation on an IPU is explicitly programmed as a data-flow graph, where each vertex implements the code executed on a tile and each edge depicts the data transfers between vertices. The IPU compiler is responsible for mapping each vertex to a tile.

RAMMER's r Task abstraction can also map to IPU's MIMD model: a vEU can map to a tile and a vertex can be treated as an r Task. Thus, an r Operator on IPU can be implemented as a set of vertices. More importantly, IPU compiler allows to control the vertex-tile mapping at compile-time. This provides the core functionality required in vDevice abstraction. Restricted by the hardware BSP model, IPU does not provide a fine-grained synchronization mechanism. We therefore implement barrier- r Task with a global barrier, which may reduce scheduling space for RAMMER. Even with this limitation, RAMMER

Model	Dataset	Model Type	Note
ResNeXt	CIFAR-10	Computer Vision	layers: 29, cardinality: 16, bottleneck width: 64d (16×64d, paper parameter)
NASNet	CIFAR-10	Computer Vision	repeated cells: 6, filters: 768 (6@768, paper parameter)
AlexNet	ImageNet	Computer Vision	(paper parameter)

Table 1: Deep learning models and datasets.

still can schedule r Tasks of different operators at the same computing step to increase utilization. To evaluate RAMMER, we implemented total 15 r Operators and 18 r Kernels.

4.2.3 RAMMER on x86 CPUs

We also implemented RAMMER on multi-core x86 CPUs. However, we see little performance benefit of adopting the RAMMER abstractions on x86-based platforms. On x86, the operator runtime is high due to the relatively low performance of x86 cores for numerical computations, and the small number of cores can be fully occupied by almost any DNN operators. Moreover, scheduling overhead is not significant because kernel launch is just a regular function call. Therefore, RAMMER cannot provide additional benefit compared with the traditional two-layered scheduling approach.

5 Evaluation

In this section, we present the detailed evaluation results to demonstrate the effectiveness of RAMMER with comparison with other state-of-the-art frameworks.

5.1 Experimental Setup

Machine environment. We evaluated RAMMER on three servers with different accelerators equipped. The CUDA GPU evaluations use an Azure NC24s_v3 VM equipped with Intel Xeon E5-2690v4 CPUs and 4 NVIDIA Tesla V100 (16GB) GPUs, with Ubuntu 16.04, CUDA 10.0 and cuDNN 7.6.5. The AMD ROCm GPU evaluations use a server equipped with Intel Xeon CPU E5-2640 v4 CPU and 2 AMD Radeon Instinct MI50 (16GB) GPUs, installed with Ubuntu 18.04 and ROCm 3.1.1 [1]. The IPU evaluations use an Azure ND40s_v3 preview VM equipped with Intel Xeon Platinum 8168 CPUs and 16 IPU with Poplar-sdk 1.0.

We compare RAMMER with other DNN frameworks and compilers, including TensorFlow (v1.15.2) representing the state-of-the-art DNN framework, TVM (v0.7) [23] and TensorFlow-XLA representing the state-of-the-art DNN compilers, and TensorRT (v7.0) (with TensorFlow integration version), a vendor-specific inference library for NVIDIA GPUs.

Benchmarks and datasets. Our evaluation is performed using a set of representative DNN models that covers typical deep neural architectures such as CNN and RNN; and different application domains including image, NLP and speech. Among them, ResNeXt [49] is an improved version of ResNet [30]; NASNet [54] is a state-of-the-art CNN model obtained by the neural architecture search; AlexNet [35] represents a classic CNN model with a simple architecture. LSTM-TC [31] is an RNN model for text classification; DeepSpeech2 [19] is a representative speech recognition model; and Seq2Seq [46] is for neural machine translation. All the implementations of these benchmarks, including the r Kernels used in each model, are available in our artifact evaluation repository³.

We focus our evaluation on model inference. There is no fundamental reason limiting RAMMER from model training, except that supporting training requires us to develop more operators. We evaluate these models on a set of datasets including CIFAR-10 [2], ImageNet [26], LibriSpeech [11] and synthetic datasets. Table 1 lists the models, hyper-parameters, and the corresponding datasets used. All performance numbers in our experiments are averages over 1,000 runs; in all cases we observed very little variations.

5.2 Evaluation on CUDA GPUs

This section answers the following questions: 1) How does RAMMER perform comparing with the state-of-the-art DNN frameworks or compilers? 2) How well does RAMMER utilize the GPU’s parallel resource? 3) How much does RAMMER reduce the runtime scheduling overhead? 4) How much performance gain comes from RAMMER’s scheduling leveraging both the intra and inter operator parallelism? 5) How effective is the fine-grained synchronization in improving the overall performance?

5.2.1 End-to-end Performance

We first demonstrate the end-to-end efficiency of RAMMER by comparing with TensorFlow (TF), TensorFlow-XLA (TF-

³https://github.com/microsoft/nnfusion/tree/osdi20_artifact/artifacts

Figure 11: End-to-end model inference time with batch size of 1 on NVIDIA V100 GPU.

XLA), TVM and TensorRT (TF-TRT). To show the benefit of the abstractions introduced in RAMMER, we create a base-line version of RAMMER (called RAMMERBASE), which only implements the optimizations similar to those in existing compilers and still uses a two-layered scheduling approach. Thus, RAMMERBASE can be treated as just another regular DNN compiler implemented in the same codebase of RAMMER. Figure 11 shows the execution time of the benchmarks with batch size of 1.

First, RAMMER significantly outperforms TF by $14.29\times$ on average, and up to $33.94\times$ for the LSTM-TC model. The performance improvement of RAMMER against TF is mainly because TF suffers from heavy runtime scheduling overhead at DFG level, especially when the individual operator’s execution time is relatively short, as is the case in small batch inference. TF-XLA, as a DNN compiler, can improve TF’s performance through DFG level optimizations (e.g., operator fusion) and operator-level code specializations (e.g. customized kernel generation). However, it still cannot fully avoid scheduling overhead, which leads to an average of $11.25\times$ (up to $20.12\times$) performance gap compared to RAMMER. We observed that TF-XLA incurs even higher overhead for some CNN models such as ResNeXt and NASNet compared with TF. TVM, as another state-of-the-art DNN compiler, mainly leverages a kernel tuning technique to generate a specialized kernel for each operator. In our evaluation, TVM tunes 1,000 steps and chooses the fastest kernel for each operator. With such specialized optimization, TVM can improve the performance significantly compared with TF and TF-XLA. Still, RAMMER can outperform TVM by $3.48\times$ on average and up to $6.46\times$. Even though TVM can make individual operator run faster through tuning, it still lacks the capability to leverage the fine-grained parallelism as RAMMER. An exception is that, for AlexNet, RAMMER can only achieve comparable performance with TVM. This is mainly because AlexNet, being one of the earliest modern DNN models, can be easily optimized due to its simple sequential model architecture and relatively fewer, but larger operators. Finally, TensorRT is a specialized DNN inference library with highly optimized operators provided by NVIDIA. We use its official TensorFlow-integration version (TF-TRT) to compile and run our models, as its stand-alone version fails to directly compile these benchmarks. However, for RNN models like DeepSpeech2, LSTM-TC and Seq2Seq-NMT, TF-TRT failed

Figure 12: End-to-end model inference time with different batch sizes (BS).

to produce results after compiling for over 50 hours. Thus, we reimplemented these three models with the TensorRT native APIs. Our evaluation shows that RAMMER can outperform the vendor optimized TensorRT on all the benchmarks, with an averaged $2.18\times$ and up to $3.09\times$ lower latency. Finally, compared to RAMMERBASE, RAMMER can further improve the end-to-end performance by $2.59\times$ and up to $6.29\times$.

Performance with different batch sizes. We also evaluate RAMMER’s performance with larger batch sizes. Figure 12 shows the performance comparison on two representative CNN and RNN models, i.e., ResNeXt and LSTM-TC, with batch sizes of 4 and 16. We limit our benchmarks in this test due to the cost of developing optimized *rOperator* kernels for RAMMER: we have to hunt for efficient open-sourced operator kernel implementations or perform tuning by hand or through automatic tuning tools, which is time consuming. As it shows, using larger batch sizes can reduce scheduling overhead in existing frameworks due to the increased per-operator execution time. Even so, RAMMER can still outperform all the systems except for TensorRT on the ResNeXt model with batch size of 16. For this case, TensorRT uses some operators whose source codes are not publicly available, and our implementations do not yet match their performance. In fact, implementing operators to match the performance of close-sourced kernels is one of the major challenges for RAMMER. Compared to the other open source frameworks and compilers, RAMMER has a significant gain. For example, when using batch size of 16, RAMMER can outperform TF by $2.25\times$, and TVM by $1.25\times$ on ResNeXt. For the LSTM-TC model, RAMMER can get $20.08\times$ and $9.0\times$ performance gains compared with TF and TVM respectively.

Figure 13: End-to-end model inference time with the batch size of 1 on the ImageNet dataset (image size: 224×224).

Figure 14: Comparison of GPU utilization.

Performance with larger input sizes. In our default settings, ResNeXt and NASNet are evaluated on images of 32×32 size in the CIFAR-10 dataset. To show RAMMER's performance on larger images, we also evaluate these two models on the ImageNet dataset with the same model hyperparameters in their original papers [49, 54]. Specifically, ResNeXt on ImageNet uses 101 layers with cardinality of 64 and bottleneck width of 4d; and for NASNet, the number of repeated cells is 4 and the number of filters is 1056. Figure 13 shows the end-to-end model inference time. From the results, we observe that using larger input size has little impacts on RAMMER's performance gain. For example, using ImageNet, RAMMER can still outperform TF by $18.91 \times$, TVM by $4.96 \times$, and even TF-TRT by $2.06 \times$ on ResNeXt. For the NASNet model, RAMMER can also get $6.99 \times$, $1.33 \times$ and $2.34 \times$ performance gains compared with TF, TVM and TF-TRT respectively. The significant performance improvement is mainly because that the model structure for larger dataset usually have more inter-operator parallelism that can be better leveraged by RAMMER's optimization. For example, the cardinality for ResNeXt is increased from 16 to 64 when replacing the dataset from CIFAR-10 to ImageNet.

Note that in the above evaluations, RAMMERBASE can already get a comparable or even better performance than compilers like TF-XLA and TVM. Thus, we will use RAMMERBASE as the baseline of the state-of-the-art compiler and TF-TRT as the state-of-the-art DNN inference library to evaluate the benefits of RAMMER in the rest of the evaluations. RAMMERBASE can also help remove the side effects caused by different implementations in the performance comparison.

5.2.2 GPU Utilization

RAMMER's scheduling enables r Tasks from different opera-

Figure 15: TF performance with different stream(STM) number. (Note: The number atop a bar indicates kernel time.)

tors to execute alongside each other to achieve better GPU utilization. We evaluate the utilization improvement by RAMMER through comparing it with both TF, TF-TRT and RAMMERBASE. Figure 14 shows the average utilization for the 6 DNN models (with batch size of 1) through their execution time. The average GPU utilization only accounts for kernel execution, excluding other stages like operator emitting. Specifically, we use the metric *SM-efficiency* provided by NVIDIA profiler *nvprof* [6] to measure the utilization, which calculates the percentage of time when at least one warp is active on a multiprocessor. Compared to TF and TF-TRT, RAMMER can improve GPU utilization by $4.32 \times$ and $2.45 \times$ on average respectively across different models. This improvement comes from both the lower runtime scheduling overhead and the capability to co-schedule operators in RAMMER. Through comparing RAMMER with highly optimized RAMMERBASE, which uses the same set of kernels, our evaluation shows that RAMMER's scheduling by itself can improve the utilization by $1.61 \times$ on average, and up to $2.39 \times$ for the LSTM-TC model.

As mentioned in §2, modern GPUs support the multi-streaming mechanism to increase utilization through concurrently scheduling independent kernels. We evaluate the efficiency of multi-streaming by increasing the stream numbers in TF. Figure 15 shows both the end-to-end execution time and the kernel time when using stream number of 1, 2, and 4 for each model. We observe that using more streams can harm the end-to-end performance, a phenomenon observed by others [45]. For example, using 4 streams increases the end-to-end time by $2.72 \times$ on average compared with using a single stream. Moreover, the kernel time in each model only sees very small reduction after enabling multi-streaming, which implies most kernels are still sequentially executed, thus providing little improvement on the GPU utilization. The major reason is because multi-streaming introduces even higher operator scheduling overhead, as shown in Figure 15.

5.2.3 Scheduling Overhead

The techniques proposed by RAMMER can effectively reduce scheduling overhead. To verify this, we evaluate the run-time

Figure 16: GPU scheduling overhead on different models. (The number atop a bar indicates the overhead in percentage.) TF: TensorFlow, TRT: TF-TRT, RB: RAMMERBASE, R: RAMMER

Figure 17: Performance with different kernel sets and batch sizes (BS).

scheduling overhead by comparing RAMMER with both TF, TF-TRT and RAMMERBASE. Figure 16 shows the total kernel time and the scheduling overhead (i.e., the time not spent on actual computation) for each model. Specifically, compared with TF, RAMMERBASE can reduce the scheduling time from an average of 32.29 milliseconds to only 2.27 milliseconds (overhead percentage from 55.41% to 18.43%) over all models. Even compared with TF-TRT, RAMMERBASE can reduce the average scheduling overhead from 31.38% to 18.43%. RAMMERBASE achieves this reduction by optimizing the scheduling execution code path and leveraging operator fusion to reduce kernel launches. The significant reduction demonstrates the heavy overhead of operator scheduling in existing DNN frameworks. Compared with RAMMERBASE, RAMMER can further reduce the average overhead from 2.27 milliseconds to 0.37 milliseconds, a 6.14 \times reduction. This significant reduction is due to static compile-time operator scheduling, i.e. packing operators into *rProgram* so that several operators can be executed by a single GPU kernel launch.

5.2.4 Interplay of Intra and Inter Operator Scheduling

RAMMER enables scheduling policies to optimize the interplay of intra and inter operator scheduling, instead of just focusing on making individual operators fast. This is implemented through selecting appropriate *rKernel* for each *rOperator*, as introduced in §3.3. We evaluate the effect of such scheduling by using two sets of kernels: the fastest ker-

Figure 18: An irregular DFG generated by NASBench

nels only for each individual operator, and the kernels selected by RAMMER’s scheduling policy. Figure 17 shows the performance of RAMMER and RAMMERBASE with these two kernel sets on two representative CNN and RNN models, i.e., ResNeXt and LSTM-TC. First, no matter which set of kernels is used, RAMMER can always improve the performance significantly. For example, if RAMMER uses the same fastest kernels (i.e., the RAMMER-fast) as used in RAMMERBASE (i.e., RAMMERBASE-fast), it can improve the performance by 2.89 \times on average. If more *rKernels* are available for a given *rOperator* and RAMMER can select kernels based on its policy (i.e., the RAMMER-select), it can further improve the end-to-end performance by 1.44 \times on average, and up to 2.28 \times compared with RAMMER-fast, even though the selected kernels may be not the fastest in isolation. In fact, if we use these kernels in RAMMERBASE (i.e., the RAMMERBASE-select), its performance will drop by 1.84 \times on average.

We further perform detailed analysis of the kernels used in LSTM-TC model with batch size of 4. For example, for the Matmul operator, the fastest kernel uses 1,024 *rTasks* to get the optimal execution time of 4.28 microseconds; while the selected kernel by RAMMER only consists of 16 *rTasks* and gets a slower execution time of 7.46 microseconds when launched alone. However, RAMMER chooses this kernel to trade a slower individual kernel (by reducing intra-operator parallelism) for a better overall performance (through increasing the inter-operator parallelism), thanks to the holistic scheduling capability of RAMMER.

5.2.5 Fine-grained Synchronization

As a synchronization mechanism, barrier-*rTask* provides some extra optimization spaces for the DFGs with irregular structure, which is common in the models generated by neural architecture search (NAS) [54]. To highlight such extra benefit, we leverage NASBench [50], a state-of-the-art NAS benchmark, to randomly generate 5,000 modules, where each module is a small DFG that consists of up to 9 operators and 7 edges. We first compare the end-to-end performance of RAMMER and RAMMERBASE on all these modules, which shows RAMMER can improve the performance by 1.28 \times on average, and up to 3.40 \times than RAMMERBASE. Among all these modules, our measurement shows that 28.3% of them has obvious irregular structures, e.g., heterogeneous operators

Figure 19: End-to-end model inference time with batch size of 1 on AMD MI50 GPU.

in a wave decided by our policy (Algorithm 1). For these modules, we compare the end-to-end performance of using our barrier- r Task implementation and a global barrier. The results show that using the barrier- r Task can provide extra performance speedup of $1.11\times$ on average and up to $1.89\times$. Figure 18 illustrates one of such modules, where the execution time and r Task number in each operator are also listed. For such a DFG, our barrier- r Task provides a possibility to overlap the execution of operators from different waves (e.g., the two STEM-Conv operators from wave 1 and 2) through removing the global barriers between waves and inserting fine-grained r Task-level synchronizations.

5.3 Evaluation on Other Accelerators

5.3.1 End-to-end Performance on ROCm GPUs

We evaluate the efficiency of RAMMER on AMD ROCm GPUs by comparing it with TF, TVM, and RAMMERBASE. TF-XLA is not included because it cannot be successfully enabled on AMD GPUs in our experiments, and TensorRT is not included because it is proprietary and is exclusive for NVIDIA. Figure 19 shows the end-to-end performance of the 6 benchmarks with batch size of 1. Compared with TF, RAMMER can outperform it by $13.95\times$ on average, and up to $41.14\times$ for the LSTM-TC model. Compared to TVM, RAMMER can improve the performance by $5.36\times$ on average, and up to $7.57\times$. Note that we fail to make the TVM auto tuning feature works on ROCm GPUs, so TVM just uses its default kernels in this experiment. Compared with RAMMERBASE, we can see that the proposed scheduling of RAMMER's can bring average of $2.19\times$ and up to $4.12\times$ speedup. Finally, RAMMERBASEK in the figures is exactly the same as RAMMERBASE, except that it uses kernels from RAMMER. Notice that RAMMER might not always choose the fastest kernel implementations for the r Operators. Though there are little performance change for most models, for the ResNeXt model there is a $3.02\times$ performance drop. This demonstrates the importance of the interplay of scheduling and kernel selection.

5.3.2 End-to-end Performance on Graphcore IPU

We also conduct a preliminary evaluation of RAMMER on a Graphcore IPU. In this experiment, we choose only the three

Figure 20: End-to-end model inference time with batch size of 1 on Graphcore IPU.

Figure 21: End-to-end model training time of LSTM-TC with batch size of 256 on NVIDIA V100 GPU. Note that TVM and TF-TRT do not support training, hence the data is missing.

RNN benchmarks, again, because it takes effort implementing efficient r Operators to support other models. Currently, RAMMER only supports a single IPU device. We leave the multi-IPU support of RAMMER to future work. For the three RNN models, due to the limited memory available on IPU (256 KB on each tile), we configure the layers of these models to 4 in order to fit in a single IPU. Figure 20 shows the end-to-end performance of RAMMER on these models with batch size of 1. It shows that RAMMER's preliminary implementation can bring up to $5.37\times$ performance improvement compared with RAMMERBASE, which demonstrates the applicability and effectiveness of the abstractions of RAMMER on new accelerator architectures.

6 Discussion

Having shown the advantages, we discuss some RAMMER's limitations and future work in this section.

Performance gain on large batch sizes. RAMMER's benefits are more significant when the intra-operator parallelism

is insufficient to saturate hardware. This is the case when the input batch size is small, often found in online DNN inference. Moreover, our preliminary experiment shows that this is also the case for some model training workloads with large batch sizes (e.g., 256), such as the LSTM-TC model. Figure 21 shows the training performance of LSTM-TC with batch size of 256. As it shows, with holistic optimizations on both intra- and inter-operator parallelism, RAMMER improves the performance by $2.28\times$ than our baseline implementation RAMMERBASE and $2.36\times$ than TF-XLA. We will leave a more detailed analysis and further optimizations on model training with large batch sizes as our future work.

Dynamic graph. Currently, RAMMER only supports static graph. For DFGs with dynamic control flow [51], RAMMER can compile each of the static sub-graphs, e.g., a branch of conditionals or a body of loops, into individual *r*Programs. We leave this implementation to our future work.

Inter-job scheduling. RAMMER focuses on optimizing a single deep learning job and is orthogonal to inter-job scheduling, e.g., through scheduling multiple models in a batch or precisely controlling each job’s hardware resource with *v*Device. Nevertheless, it is an interesting topic to explore the possibility to co-schedule *r*Tasks not only from different operators, but from different jobs within an accelerator.

7 Related Work

DNN compiler optimization can be generally divided into two classes based on its two-layered representations. DFG-level optimizations, such as operator fusion, are exploited in many DNN frameworks and compilers, e.g., TensorFlow [18], PyTorch [15], TVM [23], XLA [17], etc. TASO [34] proposes an automatic graph substitutions approach to optimize the DFG. On the operator-level, recent work has leveraged different approaches to tune and generate efficient hardware-specific operator code, e.g., AutoTVM [24], Tensor comprehension [47], FlexTensor [53], Tiramisu [21], Halide [43], etc. RAMMER is compatible with all these optimizations through taking an optimized DFG as input and generating efficient *r*Kernels with those kernel generators.

DNN inference and its optimization have attracted a lot of recent attention. DeepCPU [52], BatchMaker [27], GRNN [32], and NeoCPU [40] optimize the inference for RNN or CNN specific models on either CPU or GPUs. Jain et al. [33] proposes to leverage both temporal and spatial multiplexing for multiple inference jobs to improve the GPU utilization. RAMMER differentiates with these works in two aspects: 1) RAMMER can apply to general DNN models and accelerators; and 2) more than just compiler optimizations, RAMMER provides a new abstraction and a larger optimization space for DNN computation. Astra [45] exploits the

predictability of DNN to perform online optimization for DNN training, while RAMMER leverages the same property to reduce the individual *r*Task scheduling overhead. There are also many inference systems proposed to optimize the overall throughput under the guaranteed query latency, e.g., Nexus [44], PRETZEL [38], Clipper [25], TF-serving [42], etc. RAMMER instead focuses on optimizing a single model and is orthogonal to these works.

Some other work from the GPU community has proposed software-based schedulers within a GPU to schedule general workload. For example, Juggler [22] proposes a framework to dynamically execute a job represented as a DAG of tasks. Wu et al. [48] proposes a software approach to control the job locality on SMs. However, driven by the property of DNN workload, RAMMER proposes a new computation representation with *r*Task and *r*Operator; and adopts a compile-time scheduling approach to avoid runtime overhead systemically.

8 Conclusion

DNN computation suffers from unnecessary overheads due to the fundamental limitations of existing deep learning frameworks, which adopt a two-layer scheduling design that manages the inter-operator scheduling in the framework and delegates intra-operator scheduling to the hardware accelerator. RAMMER addresses this issue with a holistic compiler solution that (1) provides an *r*Task-operator abstraction that exposes the fine-grained intra-operator parallelism. (2) virtualizes the modern accelerator with parallel execution units to expose the hardware’s fine-grained scheduling capability. (3) leverages the predictability of DNN computation to transform run-time scheduling into a problem of generating compile-time *r*Task execution plans. Our evaluations show that RAMMER can achieve significant improvements compared to native deep learning frameworks, compilation frameworks and even vendor-specific inference engine on GPUs. This positions RAMMER as a new enhancement to the existing ecosystem of DNN compiler infrastructure.

Acknowledgments

We thank anonymous reviewers and our shepherd, Prof. Jinyang Li, for their extensive suggestions. We thank Jim Jernigan and Kendall Martin from the Microsoft Grand Central Resources team for the support of GPUs. Fan Yang thanks the late Pearl, his beloved cat, for her faithful companion during writing this paper. Abstract

Machine Learning (ML) adoption in the enterprise requires simpler and more efficient software infrastructure—the bespoke solutions typical in large web companies are simply untenable. Model scoring, the process of obtaining predictions from a trained model over new data, is a primary contributor to infrastructure complexity and cost as models are trained once but used many times. In this paper we propose HUMMINGBIRD, a novel approach to model scoring, which compiles featurization operators and traditional ML models (e.g., decision trees) into a small set of tensor operations. This approach inherently reduces infrastructure complexity and directly leverages existing investments in Neural Network compilers and runtimes to generate efficient computations for both CPU and hardware accelerators. Our performance results are intriguing: despite replacing imperative computations (e.g., tree traversals) with tensor computation abstractions, HUMMINGBIRD is competitive and often outperforms hand-crafted kernels on micro-benchmarks on both CPU and GPU, while enabling seamless end-to-end acceleration of ML pipelines. We have released HUMMINGBIRD as open source.

1 Introduction

Enterprises increasingly look to Machine Learning (ML) to help solve business challenges that escape imperative programming and analytical querying [35]—examples include predictive maintenance, customer churn prediction, and supply-chain optimizations [46]. To do so, they typically turn to technologies now broadly referred to as “*traditional ML*”, to contrast them with Deep Neural Networks (DNNs). A recent analysis by Amazon Web Services found that 50 to 95% of all ML applications in an organization are based on traditional ML [38]. An analysis of 6M notebooks in public GitHub repositories [64] paints a similar picture: NumPy [69], Matplotlib [11], Pandas [7], and scikit-learn [62] are the four most used libraries—all four provide functions for traditional ML. As a point of comparison with DNN frameworks, scikit-learn is used about 5 times more than PyTorch [61] and

TensorFlow [13] combined, and growing faster than both. Acknowledging this trend, traditional ML capabilities have been recently added to DNN frameworks, such as the ONNX-ML [4] flavor in ONNX [25] and TensorFlow’s TFX [39].

When it comes to owning and operating ML solutions, enterprises differ from early adopters in their focus on long-term costs of ownership and amortized return on investments [68]. As such, enterprises are highly sensitive to: (1) complexity, (2) performance, and (3) overall operational efficiency of their software infrastructure [14]. In this work we focus on *model scoring* (i.e., the process of getting a prediction from a trained model by presenting it with new data), as it is a key driving factor in each of these regards. First, each model is trained once but used multiple times for scoring in a variety of environments, thus scoring dominates infrastructure complexity for deployment, maintainability, and monitoring. Second, model scoring is often in the critical path of interactive and analytical enterprise applications, hence its performance (in terms of latency and throughput) is an important concern for enterprises. Finally, *model scoring is responsible for 45-65% of the total cost of ownership of data science solutions* [38].

Predictive Pipelines. The output of the iterative process of designing and training traditional ML models is *not just* a model but a *predictive pipeline*: a Directed Acyclic Graph (DAG) of operators. Such pipelines are typically comprised of up to tens of operators out of a set of hundreds [64] that fall into two main categories: (1) *featurizers*, which could be either stateless imperative code (e.g., string tokenization) or data transformations fit to the data (e.g., normalization); and (2) *models*, commonly decision tree ensembles or (generalized) linear models, fit to the data. Note that the whole pipeline is required to perform a prediction.

A Missing Abstraction. Today’s featurizers and model implementations *are not expressed in a shared logical abstraction, but rather in an ad-hoc fashion* using programming languages such as R, Python, Java, C++, or C#. This hints to the core problem with today’s approaches to model scoring: *the combinatorial explosion of supporting many operators*

*The work was done while the author was at Microsoft.

(and frameworks) across multiple target environments. Figure 1 (top) highlights this visually by showing how existing solutions lead to an $O(N \times M)$ explosion to support N operators from various ML frameworks against M deployment environments (e.g., how to run a scikit-learn model on an embedded device?). Furthermore, [64] shows that the number of libraries used in data science (a metric correlated to N) increased by roughly $4\times$ in the last 2 years. Our expectation is that M is also destined to grow as ML is applied more widely across a broad range of enterprise applications and hardware (e.g., [1, 15, 30, 48, 49]). From the vantage point of implementing runtimes for model scoring, this is a daunting proposition. We argue that any brute-force approach directly tackling all combinations would dilute engineering focus leading to costly and less optimized solutions. In fact, today, with very few exceptions (e.g., NVIDIA RAPIDS [3] for GPU), traditional ML operators are only implemented for CPUs.

This state of affairs is in contrast with the DNN space, where neural networks are authored using tensor transformations (e.g., multiplications, convolutions), providing an algebraic abstraction over computations. Using such abstractions rather than imperative code not only enables evolved optimizations [33, 41] but also facilitates support for diverse environments (such as mobile devices [26], web browsers [32], and hardware accelerators [15, 48, 49]), unlocking new levels of performance and portability.

Our Solution. To bypass this $N \times M$ explosion in implementing traditional ML operators, we built HUMMINGBIRD (HB for short). HB leverages compilation and optimization techniques to translate a broad set of traditional ML operators into a small set of K core operators, thereby reducing the cost to $O(N) + O(K \times M)$, as shown in Figure 1 (bottom). This is also the key intuition behind the ONNX model format [25] and its various runtimes [6]. However, with HB we take one further bold step: we demonstrate that this set of core operators can be reduced to tensor computations and therefore be executed over DNN frameworks. This allows us to piggyback on existing investments in DNN compilers, runtimes, and specialized-hardware, and reduce the challenge of “running K operators across M environments” for traditional ML to just $O(N)$ operator translations. This leads to improved performance and portability, and reduced infrastructure complexity.

Contributions. In this paper we answer three main questions:

1. Can traditional ML operators (both linear algebra-based such as linear models, and algorithmic ones such as decision trees) be translated to tensor computations?
2. Can the resulting computations in tensor space be competitive with the imperative alternatives we get as input (e.g., traversing a tree)?
3. Can HB help in reducing software complexity and improving model portability?

Concretely, we: (1) port thousands of benchmark predictive pipelines to two DNN backends (PyTorch and TVM);

Figure 1: Prediction serving complexity: state-of-the-art (top) vs. HUMMINGBIRD (bottom).

(2) show that we can seamlessly leverage hardware accelerators and deliver speedups of up to $3\times$ against hand-crafted GPU kernels, and up to $1200\times$ for predictive pipelines against state-of-the-art frameworks; and (3) qualitatively confirm improvements in software complexity and portability by enabling scikit-learn pipelines to run across CPUs and GPUs.

HB is open source under the MIT license¹, and is part of the PyTorch ecosystem [28]. We are integrating HB with other systems, such as the ONNX converters [58].

Organization. The remainder of the paper is organized as follows. Section 2 provides some background, and Section 3 presents an overview of HB. Section 4 describes the compilation from traditional ML to tensor computations, whereas Section 5 discusses various optimizations. Section 6 presents our evaluation. Section 7 is related work, then we conclude.

2 Background and Challenges

We first provide background on traditional ML and DNNs. We then explain the challenges of compiling traditional ML operators and predictive pipelines into tensor computations.

2.1 Traditional ML and DNNs

Traditional Predictive Pipelines. The result of the data science workflow over traditional ML are predictive pipelines, i.e., DAG of operators such as trained models, preprocessors, featurizers, and missing-value imputers. The process of presenting a trained predictive pipeline with new data to obtain a prediction is referred to in literature interchangeably as: model scoring/inference/serving, pipeline evaluation, or prediction serving. We favor model scoring in our writing.

¹<https://github.com/microsoft/hummingbird>

Packaging a trained pipeline into a single artifact is common practice [36]. These artifacts are then embedded inside host applications or containerized and deployed in the cloud to perform model scoring [43, 63]. ML.NET [36] (.NET-based), scikit-learn [62] (Python-based), and H₂O [9] (Java-based) are popular toolkits to generate pipelines. However, they are primarily optimized for training. Scoring predictive pipelines is challenging, as their operators are implemented in imperative code and do not follow a shared abstraction. Supporting every operator in all target environments requires a huge effort, which is why these frameworks have limited portability.

DNNs. Deep Neural Networks (DNNs) are a family of ML models that are based on artificial neurons [47]. They take raw features as input and perform a series of transformation operations. Unlike traditional ML, transformations in DNNs are drawn from a common abstraction based on tensor operators (e.g., generic matrix multiplication, element-wise operations). In recent years, DNNs have been extremely successful in vision and natural language processing tasks [45, 54]. Common frameworks used to author and train DNNs are TensorFlow [13], PyTorch [61], CNTK [10], and MXNet [12]. While these frameworks can also be used to perform model scoring, next we discuss systems specifically designed for that.

Runtimes for DNN Model Scoring. To cater to the demand for DNN model inference, a new class of systems has emerged. ONNX Runtime (ORT) [5] and TVM [41] are popular examples of such systems. These capitalize on the relative simplicity of neural networks: they accept a DAG of tensor operations as input, which they execute by implementing a small set of highly optimized operator kernels on multiple hardware. Focusing on just the prediction serving scenario also enables these systems to perform additional inference-specific optimizations, which are not applicable for training. HB is currently compatible with all such systems.

2.2 Challenges

HB combines the strength of traditional ML pipelines on structured data [56] with the computational and operational simplicity of DNN runtimes for model scoring. To do so, it relies on a simple yet key observation: once a model is trained, it can be represented as a *prediction function* transforming input features into a prediction score (e.g., 0 or 1 for binary classification), regardless of the training algorithm used. The same observation naturally applies to featurizers fit to the data. Therefore, HB only needs to compile the prediction functions (not the training logic) for each operator in a pipeline into tensor computations and stitch them appropriately. Towards this goal, we identify two challenges.

Challenge 1: *How can we map traditional predictive pipelines into tensor computations?* Pipelines are generally composed of operators (with predictive functions) of two classes: *algebraic* (e.g., scalars or linear models) and *algorithmic* (e.g., one-hot encoder and tree-based models). While translating algebraic operators into tensor computations is

straightforward, the key challenge for HB is the translation of algorithmic operators. Algorithmic operators perform arbitrary *data accesses and control flow decisions*. For example, in a decision tree ensemble potentially every tree is different from each other, not only with respect to the structure, but also the decision variables and the threshold values. Conversely, tensor operators perform *bulk operations* over the entire set of input elements.

Challenge 2: *How can we achieve efficient execution for tensor-compiled traditional ML operators?* The ability to compile predictive pipelines into DAGs of tensor operations does not imply adequate performance of the resulting DAGs. In fact, common wisdom would suggest the opposite: even though tensor runtimes naturally support execution on hardware accelerators, tree-based methods and commonly used data transformations are well known to be difficult to accelerate [42], even using custom-developed implementations.

3 System Overview

In this section we explain our approach to overcome the challenges outlined in Section 2.2, and present HB's architecture and implementation details. We conclude this section by explaining assumptions and limitations.

3.1 High-level Approach

In HB, we cast algorithmic operators into tensor computations. You will notice that this transformation *introduces redundancies*, both in terms of *computation* (we perform more computations than the original traditional ML operators) and *storage* (we create data structures that store more than what we actually need). Although these redundancies might sound counter-intuitive at first, we are able to transform the arbitrary data accesses and control flow of the original operators into tensor operations that lead to efficient computations by leveraging state-of-the-art DNN runtimes.

For a given traditional ML operator, there exist different strategies for compiling it to tensor computations, each introducing a different degree of redundancy. We discuss such strategies for representative operators in Section 4. The optimal tensor implementation to be used varies and is informed by model characteristics (e.g., tree-structure for tree-based models, or sparsity for linear models) and runtime statistics (e.g., batch size of the inputs). *Heuristics at the operator level, runtime-independent optimizations at the pipeline level, and runtime-specific optimizations at the execution level* enable HB to further improve predictive pipelines performance end-to-end. The dichotomy between runtime-independent and runtime-specific optimizations allow us to both (1) apply optimizations unique to traditional ML and not captured by the DNN runtimes; and (2) exploit DNN runtime optimizations once the traditional ML is lowered into tensor computations. Finally, HB is able to run end-to-end pipelines on the hardware platforms supported by the target DNN runtimes.

Figure 2: High-level architecture of HB.

3.2 System Architecture and Implementation

The high-level architecture of HB is shown in Figure 2. HB has three main components: (1) *Pipeline Parser*, (2) *Optimizer*, and (3) *Tensor DAG Compiler*.

Pipeline Parser. In this phase, input pipelines are parsed one operator at a time, and each operator is *wrapped* into a *container* object. Each operator’s container maintains (1) the inputs and outputs of the operator, and (2) the *operator signature* that codifies the operator type (e.g., “scikit-learn decision tree”). HB parser also introduces a set of *extractor functions* that are used to extract the parameters of each operator (e.g., weights of a linear regression, thresholds of a decision tree). Operator signatures dictate which extractor function should be used for each operator. At startup time, extractor functions are registered into a hash table, mapping operator signatures to the related extractor function. HB parser is extensible, allowing users to easily add new extractor functions. HB currently supports over 40 scikit-learn operators (listed in Table 1), as well as parsers for XGBoost [40], LightGBM [51], and ONNX-ML [4]. At the end of the parsing phase, the input pipeline is “logically” represented in HB as a DAG of containers storing all the information required for the successive phases. HB parser is based on skl2onnx [31].

Optimizer. In this phase, the DAG of containers generated in the parsing phase is traversed in topological order in two passes. During the first traversal pass, the Optimizer extracts the parameters of each operator via the referenced extractor function and stores them in the container. Furthermore, since HB supports different operator implementations based on the extracted parameters, the Optimizer annotates the container with the compilation strategy to be used for that specific operator (5.1). During the second pass, HB tries to apply runtime-independent optimizations (5.2) over the DAG.

Tensor DAG Compiler. In this last phase, the DAG of containers is again traversed in topological order and a *conversion-to-tensors function* is triggered based on each operator signatures. Each conversion function receives as input the extracted parameters and generates a PyTorch’s *neural network module* composed of a small set of tensor operators (listed in Table 2). The generated module is then exported into the target runtime format. The current version of HB supports PyTorch/TorchScript, ONNX, and TVM output formats. The runtime-specific optimizations are triggered at this level.

Supported ML Models

LogisticRegression, SVC, NuSVC, LinearSVC, SGDClassifier, LogisticRegressionCV, DecisionTreeClassifier/Regression, RandomForestClassifier/Regression, ExtraTreesClassifier/Regressor, GradientBoostingClassifier/Regression, HistGradientBoostingClassifier/Regressor, IsolationForest, MLPClassifier, BernoulliNB, GaussianNB, MultinomialNB

Supported Featurizers

SelectKBest, VarianceThreshold, SelectPercentile, PCA, KernelPCA, TruncatedSVD, FastICA, SimpleImputer, Imputer, MissingIndicator, RobustScaler, MaxAbsScaler, MinMaxScaler, StandardScaler, Binarizer, KBinsDiscretizer, Normalizer, PolynomialFeatures, OneHotEncoder, LabelEncoder, FeatureHasher

3.3 Assumptions and Limitations

In this paper, we make a few simplifying assumptions. First, we assume that predictive pipelines are “pure”, i.e., they do not contain arbitrary user-defined operators. There has been recent work [65] on compiling imperative UDFs (user-defined functions) into relational algebra, and we plan to make use of such techniques in HB in the future. Second, we do not support sparse data well. We found that current support for sparse computations on DNN runtimes is primitive and not well optimized. We expect advances in DNN frameworks to improve on this aspect—TACO [52] is a notable such example. Third, although we support string operators, we currently do not support text feature extraction (e.g., *TfidfVectorizer*). The problem in this case is twofold: (1) compiling regex-based tokenizers into tensor computations is not trivial, and (2) representing arbitrarily long text documents in tensors is still an open challenge. Finally, HB is currently limited by single GPU memory execution. Given that several DNN runtimes nowadays support distributed processing [57, 66], we plan to investigate distributed inference as future work.

4 Compilation

HB supports compiling several algorithmic operators into tensor computations. Given their popularity [64], in Section 4.1 we explain our approach for tree-based models. Section 4.2 gives a summary of other techniques that we use for both algorithmic and arithmetic operators.

4.1 Compiling Tree-based Models

HB has three different strategies for compiling tree-based models. Strategies differ based on the degree of redundancy introduced. Table 3 explains the notation used in this section. We summarize the worst-case runtime and memory footprints of each strategy in Table 4. HB currently supports only trees built over numerical values: support for missing and categorical values is under development. For the sake of presentation, we assume all decision nodes perform $<$ comparisons.

Figure 3: Compiling an example decision tree using the GEMM strategy.

Table 3: Notation used in Section 4.1

Symbol	Description
N, I, L, F, C	Ordered lists with all nodes, internal nodes, leaf nodes, features, and classes, respectively.
$X \in \mathbb{R}^{n \times F }$	Input records (n is the number of records).
$A \in \mathbb{R}^{ F \times I }$	$A_{i,j} = \begin{cases} 1, & I_j \text{ evaluates } F_i \\ 0, & \text{Otherwise} \end{cases}$
$B \in \mathbb{R}^{ I }$	$B_i = \text{ThresholdValue}(I_i)$
$C \in \mathbb{R}^{ I \times L }$	$C_{i,j} = \begin{cases} -1, & L_j \in \text{RightSubTree}(I_i) \\ 1, & L_j \in \text{LeftSubTree}(I_i) \\ 0, & \text{Otherwise} \end{cases}$
$D \in \mathbb{R}^{ L }$	$D_k = \sum_{k \in L \xrightarrow{\text{path}} \text{Root}} \mathbf{1}(k == \text{LeftChild}(\text{Parent}(k)))$
$E \in \mathbb{R}^{ L \times C }$	$E_{i,j} = \begin{cases} 1, & L_i \xrightarrow{\text{map to}} C_j \\ 0, & \text{Otherwise} \end{cases}$

Table 4: Worst-case memory and runtime analysis of different tree compilation strategies, assuming the number of input records and number of trees are fixed. The notation is explained in Table 3.

Strategy	Memory	Runtime
GEMM	$O(F N + N ^2 + C N)$	$O(F N + N ^2 + C N)$
TT	$O(N)$	$O(N)$
PTT	$O(2^{ N })$	$O(N)$

Strategy 1: GEMM. We cast the evaluation of a tree as a series of three GEMM operations interleaved by two element-wise logical operations. Given a tree, we create five tensors which collectively capture the tree structure: A, B, C, D , and E . A captures the relationship between input features and internal nodes. B is set to the threshold value of each internal node. For any leaf node and internal node pair, C captures whether the internal node is a parent of that internal node, and if so, whether it is in the left or right sub-tree. D captures the count of the internal nodes in the path from a leaf node to the tree root, for which the internal node is the left child of its parent. Finally, E captures the mapping between leaf nodes and the class labels. Given these tensors, Algorithm 1 presents how we perform tree scoring for a batch of input records X . A graphical representation of an execution of the GEMM strategy is depicted in Figure 3.

The first GEMM is used to match each input feature with

Algorithm 1 GEMM Strategy (Notation explained in Table 3)

```

Input :  $X \in \mathbb{R}^{n \times |F|}$ , Input records
Output :  $R \in \{0, 1\}^{n \times |C|}$ , Predicted class labels

/* Evaluate all internal nodes */
 $T \leftarrow \text{GEMM}(X, A)$  //  $T \in \mathbb{R}^{n \times |I|}$ 
 $T \leftarrow T < B$  //  $T \in \mathbb{R}^{n \times |I|}$ 

/* Find the leaf node which gets selected */
 $T \leftarrow \text{GEMM}(T, C)$  //  $T \in \mathbb{R}^{n \times |L|}$ 
 $T \leftarrow T == D$  //  $T \in \mathbb{R}^{n \times |L|}$ 

/* Map selected leaf node to class label */
 $R \leftarrow \text{GEMM}(T, E)$  //  $R \in \mathbb{R}^{n \times |C|}$ 

```

the internal node(s) using it. The following $<$ operations is used to evaluate all the internal decision nodes and produces a tensor of 0s and 1s based on the false/true outcome of the conditions. The second GEMM operation generates an encoding for the path composed by the true internal nodes, while the successive $==$ operation returns the leaf node selected by the encoded path. Finally, the third GEMM operation maps the selected leaf node to the class label.

This strategy can be easily applied to support tree ensembles and regression tasks too. For tree ensembles, we create the above 2-dimensional tensors for each tree and batch them together. As the number of leaf nodes and internal nodes can vary among trees, we pick the maximum number of leaf nodes and internal nodes for any tree as the tensor dimensions and pad the smaller tensor slices with zeros. During scoring, we invoke the batched variants of GEMM and logical operations and perform a final `ReduceMean` operation over the batched dimension to generate the ensemble output. For regression tasks, we initialize E with label values.

Strategy 2: TreeTraversal (TT). In the GEMM strategy, we incorporated a high degree of computational redundancy by evaluating all internal nodes and leaf nodes. Here, we try to reduce the computational redundancy by mimicking the typical tree traversal—but implemented using tensor operations. In this strategy, the tree structure is captured by five tensors: N_L, N_R, N_F, N_T , and N_C . We formally define these tensors in Table 5. The same column index (last dimension) across all tensors corresponds to the same tree node. N_L and N_R capture the indices of the left and right nodes for a given node. If the node is a leaf node, we set these to the index of the given node. Similarly, N_F and N_T capture the feature index and threshold

Table 5: Additional notation used in Strategy 2: TreeTraversal

Symbol	Description
$N_L \in \mathbb{Z}^{ N }$	$N_{L_i} = \begin{cases} \text{LeftChild}(N_i), N_i \in I \\ i, \text{Otherwise} \end{cases}$
$N_R \in \mathbb{Z}^{ N }$	$N_{R_i} = \begin{cases} \text{RightChild}(N_i), N_i \in I \\ i, \text{Otherwise} \end{cases}$
$N_F \in \mathbb{Z}^{ N }$	$N_{F_i} = \begin{cases} k, (N_i \in I) \wedge (N_i \text{ evaluates } F_k) \\ 1, \text{Otherwise} \end{cases}$
$N_T \in \mathbb{R}^{ N }$	$N_{T_i} = \begin{cases} \text{ThresholdValue}(N_i), N_i \in I \\ 0, \text{Otherwise} \end{cases}$
$N_C \in \mathbb{Z}^{ N \times C }$	$N_{C_{i,k}} = \begin{cases} 1, (N_i \in L) \wedge (N_i \xrightarrow{\text{map to}} C_k) \\ 0, \text{Otherwise} \end{cases}$

Algorithm 2 TreeTraversal Strategy (Notation in Tables 5)

Input : $X \in \mathbb{R}^{n \times |F|}$, Input records
Output : $R \in \{0, 1\}^{n \times |C|}$, Predicted class labels

/* Initialize all records to point to k , with k the index of Root node. */
 $T_I \leftarrow \{k\}^n$ // $T_I \in \mathbb{Z}^n$

for $i \leftarrow 1$ **to** TREE_DEPTH **do**

 /* Find the index of the feature evaluated by the current node. Then find its value. */
 $T_F \leftarrow \text{Gather}(N_F, T_I)$ // $T_F \in \mathbb{Z}^n$
 $T_V \leftarrow \text{Gather}(X, T_F)$ // $T_V \in \mathbb{R}^n$

 /* Find the threshold, left child and right child */
 $T_T \leftarrow \text{Gather}(N_T, T_I)$ // $T_T \in \mathbb{R}^n$
 $T_L \leftarrow \text{Gather}(N_L, T_I)$ // $T_L \in \mathbb{Z}^n$
 $T_R \leftarrow \text{Gather}(N_R, T_I)$ // $T_R \in \mathbb{Z}^n$

 /* Perform logical evaluation. If true pick from T_L ; else from T_R . */
 $T_I \leftarrow \text{Where}(T_V < T_T, T_L, T_R)$ // $I \in \mathbb{Z}^n$

end

/* Find label for each leaf node */
 $R \leftarrow \text{Gather}(N_C, T_I)$ // $R \in \mathbb{Z}^n$

value for each node, respectively. For leaf nodes, we set N_F to 1 and N_T to 0. Finally, N_C captures the class label of each leaf node. For internal nodes this can be any value; we set it to 0.

Given these tensors, Algorithm 2 presents how we perform scoring for a batch of input records X . We use `Gather` and `Where` operations which can be used to perform index-based slicing and conditional value selection. We first initialize an index tensor T_I corresponding to all records in X , which points to the root node. Using T_I , we `Gather` the corresponding feature indices and use them to `Gather` the corresponding feature values from X . Similarly, we also `Gather` left node indices, right node indices, and node thresholds. Using these gathered tensors, we then invoke a `Where` operation which checks for the tree node decisions. Based on the evaluation, for each record the `Where` operator either returns the left child index or right child index. To perform full tree scoring, the above steps have to be repeated until we reach a leaf node for all records in X . We exploit the fact that (1) TREE_DEPTH is a known property of the input model at compilation time,

and (2) all leaf nodes are at a depth $\leq \text{TREE_DEPTH}$, to iterate for that fixed number of iterations to ensure that all records have found their corresponding leaf node. Tensors are created in such a way that if one of the indices reaches a leaf node before running for TREE_DEPTH iterations, the same class label will keep getting selected. At compile time, we unroll all iterations and remove the `for` loop to improve efficiency. For ensembles, we create tensors for each tree and batch them together. However, between trees the number of nodes and dimensions may differ, so we use the maximum node count for any tree as the dimension and pad the remaining elements.

Strategy 3: PerfectTreeTraversal (PTT). Similar to the previous one, this strategy also mimics the tree traversal. However, here we assume the tree is a *perfect binary tree*. In a perfect binary tree, all internal nodes have exactly two children and all leaf nodes are at the same depth level. Assume we are given a non-perfect binary tree with a TREE_DEPTH of D , and L_k is a leaf node which is at a depth of $D_k < D$. To push L_k to a depth D , we replace L_k with a perfect sub-tree of depth $D - D_k$ and map all the leaf nodes of the sub-tree to C_k : the label of the original leaf node. The decision nodes in the introduced sub-tree are free to perform arbitrary comparisons as the outcome is the same along any path. By pushing all leaf nodes at depth $< D$ to a depth of D , we transform the original tree to a perfect tree with the same functionality.

Table 6: Additional notation used in Strategy 3

Symbol	Description
$I' \in \mathbb{Z}^{2^{D-1}}, L' \in \mathbb{Z}^{2^D}$	Internal and leaf nodes of the perfect tree ordered by level.
$N'_F \in \mathbb{Z}^{ I' }$	$N'_{F_i} = k \iff I'_i \text{ evaluates } F_k$
$N'_T \in \mathbb{R}^{ I' }$	$N'_{T_i} = \text{ThresholdValue}(I'_i)$
$N'_C \in \mathbb{Z}^{ L' \times C }$	$N'_{C_{i,k}} = \begin{cases} 1, N_i \xrightarrow{\text{map to}} C_k \\ 0, \text{Otherwise} \end{cases}$

Working on perfect trees enables us to get rid of N_L and N_R tensors as we can now calculate them analytically, which also reduces memory lookup overheads during scoring. Thus we create only three tensors to capture the tree structure: N'_F, N'_T , and N'_C (Table 6). They capture the same information as N_F, N_T, N_C but have different dimensions and have a strict condition on the node order. Both N'_F and N'_T have 2^{D-1} elements and the values correspond to internal nodes generated by level order tree traversal. N'_C has 2^D elements with each corresponding to an actual leaf node from left to right order.

Given these tensors, in Algorithm 3 we present how PTT works. From a high-level point of view, it is very similar to the TT strategy with only a few changes. First, the index tensor T_I is initialized to all ones as the root node is always the first node. Second, we get rid of finding the left index and right index of a node and using them in the `Where` operation. Instead, the `Where` operation returns 0 for true case and 1 for

Algorithm 3 PTT Strategy (Notation in Tables 6)

```
Input :  $X \in \mathbb{R}^{n \times |F|}$ , Input records
Output :  $R \in \{0, 1\}^{n \times |C|}$ , Predicted class labels

/* Initialize all records to point to the root node. */
 $T_I \leftarrow \{1\}^n$  //  $T_I \in \mathbb{Z}^n$ 

for  $i \leftarrow 1$  to  $\text{TREE\_DEPTH}$  do
    /* Find the index of the feature evaluated by the
       current node. Then find its value. */
     $T_F \leftarrow \text{Gather}(N_F, T_I)$  //  $T_F \in \mathbb{Z}^n$ 
     $T_V \leftarrow \text{Gather}(X, T_F)$  //  $T_V \in \mathbb{R}^n$ 

    /* Find the threshold */
     $T_T \leftarrow \text{Gather}(N_T, T_I)$  //  $T_T \in \mathbb{R}^n$ 

    /* Perform logical evaluation. If true pick left child;
       else right child. */
     $T_I \leftarrow 2 \times T_I + \text{Where}(T_V < T_T, 0, 1)$  //  $I \in \mathbb{Z}^n$ 
end

/* Find label for each leaf node */
 $R \leftarrow \text{Gather}(N'_C, T_I)$  //  $R \in \mathbb{Z}^n$ 
```

the false case. By adding this to $2 \times T_I$ we get the index of the child for the next iteration. For ensembles, we use the maximum TREE_DEPTH of any tree as D for transforming trees to perfect trees. We create tensors separate for each tree and batch them together for N'_C . But for N'_F and N'_T instead of batching, we interleave them together in some order such that values corresponding to level i for all trees appear before values corresponding to level $i + 1$ of any tree.

4.2 Summary of Other Techniques

Next, we discuss the other techniques used across ML operators to efficiently compile them into tensor computations.

Exploiting Automatic Broadcasting. Broadcasting [21] is the process of making two tensors shape compatible for element-wise operations. Two tensors are said to be shape compatible if each dimension pair is the same, or one of them is 1. At execution time, tensor operations implicitly repeat the size 1 dimensions to match the size of the other tensor, without allocating memory. In HB, we heavily use this feature to execute some computation over multiple inputs. For example, consider performing an one-hot encoding operation over column $X_i \in \mathbb{R}^n$ with a vocabulary $V \in \mathbb{Z}^m$. In order to implement this using tensor computations, we Reshape X_i to $[n, 1]$ and V to $[1, m]$ and calculate $R = \text{Equal}(X, V)$, $R \in \{0, 1\}^{n \times m}$. The Reshape operations are for free because they only modify the metadata of the tensor. However, this approach performs redundant comparisons as it checks the feature values from all records against all vocabulary values.

Minimize Operator Invocations. Given two approaches to implement an ML operator, we found that often picking the one which invokes fewer operators outperforms the other—even if it performs extra computations. Consider a featurizer that generates feature interactions. Given an input $X \in \mathbb{R}^{n \times d}$, with $d = |F|$, it generates a transformed output $R \in \mathbb{R}^{n \times \frac{d(d+1)}{2}}$ with $R_i = [X_{i,1}^2, \dots, X_{i,d}^2, X_{i,1}X_{i,2}, \dots, X_{i,d-1}X_{i,d}]$. One way to implement this operator is to compute each new feature separately by first Gathering the corresponding in-

put feature columns, perform an element-wise Multiplication, and concatenate all new features. However, this approach requires performing $d^2 + d + 1$ operations and hence is highly inefficient due to high operator scheduling overheads. Alternatively, one could implement the same operator as follows. First, Reshape X into $X' \in \mathbb{R}^{n \times d \times 1}$ and $X'' \in \mathbb{R}^{n \times 1 \times d}$. Then perform a batched GEMM using these inputs, which will create $R' \in \mathbb{R}^{n \times d \times d}$. Finally, Reshape R' to $R'' \in \mathbb{R}^{n \times d^2}$. Notice that each row in R'' has all the values of the corresponding row in R , but in a different order. It also has some redundant values due to commutativity of multiplication (i.e., $x_i x_j = x_j x_i$). Hence, we perform a final Gather to extract the features in the required order, and generate R . Compared to the previous one, this approach increases both the computation and the memory footprint roughly by a factor of two. However, we can implement feature interaction in just two tensor operations.

Avoid Generating Large Intermediate Results. Automatic broadcasting in certain cases can become extremely inefficient due to the materialization of large intermediate tensors. Consider the Euclidean distance matrix calculation, which is popular in many ML operators (e.g., SVMs, KNN). Given two tensors $X \in \mathbb{R}^{n \times d}$ and $Y \in \mathbb{R}^{m \times d}$, the objective is to calculate a tensor $D \in \mathbb{R}^{n \times m}$, where $D_{i,j} = \|X_i - Y_j\|_2^2$. Implementing this using broadcasting requires first reshaping X to $X' \in \mathbb{R}^{n \times 1 \times d}$, Y to $Y' \in \mathbb{R}^{1 \times m \times d}$, calculate $(X' - Y') \in \mathbb{R}^{n \times m \times d}$, and perform a final Sum over the last dimension. This approach causes a size blowup by a factor of d in intermediate tensors. Alternatively, a popular trick [37] is to use the quadratic expansion of $D_{i,j} = \|X_i\|_2^2 + \|Y_j\|_2^2 - 2 \cdot X_i Y_j^T$ and calculate the individual terms separately. This avoids generating intermediate tensors.

Fixed Length Restriction on String Features. Features with strings of arbitrary lengths pose a challenge for HB. Strings are commonly used in categorical features, and operators like one-hot encoding and feature hashing natively support strings. To support string features, HB imposes a fixed length restriction, with the length being determined by the max size of any string in the vocabulary. Vocabularies are generated during training and can be accessed at compile time by HB. Fixed length strings are then encoded into an `int8`.

5 Optimizations

In this section we discuss the key optimizations performed by the HB's Optimizer: heuristics for picking operator strategies (Section 5.1) and runtime-independent optimizations (Section 5.2). Recall that our approach also leverages runtime-specific optimizations at the Tensor Compiler level. We refer to [8, 41] for runtime-specific optimizations.

5.1 Heuristics-based Strategy Selection

For a given classical ML operator, there can be more than one compilation strategy available. In the previous section we explained three such strategies for tree-based models. In practice, no strategy consistently dominates the others, but each is preferable in different situations based on the input

and model structure. For instance, the GEMM strategy gets significantly inefficient as the size of the decision trees gets bigger because of the large number of redundant computations. This strategy performs $O(2^D)$ (D is the depth of the tree) computations whereas the original algorithmic operator needs to perform only $O(D)$ comparisons. Nevertheless, with small batch sizes or a large number of smaller trees, this strategy can be performance-wise optimal on modern hardware, where GEMM operations can run efficiently. With large batch sizes and taller trees, TT techniques typically outperform the GEMM strategy and PTT is slightly faster than vanilla TT due to the reduced number of memory accesses. But if the trees are too deep, we cannot implement PTT because the $O(2^D)$ memory footprint of the associated data structures will be prohibitive. In such cases, we resort to TT. The exact crossover point where GEMM strategy outperforms other strategies is determined by the characteristics of the tree model (e.g., number of trees, maximum depth of the trees), runtime statistics (e.g., batch size), and the underlying hardware (e.g., CPUs, GPUs). For instance, from our experiments (see Figure 8) we found that the GEMM strategy performs better for shallow trees ($D \leq 3$ on CPU, ≤ 10 on GPU) or for scoring with smaller batch sizes. For tall trees, using PTT when $D \leq 10$ give a reasonable trade-off between memory footprint and runtime, which leaves vanilla TreeTraversal the only option for very tall trees ($D > 10$). These heuristics are currently hard-coded.

5.2 Runtime-independent Optimizations

We discuss two novel optimizations, which are unique to HB. HB’s approach of separating the prediction pipeline from training pipeline, and representing them in a logical DAG before compilation into tensor computations facilitate the optimization of end-to-end pipelines.

Feature Selection Push-Down. Feature selection is a popular operation that is often used as the *final featurization step* as it reduces over-fitting and improves the accuracy of the ML model [44]. However, during scoring, it can be pushed down in the pipeline to avoid redundant computations such as scaling and one-hot encoding for discarded features or even reading the feature at all. This idea is similar to the concept of projection push-down in relation query processing but through user-defined table functions, which in our case are the ML operators. For operators such as feature scaling, which performs 1-to-1 feature transformations, selection push-down can be easily implemented. However, for operators such as one-hot encoding and polynomial featurization, which perform 1-to-m or m-to-1 feature transformations, the operator will have to absorb the feature selection and stop generating those features. For example, say one-hot encoding is applied on a categorical feature column which has a vocabulary size of 10, but 4 of those features are discarded by the feature selector. In such cases, we can remove such features from the vocabulary. Note that for some “blocking” operators [55], such as normalizers, it is not possible to push-down the feature selection.

Feature Selection Injection. Even if the original pipeline doesn’t have a feature selection operator, it is possible to inject one and then push it down. Linear models with L1 regularization (Lasso) is a typical example where feature selection is implicitly performed. The same idea can be extended to tree-based models to prune the features that are not used as decision variables. In both of these examples, the ML model also has to be updated to take into account the pruned features. For linear models we prune the zero weights; for tree models, we update the indices of the decision variables.

6 Experimental Evaluation

In our experimental evaluation we report two micro-benchmark experiments showing how HB performs compared to current state-of-the-art for inference over (1) tree ensembles (Section 6.1.1); (2) other featurization operators and ML models (Section 6.1.2). Then we evaluate the optimizations by showing: (1) the need for heuristics for picking the best tree-model implementation (Section 6.2.1); and (2) the benefits introduced by the runtime-independent optimizations (Section 6.2.2). Finally, we conduct an end-to-end evaluation using pipelines (Section 6.3). We evaluate both CPUs and hardware accelerators (GPUs).

Hardware and Software Setup. For all the experiments (except when stated otherwise) we use an Azure NC6 v2 machine equipped with 112 GB of RAM, an Intel Xeon CPU E5-2690 v4 @ 2.6GHz (6 virtual cores), and an NVIDIA P100 GPU. The machine runs Ubuntu 18.04 with PyTorch 1.3.1, TVM 0.6, scikit-learn 0.21.3, XGBoost 0.9, LightGBM 2.3.1, ONNX runtime 1.0, RAPIDS 0.9, and CUDA 10. We run TVM with `opt_level 3` when not failing; 0 otherwise.

Experimental Setup. We run all the experiments 5 times and report the truncated mean (by averaging the middle values) of the processor time. In the following, we use ONNX-ML to indicate running an ONNX-ML model (i.e., traditional ML part of the standard) on the ONNX runtime. Additionally, we use **bold numbers** to highlight the best performance for the specific setup (CPU or GPU). *Note that both scikit-learn and ONNX-ML do not natively support hardware acceleration.*

6.1 Micro-benchmarks

6.1.1 Tree Ensembles

Setup. This experiment is run over a set of popular datasets used for benchmarking gradient boosting frameworks [22]. We first do a 80%/20% train/test split over each dataset. Successively, we train a scikit-learn *random forest*, *XGBoost* [40], and *LightGBM* [51] models using the default parameters of the benchmark. Specifically, we set the number of trees to 500 and maximum depth to 8. For XGBoost and LightGBM we use the scikit-learn API. Note that each algorithm generates trees with different structures, and this experiment helps with understanding how HB behaves with various tree types and dataset scales. For example, XGBoost generates balanced

trees, LightGBM mostly generates skinny tall trees, while random forest is a mix between the two. Finally, we score the trained models over the test dataset using different batch sizes. We compare the results against HB with different runtime backends and an ONNX-ML version of the model generated using ONNXMLTools [18]. When evaluating over GPU, we also compared against NVIDIA RAPIDS Forest Inference Library (FIL) [29]. We don't compare against GPU implementations for XGBoost or LightGBM because we consider FIL as state-of-the-art [19]. For the CPU experiments, we use all six cores in the machine, while for request/response experiments we use one core. We set a timeout of 1 hour for each experiment.

Datasets. We use 6 datasets from NVIDIA's gbm-bench [22]. The datasets cover a wide spectrum of use-cases: from regression to multiclass classification, from 285K rows to 100M, and from few 10s of columns to 2K.

List of Experiments. We run the following set of experiments: (1) batch inference, both on CPU and GPU; (2) request/response where one single record is scored at a time; (3) scaling experiments by varying batch sizes, both over CPU and GPU; (4) evaluation on how HB behaves on different GPU generations; (5) dollar cost per prediction; (6) memory consumption; (7) validation of the produced output wrt scikit-learn; and finally (8) time spent on compiling the models.

Batch Inference. Table 7 reports the inference time for random forest, XGBoost and LightGBM models run over the 6 datasets. The batch size is set to 10K records. Looking at the CPU numbers from the table, we can see that:

1. Among the baselines, scikit-learn models outperform ONNX-ML implementations by 2 to 3 \times . This is because ONNX-ML v1.0 is not optimized for batch inference.
2. Looking at the HB's backends, there is not a large difference between PyTorch and TorchScript, and in general these backends perform comparable to ONNX-ML.
3. The TVM backend provides the best performance on 15 experiments out of 18. In the worst case TVM is 20% slower (than scikit-learn); in the best cases it is up to 2 \times faster compared to the baseline solutions.

Let us look now at the GPU numbers of Table 7:

1. Baseline RAPIDS does not support random forest nor multiclass classification tasks. For the remaining experiments, GPU acceleration is able to provide speedups of up to 300 \times compared to CPU baselines.²
2. Looking at HB backends, TorchScript is about 2 to 3 \times slower compared to RAPIDS. TVM is instead the faster solution on 14 experiments out of 18, with a 10% to 20% improvement wrt RAPIDS.

²The original FIL blog post [19] claims GPU acceleration to be in the order of 28 \times for XGBoost, versus close to 300 \times in our case (Airline). We think that the difference is in the hardware: in fact, they use 5 E5-2698 CPUs for a total of 100 physical cores, while we use a E5-2690 CPU with 6 (virtual) physical cores. Additionally, they use a V100 GPU versus a P100 in our case.

Figure 4: Performance wrt scaling the batch size.

The results are somehow surprising: HB targets the high-level tensor APIs provided by PyTorch and TVM, and still it is able to outperform custom C++ and CUDA implementations.

Request/response. In this scenario, one single record is scored at a time. For this experiment we run inference over the entire test datasets, but with batch size equal to 1. We used the same datasets and setup of Section 6.1.1, except that (1) we removed the Airline dataset since no system was able to complete within the 1 hour timeout; and (2) we only use one single core. The results are depicted in Table 8:

1. Unlike the batch scenario, ONNX-ML is much faster compared to scikit-learn, in some cases even more than 100 \times . The reason is that ONNX-ML is currently optimized for single record, single core inference, whereas scikit-learn design is more towards batch inference.
2. PyTorch and TorchScript, again, behave very similarly. For random forest they are faster than scikit-learn but up to 5 \times slower compared to ONNX-ML. For LightGBM and XGBoost they are sometimes on par with scikit-learn, sometime slower.
3. TVM provides the best performance in 11 cases out of 15, with a best case of 3 \times compared to the baselines.

These results are again surprising, considering that tensor operations should be more optimized for bulk workloads rather than request/response scenarios.

Scaling the Batch Size. We study how the performance of baselines and HB's backends change with the batch size. Figures 4a and 4b depicts the performance variation over CPU and GPU, respectively. We report only a few combinations of dataset / algorithm, but all the other combinations behave similarly. Starting with the CPU experiment, we can see that ONNX-ML has the best runtime for batch size of 1, but then its performance remains flat as we increase the batch size. TorchScript and scikit-learn did not complete within the timeout for batch equal to 1, but, past 100, they both scale linearly as we increase the batch size. TVM is comparable to ONNX-ML for batch of 1; for batches of 100 records it gets about

Table 7: Batch Experiments (10K records at-a-time) for both CPU (6 cores) and GPU. Reported numbers are in seconds.

TVM	568	620	811

5× faster, while it scales like TorchScript for batches greater than 100. This is likely due to the fact that TVM applies a set of optimizations (e.g., operator fusion) that introduce a constant-factor speedup compared to TorchScript.

Looking at the GPU numbers (Figure 4b), TorchScript and TVM again follow a similar trend, with TVM being around 3× faster than TorchScript. Both TVM and TorchScript plateau at about a batch size of 10K. RAPIDS FIL is

Figure 6: Performance across GPUs for Airline, LightGBM

slower than TorchScript for small batch sizes, but it scales better than HB. This is because of its custom CUDA implementation that is able to better use hardware under higher utilization. Interestingly, FIL as well plateaus at around 100K records. The custom CUDA implementation introduces a 50% gain over HB with TVM runtime over large batches.

Scaling Hardware. We tested how RAPIDS FIL and HB (TorchScript and TVM) scale as we change the GPU model. For this experiment we tried both with a large batch size (1M records, Figure 6 (a)) to maximize hardware utilization, and a smaller batch size (1K, Figure 6 (b)). We ran this on all datasets across random forest, LightGBM, XGBoost with similar results, and present the Airline dataset (the largest) with LightGBM as a representative sample. We tested on three NVIDIA devices: K80 (the oldest, 2014), P100 (2016), and V100 (2017). From the figures, in general we can see that:

Table 10: Conversion times (in seconds) over one core.

	Airline				

(1) RAPIDS FIL does not run on the K80 because it is an old generation; (2) with a batch size of 1K we get slower total inference time because we don't utilize the full hardware; (3) TorchScript and TVM runtimes for HB scale similarly on different hardware, although TVM is consistently 4 to 7 \times faster; (4) FIL scales similarly to HB, although it is 50% faster on large batches, 3 \times slower for smaller batches; (5) TorchScript is not optimal in memory management because for batches of 1M it fails on the K80 with an OOM exception. Finally, we also were able to run HB on the new Graphcore IPU [15] over a single decision tree.

Cost. Figure 7 shows the cost comparison between the Azure VM instance equipped with GPU, and a comparable one without GPU (E8 v3). The plot shows the cost of executing 100k samples with a batch size of 1K for random forest. The cost is calculated based on the hourly rate of each VM divided by the amortized cost of a single prediction. We executed scikit-learn on the CPU and TorchScript and TVM on the GPU for comparison. We found that the CPU cost was significantly higher (between 10 \times -120 \times) across all experiments.³ An interesting result was that the oldest GPU was the most cost effective, with the K80 and TVM having the lowest cost for 13 out of the 18 experiments (including LightGBM and XGBoost, not pictured). This result is explained by the fact that the K80 is readily available at significantly lower cost.

Memory Consumption. We measured the peak memory consumption over the Fraud dataset and for each algorithm. We used the `memory_usage` function in the `memory_profiler` library [2]. The numbers are reported in Table 9, and are the result of the execution over 1 core with a batch size of 1K. As we can see, scikit-learn is always the most memory effi-

Figure 7: Cost for random forest 100k samples, batch size of 1K.

cient. ONNX-ML consumes from 10% to 50% more memory, while HB with TorchScript runtime consumes from 50% to about 2 \times more memory than scikit-learn. Conversely, TVM consumes from 2 \times to 3 \times more memory wrt scikit-learn. We think that TVM is more memory hungry because it optimizes compute at the cost of memory requirements. Note that the batch size influences the total memory consumption.

Output Validation. Since we run tree ensemble models as tensor operations, we could introduce rounding errors over floating point operations. Therefore, we need to validate that indeed the outputs produced match. To evaluate this, we used the `numpy.testing.assert_allclose` function, and we set the relative and absolute errors to 10^{-5} . We validate both the final scores and the probabilities (when available) for all combinations of datasets and algorithms. Out of the 18 experiments listed in Table 7, 9 of them returned no mismatches for HB, 12 in the ONNX-ML case. Among the mismatches, the worst case for HB is random forest with Covtype where we have 0.8% of records differing from the original scikit-learn output. For the Epsilon dataset, HB with random forest returns a mismatch on 0.1% of records. All the remaining mismatches effect less than 0.1% of records. Note that the differences are small. The biggest mismatch is of 0.086 (absolute difference) for Higgs using LightGBM. For the same experiment ONNX-ML has an absolute difference of 0.115.

Conversion Time. Table 10 shows the time it takes to convert a trained model into a target framework. The numbers are related to the generation of models running on a single core. This cost occurs only once per model and are not part of the inference cost. As we can see, converting a model to ONNX-ML can take up to a few tens of seconds; HB with PyTorch backend is constantly about 2 \times to 3 \times faster wrt ONNX-ML in converting random forests models, while it varies for LightGBM and XGBModels. TorchScript models are generated starting from PyTorch models, and in general this further compilation step does not introduce any major overhead. Finally, conversion to TVM is much slower, and it might take more than 3 minutes. This is due to code generation and optimizations introduced in TVM.

As a final note: parallel (i.e., more than 1 core) and GPU execution introduced further conversion time overheads, especially on TVM. For instance, TVM can take up to 40 minutes to convert a random forest model for execution on GPU.

³Note: airline times out for random forest for CPU with 1K batch.

6.1.2 Operators

Setup. This micro-benchmark is a replication of the suite comparing scikit-learn and ONNX-ML operators [17]. We test all scikit-learn operators of the suite that are supported by both ONNX-ML and HB (minus tree ensembles models). The total number of tested operators is 13, and they are a mix of ML models (Logistic Regression, Support Vector Machines, etc.) and featurizers (e.g., Binarizer, Polynomial, etc.). For this micro-benchmark we score 1 million records.

Datasets. We use the Iris datasets [23] with 20 features.

List of Experiments. We run the following experiments: (1) batch inference over 1M records, both on CPU and GPU; (2) request/response over 1 record; (3) memory consumption and conversion time. All the output results are correct.

Table 11: Batch experiments for operators on both CPU (1 core) and GPU. Numbers are in milliseconds. (TS is short for TorchScript)

Operator	Baselines (CPU)		HB CPU		HB GPU	
	Sklearn	ONNX-ML	TS	TVM	TS	TVM

StandardScaler	150	200	77	58	38	38

Batch Inference. The batch numbers are reported in Table 11. On CPU, scikit-learn is faster than ONNX-ML, up to $6\times$ for polynomial featurizer, although in most of the cases the two systems are within a factor of 2. HB with TorchScript backend is competitive with scikit-learn, whereas with TVM backend HB is faster on 8 out of 13 operators, with in general a speedup of about $2\times$ compared to scikit-learn. If now we focus to the GPU numbers, we see that HB with TorchScript backend compares favorably against TVM on 11 operators out of 13. This is in contrast with the tree ensemble micro-benchmark where the TVM backend was faster than the TorchScript one. We suspect that this is because TVM optimizations are less effective on these “simpler” operators. For the same reason, GPU acceleration does not provide the speedup we instead saw for the tree ensemble models. In general, we see around $2\times$ performance improvement over the CPU runtime: only polynomial featurizer runs faster, with almost a $10\times$ improvement. TVM returns a runtime error when generating the polynomial featurizer model on GPU.

Request/response. Table 12 contains the times to score 1 record. The results are similar to the request/response scenario

for the tree ensemble micro-benchmark. Namely, ONNX-ML outperform both scikit-learn and HB in 9 out of 13 cases. Note, however, that all frameworks are within a factor of 2. The only outlier is polynomial featurizer which is about $10\times$ faster on HB with TVM backend.

Table 12: Request/Response experiments for operators on CPU (single core). Reported numbers are in milliseconds.

PolynomialFeatures	1.2	1	0.5	0.1
StandardScaler	0.069	0.048	0.059	0.1

Memory Consumption and Conversion Time. We measured the peak memory consumed and conversion time for each operator on each framework. We used batch inference over 1K records. For memory consumption, the results are in line with what we already saw in Section 6.1.1. Regarding the conversion time, for ONNX-ML and HB with TorchScript, the conversion time is in the order of few milliseconds. The TVM backend is slightly slower but still in the order of few tens of milliseconds (exception for NuSVC and SVC which take up to 3.2 seconds). In comparison with the tree ensembles numbers (Table 10), we confirm that these operators are simpler, even from a compilation perspective.

6.2 Optimizations

6.2.1 Tree Models Implementation

Next we test the different tree-based models implementation to make the case for the heuristics.

Datasets. For this experiment we employ a synthetic dataset randomly generated with 5000 rows and 200 features.

Experiments Setup. We study the behavior of the tree implementations as we change the training algorithm, the batch size, and the tree depth. For each experiment we set the number of trees to 100. We use the TVM runtime backend. Each experiment is run on 1 CPU core.

Results. Figure 8 shows the comparison between the different tree implementations, and the two scikit-learn and ONNX-ML baselines. In the top part of the figure we run all experiments using a batch size of 1; on the bottom part we instead use a batch size of 1K. In the column on the left-hand side, we generate trees with a max depth of 3; 7 for the middle column, and 12 for column on the right-hand side. In general, two things are apparent: (1) HB is as fast as or better than the

Figure 8: Comparison between the different tree strategies as we vary the batch size and depth.

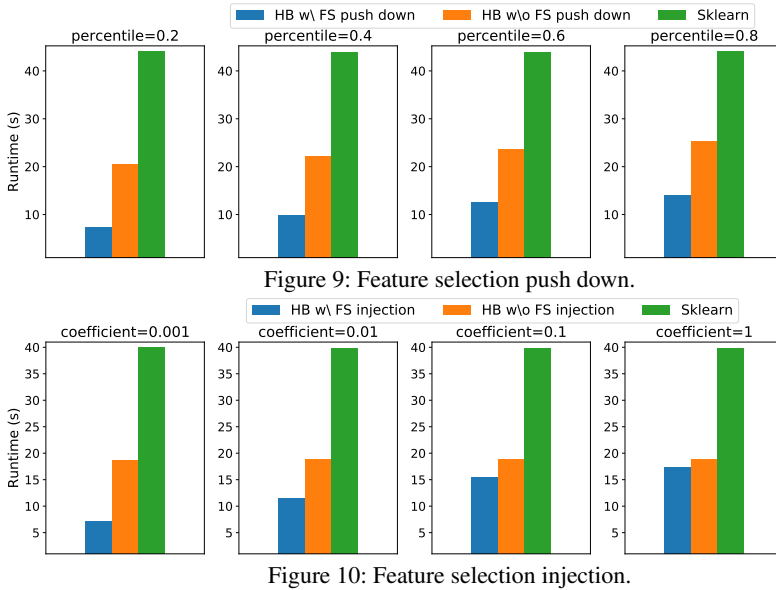

Figure 9: Feature selection push down.

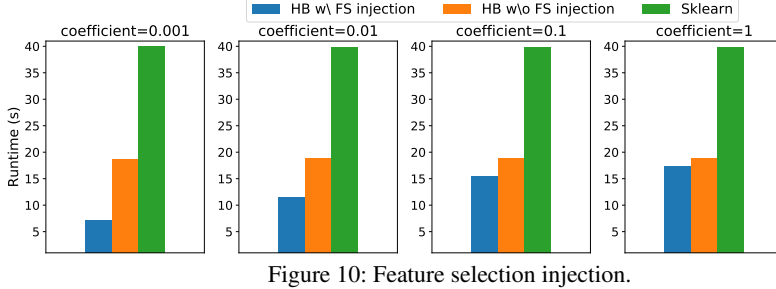

Figure 10: Feature selection injection.

baselines; and (2) no tree implementation is always better than the others. The GEMM implementation outperforms the other two for small batch sizes, whereas TT and PTT are better over larger batch sizes. Between TT and PTT, the latter is usually the best performant (although not by a large margin). PTT however creates balanced trees, and fails for very deep trees.

6.2.2 Runtime-independent Optimizations.

Next we test the optimizations described in Section 5.2.

Dataset. We use the Nomao dataset [24] with 119 features.

Feature Selection Push Down. In this experiment we measure the benefits of the feature selection push down. In Figure 9 we compare HB with and without feature selection push-down, and the baseline implementation of the pipelines in scikit-learn. We use a pipeline which trains a logistic regression model with L2 loss. The featurization part contains one-hot encoding for categorical features, missing value imputation for numerical values, followed by feature scaling, and a

final feature selection operator (scikit-learn's `SelectKBest`). We vary the percentile of features that are picked by the feature selection operator. In general, we can see that HB without optimization is about $2\times$ faster than scikit-learn in evaluating the pipelines. For small percentiles, the feature selection push-down optimization delivers a further $3\times$. As we increase the percentile of features that are selected, the runtime of HB both with and without optimizations increase, although with the optimization HB is still $2\times$ faster than without.

Feature Selection Injection. In this experiment we evaluate whether we can improve the performance of pipelines with sparse models by injecting (and then pushing down) feature selection operators. The pipeline is the same as in the previous case but without the feature selection operator. Instead we train the logistic regression model with L1 regularization. In Figure 10 we vary the L1 regularization coefficient and study how much performance we can gain. Also in this case, with

Figure 12: Speedup/slowdown of pipelines when using HB wrt baseline Sklearn.

very sparse models we can see up to $3\times$ improvement wrt HB without optimization. Performance gains dissipate as we decrease the sparsity of the model.

6.3 End-to-end Pipelines

Setup. In this experiment we test HB over end-to-end pipelines. We downloaded the 72 tasks composing the OpenML-CC18 suite [27]. Among all the tasks, we discarded all the “not pure scikit-learn” ML pipelines (e.g., containing also arbitrary Python code). We successively discarded all the pipelines returning a failure during training. 88% of the remaining pipelines are exclusively composed by operators supported by HB, for a total of 2328 ML pipelines. Among these, 11 failed during inference due to runtime errors in HB; we report the summary of executing 2317 pipelines. These pipelines contain an average of 3.3 operators, which is in line with what was observed elsewhere [64].

Datasets. For this experiment we have 72 datasets in total [27]. The datasets are a curated mix specifically designed for ML benchmarking. We did the typical 80%/20% split between training and inference. The smaller dataset has just 100 records, the bigger 19264, while the median value is 462. The minimum number of columns for a dataset is 4, the maximum 3072, with a median of 30.

Results. Figure 12 summarizes the speedup / slowdown introduced by HB when scoring all 2317 pipelines. As we can see, HB is able to accelerate about 60% of the pipelines on CPU (11a). In general, the slowest pipeline gets about $60\times$ slower wrt scikit-learn, the fastest instead gets a $1200\times$ speed up. The slowdowns are due to a couple of factors: (a) the datasets used for these experiments are quite small; (b) some pipelines contain largely sparse operations (i.e., SVM on sparse inputs); (c) several pipelines are small and do not require much computation (e.g., a simple inputer followed by a small decision tree). These three factors are highlighted also by the fact that even if we move computation to the GPU (11b), still 27% of the pipelines have some slowdown. Note however that (1) both sparse and small pipelines can be detected at compile time, and therefore we can return a warning or an error; (2) DNN frameworks are continuously adding new sparse tensor operations (e.g., [34]); and (3) an option could be to add a specific runtime backend for sparse tensor operations (e.g., we have a prototype integration with TACO [52]). In general, DNN frameworks are relatively young, and HB will exploit any future improvement with no additional costs.

With GPU acceleration (Figure 11b), 73% of the pipelines show some speedup. The slowest pipeline gets about $130\times$ slower wrt scikit-learn, the fastest instead gets a speedup of 3 orders of magnitude. Some of the pipelines get worse from CPU to GPU execution. This is due to (1) sparsity; (2) small compute; and (3) data movements between CPU and GPU memory. Indeed we run all pipelines on GPU, even the ones for which in practice would not make much sense (e.g., a decision tree with 3 nodes). We leave as future work an extension

to our heuristics for picking the right hardware backend.

7 Related Work

PyTorch [61], TensorFlow [13], MXNet [12], CNTK [10] are DNN frameworks that provide easy-to-use (tensor-based) APIs for authoring DNN models, and heterogeneous hardware support for both training and inference. Beyond these popular frameworks, inference runtimes such as ONNX [5], nGraph [16], TVM [41], and TensorRT [20] provide optimizations and efficient execution targets, specifically for inference. To prove the versatility of our approach, we have tested HB with both PyTorch and TVM. HB uses a two-level, logical-physical optimization approach. First, logical optimizations are applied based on the operators composing the pipeline. Afterwards, physical operator implementations are selected based on model statistics, and physical rewrites, which are externally implemented by the DNN runtime, are executed (e.g., algebraic rewrites, operator fusion). Willump [53] uses a similar two-level optimization strategy, although it targets Weld [60] as its low level runtime and therefore it cannot natively support inference on hardware accelerators. Conversely, HB casts ML pipelines into tensor computations and takes advantage of DNN serving systems to ease the deployment on target environments. Other optimizers for predictive pipelines, such as Pretzel [55], only target logical optimizations. We have integrated HB into Raven [50] as part of our bigger vision for optimizing ML prediction pipelines.

Several works deal with executing trees (ensembles) [29, 59, 67] on hardware accelerators. These systems provide a custom implementation of the PTT strategy specific to the target hardware (e.g., NVIDIA GPUs for RAPIDS FIL [29], FPGAs for [59]), and where computation is parallelized along on the tree-dimension. Alternatively, HB provides three tree inference strategies, including two novel strategies (GEMM and TT), and picks the best alternative based on the efficiency and redundancy trade-off.

8 Conclusions

In this paper, we explore the idea of using DNN frameworks as generic compilers and optimizers for heterogeneous hardware. Our use-case is “traditional” ML inference. We ported 40+ data featurizers and traditional ML models into tensor operations and tested their performance over two DNN frameworks (PyTorch and TVM) and over different hardware (CPUs and GPUs). The results are compelling: even though we target high-level tensor operations, we are able to outperform custom C++ and CUDA implementations. To our knowledge, HUMMINGBIRD is the first system able to run traditional ML inference on heterogeneous hardware.

9 Acknowledgements

We thank the anonymous reviewers and our shepherd, Chen Wenguang, for their feedback and suggestions to improve the paper. We would also like to thank Nellie Gustafsson, Gopal Vashishtha, Emma Ning, and Faith Xu for their support.

A Artifact Appendix

A.1 Abstract

Hummingbird compiles trained traditional ML models into tensor computation for faster inference. Hummingbird allows users to score models both on CPU and hardware accelerators.

A.2 Artifact check-list

- **Program:** PyTorch, ONNX Runtime, TVM.
- **Data set:** Fraud, Epsilon, Year, Covtype, Higgs, Airline, Iris, Nomao, OpenMLCC-18.
- **Run-time environment:** Ubuntu 18.04.
- **Hardware:** Azure NC6 v2 machine.
- **Experiments:** tree-models (Random Forest, XGBoost, LightGBM), operators (LogisticRegression, SGDClassifier, LinearSVC, NuSVC, SVC, BernoulliNB, MLPClassifier, DecisionTreeClassifier, Binarizer, MinMaxScaler, Normalizer, PolynomialFeatures, StandardScaler), end-to-end pipelines.
- **Public link:** <https://github.com/microsoft/hummingbird>.
- **Code licenses:** MIT.

A.3 Description

A.3.1 How to access

Hummingbird is open source and can be accessed directly from <https://github.com/microsoft/hummingbird>. Otherwise, Hummingbird can also be downloaded from pip with `pip install hummingbird-ml`.

A.3.2 Hardware dependencies

No specific hardware dependencies. The artifact has been evaluated on different NVIDIA GPU generations (K80, P100, V100) but it should work on any hardware supported by the target DNN runtime.

A.3.3 Software dependencies

Hummingbird requires Python ≥ 3.5 , numpy ≥ 1.15 , onnxconverter-common $\geq 1.6.0$, scikit-learn $\geq 0.21.3$, torch $\geq 1.3.1$. Additional dependencies for reproducing the results are onnxruntime ≥ 1.0 , onnxmltools $\geq 1.6.0$, xgboost ≥ 0.90 and lightgbm ≥ 2.2 , psutil, memory-profiler.

A.3.4 Data sets

For the experiments on tree algorithms we used Fraud⁴, Epsilon⁵, Year⁶, Covtype⁷, Higgs⁸, and Airline⁹. For the experiments on operators we instead used Iris¹⁰. Finally, for the pipeline experiments we used OpenML-CC18 [27]. The experiment scripts automate the download and preparation of all the datasets.

A.4 Installation

Hummingbird can be installed from pip with `pip install hummingbird-ml` or by cloning the code available on GitHub and by calling `python setup.py install` from the main directory. Hummingbird will automatically detect the available backends at runtime. We refer to <https://github.com/microsoft/hummingbird/blob/master/TROUBLESHOOTING.md> for problems related to installations.

A.5 Experiment workflow

The scripts for the experiments are divided in three main folders: *trees*, *operators* and *pipelines*. Each folder contains a README.md file containing the specific instructions for that particular set of experiments.

Trees: This directory contains the script to generate the result of Section 6.1.1. We suggest to start with running `python run.py -dataset fraud,year,covtype,epsilon` (skipping higgs/airline) because the complete script (which can be run with just `python run.py`) over all backends and datasets takes more than one day to complete. After the script is run for the first time, the datasets and trained models are cached (in *datasets* and *models* folders, respectively), so that following executions will be faster. Several other arguments can be changed in the script (e.g., batch size, number of trees, etc.).

The output of the above commands is a JSON file reporting the training time and accuracy (if the model is not cached), and prediction (process) time in seconds, as well the peak memory used. The baseline is then compared against Hummingbird with PyTorch (hb-pytorch), TorchScript (hb-torchscript) and TVM (hb-tvm) backends. The entry `is_same_output` specifies whether the results of the translated models match those of the baseline (up to a tolerance of 10^{-6}). If the result is false, the script can be re-run with the `-validate` flag on to check the percentage of wrong results. The `-gpu` flag can be used to run the experiments on GPU.

Operators: This directory contains the scripts to reproduce the experiments of Section 6.1.2. The scripts are configured to run scikit-learn and compare it against ONNX-ML, TorchScript and TVM (the last 2 using Hummingbird), for the Iris dataset over 1 core, and with batch of 1M. `python run.py` runs the benchmark for CPU, `python run.py -gpu` runs the benchmark for GPU.

Pipelines: This directory contains the script to reproduce the experiments of Section 6.3. There are two main scripts to run for this experiment:

- `openml_pipelines.py` is used to download and train all the scikit-learn pipelines of the openML-CC18 benchmark.
- `run.py` is used to run evaluate the performance of scikit-learn and Hummingbird over the trained pipelines.

⁴<https://www.kaggle.com/mlg-ulb/creditcardfraud>

⁵<https://www.csie.ntu.edu.tw/~cjlin/libsvmtools/datasets/binary.html>

⁶<https://archive.ics.uci.edu/ml/datasets/yearpredictionmsd>

⁷<https://archive.ics.uci.edu/ml/datasets/covtype>

⁸<https://archive.ics.uci.edu/ml/datasets/HIGGS>

⁹http://kt.ijs.si/elena_ikononovska/data.html

¹⁰<https://archive.ics.uci.edu/ml/datasets/iris>

This experiment is composed of two steps. The first step in this experiment is the generation of the prediction pipelines. This can be achieved by running `python openml_pipelines.py | tee openml-cc18.log`. This script takes several hours to run. While executing, this script will log the number of successfully trained pipelines, as well as additional statistics. Once completed, the `openml-cc18.log` file contains the statistics. Per task statistics are logged into the relative folder.

Once the first step is completed, in the second step we evaluate the scoring time of the generated pipelines, and compare the speed-ups introduced by Hummingbird against scikit-learn. This experiment can be executed both on CPU and GPU, and in both cases it takes about an hour. `python run.py` runs inference over all the generated pipelines, while `python run.py -gpu` can be used for GPU execution.

A.6 Evaluation and expected result

In May we open sourced Hummingbird (blog post: <https://azuredata.microsoft.com/articles/ebd95ec0-1eae-44a3-90f5-c11f5c916d15>). Since then we have been pushing our internal code into the open source repository, but the 2 versions do not match yet. Specifically:

- TVM integration is not complete. In our internal version we re-implemented all the operators directly in TVM's Relay but this is not a good strategy in the long term. In the open source version, we directly export Relay graphs from PyTorch models. However the exporter does not cover PyTorch 100% yet. We are however working with the TVM community for bringing full support of TVM in Hummingbird (we suggest to check the related issue #232 on Hummingbird's GitHub if interested). In practice, this means that: (1) not all operators are currently exportable into TVM; and (2) the performance we reported in the paper for TVM can be a bit different.
- The optimizer is not yet open sourced. This means that Figures 9 and 10 are not reproducible as of now. We hope to be able to bring the optimizer open source in the coming months.

Besides the above two limitations, the scripts allow the reproduction of the following main results of the paper:

- `trees` allows the reproduction of the results of Tables 7, 9 and 10. Please check the above description for specifics.

- `operators` allows the reproduction of the results of Table 11 (however not all operators will run on the TVM backend). Again, please check the related description for specifics.
- `pipelines` allows the reproduction of the results of Figure 12. Also in this case we don't cover yet 100% of the operators, but we are close.

Keep in mind that running all the experiments for completely reproducing the results will take several days.

A.7 Experiment customization

The above mentioned scripts can be customized by running them with different input arguments. For instance, Table 8 in the paper can be reproduced by setting the batch size to 1 (using the `-batch_size` argument.) in the `run.py` script.

A.8 Notes

The numbers in the paper were run on the reported VM, however:

- As this is an Azure VM, the underlying machine can receive upgrades necessitating the reinstallation of the NVidia drivers.
- The original experiments were run inside the context of an Nvidia-docker container. This setup should not have a large impact on results

Additionally, a few operators are not yet available in the open source version of Hummingbird, therefore the final coverage reported in the log file for the pipelines will be different than the one reported in the paper. To check the expected coverage once all the operators are open source, the script allows to add new operators. The same consideration holds for the operators experiment.

As a final note: to allow third-party reproducibility, we are open sourcing all the scripts used for the experiments.

A.9 AE Methodology

Submission, reviewing and badging methodology:

Retiarii: A Deep Learning Exploratory-Training Framework

Quanlu Zhang, Zhenhua Han, Fan Yang, Yuge Zhang, Zhe Liu, Mao Yang, Lidong Zhou

Microsoft Research

Abstract

Traditional deep learning frameworks such as TensorFlow and PyTorch support training on a single deep neural network (DNN) model, which involves computing the weights iteratively for the DNN model. Designing a DNN model for a task remains an experimental science and is typically a practice of deep learning model exploration, dovetailed with training and validation, aiming to find the best model among a set that yields the best result. Retrofitting such exploratory-training into the training process of a single DNN model, as supported by current deep learning frameworks, is unintuitive, cumbersome, and inefficient, because of the fundamental mismatch between exploring a set of models and training a single one.

Retiarii is the first framework to support deep learning exploratory-training. In particular, Retiarii (i) provides a new programming interface to specify a DNN model space for exploration, as well as an interface to describe the exploration strategy that decides which order to instantiate and train models in, how to prioritize model training, and when to terminate training of certain models; (ii) offers a Just-In-Time (JIT) engine that instantiates models, manages the training of the instantiated models, gathers the information for the exploration strategy to consume, and executes the decisions accordingly; (iii) identifies the correlations between the instantiated models and develops a set of cross-model optimizations to improve the overall exploratory-training process. Retiarii does so by introducing a key abstraction, *Mutator*, that connects the specifications of DNN model spaces and exploration strategies, while exposing the correlations between models for optimization. As a result, Retiarii's clean separation of DNN model space specification, exploration strategy, and cross-model optimizations, connected through the single mutator abstraction, leads to ease of programming, reuse of components, and vastly improved (up to 8.58x) overall exploratory-training efficiency.

1 Introduction

Deep neural networks (DNNs) have been successfully applied to a variety of perception-based tasks such as vision and speech. For each such task, a DNN model architecture, depicted as a graph of operators as vertices, connected with weighted edges, is designed. The model is then trained to populate the weights, before it can be used to perform the task. Deep learning frameworks, such as TensorFlow [11] and PyTorch [48], have been designed to describe an individual

DNN model and train the model as a (training) job to run on target hardware, such as GPUs. Training a deep learning model is often resource intensive and costly.

Devising a model for a particular task often involves an iterative exploration process, where a developer would often start with a model architecture that captures the main intuitions and tweak it repeatedly until a model with satisfactory results is identified in a continuous training and validation process. Alternatively, a model architecture could also evolve from simple models following a simple set of evolution rules.

There are clear gaps between the needs to support this *exploratory-training* process and the existing deep learning frameworks. First, this exploratory-training process works on a series of deep learning models, rather than a single one, as supported by the existing deep learning frameworks. A developer either has to specify each model individually in a manual, tedious, and repetitive process, or encodes this series of models as one “jumbo” model [13, 27, 50, 65] using advanced features such as dynamic graph and control flow. Such a “jumbo” model pollutes the original model architecture and makes it significantly harder to understand as changes are scattered across the model description with complex dynamic, control-flow structures. It is also more difficult to optimize due to the use of those dynamic, control-flow structures.

Second, deep learning frameworks manage individual training jobs and cannot capture or leverage the correlation among the set of training jobs in the same exploratory-training process. A developer is again forced to code certain exploration strategies in a “jumbo” model, together with ad hoc runtime mechanisms to manipulate the priorities of jobs or stop not-so-promising jobs early. Such implementations of exploration strategies are hardly reusable as they are deeply coupled with and embedded in a particular exploratory-training process. And there is no easy way to expose the correlations among those models, which tend to share many common structures, for cross-model optimizations. Training a set of models often incurs significant cost; any efficiency gains through optimizations would often allow an exploratory-training process to find a better model under the same budget.

We therefore propose Retiarii, the first deep learning framework specifically designed to support exploratory-training. To address the gaps we have previously identified in the existing deep learning frameworks, we address three core problems of exploratory-training: (i) specifying a DNN model space to explore, (ii) defining and realizing exploration strategies

to decide when to instantiate a model in the space, which ones to instantiate, how to prioritize the training of the instantiated models, and when to terminate the jobs for training those models, and (iii) exposing the correlations among the instantiated models and optimizing training across models by leveraging the correlation information.

Retiarii embraces a new *Mutator* abstraction as the basis for specifying a DNN model space and for defining an exploration strategy. Observing that the exploratory-training process tends to introduce relatively minor modifications to existing models or to compose simple models together following a set of evolution rules, Retiarii allows developers to specify each such modification or evolution as a *mutator* on a model graph. A DNN model space for an exploratory-training process can be defined as a set of base models (each specified as in the original deep learning frameworks, with no “pollution”) and a set of mutators. The DNN model space is then the base models, plus any subsequent models produced by applying mutators to the current models, and so on. An exploration strategy can then be partly defined to govern when to generate new models by applying mutators, as well as which current models and mutators to choose.

Retiarii further designs a Just-In-Time (JIT) engine for the exploratory-training process, which essentially manages the logical collection of all models and their corresponding training jobs. The engine instantiates new models dynamically, exposes the correlations of the instantiated models for cross-model optimizations, schedules the optimized jobs for execution, and manages the execution of the scheduled jobs, governed by the specified exploration strategy.

Retiarii advocates a clean separation of concerns and strives for simplicity and modularity. The mutator abstraction focuses on the changes to an existing model and exposes the differences (and similarities) of models for cross-model optimizations. Each mutator is fine-grained, to capture a logical unit of modification, and intended to be composable and reusable. The cross-model optimizations are also designed and implemented as general capabilities, enabled by the mutator abstraction, in Retiarii’s JIT engine. Exploration strategies are decoupled from the specification of the model spaces (through base models and mutators) to maximize reusability, even though some exploration strategies might unavoidably have dependencies on certain types of model spaces.

We have fully implemented and open sourced Retiarii¹. So far, Retiarii implements 6 mutators to define 18 different model spaces, 11 different exploration strategies, and 3 cross-model optimizations. These combinations have already covered 27 NAS algorithms from the research community, and benefit from vastly improved performance with cross-model optimizations. Our evaluation shows that (1) Retiarii reduces the exploration time of popular Neural Architecture Search (NAS) algorithms by up to 2.57 \times , and (2) Retiarii im-

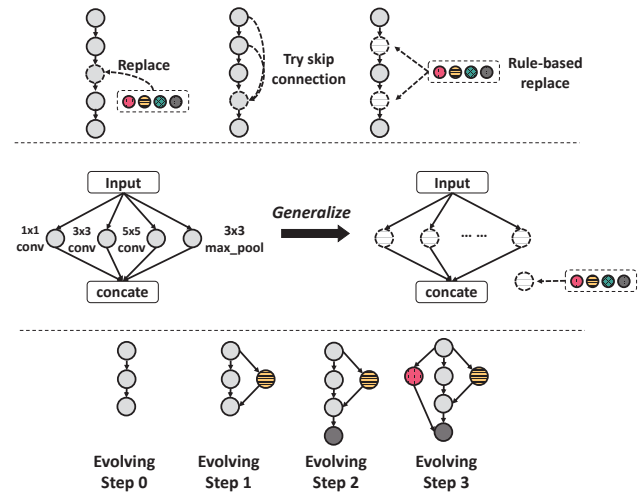

Figure 1: Three typical types of model space explorations.

proves the scalability of NAS algorithms using weight sharing with a speed-up of 8.58 \times .

2 Background and Motivation

The many ways of creating candidate model variations.

Developing a model typically involves creating interesting candidate model variations following some design intuitions; for example, by 1) tweaking a substructure (*e.g.*, a layer or a cell) of a base model, 2) coming up with generalized cell structure, 3) or evolving network structure gradually, as shown in Figure 1.

The top set of examples in Figure 1 shows different ways of modifying a base model. One could replace an operator at a layer with some candidate operators (*e.g.*, *normal conv*, *depthwise conv*), or changing a layer’s input (*e.g.*, adding some skip connections). The modification can also be applied to a *cell* containing several interconnected layers, but treated as a one logical layer. More generally, a matching rule can be defined to apply modifications on the entire model (*e.g.*, adding *BatchNorm* after convolution layers or replacing all *ShuffleNet* cells [42] with *Inverted Residual* cells [54]).

The middle example in Figure 1 shows how one could generalize a cell structure in order to find a better one. For example, an Inception cell [57] can be generalized to explore a space with different numbers of paths and a different operator on each path. Similarly, an LSTM structure can be generalized to an RNN cell [69]. A generalized structure usually contains a large number of different structures.

The bottom example in Figure 1 shows how the final network gradually evolves from a simple network following some rules. The rules could be adding a layer/edge or changing a layer’s operator in each evolution step [23].

Figure 2: The jumbo model compared to a single model in the model space. Colored circles are different operators.

The pain of specifying and exploring a model space. Exploring a model space, as exemplified in Figure 1, is not directly supported by the existing deep learning frameworks, such as TensorFlow and PyTorch. A model developer often has to program and train each model manually, or to code up all the variations of models in a model space as a single *jumbo model* in TensorFlow/PyTorch through complex control-flow, such as using specified values on the condition of control-flows to route to each model [27, 50, 62, 70]. Figure 2 shows a simple example, a layer has four candidate operators (e.g., *normal conv*, *depthwise conv*, *avgpool*, and *maxpool*), there should be a control-flow to pick one during model construction. If a layer’s input is the output of one of the previous layers (e.g., skip connection), there should be a dynamic control-flow to route to the right path during model *forward* (i.e., forward pass of data flow graph). Some popular model spaces [50, 62] change operators and inputs on as many as tens of layers, leading to excessive complexity, making the code hard to understand, and going beyond the limited capabilities of current frameworks to handle control-flow. The control-flow in jumbo models also make them hard to apply compiler optimization techniques, such as operator fusion [15, 38] and memory planning [16]. Figure 3 shows the performance gaps in terms of throughput for ResNet50, as a single model vs. as one encoded as part of a jumbo model.

Automatic model exploration. A DNN model space can be explored automatically with an *exploration strategy*. The action scope of exploration strategy spans from model generation to model execution.

When exploring a huge model space, it is usually impossible and unnecessary to train all the models in the space. An exploration strategy is responsible for deciding which models to instantiate and train, in what priority, and when to terminate. A typical strategy on which models to instantiate could be *brute force* (e.g., random search [56] and grid search [60]), *heuristic-based* (e.g., evolution [23, 30] and annealing algorithms [36]), or more advanced *model-based* (e.g., Bayesian

Figure 3: The throughput of ResNet50 built as a single model and a jumbo model. The space contains 4 choices of convolution operator at each layer. Both computation graphs are optimized by TensorFlow XLA [38].

models [33, 67] and reinforcement learning [59, 69, 70]).

An exploration strategy further manages the executions of training instantiated model; for example, to stop the execution of a bad-performing model early based on a performance predictor [20], or to dynamically adjust the computation resource provided to each model depending on the model’s performance [64], or to run several mini-batches only and share the weights of overlapped layers among the models to reduce each model’s execution time significantly [27, 50].

The pain of implementing exploration strategies. An exploration strategy naturally manages a set of models. Implementing such a strategy with the existing deep learning frameworks is unintuitive and cumbersome, as those frameworks are designed for training individual models and have no support for an exploration strategy.

Because an exploration strategy intensively involves instantiating models from a model space, the implementation often tightly couples an exploration strategy with a specific model space, further increasing the complexity of already complicated jumbo models. For example, an RNN-based RL algorithm (a popular exploration strategy) uses each of its time steps to control the condition value of each control-flow in the jumbo model [50]. Further incorporating the logic of controlling model training makes the jumbo model unmanageable. As a result, though most exploration strategies are logically applicable to different model spaces, the implementations embedded in the jumbo models are hardly reusable by other model spaces.

Encoding an exploration strategy in a jumbo model also makes it hard to expose cross-model optimization opportunities as an exploratory-training usually produces many models. The models explored tend to have strong correlations (e.g., common computation logic) among them, as the variations produced tend to touch only a certain part of the model, while keeping the rest unchanged. The training of those models also share the same dataset and data preprocessing logic. To adapt a model to different tasks, the large backbone network (e.g., BERT) is often fixed: the exploration tends to focus on varying the structure of several added layers. Significant opportunities, therefore, exist in leveraging common computation across model training to speed up an exploratory-training process as a whole. When encoding an exploration strategy in

Figure 4: Base model and mutation: An example.

a jumbo model, it also becomes challenging to scale the training of this jumbo job to multiple GPUs and servers [27, 50]; in contrast, scaling to multiple GPUs is straightforward for a set of individual jobs, each training a single model.

Insufficiency of existing AutoML systems. Previous AutoML systems (*e.g.*, Google Vizier [24], Auto-WEKA [61], Auto-Sklearn [22]) abstract the AutoML problem as hyper-parameter tuning. Although a certain NAS problem can be modeled as the tuning of specific hyper-parameters, it often involves the definition of an ad-hoc set of hyper-parameters, making it cumbersome to express different model spaces in a general way. It is especially painful to hyper-parameterize evolutionary NAS [13, 23, 51] where neural architectures can randomly evolve. Moreover, the expressed architectures are hardly understood by compilers, making optimizations almost impossible. Some recently emerged AutoML systems (*e.g.*, AutoKeras [32]) provide more support to NAS. They can automatically search neural architectures but with specifically implemented model spaces and exploration strategies, where system optimizations are hardly applicable.

Retarii is designed to address the abovementioned pains. It provides great expressiveness to support various model spaces and strategies in a systematic and programmable way. It clearly decouples model space from exploration strategy and enables system optimizations to speed up exploration process.

3 Mutator as the Core Abstraction

Exploratory-training is all about exploring a model space. Mutator is the core abstraction that connects the specification and exploration of a model space, while exposing the correlations between models for further optimizations.

Base models. Retarii follows the standard practice of characterizing a DNN model as a data-flow graph (DFG), where each node represents an operator (or a subgraph) with one or multiple input and output tensors and an edge connects an output tensor of a node to an input tensor of another node.

Retarii introduces the notion of *base models* as the starting points of an exploratory-training and preserves the way a single DNN model is specified for base models. In fact,

```
1 create_node(name:str, op:Op, params:dict={})
2 delete_node(node:Node)
3 connect(src:NodeOutput, dst:NodeInput)
4 del_connect(src:NodeOutput, dst:NodeInput)
5 update_node(node:Node, op:Op=None, params:dict={},
6             inputs:list=None)
7 choose(candidates:list, n_chosen:int=1,
8        type:str="choice", ctx:dict=None)
```

Figure 5: Mutation primitives and the choose primitive.

Retarii can simply import base models defined in an existing deep learning framework such as TensorFlow. Figure 4 illustrates an example base model with a chain of 4 operators (a convolutional neural network).

Mutator. Exploratory-training is typically a process of applying modifications (*e.g.*, as depicted in Figure 1) to existing models, starting from base models. Rather than encoding modifications in a complex jumbo model, Retarii cleanly separates modifications from the original target models and encode each as a Mutator, an abstraction designed to be expressive, modular, reusable, and composable. The model space to be explored by an exploratory-training process is then the base models, plus all the resulting models from applying mutators to the base models and to any subsequently generated models.

Graph matching and manipulation in Mutator. Each mutator specifies matching criteria to identify subgraphs of a target model’s DFG to operate on, followed by a series of graph construction operations to modify the matched subgraphs to create a new model. The mutator abstraction can also use the *choose* primitive to describe different options to choose from in a mutator, so that the mutator can produce a number of models without duplicating the mutator code to create a new mutator for each option.

Retarii’s current graph matching is based on node type or node name, which is simple, but sufficient for all the use cases we have implemented. But it can be extended easily to more expressive graph matching if necessary.

Retarii introduces general mutation primitives like *create_node* for a mutator to manipulate the node and edge in a model. The primitives are summarized in Figure 5. Note that a node in Retarii can also represent a subgraph. Thus the primitives can also be applied to a subgraph (*e.g.*, a layer or a cell) of a model.

For each model instantiation, Retarii records all the mutation primitives called in a mutator. Hence Retarii can easily identify model correlations across instantiated models. For example, between two instantiations of the same base model, the nodes *not* modified by the mutator are considered identical. Retarii can leverage such information to optimize the multi-model training (details in §5).

Mutator: an example. Figure 4 depicts a model space in which the third node (“model/maxpool”) of the base model

```

1 # define the graph mutation behavior
2 class InceptionMutator(BaseMutator):
3     def __init__(self, paths_range, candidate_ops):
4         self.paths_range = paths_range # [2, 3, 4, 5]
5         self.ops = candidate_ops # {conv, dconv, ...}
6     def mutate(self, targets):
7         if not three_node_chain(targets):
8             return err
9         n = choose(candidates=self.paths_range)
10        delete_node(targets[1])
11        for i in range(n): # create n paths
12            op = choose(candidates=self.ops)
13            nd = create_node(name='way_'+str(i), op=op)
14            connect(src=targets[0].output, dst=nd.input)
15            connect(src=nd.output, dst=targets[2].input)
16
17 # mutation applied to the graph
18 apply_mutator(targets=["model/relu", "model/
19                        maxpool", "model/dense"],
20                mutator=InceptionMutator(
21                    [2, 3, 4, 5], [conv, dconv, pool]))

```

Figure 6: A mutator that constructs an Inception-like cell.

can be mutated with a multi-path cell. The cell could have 2 to 5 paths, each of which chooses an operator from *Conv*, *DepthwiseConv* and *Maxpool*. Figure 6 shows the code of the mutator, *i.e.*, *InceptionMutator*, which implements the model space illustrated in Figure 4.

All the mutation logic is encapsulated in the *mutate* function (lines 6-15). The entry point of the mutator is given by *targets* in the *mutate* function (line 6 of Figure 6), to match nodes/subgraphs in the given model. The *targets* of *InceptionMutator* is a chain of 3 nodes. This shows that a mutator can be applied to a subgraph with a specific pattern, which improves the reusability of a mutator. In the example code, the mutator first ensures that the matching is a chain of 3 nodes (lines 7-8). It will then call *choose* (line 9) to select an integer *n* to create *n* paths subsequently. On creating each path, the mutator will call *choose* (line 12) again to select an operator for the node in the path. Note that the code for a mutator can contain arbitrary complex control flow in a mutator (*e.g.*, the control loop in lines 11-15 of Figure 6), without polluting the instantiated models, unlike in the case of jumbo models with control flows. Finally, a call to *apply_mutator* will create a mutator instance (line 18), which matches a chain of *relu*, *maxpool*, and *dense*.

4 Retiarii Just-In-Time Engine

A key design decision for Retiarii to support exploratory-training is to instantiate models to explore on the fly and manage the training of instantiated models dynamically. This is accomplished by Retiarii’s just-in-time (JIT) engine (Figure 7), which takes as input one or more base models, a set of mutators, and a policy describing the exploration strategy.

The end-to-end exploratory-training process is driven by

Figure 7: The architecture of Retiarii.

the policy described as a *Model Exploration Strategy*. The JIT engine maintains a set of *target models*, initialized with the set of base models, and consults the model exploration strategy to decide which target model(s) and mutator(s) to choose (*i.e.*, *Instantiation Control*), as well as which choices to make for each choose within those mutators (*i.e.*, *Choice Suggestion*), to instantiate new models. The decision can be guided by a context-free strategy (*e.g.*, making a random choice upon each choose) or by a history-based strategy, generating choices based on which models have been previously instantiated [60]. The *choose* interface in Mutator enables the customization of the choices.

Once new models are instantiated (*i.e.*, *Apply Mutators*) as Raw DFGs, the JIT engine transparently performs *Cross-Model Optimization* (§5). Because the JIT engine records the mutation history, the Cross-Model Optimization module can easily detect identical nodes across models to produce optimized DFGs by applying common sub-expression elimination [44], cross-model operator batching [15, 41], and NAS optimizations (§5). The optimized DFGs are then converted to the standard model format for the existing deep learning frameworks to perform single-model optimizations before training. In *Training Control*, the JIT engine launches training on new models, monitors the training of instantiated and optimized models, collects training feedbacks (*e.g.*, model accuracy), adjusts training priorities and resource allocation, and terminates training of less promising models, all guided by a model exploration strategy.

Retiarii’s Mutator abstraction and JIT engine offers an elegant architecture to support exploratory-training, following the principles of separating policy from mechanisms and separation of concerns, and maximizing modularity, reusabil-

ity, and opportunities for optimizations. In addition to the common functionalities (*e.g.*, Cross-Model Optimization) in the overall infrastructure, mutators and policies encoding the model exploration strategies might also be reused. This is in sharp contrast to the current practice of encoding everything in a jumbo code, which is hardly understandable or reusable due to tight coupling.

5 Cross-Model Optimization

The DNN models instantiated by Retiarii in an exploratory-training process tend to have significant similarities as their DFGs share common subgraphs, thereby offering huge opportunities for Retiarii to optimize the training of multiple models. With mutators that identify and record all modifications to a model’s DFG, Retiarii can easily find the common subgraphs of multiple DFGs, circumventing the generally NP-hard and APX-hard problem of identifying maximum common subgraphs [34].

5.1 Cross-Model Optimization Opportunities

Three different cross-model optimization opportunities are identified, depending on the inputs, weights, and trainability² of operators in the common subgraphs.

Common Sub-expression Elimination (CSE). CSE is a common compiler optimization to eliminate identical operations of a program by only computing them once. CSE can be applied to the non-trainable operators in the common subgraphs with common inputs and outputs, but cannot be applied to trainable operators as their weights will change during training, rendering their computation different after the first iteration. In practice, we find CSE particularly useful for merging prefix nodes of a DFG, because they are often non-trainable operators for data loading and preprocessing, as neural architecture search often uses the same dataset, batch size, and preprocessing procedures. When running multiple data-flow graphs concurrently on a single server, CSE can also avoid contention on shared storage and CPUs to maximize utilization of expensive GPUs.

Operator Batching. Common operators with different inputs and weights can potentially be batched together and computed in a single operator kernel. This optimization is useful for model exploration in multi-domain deep learning and transfer learning [28, 52, 53]. In this scenario, a model is modified to a new task with only minor changes, thus those modified models usually share a common skeleton. Adapter-based transfer learning is a one such example: networks have the same architecture from a pre-trained network, with adapters

²Similar to most popular deep learning frameworks, Retiarii allows model developers to specify whether the weights associated with an operator are *trainable*, whose weights will be applied with gradients during back-propagation.

Figure 8: Operator batching: An example.

inserted at different locations. Only the inserted layers are fine-tuned [28, 52, 53]. Figure 8 illustrates an example that two graphs share multiple layers with the same weights. After merging the two graphs, the input of the common operators are batched along the batch dimension, and the output of the batched operators are split before adapters. Common operations with different weights (*e.g.*, trainable weights) can also be batched by leveraging special kernels (*e.g.*, grouped convolution [37], *batch_matmul*) that can parallelly compute on slices of an input tensor. This allows Retiarii to enable more fine-grained sharing of GPUs by increasing SIMD utilization with less GPU memory.

Super-Graph for Weight Sharing. Weight sharing is a machine-learning optimization shown to deliver improved empirical performance for certain model training: instead of training a graph’s weights from scratch, shared weights are inherited from other graphs to continue the training in this graph [27, 50]. Retiarii naturally supports this training optimization by allowing model developers to annotate operator weights they want to share. Retiarii will automatically identify the weight sharing-enabled operators in common subgraphs. The DFGs with shared weights will be merged to build a super-graph. By training the super-graph together in one DFG, Retiarii can avoid overhead of checkpointing shared weights, because with weight sharing each graph has short training time (*e.g.*, several mini-batches). To accelerate the training of the merged super-graph, we further introduce a new type of parallelism when constructing executable graphs (§5.2) by increasing its scalability on distributed GPU clusters. Note that super-graphs are generated and used for optimizations only, and not exposed to developers.

5.2 Executable Graph Construction

To exploit these cross-model opportunities, Retiarii needs to construct executable graphs from the raw DFGs. The construction involves decisions of model merging, device placement of operators, and training parallelism, constrained by physical environment (*e.g.*, server configuration). Retiarii adopts a policy similar to Gandiva [64] that introspectively selects graphs to merge. Moreover, Retiarii specifically optimizes device placement of CSE-optimized graphs and training parallelism

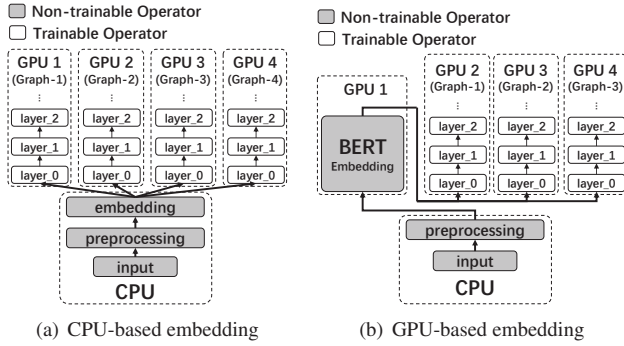

Figure 9: Device placement for CPU/GPU-based pre-trained embedding when constructing executable graphs.

of weight sharing.

Device Placement of CSE-Optimized Graphs For DFGs sharing the same dataset and preprocessing, these common operators can be merged by common sub-expression elimination. The most efficient execution plan of merged graphs depends on the types of merged operators and configuration of GPU servers. Figure 9 shows two different execution plans of CSE-optimized graphs. Both examples use a pre-trained embedding before the trainable layers. The difference is that the embedding in 9(a) is CPU-based (*e.g.*, word2vec [43]) while the embedding in 9(b) is GPU-based (*e.g.*, BERT [10, 19]). When BERT-embedding is the bottleneck of model computation and consumes most of GPU memory, dedicating one GPU for it can improve the pipeline and reduce memory consumption. Thus, we may pack more graphs on the rest of GPUs to improve the training throughput. Retiarii currently uses a whitelist to identify operators that require dedicated GPUs. We leave the automatic graph partitioning and optimization to future work.

In Retiarii, all cross-graph optimizations are applied within every batch of models. We first profiled the iteration time, peak GPU memory, and GPU utilization of each model by independently running for a few iterations. Then the models are sorted based on the iteration time. Retiarii greedily packs as many models as possible into one GPU. If the executable graph’s total training throughput is lower than that before optimization, the optimization will be reverted.

Mixed Parallelism for Weight Sharing. Weight sharing suffers from the scalability issue. After an exploration strategy instantiates a set of models, these models need to be trained sequentially (in an interleaved way) with different data to guarantee that every model can use the latest version of shared weights without losing training accuracy. A single model can hardly scale to a large number of GPUs using data parallelism, because a large batch size would harm model accuracy [25, 35]. Figure 10 shows an example of how Retiarii trains weight-shared models on two GPUs. Retiarii can

Figure 10: Retiarii uses mixed parallelism to improve scalability of weight sharing-based training.

improve the scalability by splitting the super-graph onto multiple GPUs, when the super-graph of all models is too large to fit into one GPU. Retiarii spreads the instantiated models into multiple super-graphs (each on a GPU) to be trained together. This can be regarded as model parallel training of the super-graph of all models. Moreover, in each iteration, models in different GPUs will be fed with different batches of data (like data parallelism), following the requirement of weight-shared training. The shared weights will be synchronously updated using parameter servers by averaging their gradients. Note that, it is difficult to apply Retiarii’s mixed parallelism to a jumbo model, since a compiler can hardly understand and partition the sophisticated jumbo model without knowing each individual model’s architecture. Our evaluation in §7.4 shows Retiarii’s mixed parallelism yields better scalability that reduces the training time by up to $8.58\times$ without affecting validation accuracy, compared with the traditional approach that trains the jumbo model using data parallelism.

6 Implementation

We have implemented Retiarii in about 19,723 lines of code, in which about 5,436 lines of code for the core Retiarii JIT engine, 5,203 lines of code for model, state, data management with failure recovery, and 9,084 for managing training with interfaces to various training services, such as Kubeflow [2]. We also wrote an additional 6,157 lines of code to implement 11 exploration strategies, 6 mutator classes, and 27 model spaces [4].

Building internal representations of base models and mutators. Our implementation supports base models defined in PyTorch and TensorFlow, which we convert to their graph representations. The conversion is done through TorchScript [9] for PyTorch. TensorFlow naturally supports a similar graph representation and offers the utility to output in a protobuf format. We do not yet support dynamic graphs. The mutators are extracted through Python Abstract Syntax Trees (AST) [1].

```

12    def on_receive_feedbacks(self, graph_id, feedback)

```

Figure 11: Some key APIs for an exploration strategy.

The base graph and mutators are then passed to the JIT engine.

Materializing the JIT engine. The JIT Engine drives the whole exploratory-training process. It first starts an exploration strategy which is an independent executable Python script. The strategy uses the APIs listed in Figure 11 to interact with the engine. Users are free to customize a new one following the interface. For instantiating a model, the mutators are applied one after another. On applying a mutator, the JIT engine retrieves the subgraphs specified by *targets*, and feeds them into the mutator. The instantiation is guided by an exploration strategy through those callback functions (*i.e.*, “on_”). The JIT Engine maintains all the instantiated and trained models in a data store (*i.e.*, SQLite in our implementation) and collects runtime information of those models, such as model accuracy, execution time, which can be queried by the exploration strategy. Each model can have its training approach, *e.g.*, a training loop with a configured epoch number and batch size. We follow the practice in PyTorch Lightning [8] to provide a wrapper for programming and configuring a training approach. An exploration strategy can specify the training approach for each instantiated model.

Converting models for training. In our implementation, the optimized graphs are trained on current deep learning frameworks, such as TensorFlow and PyTorch. To make the optimized graph executable on those frameworks, we implement a converter to translate an optimized graph into TensorFlow or PyTorch code. Taking PyTorch as an example, the optimized graph is converted to a PyTorch module, *i.e.*, graph nodes in `__init__()` and connections in `forward()`. In cases where an optimized graph could contain multiple models, the losses are either added or concatenated to produce a single one. We enable device placement for a model with each framework’s utility, such as the `to()` method in PyTorch and with `tf.device()` in TensorFlow.

Distributing exploratory-training. Exploratory-training usually requires lots of computation resources. In our implementation, Retiarii’s JIT engine runs on a single machine, while the instantiated models can be distributed to wherever computing resources are available (*e.g.*, a cluster). For train-

ing of each model, Retiarii implements a wrapper to monitor its execution and collects metrics (*e.g.*, training performance) to report back to the JIT engine.

Tolerating and handling failures. As exploratory-training is usually time-consuming, in our implementation we deal with failures of both the JIT engine and model execution. All the exploration history is kept in the data store. When the JIT engine fails, it will be restarted and recover the state of exploration strategy by replaying the data in data store. For model exploration, the most valuable data are the set of models that have been explored and their observed results. These data are usually enough to continue an interrupted exploration from a previously known state. For an exploration strategy that maintains its own, additional states that cannot be recovered by our automatic mechanism, its own recovery logic must be provided. Another type of failure comes from the optimized graphs. If the execution of an optimized graph fails (*e.g.*, out of GPU memory, tensor shape mismatch), while each model in this graph runs without error, Retiarii will revert to running the individual models separately.

Limitations. Retiarii has limited support to dynamic graphs. Retiarii’s mutators are applied to a base model. However, sometimes it is difficult to extract a graph representation from the a highly dynamic base model (*e.g.*, Tree-LSTMs [58]). Also, the current implementation of operator batching is limited. Some operator batching is possible but is not implemented as it requires implementing new GPU kernels. Moreover, when a model is mutated, it requires additional programming efforts to match the shape of adjacent layers’ input/output tensors. It is currently out of the scope of Retiarii to handle possible shape mismatch after mutation. We leave automatic shape inference and matching to our future work.

7 Evaluation

We evaluate the performance of Retiarii for exploring neural network architectures. Overall, the key findings include:

- The separation of model space and exploration strategy makes it easy for Retiarii to try different combinations. Retiarii currently supports 27 popular Neural Architecture Search (NAS) solutions. Most of them can be implemented by the three mutator classes provided by Retiarii.
- A number of micro-benchmarks show how Retiarii’s cross-model optimizations greatly improve training efficiency.
- Retiarii improves the model exploration speed of three NAS solutions by up to 2.58 \times , compared with traditional approaches.
- Retiarii improves the scalability of weight sharing-based NAS solutions and brings up to 8.58 \times speed-up using the proposed mixed parallelism, compared with data parallelism.

NAS Solution	Model Space	Exploration Strategy	Required Mutator Class			
			Input Mutator	Operator Mutator	Inserting Mutator	Customized Mutator
MnasNet [59]	MobileNetV2-based space	Reinforcement Learning		✓	✓	
NASNet [70]	NASNet cell	Reinforcement Learning	✓	✓		
ENAS-CNN [50]	NASNet cell variant	Reinforcement Learning	✓	✓		
AmoebaNet [51]	NASNet cell	Evolutionary	✓	✓		
Single-Path One Shot (SPOS) [27]	ShuffleNetV2-based space	Evolutionary		✓		
Weight Agnostic Networks [23]	Evolving space w/ adding/altering nodes adding connections	Evolutionary		✓		✓
Path-level NAS [13]	Evolving space w/ replication and split	Reinforcement Learning				✓
TextNAS [62]	TextNAS space	Reinforcement Learning	✓	✓		
...

Table 1: NAS solutions currently supported by Retiarii, and required mutators to implement them in Retiarii. Please refer to [4] for the full list that contains 27 NAS solutions in total.

7.1 Expressiveness and Reusability

Table 1 shows 8 out of 27 NAS solutions currently supported by Retiarii (please refer to [4] for the full list). After decoupling model spaces from exploration strategies, developers can easily reuse them without extra coding efforts. For example, the exploration strategy "reinforcement learning" is reused by MnasNet [59], NASNet [70] and ENAS-CNN [50]. Several machine learning researchers at Microsoft Research are now using Retiarii to explore more NAS solutions by leveraging different combinations of model spaces and exploration strategies.

To build these model spaces, Retiarii provides three default mutator classes. *Input Mutator* is to mutate inputs of matched operators. *Operator Mutator* is to replace matched operators with other operators. *Inserting Mutator* is to insert new operators or sub-graphs after matched operators. We find the three mutator classes are enough to implement most of the listed NAS solutions. Moreover, Retiarii allows model developers to build customized mutator classes using basic graph mutation primitives to implement more complex model spaces, *e.g.*, Weight Agnostic Networks [23] and Path-level NAS [13].

7.2 Micro-benchmarks

7.2.1 Shared Data Loading and Preprocessing

The following experiments demonstrate two micro-benchmarks of common sub-expression elimination, where multiple models share the same data loading and preprocessing. These micro-benchmarks are evaluated on 4 V100 GPUs with 20 CPU cores. We compare Retiarii with a baseline that runs each model independently without CSE. For a fair comparison, CUDA Multi-Process Service (MPS) [5] is enabled for the baseline when Retiarii decides to packed more than one model in a GPU.

Avoiding CPU Bottleneck. Figure 12 shows the aggregate throughput and CPU usage with the increased number of MnasNet0.5 (*i.e.*, depth multiplier=0.5) models [59] running concurrently on the 4 V100 GPUs and 20 CPU cores. The models are trained on ImageNet with a batch size of 224 with the same preprocessing as in [59]. The baseline approach runs each model independently, thus each batch of data will be loaded and preprocessed multiple times. Retiarii merges the data loading and preprocessing across different models thus they are executed only once. Both Retiarii and the baseline can further pack multiple models into one GPU to run them concurrently. The models are distributed in a round-robin way. For example, when running 6 models, the first two GPUs are packed with two models on each GPU, while each of rest two GPUs runs only one model. The measured performance is averaged over one training epoch.

Figure 12: The aggregate throughput and CPU usage with varying number of concurrently running MnasNet0.5 models.

Overall, Retiarii increases the throughput by $3.41\times$ when running 8 models on 4 GPUs. The bottom figure in Figure 12 shows that training one MnasNet0.5 model has already consumed about 75% of CPU cores. Thus, CPU will become

the bottleneck when running more than one model without sharing. On the contrary, Retiarii eliminates the redundant data loading and preprocessing. Increasing the number of concurrent models does not affect the CPU usage for data loader. The marginal increase of CPU usage in Retiarii is due to other computations, which can not be merged (*e.g.*, overhead of the training runtime).

Also note that, running 5 models does not bring higher throughput than running 4 models. This is due to the overhead of synchronization brought by unbalanced model assignment, *i.e.*, the first GPU is packed with two models while each of the rest three GPUs runs only one model. In Retiarii, merging the graphs will force them to be trained synchronously. Packing two models in one GPU may increase their iteration time, thus the rest three GPUs have to wait for the two slower models in the first GPU in every iteration. This suggests to merge the graphs with a similar iteration time to avoid severe synchronization overheads.

Avoiding GPU Bottleneck. Non-trainable embedding [49] can be regarded as a special type of data preprocessing. In this micro-benchmark, we use BERT [19] to obtain pre-trained contextual embeddings of input tokens from Stanford Sentiment Treebank (SST) dataset [55] for training TextNAS [62], which is one of the state-of-the-art natural language processing models. The batch size for each TextNAS model is 128. Different from the micro-benchmark of avoiding CPU bottleneck, the embedding computation is placed on GPU because the BERT embedding runs much faster on GPU than CPU [3]. The baseline still runs multiple models independently. The performance is measured by averaging over one training epoch.

Figure 13: The aggregate throughput with varying number of TextNAS models.

Figure 13 shows the result. Overall, Retiarii achieves $1.97\times$ throughput of the baseline when training 12 TextNAS models on 4 V100 GPUs. Both the baseline and Retiarii meet out-of-memory when running more than 12 TextNAS models. As we have shown in Figure 9, Retiarii uses model parallelism to dedicate one GPU to compute the BERT embedding, which is pipelined with the training of TextNAS models on the other three GPUs. Since the BERT embedding is the bottleneck in each training iteration, this optimization allows the training of more TextNAS models to be overlapped with the BERT

Figure 14: The aggregate throughput with varying number of batched models.

embedding. In this experiment, we find Retiarii can pack two TextNAS models on each GPU (*i.e.*, 6 models in total) without affecting the iteration time. And 12 models can be packed in total with better aggregated throughput, but each model’s iteration time is degraded. Although the baseline can also pack up to 12 models on 4 GPUs, the compute-intensive BERT embedding repeats three times per GPU that greatly increases the iteration time. Only marginal improvement on throughput is observed in the baseline when packing more models using CUDA MPS.

7.2.2 Operator Batching

To evaluate operator batching across graphs, we insert adapter layers to a pre-trained MobileNet [29]. Weights from the MobileNet are fixed during training. These models use the same batch size, which is 8 images per mini-batch. Synthetic data without preprocessing is used to avoid the gain from shared data loading. The models are trained on one V100 GPU of 16GB GPU memory. Similar to previous micro-benchmarks, the baseline uses CUDA MPS to execute multiple models in one GPU. The performance is measured by averaging the throughput over 1500 mini-batches.

Figure 14 shows the average throughput of concurrently running models. Overall, Retiarii’s operator batching improves the aggregate throughput by $3.08\times$ when batching 192 models, compared with the baseline that can only train at most 12 models together. Retiarii can batch more models than the baseline because it only has one copy of (fixed) weights from MobileNet. Only the memory for adapters is increased when batching more models. Even when Retiarii batches 12 models, it still achieves $1.76\times$ improvement on the aggregate throughput. This improvement comes from the benefit of vectorization to execute the batched operators in a single kernel, which increases GPU utilization.

7.2.3 Optimization for Weight Sharing

To evaluate Retiarii’s optimization for weight sharing, we use Single Path One-Shot (SPOS) [27] to explore a model space built by ShuffleNetV2 blocks, where a model is instantiated for every batch of data. The models are trained with

Figure 16: The completion time of the search phase of three NAS approaches, each of which generates 1,000 models for training.

synthetic data on a V100 GPU of 16GB GPU memory. We implemented two baselines that share weights of overlapped operators among the instantiated models through weight saving and loading. In the first baseline, a checkpoint file is used for weight sharing, *i.e.*, a model loads its weights from the file, then saves its updated weights to the file after training a mini-batch. In the second baseline, the file is replaced with a `dict` object located in GPU memory. Both model weights and optimizer states (*e.g.*, momentum) need to be checkpointed.

Figure 15: The throughput of weight sharing with and without cross-model optimization.

The result is shown in Figure 15. By merging multiple models as a super-graph, Retiarii’s cross-model optimization improves the throughput by up to $6.52\times$ when batch size is 32, and $2.08\times$ when batch size is 256 (compared with checkpoint-to-file). Since SPOS only trains an instantiated model with a batch of data, frequent checkpointing brings significant overheads. Merging instantiated models into a super-graph allows Retiarii to load the models only once (at the beginning). Thus, Retiarii can use control flow to only activate the desired model, which also saves the time of model initialization. The performance of a jumbo model is similar to that of Retiarii’s super-graph, the difference is that the super-graph is automatically built by Retiarii’s JIT engine

while the same graph is manually programmed in the jumbo model approach. This leads to a big performance gap on parallel training which will be illustrated in §7.4, as Retiarii fully understands each sampled graph and the weight sharing pattern.

7.3 Speeding up Neural Architecture Search

To evaluate the performance of running NAS solutions on Retiarii, we select three popular and representative NAS solutions from Table 1: (1) MnasNet [59], (2) NASNet [70], and (3) AmoebaNet [51]. They cover different combinations of model spaces and exploration strategies: MnasNet and NASNet use the same search strategy; NASNet and AmoebaNet have the same model space. We compare Retiarii against the one-off solutions built by traditional deep learning frameworks. Since Retiarii separates the cross-model optimization from model generation, all the three NAS solutions can leverage the three cross-model optimizations in §5 to accelerate the search of architectures without extra effort.

To evaluate the traditional approaches, which are unaware of cross-model relations, we test the following two baselines. (1) **Exclusive execution**: a model is trained independently and exclusively on one GPU. (2) **Packing**: multiple models may share the same GPU using CUDA MPS without merging their graphs; it uses Retiarii’s decisions to choose the models to be packed onto the same GPU.

In the experiments, each NAS approach will generate 1,000 models in 20 batches (each batch contains 50 models). For a fair comparison, Retiarii and the two baselines are given the same set of models in the same order. We compare the time to finish the training of all the 1,000 models for 1 epoch on ImageNet’s training images [18]. We vary the batch size from 32 to 96 (batch size larger than 96 will lead to Out-of-Memory). We also compare the performance using two implementations of the data loader, *i.e.*, NVIDIA Data Loading Library (DALI) [6] and PyTorch DataLoader [7], to understand the impact of data loading. The experiments are conducted on 4

NVIDIA Tesla V100 GPUs (each has 16GB GPU memory). Similar to [64], we “fast-forward” the experiment by instructing model trainings to skip a number of iterations when the iteration time becomes stable. We measure the average iteration time over 100 mini-batches, which is used to project the entire training time.

Figure 16 shows the results of the search time of different settings. In most settings, Retiarii is substantially faster than the two baselines due to the cross-model optimizations. Overall, Retiarii achieves up to $2.57\times$ speed-up on the search time compared with the two baselines. The performance gain mainly comes from packing multiple models in the same GPU, and shared dataloading and preprocessing. Because the packing baseline is agnostic to the cross-model relations, it cannot apply cross-model optimizations thus only brings up to $1.42\times$ speed-up over the exclusive execution. Moreover, due to the increased CPU burden on the larger batch size, the packing baseline runs even slower by 31% than the exclusive execution on PyTorch DataLoader when the batch size is 96. Note that, an introspective policy, *e.g.*, Gandiva [64], can remedy the packing baseline’s slow-down by reverting the packing when the training speed is slower. But the key insight in this experiment is that only using packing without cross-model merging will limit the space for improvement.

Retiarii achieves higher speed-up on MnasNet than NASNet and AmoebaNet. Because the models from MnasNet are designed for mobile devices that have a lower GPU memory usage and shorter iteration time, Retiarii can pack more MnasNet models into one GPU and merge their graphs for cross-model optimizations. As the generated models have different memory consumption, the number of models that can be fit in the same GPU varies accordingly. When the batch size is 32, Retiarii can run 4-22 MnasNet models simultaneously; but only 4-8 NASNet/AmoebaNet models due to the larger model size. We also observe Retiarii achieves higher speed-up on PyTorch DataLoader, because DALI is more efficient on data preprocessing that reduces the probability of bottleneck on CPU.

7.4 Scaling Weight-Shared Training

In addition to system optimizations, Retiarii also enables and enhances the weight sharing optimization advocated by the machine learning community. As shown in §7.2.3, Retiarii builds a super-graph for weight sharing to avoid the overhead of model building and checkpointing. This optimization can be further improved by training the super-graph using mixed parallelism to scale it to a GPU cluster.

In this experiment, we build a model space with ShuffleNetV2 blocks described in the Single Path One-Shot (SPOS) paper [27]. Each model in the model space is randomly sampled and trained for one batch of data [17, 27]. The models are trained for 60 epochs in total on the ImageNet dataset (with 1,281,167 images). As a result, a new model

is instantiated for every batch of data (*e.g.*, $1281167/256 \times 60 = 300240$ models are instantiated when the batch size is 256). The experiment runs on two servers, each has 4 V100 GPUs. We use the common evaluation metric of weight sharing-based approaches [12, 27] to evaluate the searched space. We randomly sample 196 models and evaluate each model using 256 images from ImageNet’s validation set. Then we calculate the average validation accuracy of the 196 models. The higher the average validation accuracy is, the better the space is explored. We compare Retiarii’s mixed parallelism with three commonly used data parallelism approaches. To understand the benefit of mixed parallelism, all the three baselines of data parallelism and Retiarii’s mixed parallelism enable the super-graph optimization (*i.e.*, no saving and loading of weights). Specifically, the former three are manually programmed jumbo-models, while the latter is a super-graph automatically built by Retiarii.

Figure 17: Training time and validation accuracy of weight sharing. The left y-axis shows the training time (bar chart). The right y-axis shows the validation accuracy (line chart).

Figure 17 shows the training time and validation accuracy of the three data parallelism approaches and Retiarii’s mixed parallelism. The data parallelism of the left two bars and Retiarii’s mixed parallelism use the batch size of 256 with a learning rate of 0.125 per model (or per 256 data samples). As a common practice of data parallelism, scaling to 8 GPUs requires to split each batch of data across the 8 GPUs (*i.e.*, the batch size per GPU is 32). SyncBN [66] is an optimization to calculate batch normalization across multiple GPUs, which proves to improve the model quality, but slows down the training due to intensive synchronization and data transmission across GPUs. As shown in Figure 17, SyncBN-based data parallelism requires more than 60 hours of training time. Disabling SyncBN reduces the training time to ~ 20 hours but harms the model accuracy. In contrast, Retiarii’s mixed parallelism greatly reduces training time (only 7.45 hours), achieving up to $8.58\times$ speed-up over SyncBN-based Data Parallel training. This is because the mixed parallel training avoids the synchronization overhead of SyncBN as each GPU runs a different model requiring no cross-GPU synchroniza-

tion. Moreover, Retiarii’s mixed parallel training produces a comparable validation accuracy to SyncBN-based Data Parallel training (61.49% v.s. 61.11%). Another practice of data parallelism is to increase batch size and learning rate with the increased number of GPUs. The result is shown as the second bar on the right of Figure 17. Although the training time is reduced to 7.04 hours, the model’s validation accuracy degrades significantly. This result is consistent with the common wisdom in deep learning community that larger batch size could hurt model accuracy [25, 35]. In summary, Retiarii’s mixed parallelism achieves better scalability for weight-shared training, without sacrificing model accuracy.

8 Related Work

Deep Learning Frameworks. Deep learning frameworks (*e.g.*, PyTorch [48], TensorFlow [11], and MXNet [14]) are designed to describe and train an individual DNN model, which covers only one step in the end-to-end exploration-training process of devising a high-quality model.

Network Architecture Search Algorithms. To automate the design of neural networks, Neural Architecture Search (NAS) [39, 50, 59, 60, 69, 70] develops algorithms to discover the state-of-the-art neural model architecture. Limited by the existing deep learning frameworks, their implementations often couple model space, exploration strategy, and model training together, introducing barriers to innovations and optimizations. In contrast, Retiarii’s modular and decoupled approach maximizes reusability and facilitates optimizations.

AutoML Systems. Automated Machine Learning (AutoML) automates the end-to-end process of real-world machine learning problems, *e.g.*, AutoGluon [21], TPOT [47], Auto-Sklearn [22], Auto-WEKA [61], AutoKeras [32]. The implementations of these systems still couple the domain-specific model space and exploration strategy, making it hardly reusable to other problem domains.

The hyper-parameter tuning systems like Google Vizier [24] and Katib [68] can be used for neural architecture search. To use a hyper-parameter tuning system, the model space and exploration strategy are being parameterized. Since different model space and exploration strategy often use a different set of parameters, this approach limits the reusability of the implementation. Moreover, the hyper-parameter tuning approach can limit the expressiveness of the system as well. Some model space is hard to be parameterized, *e.g.*, evolutionary NAS [13, 23, 51]. It is worth noting that Retiarii’s Mutator abstraction can also be used for hyper-parameter tuning. The hyper-parameter tuning can be treated as a special case of neural model mutation.

DeepArchitect [46] also strives to decouple model spaces and exploration strategies. Compared to DeepArchitect, Retiarii differentiates itself with the Mutator abstraction. As shown in §7, Retiarii can implement multiple model spaces

using a few mutators, demonstrating great reusability and composability. More importantly, with the Mutator abstraction, Retiarii is able to exploit cross-model optimizations easily, which is not addressed previously.

Graph Optimization for Deep Learning. Recently, there are many proposals to optimize the computation of a single neural network model by optimizing the data-flow graph, *e.g.*, TVM [15], DLVM [63], TensorFlow-XLA [38], TASO [31], TensorFlow-Fold [41]. In contrast, Retiarii exploits the cross-model optimizations exposed by Mutator. HiveMind [45], FLEET [26] and some other works [40] apply common sub-expression elimination in the AutoML scenario to deduplicate the common prefix nodes of multiple graphs. This can be considered a special case in Retiarii’s larger optimization space, which includes other techniques like operator batching and weight sharing.

9 Conclusion

We propose Retiarii, the first deep learning framework that supports the exploratory training on a neural network model space, rather than on a single neural network model. The core of Retiarii is the Mutator abstraction, which not only allows the specification of different neural network model spaces, interacts with various model exploration strategies, and exposes the model correlations for further optimization, but also serves as a clean interface to separate the three. The design leads to ease of programming, reuse of model space, exploration strategy, and cross-model optimization. Our evaluation demonstrates the effectiveness of the design, showing more than $8\times$ improvement in the overall exploratory-training performance over approaches that rely on existing deep learning frameworks, which only support one model at a time. The artifacts of Retiarii are available at https://github.com/microsoft/nni/tree/retiarii_artifact.

Acknowledgments

We thank anonymous reviewers and our shepherd, Prof. Byung-Gon Chun, for their extensive suggestions. We thank Jim Jernigan and Kendall Martin from the Microsoft Grand Central Resources team for providing GPUs for the evaluation of Retiarii. We also thank our colleagues at Microsoft, for their help in implementing and deploying Retiarii: Chengmin Chi (STCA), Shinai Yang (STCA), Deshui Yu (STCA), Chuanjie Liu (STCA). Fan Yang thanks the late Pearl, his beloved cat, for her faithful companion during writing this paper.

A Artifact Appendix

A.1 Abstract

This artifact is designed to reproduce the main results of this work, which have two goals:

- **Functionality:** Retiarii can express NAS spaces using mutators, explore spaces using Exploration Engine, and accelerate the exploration using cross-model optimization.
- **Performance:** Retiarii’s cross-model optimization achieves the performance number claimed in §7.

A.2 Artifact check-list

- **Algorithm:** yes
- **Data set:** ImageNet [18], SST [55]
- **Run-time environment:** Ubuntu 16.04, CUDA 10.0, cuDNN 7.6.5. Root access is required.
- **Hardware:** GPUs with NVIDIA MPS.
- **Metrics:** training throughput; job completion time; model validation accuracy.
- **Output:** Web UI; stdout from console.
- **Required disk space:** 200 GB
- **Expected experiment run time:** 20 hours
- **Public link:** https://github.com/microsoft/nni/tree/retiarii_artifact
- **Code licenses:** MIT License

A.3 Description

A.3.1 How to access

Clone the “retiarii_artifact” branch of Microsoft NNI’s GitHub repository.

```
git clone -b retiarii_artifact https://github.com/Microsoft/nni.git
```

A.3.2 Hardware dependencies

This artifact requires at least one server with four NVIDIA V100 GPUs.

A.3.3 Software dependencies

- CUDA 10.1;
- cuDNN 7.6.5;
- Python 3.7;
- NVIDIA DALI;
- NVIDIA Apex;
- PyTorch 1.5.1;
- TensorFlow 2.3;
- Other Python packages in “requirements.txt”.

A.3.4 Data sets

- ImageNet: should be placed at “retiarii_perf/data/imagenet”.
- SST: The three text files (dev.txt, test.txt, train.txt) SST should be placed at “retiarii_perf/data/sst/trees”.

A.4 Installation

For running Retiarii’s artifact, please install NNI v1.8 first. This artifact contains two parts. In the folder of “retiarii_nas”, we demonstrate the functionality of Retiarii to express different NAS solutions. In the folder of “retiarii_perf”, we evaluate Retiarii’s performance using cross-model optimization.

For some experiments, it requires NVIDIA MPS to be enabled. To start NVIDIA MPS:

```
1 sudo ./mps_scripts/init_mps_for_all_gpus.sh
2 ./mps_scripts/set_mps_env_for_all_gpus.sh
```

To stop NVIDIA MPS:

```
1 sudo ./mps_scripts/stop_mps_for_all_gpus.sh
```

A.5 Evaluation: NAS Solution All-stars

In the folder of “retiarii_nas”, we have implemented 17 NAS solutions using Retiarii. We support both PyTorch and TensorFlow. Weight Agnostic Networks (wann), Path-level NAS (path_level), and Hierarchical Representation (hierarchical) are implemented with TensorFlow. Other NAS solutions are implemented with PyTorch. We also provide a script to test them, which can be started using the following command.

```
python3 retiarii.py e2e_launch.py [nas_model]
```

(Use “python3 retiarii.py -L” to get the list of supported models)

After the command is executed, a Web UI URL will be given, which contains the trial execution status.

Note that, to speed up the test, we run each generated model by only one mini-batch (thus, returned values are all 0), you are free to remove the ‘break’s in e2e_launch.py (ModelTrain, ModelTrainCifar, ModelTrainTextNAS) to run each generated model completely.

This artifact has supported three classic exploration strategies: random, reinforcement learning, and evolution, and also has supported two differentiable training strategies: DARTS training strategy and ProxylessNAS training strategy. Other exploration strategies have been supported in NNI (https://github.com/microsoft/nni/blob/retiarii_artifact/backend_nni/docs/en_US/Tuner/BuiltinTuner.md), have not been integrated into this artifact. They will be formally supported in Retiarii official release.

Paper Claim: Retiarii is able to support 27 NAS solutions.

Clarification: We have included 17 of the 27 NAS solutions in the artifact evaluation. The remaining ones only have minor differences with the included implementations (e.g., EfficientNet v.s. MnasNet, SCARLET-NAS v.s. FairNAS v.s. SPOS). We believe the included ones are sufficient to demonstrate the programmability of Retiarii. Full support of the 27 NAS solutions will be included in an official release version of Microsoft NNI.

A.6 Evaluation: Retiarii Performance

A.6.1 Micro-benchmark: Deduplication to avoid CPU bottleneck

Execution command:

```
python artifact_start.py micro_dedup_cpu --n=8
```

This python script will start 8 jobs (each GPU runs two jobs), then profile the total throughput. This command takes 1.5 minutes. The result will be printed after the profiling as follows. The error should be within 10%.

```
Throughput: 4746.849792184445 samples/s
```

Paper Claim: In Figure 12, when running 8 models, Retiarii can achieve about 5000 samples/s.

A.6.2 Micro-benchmark: Deduplication to avoid GPU bottleneck

Execution command:

```
python artifact_start.py micro_dedup_gpu --n=12
```

This python script will start 12 jobs. GPU-0 runs one job, each of the other three GPUs run 4 jobs). Then it profiles the total throughput. This command takes 1.5 minutes. The result will be printed after the profiling as follows. The error should be within 10%.

```
Throughput: 5028.187640607402 samples/s
```

Paper Claim: In Figure 13, when running 12 models, Retiarii can achieve about 5100 samples/s.

A.6.3 Micro-benchmark: Operator batching

Execution command:

```
python artifact_start.py micro_batching --n=192
```

This python script will use Retiarii to pack 192 models into one job to be run on a single GPU-0. Then it profiles the total throughput. This command takes 10 minutes. It is normal if it has no output for a long time, because it takes 3 minutes for the cross-model optimization policy to calculate a plan. The result will be printed after the profiling as follows. The error should be within 10%.

```
Throughput: 6124.981150684514 samples/s
```

Paper Claim: In Figure 14, when batching 192 models, Retiarii can achieve about 5800 samples/s.

A.6.4 End-to-end Evaluation: MnasNet using DALI

Execution command:

```
python artifact_start.py e2e_dali_mnasnet
```

This experiment will train 1000 MnasNet models in 20 batches (each batch has 50 models). Each model will be trained for 1 epoch on ImageNet, which will be very time-consuming and costly if we train all 1000 models. Since we only want to know the training

time but not the validation accuracy. We use a workaround to “fast-forward” the training. We profile each job for 150 mini-batches to measure the iteration time. Then we use the measured job speed to emulate the experiment with a simple job scheduler (implemented in “fast_scheduler.py”). The experiment takes about 1 hour to run. The result will be printed as follows. The error should be within 10%.

```
124.35633072276445 hours for mnasnet w/ BS=32
```

Paper Claim: In Figure 15(a), when Batch Size=32, Retiarii can finish NAS exploration of MnasNet in about 130 hours.

A.6.5 End-to-end Evaluation: SPOS training using mixed parallelism

Execution command:

```
python artifact_start.py e2e_spos_mix_parallel --n=4
```

This python script will start 4 jobs, each on one GPU, to train SPOS in mixed parallelism, a new type of training parallelism we proposed for weight sharing-based training. The super-graph is generated in the function “_gen_spos_super_graph(n_job)” in “artifact_start.py”. In the paper, we used 8 V100 GPUs in two servers, which takes about 7.45 hours to train SPOS for 60 epochs achieving 61.2% average validation accuracy. The result will be printed as follows.

```
[03/31 02:40:46] INFO (main) Epoch [60/60]
Validation Step [196/196] acc1 0.650000
(0.611117) acc5 0.887500 (0.833490) loss
2.359303 (2.586974)
```

Note that, the training of SPOS is unstable. The average validation accuracy could vary from 60% to 62%. For your reference, we also provide the training log we obtained on eight V100 GPUs in “data/spos_8_v100.log”.

Paper Claim: In Figure Figure 17, Retiarii’s mixed parallelism can train SPOS for 60 epochs with a batch size of 256 to achieve 61.11%.

A.7 Experiment customization

New experiments can be customized and added in “retiarii_nas/e2e_launch.py” and “retiarii_perf/artifact_start.py”.

A.8 Notes

NVIDIA CUDA MPS may fail if a job is not stopped properly, which requires NVIDIA CUDA MPS to be restarted. Experiments in “retiarii_nas” will kill a running job for saving time, but may trigger the failure of NVIDIA CUDA MPS. We suggest to disable NVIDIA CUDA MPS when running experiments in “retiarii_nas”.

KungFu: Making Training in Distributed Machine Learning Adaptive

Luo Mai, Guo Li, Marcel Wagenländer, Konstantinos Fertakis, Andrei-Octavian Brabete, Peter Pietzuch
Imperial College London

Abstract

When using distributed machine learning (ML) systems to train models on a cluster of worker machines, users must configure a large number of parameters: hyper-parameters (e.g. the batch size and the learning rate) affect model convergence; system parameters (e.g. the number of workers and their communication topology) impact training performance. In current systems, adapting such parameters during training is ill-supported. Users must set system parameters at deployment time, and provide fixed adaptation schedules for hyper-parameters in the training program.

We describe *KungFu*, a distributed ML library for TensorFlow that is designed to enable adaptive training. *KungFu* allows users to express high-level *Adaptation Policies* (APs) that describe how to change hyper- and system parameters during training. APs take real-time monitored metrics (e.g. signal-to-noise ratios and noise scale) as input and trigger control actions (e.g. cluster rescaling or synchronisation strategy updates). For execution, APs are translated into monitoring and control operators, which are embedded in the dataflow graph. APs exploit an efficient asynchronous collective communication layer, which ensures concurrency and consistency of monitoring and adaptation operations.

1 Introduction

The popularity of machine learning (ML) in many application domains [3, 15, 37, 75] has led to a wide adoption of distributed ML systems. Systems such as TensorFlow [1], PyTorch [60], MXNet [10] and MindSpore [53] exploit data and model parallelism [1, 54, 66, 73] to train large ML models on clusters of worker machines. Training is typically done using the stochastic gradient descent (SGD) algorithm [43, 68], which iteratively computes gradients to refine the model after each mini-batch of training data. ML systems compile training programs into dataflow graphs [1, 10, 30, 60], which can be executed efficiently on GPUs and other accelerators.

When training ML models, users face the challenge of how to set a large number of *configuration parameters*, which split into two classes: *hyper-parameters* configure the train-

ing algorithm, such as SGD, and include the batch size [68], learning rate [68], momentum [63] and floating point precision [24]. Since hyper-parameters relate to the training process itself, their value affects the convergence rate and the final accuracy of the trained model. In addition, *system parameters* [42, 73, 81] control the operation of the distributed ML system, such as the number of workers, the partitioning of the training data, and the communication topology between workers. They impact the training performance, i.e. the time taken for the model to reach a given target accuracy.

Today users spend a substantial fraction of time tuning configuration parameters. Different ML models have different structures, and thus require different hyper-parameter settings [52]: the hyper-parameters for a vision model such as ResNet [26] differ from those for a language model such as BERT [15]. For each model, hyper-parameters such as batch size, learning rate and weight decay must be adjusted separately to reach a high model accuracy [52]. Approaches for automatic hyper-parameter tuning [2, 18, 35, 45, 52] search for the best settings offline at a high resource cost. Furthermore, system parameters such as the number of workers affect the resources consumed by training and their efficiency. Especially in a cloud setting, users must control resource usage to bound costs, while achieving good training performance [52].

Recently, we have seen a growing number of proposals [5, 12, 16, 48, 71] that argue for parameters to be adapted *dynamically* during training. For example, many models only reach high accuracy if the learning rate is decreased as the model converges [26, 76]; the batch size can be set dynamically based on real-time gradient metrics [14, 52, 83]; and the communication strategy between workers can be adapted to the current training loss [72]. Similarly, system parameters can be updated to react to changes in exploitable levels of parallelism and resource availability. For example, the number of workers can be changed according to the observed resource utilisation, thus improving the utilisation of expensive accelerators such as GPUs and TPUs [46]; and the best communication topology among workers can be decided based on the available network bandwidth [56].

We observe that existing distributed ML systems and associated libraries (e.g. TensorFlow’s Distribution Strategies [1], Horovod [73] and BytePS [8]) make it difficult to support the dynamic adaptation of configuration parameters for a number of reasons: (i) systems do not provide built-in mechanisms for adaptation. Users must rely on external frameworks, e.g. AutoScaling [58] adapts the number of machines by deploying extra scaling agents on each worker. Such external mechanisms are specialised to support only one type of adaptation. Since they are not integrated with the training system, they cannot take advantage of existing functionality and optimisations. In addition, (ii) the monitoring of training metrics introduces high overheads. For example, an 8-GPU server training a ResNet model produces 4 GB of gradients per second [55]. Any monitoring system (e.g. MLFlow [84]) that computes statistical metrics (e.g. variance [78]) over this amount of data consumes substantial compute resources and network bandwidth, which impacts the performance of the training process itself. Finally, (iii) the management of worker state with adaptation is challenging. In existing systems, users typically must checkpoint and restore all state when changing configuration parameters, which can take hundreds of seconds [58].

We describe *KungFu*,¹ a distributed ML training library that is designed to adapt configuration parameters at runtime. The key idea behind *KungFu* is to support *Adaptation Policies* (APs) written by users, which change hyper- and system parameters during training based on real-time monitored metrics. *KungFu* achieves this by making three contributions:

(1) Expressing Adaptation Policies. APs describe how configuration parameters should evolve based on monitored metrics. They are based on a high-level programming abstraction following the convention of existing ML frameworks, making integration with training environments seamless.

APs are written using *monitoring*, *communication* and *adaptation* functions: (i) monitoring functions compute metrics for gradients, model variables and worker performance; (ii) communication functions combine locally monitored metrics and transfer training state while adapting parameters; and (iii) adaptation functions update configuration parameters, including hyper- and system parameters.

(2) Making training monitoring efficient. *KungFu* supports the efficient monitoring of the training process, as needed by APs. Monitoring function calls are translated to *monitoring operators*, which are embedded in the execution dataflow graph. This allows monitoring operators to observe local gradients and reuse existing computation for monitoring.

Locally monitored gradients are combined to compute globally-aggregated metrics. This is achieved by an *asynchronous collective communication layer*, which avoids blocking the dataflow during monitoring. This layer uses a decentralised architecture: each worker maintains a local view of the state for collective communication and incrementally updates

the state by exchanging messages in a peer-to-peer fashion. To maximise the performance of gradient monitoring, each *KungFu* worker has its own scheduler for collective communication. The schedulers cooperate in a decentralised fashion to exploit high-speed multi-GPU networks, e.g. as offered by NVLink through the NCCL interface.

(3) Distributed mechanism for adapting parameters. APs can adapt configuration parameters on distributed worker machines. *KungFu* represents configuration parameters as computational *configuration operators* embedded within the dataflow graph. In each training step, these operators can alter their output by reading configuration parameters provided by *KungFu*’s asynchronous collective communication layer. Reading the parameters from this layer is efficient because it reuses existing data channels between the communication layer and the dataflow.

APs can dynamically change the parameters in the communication layer, and the result is automatically reflected in the dataflow. *KungFu*’s communication layer uses a *distributed parameter adaptation algorithm* to protect the consistency of changes to configuration parameters while exploiting existing collective communication functions. These functions have been optimised for cross-machine communication, and thus allow adaptation to be performed with low latency.

We implement *KungFu*’s communication layer and adaptation mechanisms in Go (~7k LOCs) and C++ (~3k LOCs), independently of the ML framework. *KungFu* provides Python bindings (~2k LOCs) for the Adaptation Policy interface, which can be used with existing ML frameworks, including TensorFlow [1], PyTorch [60] and Keras [11].

We evaluate experimentally the benefit and overhead of *KungFu*’s Adaptation Policies. We show that *KungFu* users can implement a policy that dynamically adapts the batch size based on gradient noise scale, therefore significantly reducing the training time of a ResNet model. We also explore a policy that automatically searches for a cost-effective number of GPUs based on monitored worker performance when training a BERT model, reducing the cost by 20% compared to a static deployment. On a large-scale cloud testbed, we show that *KungFu* achieves negligible monitoring and adaptation overheads. It achieves up to 98% higher training throughput than Horovod, a state-of-the-art distributed ML system.

2 Adaptation in ML Systems

We first give background on distributed ML systems and their configuration parameters. We then describe current approaches for adapting parameters during training, highlighting why existing systems offer limited support for this.

2.1 Parameters in distributed ML systems

For many ML models, increasing the amount of training data and the size of the model improves accuracy [13, 26]. When training, ML systems therefore exploit the parallelism of modern hardware accelerators such as GPUs. Computation is typ-

¹<https://github.com/llds/KungFu>

ically expressed as a *dataflow* graph [1], which consists of individual operators that can be scaled out.

A supervised ML system trains a model using labelled samples, split into training and test data. A model gradually “learns” to predict the labels by adjusting its *model weights* based on the error. It takes several passes (or *epochs*) over the training data to minimise the prediction error. The test data is used to measure the model accuracy on previously unseen data. A key metric is *test accuracy*, which quantifies the model’s ability to make predictions “in the wild”.

The model weights are refined iteratively until the model achieves a desired test accuracy. Let w be a vector of the weights, and $\ell_x(w)$ be a loss function that, given w , measures the difference between the predicted label of a sample (x, y) and the ground truth y . During training, an ML system tries to find a w^* that minimises the average loss e.g. using *mini-batch stochastic gradient descent* (SGD) [6, 7, 68]. More formally,

$$w_{n+1} = w_n - \frac{\gamma_n}{b} \sum_{x \in B_n} \nabla \ell_x(w_n) \quad (1)$$

where γ_n is the learning rate in the n -th iteration of the algorithm, B_n is a batch of b training samples, and $\nabla \ell$ is the gradient of the loss function, averaged over the batch samples.

To scale out the training computation across multiple CPUs or accelerators, ML systems can exploit data parallelism. In *parallel synchronous SGD* (S-SGD), K parallel workers share model replicas and compute gradients for distinct partitions of training data locally. Local gradients are averaged to correct the shared model:

$$w_{n+1} = w_n - \frac{\gamma_n}{Kb} \sum_{j < K} \sum_{x \in B_{n,j}} \nabla \ell_x(w_n) \quad (2)$$

The averaging of local gradients is usually implemented using *all-reduce* operations provided by collective communication libraries such as Horovod [73] and BytePS [8].

In a distributed ML system, the above training process is affected by many configuration parameters. These parameters can be placed into two groups: (i) accuracy-oriented *hyper-parameters* such as the learning rate γ_n , the batch size $|B_n|$, momentum [63] and weight decay [38]; and (ii) performance-oriented *system parameters* such as the set of workers, their communication topology for performing synchronisation [56, 72, 73] and their roles during synchronisation, e.g. acting as primary and back-up workers to mitigate stragglers [9].

Hyper-parameters are properties that govern the training process and thus determine its final accuracy. They include variables that determine the model structure and how the network is trained (e.g. the learning rate). Choosing appropriate hyper-parameters plays a key role in training. For example, if the batch size is too high, the model may quickly settle at a local minimum and thus exhibit poor generalisation ability; conversely, if it is too low, the model may suffer from the noise of small batches and thus fail to converge.

System parameters affect the training throughput and thus the time to reach a given target accuracy. They include the configuration of workers (e.g. the number of parallel workers) and how they synchronise (e.g. the communication topology). Choosing appropriate system parameters is important for performance. For example, if the number of workers is too large, the system may suffer from low GPU utilisation due to communication bottlenecks; if the number of workers is too low, the training time for large models becomes prohibitively long.

2.2 Setting parameters in ML systems

Today users spend a substantial fraction of time setting configuration parameters [40]. They often search a large parameter space and decide on configuration parameters following a trial-and-error approach [26, 76]. Specifically, they empirically decide on a set of candidate values, and launch parallel training jobs to evaluate them [40]. They then measure the accuracy of the trained model and the system throughput, and eliminate under-performing settings using early-stop [40] and searching heuristics [29, 33, 41]. After that, they empirically choose an effective setting that reaches the target accuracy given a deadline or a resource budget.

When choosing candidate values for hyper-parameters, users must consider the characteristics of the datasets and models. For example, if the dataset is large (e.g. ImageNet [69]), the candidate batch size can be set larger (e.g. 2048) to improve the robustness of estimated gradients. If the dataset is small (e.g. CIFAR-10 [36]), the candidate batch size must be small (e.g. 64) so that it results in sufficiently many gradients to correct the model. Many large ML models (e.g. ResNet [26] and BERT [15]) have a complex loss space. When training such models, users often need to use a schedule of hyper-parameters (e.g. changing the learning rate at epochs 30, 60 and 90 for ResNet) to improve the quality of a found minima.

When choosing candidate system parameters, users consider the specification of hardware and the conditions of the network. For example, using a ring-based all-reduce topology among workers exploits the full host network bandwidth but it increases the depth of the topology, which adds to latency [80]. Setting the topology to be a star reduces latency but it requires larger bandwidth at the root node. In addition, good system parameters achieve a balance between compute and network utilisation. For example, in a cloud environment in which bandwidth is limited, training with NVIDIA V100 GPUs should only use few workers to prevent underutilising the expensive GPUs due to network bottlenecks; however, if NVIDIA K80 GPUs are used, a user would typically choose more workers to improve system throughput.

2.3 Dynamic adaptation of parameters

Recently, there has been a growing number of proposals to set configuration parameters *dynamically* based on metrics of the training process [5, 12, 16, 48, 71]. The idea is to incorporate

Class	Practitioners	Monitored metrics	Adaptation action
Accuracy	OpenAI [32, 52], Google [77]	Gradient noise scale	Scale batch size when the noise scale increases
	Kuaishou [47]	Gradient signal-to-noise ratio	Create online metrics for model generalisation ability
	Apple [31]	Gradient variance	Adapt learning rate based on the gradient variance
	DeepMind [4], NVIDIA [59]	Gradient second-order metrics	Adapt learning rate based on the second-order metrics
Performance	Microsoft [80], Uber [73]	Worker communication rate	Adapt worker communication topology based on rates
	Google [58], Huawei [82]	Worker utilisation	Adapt the number of workers based on utilisation
	Google [9], MIT [46]	Worker processing speed	Adapt the roles of workers based on straggler detection

Tab. 1: Recent proposals for the dynamic adaptation of parameters

knowledge about the training process and its progress through *gradient properties* and *performance metrics* on-the-fly.

Gradient properties include gradient signals, noise or derived signal-to-noise ratios, and they reflect the status of the trained model and the characteristics of the local loss space. They can be used to improve the setting of hyper-parameters, such as batch size and learning rates. Worker performance metrics, such as worker communication rate and processing rate, reflect the hardware and network conditions. They can be used to decide on the number of workers and their communication topology. Using monitored metrics to choose configuration parameters can significantly reduce the need for trial-and-error approaches when searching for suitable hyper-parameters. Instead of spending resources on a search process offline, fewer resources are used for the continuous calibration of configuration parameters during the learning process.

As summarised in Tab. 1, multiple proposals focus on adapting hyper-parameters to improve model accuracy. They often adapt critical hyper-parameters such as batch size and learning rate based on gradient properties. Researchers from OpenAI and Google Brain propose to monitor *gradient noise scale* to predict the optimal batch size when training deep learning models [32, 52, 77]; researchers at Kuaishou use the *gradient signal-to-noise ratio* to evaluate the generalisation ability of a model [47]; Apple automatically scales the learning rate based on gradient variance [31]; and DeepMind and NVIDIA use approximated metrics for *second-order gradients* to predict the best learning rate [4, 59]. Using such properties to set hyper-parameters has become important when training increasingly complex ML models. Users know little of the pre-conditions of these models, and hyper-parameters must be therefore set based on monitored properties [6].

Other proposals adapt system parameters to achieve higher training performance, e.g. reacting to changes in the exploitable parallelism and resource availability. As shown in Tab. 1, Microsoft and Uber propose to measure workers' *communication rates*, which are useful for optimising the topology of all-reduce operations [73, 79, 80]; Google and Huawei monitor *worker utilisation* to update the number of workers for increased resource utilisation [58, 82]; and Google detects straggling workers by analysing the distribution of *worker processing rates* and adapts the roles of workers, e.g. using backup workers to replace stragglers [9]. Using worker perfor-

mance metrics to tune system parameters is an increasingly common practice. Many distributed ML systems are being deployed in cloud [25] and heterogeneous environments [23]. In such environments, the hardware specifications and network conditions are hard to predict, and thus system parameters must be adapted in the actual environment at runtime.

2.4 Open challenges

Although promising, proposals to adapt parameters are hard to realise in current systems, such as TensorFlow [1] and PyTorch [60]. Practitioners report three main challenges:

(1) No built-in mechanisms for adaptation. Existing distributed training libraries such as Horovod [73] provide insufficient mechanisms for adaptation. Users must rely on external systems that provide custom monitoring and adaptation components, which must be integrated into training systems: AutoScaling [58] adapts the number of workers at runtime by deploying extra scaling agents on each worker using a custom TensorFlow version, which can be managed by the scaling agents; Horovod Elastic [46] requires users to modify their existing training programs so that they can be executed by a custom elastic training runner.

In general, such external systems are specialised to support only a single type of adaptation, usually elasticity. They are not general adaptive training platforms with support for flexible monitoring and different types of adaptation (e.g. related to the communication topology). The lack of unified adaptation abstractions prevents adaptive training from leveraging existing ML system mechanisms and optimisations.

(2) High monitoring overhead. The dynamic adaptation proposals from Tab. 1 require fine-grained monitored metrics as input, but monitoring is expensive: an 8-GPU server training a ResNet model produces 4 GB of gradients per second [55], and this is even larger for recent language models such as BERT [15]. Shipping such an amount of gradient data from workers to a monitoring system such as TensorBoard [1], MLFlow [84], and Prometheus [64] consumes substantial network bandwidth. In addition, there is the overhead of computing complex statistical metrics (e.g. variance [78] or signal-to-noise ratios [47]) from gradients. All of this may impact the performance of the training process itself.

(3) Expensive state management under change. Workers maintain complex state, including model variables, hyper-

parameters and system parameters. This state must be managed carefully under adaptation: changing the number of workers must be reflected correctly in all dependent hyperparameters, such as the learning rate and the data partitioning; otherwise the training result is affected adversely. In existing systems, users typically must checkpoint and restore all state when changing system parameters. This prevents users from extensively applying adaptation during training, as restoring the state can take hundreds of seconds [58].

3 Adaptation Policies

In this section, we introduce *Adaptation Policies* (APs), as supported by KungFu, which adapt configuration parameters based on monitored metrics. We provide an overview of the features of APs and describe the programming abstraction given to users to develop custom APs.

3.1 Overview

Our goals for APs are as follows: (i) we want to provide an expressive policy programming abstraction. The abstraction should follow conventions of existing ML frameworks. Users can thus develop their own policies with low effort. Moreover, (ii) we want to make policies easy to integrate with existing ML frameworks. This will allow users to choose policies based on their training scenarios and combine multiple policies for more advanced adaptation.

APs provide functions to help users implement custom monitoring and adaptation logic. Policies use *monitoring functions* to compute real-time metrics for worker performance and gradients. Locally monitored metrics can be combined using *communication functions*, which cover collective (broadcast and all-reduce) and point-to-point (serve and request) operations. Based on the monitored metrics, policies invoke *adaptation functions* to update the hyper-parameters and system parameters of the systems.

ML frameworks such as TensorFlow [1], Keras [11] and MXNet [10] provide a high-level training abstraction. Users call a generalised training method, which automatically trains a model until certain conditions (e.g. epoch counts) have been met. We want APs to be ported easily between ML frameworks, and we base APs on a framework-independent adaptation API (see Tab. 2).

To integrate this API with a framework, we observe that frameworks often support *user-defined callbacks* (e.g. Hooks in TensorFlow), which are repeatedly called during training. Today these callbacks have limited use—they usually implement checks for finishing conditions and logging functionality. KungFu’s adaptation API can be implemented with callbacks, thus facilitating the integration with existing ML frameworks.

3.2 Sample AP for batch size adaptation

Next we describe a sample AP for dynamically increasing the batch size of S-SGD training based on online *gradient noise scale* (GNS) [52, 77]. The increase in batch size is implemented by adding extra workers. This allows the policy

```

1 ... # Import ML framework libraries
2 import kungfu as kf
3
4 class GNSPolicy(kf.BasePolicy):
5     # Create policy state
6     def __init__(self, gns_opt):
7         self.opt = gns_opt
8         self.prev_gns = None
9         self.sync = True
10
11     # Synchronise model variables under adaptation
12     def before_epoch(self):
13         if self.sync:
14             for v in self.opt.variables():
15                 v = kf.broadcast(v, 0) # Synchronise state
16             self.sync = False
17
18     # Adapt the number of workers if the GNS is growing
19     def after_epoch(self):
20         avg_gns = kf.allreduce(self.opt.gns()) / kf.size()
21         if self.prev_gns is None:
22             self.prev_gns = avg_gns
23         elif avg_gns > self.prev_gns:
24             new_size = int(kf.size() * avg_gns / self.prev_gns)
25             if new_size != kf.size():
26                 kf.resize(new_size) # Scale the system
27                 self.sync = True
28                 self.prev_gns = avg_gns
29
30 model, data = ... # Import a model and a dataset
31 opt = SGDOptimizer(...)
32 opt = kf.OptimizerWithGNS(opt) # Embed monitoring
33 estimator = Estimator(model, opt, ...) # Create a trainer
34 policy = GNSPolicy(opt) # Instantiate the policy
35 estimator.train(data, hooks=[kf.PolicyHook([policy], ...)])

```

Listing 1: Sample Adaptation Policy for GNS

to increase training throughput, thus reducing completion time.

As shown Listing 1, the GNSPolicy is defined by extending a BasePolicy class (line 4). The policy includes the `__init__` function (line 6), which defines variables that maintain the policy state, such as the previously observed GNS metrics and a flag indicating if workers must synchronise their state (lines 7–9). The policy further has user-defined functions that trigger the adaptation logic at different times in a training process. The `before_epoch` function (line 12) is called at the start of each training epoch. Newly joined workers do not have state that is consistent with existing workers. It is thus necessary to broadcast (line 15) the model state. The `after_epoch` function (line 19) computes the averaged GNS metric at the end of each epoch using an all-reduce operation (line 20). Based on its value, the number of workers is increased by the `resize` function (line 26). To enable GNS monitoring, a user wraps the original SGDOptimizer with `kf.OptimizerWithGNS` (lines 31–33), which embeds the GNS monitoring operators into the training dataflow. The GNSPolicy is then passed to `PolicyHook` (line 35) to schedule its execution during training.

3.3 Adaptation Policy interface

To define APs, users implement custom *policy functions*. These functions can make API calls for *communication*, *monitoring* and *adaptation*, which are called at different times during the training process. There are three groups of pol-

Class	Functions	Description
Communication	broadcast (tensor, rank) → Tensor	Broadcast a tensor from a worker to all other workers
	allgather (tensor) → [Tensor]	Gather tensors from all workers and distribute the combined tensor to them
	allreduce (tensor) → Tensor	Aggregate tensors from all workers and distributes result back to them
	keep (tensor, tag)	Keep a tagged tensor which can be requested by other workers
Monitoring	request (rank, name, tag) → Tensor	Request a tagged tensor from a specified worker
	comm_rates () → Tensor	Measure tensor communication rates with other workers
	gns (grads, avg_grads) → float	Compute the gradient noise scale
	...	Custom gradient monitoring operators
Adaptation	rank () → int	Get the worker rank
	size () → int	Get the number of workers
	set_tree (tree) → bool	Set the tree of collective communication. Return True if succeed
	resize (size, workers=None) → bool	Resize the cluster based on a worker list. Return True if succeed
	detached () → bool	Check if the worker is detached due to resizing

Tab. 2: KungFu APIs for Adaptation Policies

icy functions: (i) the before/after_train functions are called at the start and end of a training job, respectively; (ii) the before/after_epoch functions are called at the start and end of each training epoch, respectively; and (iii) the before/after_step functions are called at the start and end of each training step (i.e. iteration), respectively.

In these policy functions, users can call APIs for training communication, monitoring and adaptation:

Communication. Tab. 2 lists the communication functions in APs. ML frameworks typically use tensors as their basic data types for gradients and model variables. To work with such data, the communication functions take tensors as inputs. APs need to collect monitored metrics from all workers, which can be achieved by calling *collective communication* functions: (i) the broadcast function distributes a tensor from a worker to all other workers; (ii) the allgather function gathers tensors from all workers and sends the combined tensor to all workers; and (iii) the allreduce function aggregates tensors from all workers and returns the results back to them.

In addition, APs must manage and communicate the state of trained models among workers. For example, APs for communication-efficient asynchronous training [44] or robust model averaging [85] must explicitly manage the lifecycle of model states and communicate states to synchronise diverged workers. To support state management and communication, the KungFu API provides a keep function that tags a model that is being trained (i.e. the state) and caches it in memory. APs can then read tagged models on other workers asynchronously using a request method.

Monitoring. Tab. 2 lists the monitoring functions, which APs use to monitor worker performance and gradients. APs use a comm_rate function to measure the tensor communication rates between a local worker and its peers. These rates are useful for deciding the optimal communication topology among workers. To monitor gradients, APs can use gns to compute the gradient noise scale. For other statistical metrics, such as variance, policies can use the above collective communi-

cation operators. For example, the computation of gradient variance requires both the sum of gradients and the sum of the square of gradients element-wise [78]; both summations can be computed using the allreduce function.

Adaptation. Based on monitored metrics, APs call adaptation functions to update configuration parameters. To update hyper-parameters, APs use the allreduce function to compute new values and assign them to hyper-parameters, represented as params. To update system parameters, APs call: (i) set_tree to set the collective communication topology among workers; and (ii) resize to update the number of workers. Some workers may need to leave the training after adaptation. APs can use the detached function to check if a local worker is still part of the training. If not, the AP can direct workers to exit gracefully.

3.4 Practical considerations

To support APs in real-world distributed ML systems, we must address several practical considerations:

Imperative and symbolic execution. To balance ease-of-use and performance, TensorFlow and PyTorch support imperative (TensorFlow Eager) and symbolic (TensorFlow AutoGraph and PyTorch TorchScript) execution, and APs must therefore also support both.

In TensorFlow Eager and PyTorch programs, users often want to customise the training process. Therefore they explicitly implement the training loop and call custom training functions (e.g. to compute gradients) imperatively in each iteration (i.e. step). This offers great flexibility but prevents callbacks from being used. In this case, KungFu allows the communication, monitoring and adaptation APIs from Tab. 2 to be called directly from inside the training loop.

To support symbolic execution, each function in Tab. 2 has a symbolic version. For example, the resize function has an equivalent symbolic version: resize_op. This allows KungFu APIs to be embedded into symbolic training programs (e.g. tf.function).

Listing 1 shows the hybrid usage of the KungFu imperative and symbolic APIs. The `OptimizerWithGNS` optimiser (line 32) appends `gns_op` operators to each gradient computation operator at compilation time of the dataflow graph, ensuring that the monitoring operator can execute immediately as long as its upstream gradient is available. The policy functions (lines 12–19) are called imperatively. This hybrid usage has an important advantage: the compute-intensive monitoring operators are embedded into the training dataflow graph, while the inexpensive user-defined adaptation logic can be triggered in different policy functions without re-compiling the dataflow graph.

Policy composition. Users can compose multiple APs to create advanced adaptive training applications (i.e. the `PolicyHook` (line 35 in Listing 1) can take multiple APs as input). For example, they can use two APs, one implementing elastic training (denoted as AP1) and the other an adaptive learning rate (denoted as AP2). These APs are chained as a list, which is passed to the training program. A current limitation is that users must decide manually on the correct invocation order: assuming AP1 modifies the worker count and AP2 uses the count to scale the learning rate, the execution order must be AP1 followed by AP2. We leave a mechanism for automatically determining the AP order to future work.

API restrictions. KungFu only imposes minimal API restrictions on AP developers, and APs can call any of the communication/monitoring/adaptation APIs in their callback functions. The calls have global atomic semantics, and there are no constraints on the call order. The only exception is that if a worker has left the cluster (checked by `detached`), it cannot further invoke collective communication APIs.

Error handling. AP developers must handle errors such as worker failures in a traditional fashion. If a KungFu API triggers an internal error, the exception is exposed as a dataflow error, as defined in existing ML frameworks, and checkpoints can be used for recovery.

4 Supporting Monitoring in KungFu

We describe *KungFu*, a distributed training library that can efficiently execute the proposed APs. APs must continuously monitor gradients to determine online adaption decisions, which must be done with low overhead. We begin with an overview of KungFu’s design and then describe its support for efficient gradient monitoring in detail.

4.1 Design overview

To support monitoring, KungFu’s design has the following goals: (i) KungFu should minimise extra computation when monitoring gradients, and worker resources should focus on training the model; (ii) KungFu should not block the training when monitoring gradients using collective communication operations due to the length of such operations; and (iii) KungFu should efficiently monitor gradients, given the

Fig. 1: KungFu architecture

large volume of gradients in today’s models.

Fig. 1 gives an overview of the KungFu architecture. Users can declare an AP (see **a**) as part of a ML training program written in TensorFlow. TensorFlow then creates a *dataflow* program to train the model. To monitor gradients in this dataflow, KungFu transforms the monitoring calls from the AP into *monitoring operators* (see **b**), which are embedded in the dataflow. This allows monitoring operators to (i) directly monitor gradients produced by the dataflow and (ii) reuse intermediate computation results in the dataflow for monitoring. For example, it becomes possible to exploit the existing averaged gradients computed when synchronising model replicas.

The monitoring process must compute globally-aggregated metrics from local gradients on workers. In KungFu, this exploits regular collective communication primitives (e.g. all-reduce and all-gather). To overlap monitoring and synchronisation as much as possible, KungFu has a new *asynchronous collective communication layer* (see **c**). Using this layer, the dataflow executed by workers can launch asynchronous collective communication operations without blocking.

The asynchronous collective communication layer also avoids having an expensive central coordinator, as used for invoking synchronous collective communication operations in existing systems, such as Horovod [73]. Instead, the KungFu communication layer follows a decentralised architecture: each worker maintains a local view of the complete cluster state used for collective communication and incrementally updates the state by exchanging messages with workers in a peer-to-peer fashion. This decentralised design avoids the need for APs to coordinate the order of collective communication across the system. It also prevents a central coordinator from becoming a potential bottleneck.

To improve the performance of collective communication, each KungFu worker has an NCCL scheduler (see **d**). This allows the worker to exploit high-speed multi-GPU networks, such as NVLink [57] and GPU RDMA, through the NCCL interface [56]. The scheduler tracks the availability of gradients on each GPU on the machine, and invokes a local NCCL library to execute a collective communication operation for fetching gradients. To combine the results on multiple workers across different machines, workers use KungFu’s asynchronous collective communication layer, thus following a hybrid architecture for collective communication.

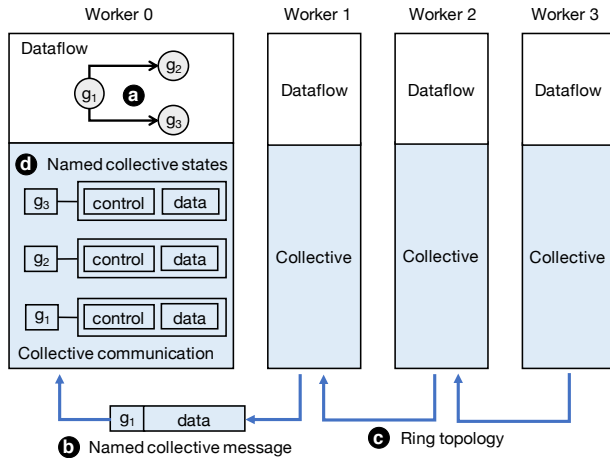

Fig. 2: Dataflow collective communication

4.2 Embedding monitoring within dataflows

To reduce the compute cost of calculating monitored metrics, KungFu exploits the fact that modern ML frameworks (e.g. TensorFlow, MXNet and PyTorch) have built-in *dataflow engines*. These engines offer efficient operators for tensor computation. They also handle the device placement of operators, leveraging parallel computation on accelerators such as GPUs and TPUs. Our observation is that a dataflow engine can also execute monitoring operators by embedding them within the dataflow graph for efficient execution.

To realise this design, KungFu implements the gradient monitoring functions (e.g. gns in Tab. 2) and the collective communication functions (e.g. allreduce, broadcast and allgather) as dataflow operators. Since gradients are represented as tensors in the dataflow graph, KungFu’s dataflow operators must accept tensors as input. The embedding occurs at compilation time of the dataflow. The monitoring operators are thus part of the dataflow, and they can be scheduled immediately by the dataflow engine when their inputs, i.e. gradients, become available.

To embed its functions as operators, KungFu provides distributed optimisers (e.g. OptimizerWithGNS in line 32 in Listing 1) to wrap the original gradient descent optimisers. The KungFu optimisers automatically embed monitoring operators into the training dataflows. These operators intercept gradient tensors produced in each training iteration and forward them to gradient computation operators. The results are maintained in the dataflow and can be read subsequently by the policy functions in APs (line 20).

4.3 Collective communication for dataflows

Dataflows that implement APs use collective communication when computing global gradient metrics. While some gradient metrics (e.g. GNS) can be fused with synchronisation operations, others (e.g. gradient variance) cannot and require extra rounds of collective communication. Asynchronous collective communication thus allows these to be overlapped

with gradient synchronisation, reducing the overhead of gradient monitoring. In addition, since dataflows are often executed asynchronously, the coordination with synchronous collective communication, as in Horovod, increases latency, which asynchronous communication avoids.

Allowing dataflows to launch collective communication asynchronously, however, can result in inconsistent computation. For example, the dataflows executed on different workers can produce gradients in different orders. If a worker receives the collective communication messages belonging to different gradients, they may compute inconsistent results.

Fig. 2 illustrates this problem. The example considers 4 workers that perform collective communication. They execute the same dataflow graph (shown as ➊), which contains 3 operators for computing gradients, g_1 , g_2 and g_3 . On different workers, the operators g_2 and g_3 can complete in a different order. To avoid mixing the collective communication data for g_2 and g_3 , Horovod [73] employs a centralised coordinator. The coordinator tracks which gradients are ready on workers and launches collective communication operators for these in the correct order. This, however, not only reduces concurrency in the collective communication layer but it also makes the central coordinator a scalability bottleneck.

KungFu adopts a decentralised architecture that efficiently and safely implements asynchronous collective communication. It comprises several components:

Named collective messages. The collective communication layer in KungFu uses *named collective messages* (see ➋ in Fig. 2) to communicate data. The delivery of these messages follows the collective communication topology (e.g. the ring topology shown in ➌). Each named collective message carries (i) the data and (ii) a key, which is used to identify which gradient the data belongs to. The key is derived from the unique key assigned by the ML framework to each dataflow operator. If such a key is unavailable, users can explicitly set it through KungFu’s collective communication API.

Named collective states. When receiving a named collective message, a KungFu worker uses it to update its local *named collective state* (see ➍). The worker extracts the key from the message and identifies the state entry with the intermediate collective communication. Each entry contains a data and a control part: the data part is the buffer with the intermediate collective communication result, e.g. *max*, *min* or *sum*, which has been accumulated so far; the control part records how many named collective messages have been processed and which worker is the next hop to deliver the local intermediate collective communication results. If the worker finds itself as the last hop in the collective communication topology, it returns the result to the dataflow.

KungFu minimises the memory footprint of the collective messages and states. Since KungFu targets synchronous data parallel training, all asynchronous all-reduce operations must have completed in one training iteration before start-

ing the next. This limits the number of concurrent collective messages and states in memory. To further reduce memory consumption, KungFu frees the states and messages when an asynchronous all-reduce operation has completed. If possible, KungFu reuses buffers from the ML framework (TensorFlow/PyTorch), and it uses a pool to recycle buffers.

4.4 Accelerating collective communication with NCCL

High-end deep learning servers have fast communication links between GPUs (e.g. NVLink, which is 10× faster than PCIe [57]) and fast network connectivity between servers (e.g. GPU RDMA using InfiniBand). To speed up gradient communication and monitoring, KungFu workers exploit these fast links for collective communication.

In practice, users often employ NVLink and GPU RDMA through the NCCL collective communication library [56]. NCCL provides a synchronous collective communication API, following an MPI model [21]. At any time, an NCCL client can only launch a single collective communication operation; otherwise multiple NCCL operations interfere on the NVLink. Existing NCCL-enabled systems (e.g. Horovod-NCCL [73]) therefore adopt a centralised master architecture to coordinate distributed workers when using NCCL operations with gradients. This design, however, is not compatible with KungFu because its collective communication layer has a decentralised architecture.

Instead, KungFu workers use decentralised NCCL schedulers. Each scheduler tracks which gradients are ready on which GPU. The schedulers guarantee that gradients are processed by each NCCL instance in the same order. In the first training step, all NCCL schedulers monitor the order of gradients produced by local dataflow computations. They gather all orders and determine which order is most frequent. The most-common order (named *gradient order*) is broadcast to all schedulers. The schedulers must strictly follow the gradient order when calling NCCL. This ensures that NCCL schedulers launch collective communication for gradients consistently, without a need for central coordination.

KungFu currently offloads all collective communication requests, including those for gradient synchronisation and monitoring, to its NCCL schedulers if NVLink and InfiniBand are available locally. A future extension is to decide *which* requests to offload based on latency requirements: gradient monitoring could use asynchronous collective communication to overlap with training as much as possible; and throughput-intensive gradient synchronisation could use the NCCL-based collective communication.

5 Adapting Parameters of Workers

In this section, we describe how KungFu uses APs to adapt the parameters of its distributed workers.

5.1 Adapting dataflow parameters

Changing configuration parameters of a distributed ML system introduces challenges. Most systems require static param-

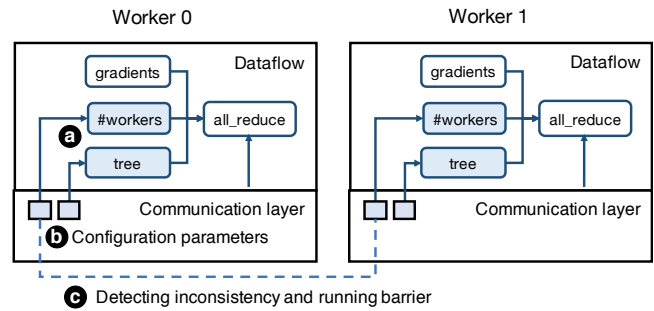

Fig. 3: Parameters as configuration operators

eters, which can be treated as constants when compiling the dataflow graph. After compilation, the dataflow graph is finalised and offloaded to GPUs for execution. Further changes to parameters are thus no longer reflected in the dataflow.

Therefore, elastic ML systems, such as Horovod Elastic [73] or Auto-Scaling [58], require users to use a *dynamic execution mode* of the ML framework, e.g. the “eager” mode in TensorFlow. The dynamic mode allows parameters to be updated in each training step, but it prevents the dataflow from being compiled, which results in large performance overheads. In addition, elastic ML systems only support changes to certain parameters, such as the number of workers. Users must still develop ad-hoc approaches when changing other parameters, such as the communication topology.

KungFu’s design supports the online adaptation of dataflow parameters, while allowing the dataflow graph to be compiled. The core idea is that, instead of providing configuration parameters as static parameters when compiling the dataflow, KungFu adds parameters as computational *configuration operators* as part of the dataflow graph. In each training step, these configuration operators can dynamically alter their output by reading configuration parameters provided by KungFu’s communication layer. This is efficient because it reuses existing data channels between the communication layer and the GPU. APs can dynamically change the parameters in the communication layer, and the result is reflected within the dataflow graph during execution.

Fig. 3 illustrates this idea. We assume that the dataflow graph is used to average local gradients, and it computes the sum of local gradients using an all-reduce operator. The AP changes (i) the number of workers and (ii) their collective communication topology. These two parameters are therefore provided as dataflow configuration operators (see a) and are used as the input to the all-reduce operator. During execution, the operators read the corresponding configuration parameters (see b) from the communication layer, and forward them to the all-reduce operator.

5.2 Protecting consistency under adaptation

APs must be able to change the configuration parameters in KungFu’s distributed communication layer. At runtime, KungFu, however, must ensure that these parameters remain

Algorithm 1 Distributed adaptation algorithm for parameters

```
1: procedure DISTRIBUTEDADAPTATION( $p, v$ )
2:    $b \leftarrow \text{bytes}(v)$  ▷ Convert  $v$  into byte array
3:    $l \leftarrow \text{length}(b)$  ▷ Get length of  $b$ 
4:    $l_0 \leftarrow \text{allreduce}(\text{bytes}(l), \text{min})$  ▷ byte-wise min
5:    $l_1 \leftarrow \text{allreduce}(\text{bytes}(l), \text{max})$  ▷ byte-wise max
6:   if  $l_0 \neq l_1$  then ▷ byte-wise comparison
7:     return false
8:   end if
9:    $b_0 \leftarrow \text{allreduce}(b, \text{min})$ 
10:   $b_1 \leftarrow \text{allreduce}(b, \text{max})$ 
11:  if  $b_0 \neq b_1$  then
12:    return false
13:  end if
14:   $p.\text{update}(v)$  ▷ Call the update function of  $p$ 
15:   $\_ \leftarrow \text{allreduce}([0], \text{min})$  ▷ Run global barrier
16:  return true
17: end procedure
```

consistent when read by the distributed dataflows on workers.

Making global parameter changes consistent with APs introduces two requirements: (i) APs are replicated by workers and executed in parallel. They hold local monitoring state and can receive adaptation commands asynchronously. APs can thus obtain inconsistent values for a given parameter, especially in a large cluster in which many GPU workers asynchronously read new parameter values with high frequency. KungFu must have a mechanism to reject such inconsistent reads. In addition, (ii) when a consistent value is given, KungFu workers assign this value to their local parameters in parallel. The workers must then share a *global barrier* when completing the assignment, which prevents the execution of different dataflows with inconsistent values.

Distributed adaptation algorithm. We describe a distributed parameter adaptation algorithm that fulfils these requirements. To execute with low latency, thus reducing the time during which dataflow execution is blocked under adaptation, it exploits the collective communication layer: since configuration parameters are already hosted by that layer, KungFu re-uses the highly optimised collective communication functions to (i) detect inconsistent updates and (ii) implement a global barrier (shown as  in Fig. 3).

Alg. 1 is executed by each KungFu worker when adapting a configuration parameter p with a new value v . It first transforms v into a byte array so that it can be consumed by an all-reduce function, together with a reduce function such as *min* or *max*. After that, the algorithm launches two all-reduce functions to check if the length of b is identical on all workers (lines 4–7). If so, it calls another two all-reduce functions to check if the content of b is consistent (lines 9–13). If this check also passes, v can be safely used for updating p (line 14). All workers must wait on a global barrier until the updates have completed. The barrier is implemented by calling an all-reduce function with a one-byte array (line 15).

Some parameters require custom adaptation logic other than a simple value assignment. For example, changing the number of workers requires workers to exit or join during

adaptation. To support this, Alg. 1 can invoke a custom function when updating a parameter (line 14). In the case of the worker set, the function chooses one worker to signal other workers to exit or launch.

Managing data under adaptation. APs can modify the worker count and the batch size. These parameters affect how the training dataset is read and thus the training result. To ensure consistent results under adaptation, all KungFu workers have access to the full dataset.

KungFu supports two approaches to read data batches, depending on if users require *data epochs* to control the training process: (i) if data epochs are not needed, users can use random sampling to read data batches, and the adaptation logic can be triggered at any training step; (ii) with data epochs, KungFu provides a *dynamic data partitioning operator* that replaces the static partitioning operator (e.g. `tf.data.shard`) in the data input pipeline (e.g. `DataSet`). The dynamic partitioning operator is replicated on all KungFu workers and the operators are synchronised to enact a new parallelism level after a scaling operation. To preserve data epochs, users must invoke the adaptation logic on epoch boundaries only.

Handling failures during adaptation. To tolerate failures, KungFu relies on a highly-available configuration provider (e.g. `ConfigMap` in Kubernetes) to maintain its cluster configuration. The configuration must be updated when a scaling action is committed. In the case of worker failures, the cluster scheduler uses the configuration to restart workers.

6 Evaluation

We experimentally explore the following aspects of the KungFu design and implementation: (i) What are the benefits of enabling adaptation in distributed ML training? (ii) What is the monitoring and adaptation overhead in the training process? (iii) How does KungFu perform in large clusters compared to existing distributed ML systems?

6.1 Experimental set-up

We use both dedicated machines and cloud VMs in our experiments: the dedicated machines are (i) an NVIDIA DGX-1 machine with 8 NVIDIA V100 GPUs interconnected using NVLink, and 72 CPU cores; and (ii) a 20-CPU-core server with 4 NVIDIA Titan X GPUs interconnected using the PCIe bus. The cloud test-bed has 32 VMs, each with 8 vCPUs, 64 GB of memory and 1 NVIDIA K80 GPU.

We use various training workloads as part of the official models provided by TensorFlow [1]: the MobileNetV2 [70] and ResNet-50 [26] models for the ImageNet image classification task [37]; and the BERT [15] model for a natural language processing task, SQuAD [67]. The MobileNetV2 model is 23 MB, ResNet-50 is 98 MB, and BERT is 1 GB in size. These model sizes cover a large spectrum that users observe in practice. We use TensorFlow v1.13.2 to train the models. When possible, we compare the performance to Horovod v0.16.1.

Fig. 4: Adaptive batch size (ResNet-56)

Fig. 5: Adaptive communication strategy (ResNet-50)

Fig. 6: Adaptive resource provisioning (BERT)

6.2 Adaptation policies

We evaluate three representative APs with KungFu that change various aspects of distributed training:

(1) Adaptive batch size. We implement an AP that adapts the batch size based on GNS when training the ResNet-56 model with the CIFAR-10 dataset. To the best of our knowledge, this AP is the first implementation that evaluates GNS-based batch size tuning in an online training scenario. Past work [52] only empirically evaluates it using offline training traces.

The AP computes GNS using an exponential moving average ($\alpha=0.1$) and adapts the batch size every 10 epochs as follows: if GNS has increased by a factor of r , it also scales the batch size by r , up to 4096. We compare this AP with two static baselines, which adopt fixed batch sizes of 128 and 4096, respectively. These baselines represent typical choices for small batch size (SBS) and large batch size (LBS). In this experiment, the model is trained for 300 epochs with a learning rate of 0.1, based on TensorFlow’s official model. The training is done on the 4 GPU Titan X testbed, with batches shared evenly across GPUs.

Fig. 4 shows the validation accuracy of the model over time. LBS reaches a low validation accuracy (60%) but finishes quickly. SBS reaches a higher validation accuracy (88%) but the constant noise in gradients due to the small batches makes it hard to converge, and the accuracy oscillates between 80% and 90%. A typical issue of SBS is the underutilisation of GPUs: SBS takes around 6000 s to complete training, $2.4\times$ longer than LBS. In practice, fixing the choice of batch size is challenging for users—they have to trade off between model accuracy and hardware utilisation.

The above AP addresses this challenge. As shown by the right y-axis in Fig. 4, the policy dynamically increases the batch size from 128 to 4096 based on GNS. This type of adaptation improves model accuracy: it reaches 88% after around 1000 s, $5\times$ faster than SBS, and eventually converges to 90% after 1300 s. Dynamically increasing the batch size reduces the noise in gradients, which enables the model to converge. Furthermore, it allows the model to better utilise the hardware: the model spends only 400 s more than LBS but achieves 30% higher accuracy.

(2) Adaptive communication strategy. Network infrastructure in cloud environments and multi-tenant clusters may suffer from contention when using all-reduce operations to synchronise gradients, and straggling workers may then slow

down the entire system [49]. To address this, we provide an AP that monitors training throughput. If the throughput drops due to network contention, the policy adjusts the topology used by all-reduce, limiting the use of contended network links. In this experiment, we train the ResNet-50 model for 100 steps on 32 VMs. After 25 steps, we introduce background traffic to create network contention. This mimics a cloud environment in which there is dynamic interference in an over-subscribed network.

We compare this AP with a static baseline that uses a fixed all-reduce topology. We also attempted to implement a dynamic baseline using OpenMPI and NCCL, but these libraries do not allow runtime control of the all-reduce topology.

Fig. 5 presents the average worker training throughput over training steps. The baseline shows that the workers reach 6.5 images/s at the beginning but this number drops to 5.5 after the network becomes contended. The AP monitors the throughput and detects network contention at step 35. It adapts the communication topology, and the topology recovers throughput: it increases to 7 images/s, even though the background traffic is still on-going.

(3) Adaptive resource provisioning. Users want to decide on a cost-effective number of GPUs when training models. Using many GPUs leads to high training throughput but it also increases cost. Large ML models are synchronising large volumes of gradients. Above a certain amount of resources, communication becomes a bottleneck. In such a case, using more GPUs only gives a marginal performance improvement, despite the higher cost.

We explore an AP that finds the most cost-effective number of GPUs. This policy adds one worker every K steps. It then evaluates the average total accumulated throughput and, if the new throughput is not $1 + \alpha(1/\text{size})$ times higher, it removes the worker and stops scaling. We choose $\alpha=0.33$ and $K=400$. We compare to a static baseline that always uses the most GPUs. We train the BERT model with a per-GPU batch size of 8 on the 8 GPU V100 testbed.

Fig. 6 shows the results. When all 8 GPUs (right-hand y-axis) are used from the beginning, the total throughput is above 90 examples/second (left-hand y-axis). For KungFu, we see that the throughput rises with the number of GPUs until only a slight increase from 6 to 7 GPUs (step 2400). Due to the small increase with 7 workers, KungFu removes worker 7 at step 2800, stops scaling and resumes training

Fig. 7: Adaptation overhead

Fig. 9: Worker throughput with different cluster sizes

with 6 workers. We use the price of a V100 GPU on Azure to estimate the cost efficiency of KungFu and the baseline. The baseline has a cost efficiency of 10,902 examples/USD, and KungFu has 13,097 examples/USD. This indicates that KungFu improves the cost efficiency of the job by 20%.

6.3 Adaptation overhead

Next we evaluate the overhead of adaptation and monitoring.

Adaptation. We evaluate the adaptation latency when changing the communication topology and worker set. We conduct the experiments on the 32 VMs testbed and train ResNet-50. During training, we repetitively change the parameters.

Fig. 7a shows the latency when changing worker communication topology. With 8 VMs, the adaptation completes in 15 ms. With 32 VMs, the delay only increases to 37 ms. This shows the benefits of using the all-reduce function to implement the required consistency checking and global barrier during adaptation.

Fig. 7b shows the latency when scaling down. We decrease the number of workers from 32 to 1 by calling the `resize` function. The function takes 0.2 s to complete. Scaling the system using the checkpoint/recovery mechanism of TensorFlow takes around 20 s to complete, 100 \times slower than KungFu. This high latency is mainly due to the stop-and-resume time of TensorFlow, and it is consistent with the observations made by others [58, 82]. This result shows the need for supporting efficient adaptation to enable scaling in practice.

Fig. 7c shows the latency when scaling out. Increasing the number of workers from 1 to 32 takes 20 s, the same as the baseline. Since KungFu must preserve the consistency of the training state on workers, it must wait for new workers to be started by TensorFlow. Breaking down this delay, we can see that KungFu spends 0.5 s to complete the scale-out operation, and waits the remaining 19.5 s for the TensorFlow

set-up. The long start-up time of TensorFlow can be masked by implementing worker pre-loading [58].

Monitoring. We also consider the overhead when monitoring two metrics, *gradient noise scale* (GNS) and *gradient variance* (GV). The computation of GNS can reuse the averaged gradients produced by the S-SGD computation and thus can be computed locally without extra collective communication; GV, however, compares the square of the sum of gradients and the sum of gradient squares [78]. To compute it, KungFu must launch an additional all-reduce operation for each gradient. We monitor these two metrics when training ResNet-50 for ImageNet on the 8 GPUs V100 testbed. We vary the monitoring interval from 1–8 steps to change load.

Fig. 8 shows the average per-worker training throughput with gradient monitoring. We compare it to the per-worker throughput without monitoring (i.e. the ideal case). The monitoring of GNS has a negligible impact on training, dropping the training throughput from 6.3% to 1.0% based on the monitoring interval. This shows that embedding the monitoring operators as part of the dataflow graph results in low overhead.

The calculation of GV has a tangible throughput impact. The overhead, however, can be amortised by increasing the monitoring interval. The throughput drops by 2.8% when the interval is 8 steps, while still providing acceptable monitoring for APs. APs keep monitored metrics in data sketches and use the accumulated result, usually every several epochs. Iterating through an ImageNet dataset takes more than 40,000 steps, which means that 5000 GV values in an epoch still make estimation reliable.

6.4 Performance

Finally, we evaluate two aspects of KungFu that contribute to overall performance: (i) the asynchronous collective communication layer and (ii) the NCCL scheduler.

Asynchronous Collective Communication Layer. We explore how the performance of KungFu’s communication layer compares to Horovod [73], which is a popular high-performance collective communication library used for distributed ML training. We compare the performance with 8, 16, 24 and 32 VMs. By varying the cluster size, we place different loads on collective communication.

Fig. 9a shows the per-VM training throughput for MobileNetV2/ImageNet under KungFu and Horovod. With 8 VMs, Horovod and KungFu achieve the same throughput. With 32 VMs, however, KungFu outperforms Horovod by 28% due to the benefits of its decentralised design for the communication layer, which avoids the bottleneck of Horovod’s master. We also note that Horovod shows a high variance in the training throughput for 32 VMs (up to 24% between min/max). This is caused by network jitter in the cloud environment affecting Horovod’s coordinator. Since KungFu workers asynchronously exchange messages for collective communication, they compensate for the network latency and thus achieve stable training throughput even with 32 VMs.

Fig. 9b shows the per-VM training throughput for ResNet50-ImageNet, which is 4× larger than MobileNetV2. With this model, there is more network traffic, and KungFu achieves 98% higher throughput than Horovod with 32 VMs. This improvement is larger than in the case of MobileNetV2 because Horovod must execute collective communication in order, following the MPI convention. KungFu, however, supports concurrent collective communication operations through its named collective message and state mechanisms. This increases concurrency in the communication layer, making it achieve a higher throughput than Horovod, especially with large models such as ResNet.

NCCL Schedulers. We also explore the benefit of the NCCL schedulers in comparison to CPU-based collective communication (i.e. CPU all-reduce) and centralised NCCL scheduling, as used by Horovod-NCCL. The experiment is executed on the DGX-1 machine with all 8 NVIDIA V100 GPUs.

Fig. 10 shows the throughput with CPU-based collective communication and NCCL as used by KungFu and Horovod, respectively. For communication between GPUs on the same machine, NCCL offers a significant performance benefit for both KungFu and Horovod. Comparing KungFu and Horovod with NCCL, we see that, for ResNet (~200 gradients; 97 MB size), KungFu and Horovod experience almost identical performance; for BERT-base (~600 gradients; 1 GB size), KungFu achieves 17% higher throughput than Horovod.

This difference can be attributed to the centralised nature of Horovod’s NCCL scheduling. The central scheduler contacts each worker to track which gradients have become available. When gradients are available on all workers, the scheduler calls an all-reduce operation to average gradients. The scheduling overhead grows with the number of gradients, and it becomes a bottleneck with many gradients (e.g. 600 gradients in BERT). A large number of gradients is increasingly

Fig. 10: Training throughput

common because large models out-perform smaller ones.

7 Related Work

Distributed ML systems. A dataflow abstraction is used in many ML systems, including TensorFlow, PyTorch [60], MXNet [10], Caffe [30] and MindSpore [53]. These systems share similar dataflow designs in which computational operators are used for tensor computation. Compiled dataflows are offloaded to GPUs for the training computation. KungFu reuses the dataflow abstraction to embed operators for the purpose of adaptation.

KungFu uses collective communication functions to implement monitoring and adaptation operations. Such functions are available in most distributed ML systems, including those built on top of MPI [1, 56, 73] as well as parameter-server-based systems [8, 42]. Compared to existing collective communication approaches, KungFu explores a decentralised architecture that is tailored to supporting dataflows used in ML frameworks. It allows multiple collective communication operations to execute concurrently, making it different from current MPI-compatible systems.

Hyper-parameter optimisation and tuning. To find the best settings for hyper-parameters, practitioners and researchers have proposed tuning systems [2, 17, 18, 35, 40, 45] with associated search algorithms [28, 29, 33, 41]. These systems launch parallel training jobs to evaluate different candidate settings of target hyper-parameters. They often aim to minimise resource consumption for finding the best setting. In contrast, KungFu explores how to optimise hyper-parameters continuously in a single training job. It thus proposes mechanisms for efficient monitoring and online adaptation of hyper-parameters during training. It can be used by existing tuning systems to speed up the time of individual training jobs.

Elastic training systems have been proposed to improve the resource utilisation of ML clusters. EDL [82] studies stop-

free scaling for TensorFlow workers, and Litz [65] proposes an elastic training framework for ML clusters that consist of parameter servers and training workers. Horovod Elastic [73] and PyTorch Elastic [60] are two open-source elastic training libraries. Compared to these dedicated elastic training systems, KungFu provides a unified framework that can execute different adaptive training jobs efficiently.

Adaptation policies have been explored in streaming systems [20, 22, 27, 61, 62]. Dhalion [19] provides policy support for Apache Storm, and its policies measure data analytics metrics, such as latency and throughput; in contrast, APs in KungFu enable the monitoring of gradients in ML systems. Chi [51] is a control plane for stream processing systems, and it supports online monitoring and adaptation. Compared to Chi, KungFu provides a solution to build adaptive distributed ML systems with high-performance gradient monitoring using dataflows and asynchronous collective communication.

Recently, practitioners have proposed adaptation policies [39, 58] tailored to ML systems. These policies use cost models to infer the performance of a training system and make scaling decisions in response. They could be implemented as APs on top of KungFu to exploit its optimised adaptation and communication infrastructure.

Monitoring training. The ML communities have recognised the importance of monitoring training [71]. CrossBow [34] monitors accelerator utilisation to infer the optimal level of data parallelism when training models. Moreover, gradients metrics are useful to optimise hyper-parameters [50]. There have been efforts on setting the batch size according to signal-to-noise ratios [12] and loss [5], or the learning rate based on other gradient metrics, e.g. square norm of expectation of gradients [16, 71, 74]. Due to the lack of support in current distributed ML systems, such efforts typically only evaluate efficacy using offline collected gradients. KungFu is inspired by these efforts and addresses the missing systems support to implement such proposals.

8 Conclusions

When training modern complex ML models, users want to adapt a wide range of hyper- and system parameters. Existing distributed ML systems were designed at a time when static training regimes were the norm. They thus lack mechanisms for monitoring training metrics and adapting configuration parameters at runtime.

We have presented *KungFu*, a distributed training library that allows users to specify and execute Adaptation Policies. KungFu executes policies efficiently by embedding monitoring and configuration operators as part of the compiled dataflow graph. All communication leverages efficient asynchronous collective communication functions, without interfering with the training process or compromising consistency.

Abstract

Emerging big-data workloads with massive I/O processing require fast, scalable, and flexible storage virtualization support. Hardware-assisted virtualization can achieve reasonable performance for fast storage devices, but it comes at the expense of limited functionalities in a virtualized environment (e.g., migration, replication, caching). To restore the VM features with minimal performance degradation, recent advances propose to implement a new software-based virtualization layer by dedicating computing cores to virtual device emulation. However, due to the dedication of expensive general-purpose cores and the nature of host-driven storage device management, the proposed schemes raise the critical performance and scalability issues with the increasing number and performance of storage devices per server.

In this paper, we propose FVM, a new hardware-assisted storage virtualization mechanism to achieve high performance and scalability while maintaining the flexibility to support various VM features. The key idea is to implement (1) a storage virtualization layer on an FPGA card (FVM-engine) decoupled from the host resources and (2) a device-control method to have the card directly manage the physical storage devices. In this way, a server equipped with FVM-engine can save the invaluable host-side resources (i.e., CPU, memory bandwidth) from virtual and physical device management and utilize the decoupled FPGA resources for virtual device emulation. Our FVM-engine prototype outperforms existing storage virtualization schemes while maintaining the same flexibility and programmability as software implementations.

1 Introduction

Storage virtualization is one of the most important components to determine the cost-effectiveness of modern datacenters, which improves the utilization of the storage devices and makes resource management much easier. For example,

Figure 1: CPU usage of native block I/O in Linux and virtualized block I/O with SPDK vhost-nvme [21]

storage virtualization can map multiple virtual storage devices onto a smaller set of physical storage devices and make them shared by many virtual machines (VMs) [66]. At the same time, it facilitates VM management by providing a variety of functionalities in a virtualized context (e.g., live migration [41, 58], replication [52, 61], consolidation [62, 65], aggregation, metering, server-side caching [35, 37]).

The importance of storage virtualization is growing for modern datacenters running I/O-intensive big-data workloads on their fast but expensive solid-state drives (SSDs). In particular, it is critical to reduce virtualization overhead and provide near-native storage performance to the VM workloads. A conventional way to overcome the virtualization overhead is to utilize hardware-assisted virtualization mechanisms (e.g., passthrough [30], SR-IOV [19]). However, the existing hardware virtualization mechanisms have become much less appealing to modern datacenters due to their extremely limited VM management support.

To provide highly flexible VM management at minimal virtualization overhead, a new software-based storage virtualization mechanism is now considered as a highly promising solution. A storage performance development kit (SPDK) vhost-target implementation not only enables flexible VM management but also significantly improves performance by exclusively dedicating computing cores (i.e., sidecores) to its user-level virtualization layer [21, 69].

However, such sidecore approaches require a significant

*Corresponding author.

amount of computing resources to execute their polling-based virtual device emulation [53, 59]. Furthermore, the required computing bandwidth quickly increases as a single server is equipped with an increasing number of storage devices, and each device gets faster. As shown in Figure 1, our projection result shows that virtualized I/O with SPDK vhost-nvme [21] necessitates 42% – 65% more CPU cores to saturate multiple Intel Optane SSDs [7] than native block I/O in Linux.

Due to the severe computing resource requirement, the software-based storage virtualization cannot provide high performance or high scalability. First, without enough computing cores dedicated to the storage virtualization layer, the storage system comes to suffer from low performance. Second, without the capability of adding virtualization-dedicated cores as needed, the system comes to suffer from low scalability. Therefore, to achieve high performance, scalability, and flexibility all together, the ideal storage virtualization should decouple itself from host CPU cores, scale with a target storage system, and exploit the most cost-effective computing solution for the programmable VM management.

In this paper, we design and implement FVM, a new hardware-assisted storage virtualization mechanism, to achieve high performance and scalability while maintaining the flexibility to support a variety of VM management features. The key idea of FVM is to implement (1) a storage virtualization layer on an FPGA card (*FVM-engine*) which is decoupled from the host resources, and (2) a hardware-based device-control mechanism to make the card directly manage the physical storage devices. FVM also leverages (3) high-level synthesis (HLS) techniques to provide easy programmability for VM management. Our solution can also be implemented on ASICs for higher performance, but in that case, the ASIC implementations lose future flexibility for new VM management features.

FVM achieves the design goals as follows. First, FVM achieves high performance by utilizing a hardware-assisted virtualization mechanism and leveraging massive parallelism in the modern storage virtualization stack. FVM-engine can cost-effectively exploit the virtualization’s parallelism by implementing many wimpy FVM cores and distributing virtual/physical I/O queues and queuing routines to them for fine-grained parallel executions.

Second, FVM achieves high scalability by executing virtual device emulation on FVM-engine, which is decoupled from host CPU cores and device resources. In addition, its direct device-control mechanism further improves the scalability by enabling FVM-engine to directly manage the physical devices. Therefore, without relying on expensive host CPU cores, FVM can achieve highly scalable virtualization performance by implementing FVM-engine on a more powerful FPGA card or adding more FPGA cards on a system board.

Third, FVM achieves highly flexible storage virtualization by implementing existing VM management features on a re-configurable FPGA card. For user programmability, we lever-

Table 1: Comparison of the existing and proposed storage virtualization mechanisms

age an HLS-based design flow and separate the virtualization layer from the I/O logic to interact with the host machine and the physical storage devices.

Table 1 summarizes FVM’s key advantages over existing software- and hardware-based storage virtualization mechanisms, in terms of performance, host efficiency, scalability, device sharing, flexibility, and programmability. FVM solves the performance and scalability issues of the recent sidecore approaches, while achieving device sharing and flexibility that the existing hardware-assisted techniques cannot provide. A detailed explanation can be found in Section 3.

For evaluation, we implemented our FVM-engine prototype on a Xilinx FPGA board [23] and Intel Optane SSDs [7]. We implemented Linux device drivers for the software support and augmented an SPDK vhost-target implementation [21] to apply FVM to an existing KVM-based virtualization system [11].

Our experimental results show that the FVM prototype obtains $1.36\times$ higher I/O throughput than the software-based virtualization method when allocating the same amount of host CPU cores. FVM also scales well with the increasing number of VMs and virtual/physical storage devices by achieving 9.5 GB/s aggregate I/O throughput with four SSDs. Also, our HLS-based design flow requires only 10s – 100s of code lines to implement example VM management functionalities.

In summary, we make the following contributions:

- **Novel storage virtualization mechanism:** We propose a novel FPGA-assisted virtual device emulation mechanism for fast, scalable, and flexible storage virtualization.
- **High performance:** FVM achieves high performance by utilizing hardware-assisted virtualization and parallelizing virtual/physical device operations on FVM-engine.
- **High scalability with host efficiency:** FVM can easily increase its computing power to match the target virtualization scalability without depending on host resources.
- **Flexibility & programmability:** Our HLS-based FVM design flow supports easy VM management and feature programmability.

Figure 2: System architectures for conventional storage virtualization mechanisms

2 Background

In this section, we introduce modern non-volatile memory (NVM) technologies and the latest advances in storage virtualization mechanisms.

2.1 NVM and NVMe Protocol

Modern NVM technologies such as 3D XPoint [8] and Z-NAND [18] have significantly improved the storage performance [39, 50, 67, 71]. At the same time, virtualization for such fast storage devices becomes one of the most critical components in cloud environments [53, 55, 59, 69]. For example, Amazon Web Services (AWS) accelerates I/O virtualization through dedicated hardware components [1, 55]. Other major cloud providers, including Microsoft Azure [12] and Google Cloud Platform (GCP) [6], are allowing advanced NVM devices to be used as primary storage for VMs.

NVM Express (NVMe) [14] is a standard storage architecture used to enable fast NVM storage through PCIe and optimized I/O paths. First, it brings multiple deep I/O queues to take full advantage of NVM technologies. The current specification supports up to 65,535 I/O queues, each with 1 – 65,535 outstanding commands. As a result, it can enable highly parallel processing on multiple cores by assigning independent I/O queues and queuing routines to each core or thread. Second, its protocol provides fast I/O submission and completion paths by reducing the number of memory-mapped I/O (MMIO) operations. For example, it does not require MMIO register reads in the common I/O paths, while including a maximum of one MMIO register write for the command submission path.

An NVMe I/O queue consists of a *submission queue* (SQ)/*completion queue* (CQ) pair. For I/O submission, host software places NVMe commands in the SQ and writes the SQ tail pointer to the target *SQ doorbell register* exposed through PCIe base address registers (BARs). The target NVMe storage device then fetches the newly added commands and processes them. Once the NVMe commands are

completed, the NVMe device writes completion messages to the associated CQ and then generates an interrupt. Lastly, the host software handles the completion messages and updates the target *CQ doorbell register* to clear the interrupt and release the CQ entries.

2.2 Storage Virtualization

2.2.1 Paravirtualization

In a paravirtualization scheme, a guest operating system (OS) is installed with a VM abstraction to make it efficient to emulate virtual devices. For example, *Virtio* [60] is an abstraction for virtual devices in a hypervisor. This abstraction allows the hypervisor to export a common set of virtual devices and makes them available to guests through an efficient device interface. Figure 2a shows the system architecture for virtio-based device emulation. The guest implements front-end virtio drivers, with particular virtual device emulation behind a set of back-end drivers in the hypervisor [60]. This paravirtualization mechanism can reduce the number of *VM exits* by reducing the number of MMIO operations for the virtual device of the guest, which addresses the huge performance overhead incurred by CPU mode switches and cache pollution [51]. However, the guest OS should be aware that it is being virtualized, which requires modifications to collaborate with the hypervisor efficiently.

Virtio SCSI (*virtio-scsi*) [47] or block (*virtio-blk*) [45] can be used to emulate an NVMe device with this paravirtualization mechanism. They handle VM requests directed at the *virtual* NVMe device as follows: (1) A guest OS makes a request to a virtual device through virtual I/O queues (e.g., *vring* [60]) in virtio front-end drivers. (2) The guest then calls a VM exit and traps into a host machine. (3) The hypervisor emulates the virtual device through virtio back-end drivers, interacting with kernel-level device drivers. (4) Once the I/O request is completed, the virtio back-end drivers read completion messages from the physical devices, confirm their completion status, and inject an interrupt to the guest OS

through the hypervisor.

2.2.2 Host Sidecore Approach

CPU-dedicated (or *sidecore*) approaches can further accelerate storage virtualization by avoiding expensive traps to the hypervisor and reducing cache pollution [33, 48]. The recently proposed SPDK *vhost-scsi* and *vhost-blk* implementations [21] can accelerate virtualization of NVMe storage. As shown in Figure 2b, a hypervisor pre-allocates *shared memory regions* for guests and allows them to exchange storage commands with SPDK *vhost-target* directly for virtual device emulation. The SPDK *vhost-target* implementations emulate VM requests as follows: (1) A user-space thread running on a dedicated sidecore continues to poll virtual I/O queues (e.g., NVMe SQ/CQ pairs) via a shared memory region. (2) It reads newly received VM SCSI or block requests and converts them to NVMe commands (i.e., *protocol conversion*). (3) It conducts the I/O operations through an SPDK *user-level* NVMe device driver. (4) Once the requests are completed, another dedicated thread in SPDK *vhost-target* deals with completion messages and injects an interrupt to the guest through the hypervisor.

The recent sidecore approaches can offer near-native performance of modern NVMe devices to VMs. A dedicated sidecore polls guest I/O operations through shared memory regions, so there is no need to call VM exits to submit NVMe commands. Moreover, SPDK’s user-level NVMe device driver enables sidecores to conduct I/O operations without user-kernel mode switches. SPDK *vhost-target* also reduces the number of data copies by allocating guest DMA buffers in a *pinned* shared memory region. For this, the software-based virtualization layer translates *guest physical addresses* (gPAs) to pinned *host physical addresses* (hPAs). Due to the address translation, the NVMe device can transfer data directly to the guest’s memory space without being aware that it receives requests from VMs.

Vhost-nvme. The SPDK *vhost-nvme* implementation [69] further optimizes the sidecore approaches by directly exposing NVMe devices to guest OSes. This transparent view of the NVMe devices can eliminate the performance loss caused by the protocol conversion between SCSI/block and NVMe. It also allows the guest OSes to exploit advanced NVMe features (e.g., shadow doorbell buffer [42]) to get higher performance. A recent study [69] demonstrated that the *vhost-nvme* implementation gets $1.11\times - 1.26\times$ higher random-read throughput than the other SPDK *vhost-target* implementations.

2.2.3 On-device Sidecore Approach

To save the host resources required for storage virtualization, a recent study [53] offloaded the virtualization layer to system-on-chip (SoC) cores in other peripheral devices (e.g., SmartNIC [2, 13]). Figure 2c shows its system architecture.

The *on-device* sidecore approach exposes virtual NVMe interfaces to guest OSes by providing a uniform address space across host CPUs and SoC cores. The SoC allows the runtime software running on the on-device cores to reach virtual NVMe queue pairs mapped in the host memory through DMA. In addition, host software allocates NVMe queue pairs in the SoC’s memory space and provides their locations to the physical NVMe device to make it interact with the SoC directly. Since it utilizes on-device sidecores to emulate virtual storage devices, it can save the host CPU resources and offer more compute power to VMs or other VM management features.

Moreover, on-device sidecore mechanisms provide flexible and programmable implementations leveraging ARM-based SoC cores. In particular, it facilitates implementing essential functionalities in storage virtualization, which are not fully offloaded or not easily composable via other hardware-based virtualization mechanisms (e.g., SR-IOV). For example, a recent study [53] implemented storage versioning, prioritization, isolation, replication, and aggregation functionalities in runtime software installed on the SoC.

2.2.4 Direct Device Assignment

To overcome the virtualization overhead, VMs can make use of support for DMA and interrupt remapping (e.g., Intel VT-d [27], AMD-Vi [26]), which allows guest software to access a target storage device directly. For the remapping support, major processor manufacturers introduced *I/O memory management units* (IOMMUs). A DMA remapping engine in an IOMMU allows DMAs from a guest to be accomplished with gPAs. The IOMMU translates them into hPAs according to page tables that are configured by host software. Likewise, an interrupt remapping engine translates interrupt vectors issued by devices based on an interrupt translation table.

The direct device assignment (or *passthrough*) eliminates the virtualization overhead in software layers since the hypervisor is no longer in a guest’s I/O paths. However, this approach requires the physical devices to be exclusively assigned to a single VM and does not support device sharing across multiple VMs. Therefore, the passthrough mechanism has limitations in improving the utilization of storage devices and reducing operating costs in modern datacenters.

SR-IOV. To address the challenges of the direct passthrough scheme, the PCIe specification currently supports *SR-IOV* [19], a standardized hardware virtualization protocol. An SR-IOV capable PCIe device supports a *physical function* (PF) and multiple *virtual functions* (VFs). The PF provides resource management for the device and is managed by the host software, and each VF can be assigned to a single VM exclusively for direct access. SR-IOV is now supported by high-performance I/O devices such as network and storage devices as well as accelerators. Recently, Xilinx released an SR-IOV capable PCIe IP block [28], supporting up to 252 VFs.

Figure 3: Random I/O throughput with a single SSD

Figure 4: CPU usage of random I/O with a single SSD

Since an SR-IOV capable device implements how to multiplex itself at the hardware level, it does not rely on host software to multiplex the virtual device instances, as shown in Figure 2d. In addition, with SR-IOV and an IOMMU in a host machine, VFs can carry out DMA transactions with gPAs, while avoiding the software-side address translation. Similarly, interrupt remapping for each VF addresses the performance overhead generated by triggering interrupts to notify guests regarding the completion of their I/O requests.

3 Motivation

In this section, we discuss the challenges of the existing virtualization mechanisms for modern datacenters. We identify the critical performance and scalability issues of the existing host and on-device sidecore approaches and the limited VM management support of the hardware-assisted virtualization technologies.

3.1 CPU-inefficient Storage Virtualization

Modern software-based storage virtualization mechanisms dedicate CPU sidecores to emulate virtual NVMe devices. For example, recent NVMe virtualization studies [59, 69] allocate multiple CPU cores to poll virtual I/O queues via shared memory regions, instead of making a trap into a host machine. Figure 3 shows the random I/O throughput of the various software-based virtualization implementations on a single CPU sidecore and a single Intel Optane SSD [7], normalized to the native performance. Virtio denotes virtio-based paravirtualization through KVM, and vhost-scsi, -blk, and -nvme mean three different virtual device interfaces through SPDK

Figure 5: CPU usage breakdown of random-read I/O with SPDK vhost-nvme

vhost-target. We ran FIO [5] random I/O benchmarks with four threads and 32 queue depth and measured the random I/O throughput on VMs. On the other hand, Figure 4 shows the relative CPU usage normalized to that of the native I/O operations on an Intel Xeon server [22] with the same experiment environments. Our experimental results show that virtio fails to offer the full native performance due to frequent VM exits, and all the SPDK vhost implementations can achieve close to the maximum native performance (i.e., 550K IOPS). However, at the same time, to get such near-native performance, they demand $1.42\times - 1.61\times$ more CPU resources than native random I/O operations.

There are two primary sources of such high CPU resource usage. First, they utilize multiple active polling cores to reduce the number of VM exits [59, 69]. Because NVMe is a highly parallel storage architecture, the conventional trap-and-emulate approach will generate an unacceptable number of VM exits for a VM to take full advantage of multiple I/O queues [59]. For this reason, the sidecore approaches allocate CPU resources exclusively and poll guest I/O operations through a shared memory region to handle such frequent NVMe requests quickly. Second, the SPDK vhost-target implementations trigger guest interrupts through *eventfd*, which requires system calls and VM exits [69]. Figure 5 shows the CPU usage breakdown of the host machine running SPDK vhost-nvme. Our experimental result demonstrates that around 22% of active CPU cycles are used to poll and emulate virtual devices (vhost) and 39% to trigger guest interrupts (interrupt). The other portions are consumed by the necessary VM management (QEMU [15]/KVM [11]) and the SPDK storage stack (bdev and nvme).

This resource-inefficiency issue poses a significant challenge to scalable storage virtualization and efficient VM management in modern cloud and datacenter environments. To support many NVMe devices and guarantee quality-of-service (QoS) at the same time, the current host sidecore approaches will continue to demand a considerable portion of host CPUs for storage virtualization [44]. Eventually, the number of VMs that can be supported within a single server will decrease, and the total datacenter costs will increase. Otherwise, the VMs will have serious performance problems due to the lack of computing resources. Also, with the limited capability of adding virtualization-dedicated CPU cores per server, the system will come to suffer from the low scalability.

Figure 6: Performance comparison of different virtualization-dedicated core implementations

3.2 Weak Computing Power of SoC Cores

Modern on-device sidecore approaches offload the virtual device emulation to SoC cores embedded in peripheral devices instead of CPU cores to reduce the burden of host CPU [53]. However, their I/O performance can be severely bounded by the SoC cores' weak computing power. To measure the performance bottleneck due to the small cores, we implemented Microblaze softcores (250 MHz) [24] on an FPGA [23] and ran storage virtualization runtime software. We linearly scaled this performance result to evaluate more aggressive SoC designs that use higher clock speed and more cores (3 GHz, 8 cores). Figure 6 shows the random I/O performance of CPU (vhost-nvme) and SoC (runtime software) sidecore approaches with many NVMe devices. Our experimental results show that, even with the number of SoC cores increased, their weak computing capabilities become the significant performance bottleneck.

In particular, SoC sidecore designs significantly suffer from inefficient DMA mechanisms incurred by SW abstraction layers. For example, SmartNICs [2, 13], which utilize SoC cores in NICs, expose RDMA APIs instead of native DMA primitives, and it nearly doubles the DMA read/write latency [56]. Our Microblaze softcore implementation emulated the overhead by adding 5 μ s per DMA transaction, and as a result, it achieved only 68% of the maximum performance of a single device. In addition, SoC sidecore designs cannot support a large number of virtual/physical devices and advanced storage management features due to their limited computing capabilities. As shown in Figure 6, an eight-core SoC cannot fully utilize two or more NVMe devices. These scalability issues will become more severe as storage devices get faster.

3.3 Absence of Interposition Layer

To save the host and on-device sidecores, hardware-assisted virtualization techniques can bypass the host software entirely. We experimentally confirmed that the two popular HW-assisted virtualization technologies in modern NVMe SSDs (i.e., passthrough and SR-IOV) provide the near-native performance in VMs. For this purpose, we installed a Samsung PM1733 SSD [17] which offers both passthrough and SR-IOV

capabilities, and measured its FIO random I/O performance in VMs. We created a single VF through SR-IOV and assigned a 128-GB namespace, eight virtual queues, and eight virtual interrupt resources. When the device is connected through PCIe Gen3, we obtained around 800k IOPS for random reads and 250k IOPS for random writes in both passthrough and SR-IOV environments.

However, they suffer from the limited VM management and storage features in cloud environments. For example, SR-IOV does not support critical features to enable easy storage management such as live migration [41, 58] and seamless switching between different I/O channels. Also, it does not allow hypervisors to add critical features that are not natively provided by physical devices: replication [52, 61], snapshot [40, 70], record-replay, deduplication [68, 72], compression, encryption [63], metering, accounting, billing, and throttling [36, 46, 54] of guest I/O activities.

In addition, such hardware techniques enabling only the specific in-storage features significantly limit their portability and fungibility in modern datacenters. Furthermore, their fixed and vendor-specific storage functionalities do not provide enough flexibility to support advanced VM management. It is still challenging to provide flexibility and high performance at the same time with the current hardware-assisted virtualization schemes.

4 FVM Design and Implementation

This section introduces the design goals for fast, scalable, and flexible storage virtualization, and proposes our FVM solution to satisfy the goals. We describe our solution by presenting (1) a front-end implementation that emulates virtual devices and (2) a back-end implementation that directly manages physical devices.

4.1 Design Goals

We set the following design goals to resolve the challenges in modern storage virtualization: (1) A next-generation virtualization mechanism should ensure the near-native performance of NVMe storage devices. (2) It should minimize the amount of host resources used for virtualization so that a host machine can provide more computing power to VMs. (3) At the same time, it should nicely scale with the number of storage devices. (4) A physical storage device should be shared by multiple VMs. (5) It should not rely on hard-wired units to enable flexible and essential management functionalities, as summarized in Table 2. For example, software-based virtualization can implement flexible VM management features, while SR-IOV makes it hard for system administrators to guarantee accurate feature behaviors as in-SSD resource allocation and scheduling are done in a vendor-specific way.

Category	Features	SW	SR-IOV	FVM

4.2 FPGA-assisted Storage Virtualization

To meet the design goals, we propose FVM, a new hardware-assisted storage virtualization mechanism. The key idea of FVM is to implement *FVM-engine*, an FPGA-based virtualization acceleration card. We implement a storage virtualization layer and a device-control mechanism on FVM-engine.

In contrast to on-device SoC cores, an FPGA can be configured only with essential elements for storage virtualization and can take advantage of highly parallel NVMe protocols. Our FPGA-based solution can implement many cost-effective cores, and distribute virtual and physical NVMe queues and management routines to the cores. In this way, our solution achieves fine-grained parallel executions and scalable performance. In addition, our solution uses an FPGA’s on-chip memory for SQ/CQ pairs and doorbell registers, which can be fast and directly accessed by VMs and NVMe devices through PCIe.

Another advantage of our FPGA-based solution is its programmability to implement new VM management features. Our FPGA-based solution has the potential of the hardware-based virtualization to solve the performance and efficiency challenges, while allowing to implement various VM management functionalities with its reconfigurability. In this work, we propose an FPGA-based virtualization layer, but it is also possible to implement the mechanism on ASICs. In such a case, an ASIC implementation can achieve higher performance by leveraging its optimized circuits for virtualization functions, but its flexibility for new storage management features will be limited.

Figure 7 shows the FVM architecture and its components. First, FVM bypasses host software stacks entirely and minimizes the use of host resources. Through the SR-IOV implementation on FVM-engine, VMs can enter a virtualization layer without any arbitration support from the host software. Moreover, its hardware-level NVMe interface makes the card directly manage the physical NVMe devices through PCIe.

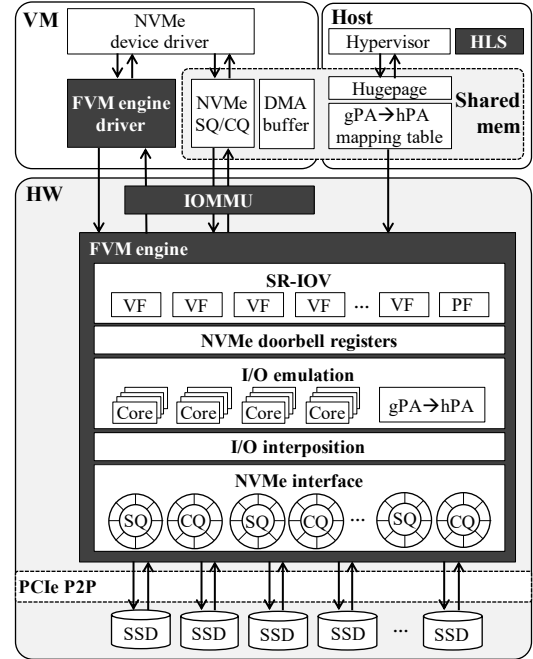

Figure 7: FVM architecture

Second, FVM is able to scale with many NVM devices by employing a parallel architecture for the device emulation. Instead of relying on on-device SoC cores, FVM-engine incorporates many specialized hardware units to poll and emulate guest I/O operations. Third, its HLS-based design flow enables flexible and programmable implementations for FVM-engine and other storage management services.

4.3 Front-end: VM-to-FVM-Engine

Direct FVM-engine assignment. FVM assigns virtual instances of FVM-engine to each VM through its SR-IOV interface. The current FVM-engine implementation integrates a PCIe IP block [28] to enable its own SR-IOV interface and supports up to four physical functions (PFs) and 252 virtual functions (VFs). The PFs are managed by host software for resource management, and each VF is assigned to a single VM exclusively for direct access to FVM-engine. Since all VFs have an identical PCIe configuration (e.g., PCIe BAR), VMs can install the same guest FVM-engine driver. FVM-engine also successfully isolates MMIO from different VMs by applying *non-overlapping* address translation to its internal address space (e.g., PCIe-to-AXI address translation [28]). At the same time, with the IOMMU support, FVM-engine can perform DMA transactions to guest memory space and inject an interrupt without a host software arbitration. To enable such *exitless* DMA transactions and interrupts, we install Linux *virtual function I/O* (VFIO) drivers in the host machine.

There are three major benefits of providing SR-IOV in FVM-engine. First, this design enables CPU-efficient virtual device emulation. All VMs can directly enter this hardware

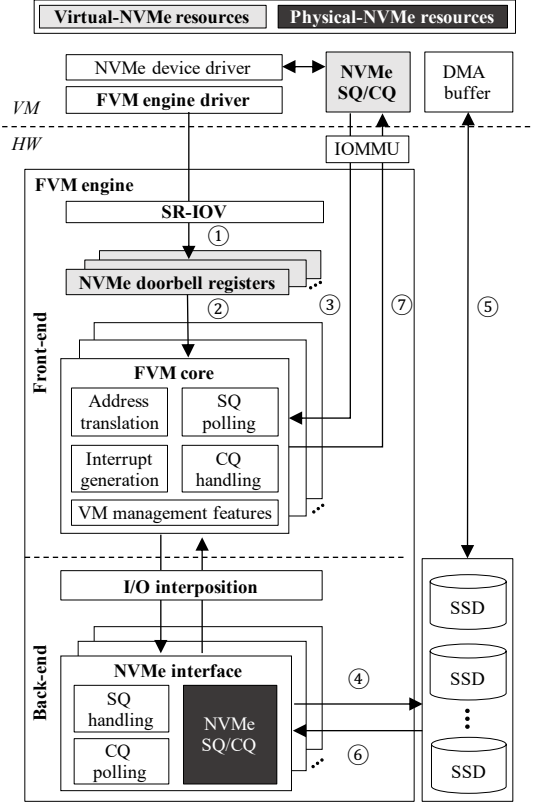

Figure 8: Hardware-level device emulation mechanism

interposition layer and handle interrupts without host software intervention. Second, it allows multiple VMs to share FVM-engine through 252 VFs. Using this interposition layer, FVM-engine can map virtual devices onto a much smaller set of physical NVMe devices. Third, it does not rely on fixed or vendor-specific storage capabilities. By simply deploying FVM-engine, any host machine can benefit from this virtualization mechanism.

Doorbell register remapping. FVM-engine reserves a memory space for NVMe doorbell registers and exposes it through PCIe BARs. When guest NVMe device drivers call `nvme_write_sq_db()` to submit I/O requests, the guest FVM-engine driver intercepts them and obtains their (*virtual*) device id, SQ id, and SQ tail information. The guest FVM-engine driver then calculates the address of the target doorbell register and writes the received SQ tail pointer to FVM-engine (Figure 8–①). In this way, the guest OS can indicate new NVMe commands to be executed. Similarly, to notice that the command completions are normally handled, FVM-engine driver intercepts `nvme_process_cq()` function and acquires (*virtual*) device id, CQ id, and CQ head information. It then writes the received CQ head pointer to the target address in the FVM-engine doorbell regions.

Virtual I/O queue emulation. To process a guest I/O request at the hardware layer, FVM-engine polls doorbell registers using multiple FVM cores (Figure 8–②). Algorithm 1 demon-

Algorithm 1: Polling function in the front-end for I/O submission

```

1 fvm_nvme_submit (devicesvirtual);
2 while true do
   /* Iterate over the assigned virtual devices and their SQs */
3   foreach vdev  $\in$  devicesvirtual do
4     foreach sq  $\in$  available_sqs(vdev) do
       /* Poll the doorbell registers mapped in FVM-engine */
5       tail = get_tail(sq)
       /* Find newly added NVMe commands from the guest OS */
6       head = get_head(sq)
       while tail  $\neq$  head do
7         cmd = get_cmd(sq, head)
8         cmd = manipulate_cmd(cmd)
9         submit_cmd(cmd)
10        head = (head + 1) % SQ_SIZE
11      end
12      set_head(sq, head)
13    end
14  end
15 end
16 end

```

strates its polling routine to emulate virtual NVMe devices. First, the FVM core gets the newly updated SQ tail (line 5) and compares it with the SQ head that stores the previous tail value (line 6). The difference between these two values indicates the number of commands that are submitted by the guest OS. Since FVM-engine reserves its doorbell memory regions using on-chip memory (e.g., BRAM [29]), it can quickly poll those regions. This design can easily scale up the number of VMs as modern FPGAs currently support tens of MBs on-chip memory [23].

To enable FVM-engine to access a submission queue in the guest memory space, we utilize an internal DMA engine [28] and an IOMMU. When VMs install guest NVMe drivers, they deliver SQ/CQ gPAs to FVM-engine. FVM cores then use these addresses to directly read the submitted commands through the DMA engine (Figure 8–③). Since FVM guarantees exitless DMA transactions with an IOMMU and VFIO drivers, each virtual instance of FVM-engine can safely access target SQ/CQ pairs allocated in the guest memory space without software intervention.

Similarly, to deliver NVMe completion entries to a VM, FVM-engine directly writes the completion messages to the guest CQ memory region (Figure 8–⑦). In addition, it triggers an interrupt to the guest directly through the interrupt remapping engine. The FVM-engine driver then forwards the interrupt with an associated IRQ vector to the NVMe driver and allows it to handle the received completions.

PRP and LBA translation. FVM-engine processes the received NVMe commands from VMs before submitting them

to physical NVMe devices. Specifically, FVM-engine manipulates *physical region page* (PRP) entries (pointing guest DMA buffers) from gPAs to hPAs. To enable such gPA-to-hPA translation at the hardware level, FVM leverages *hugepages* to allocate pinned memory [4, 20]. Since the current operating system does not change their physical locations, FVM-engine can statically translate PRP entries by incorporating the gPA-to-hPA mapping table. The translation does not incur any performance overhead in this design as FVM-engine manages the mapping table using its on-chip memory. Also, due to the hugepages (2MB), the required table size is small enough to keep them in the on-chip memory (i.e., 4KB table to cover 1GB guest memory space).

In addition, FVM-engine needs to manipulate a *start logical block address* (SLBA) to allocate separate block regions of physical devices to VMs. Since the current implementation of FVM assumes a *static* partition, the SLBA in guest NVMe command can be simply modified by applying a different offset value, which is managed by host software.

Virtual admin queue emulation. FVM manages a virtual NVMe *admin* SQ/CQ pair through QEMU and SPDK vhost-target implementations. Since QEMU and KVM can track VM exits caused by MMIO on administration doorbell registers, they are still able to interact with SPDK vhost-target via a UNIX domain socket. QEMU delivers critical administration commands (e.g., I/O queue creation, deletion, shutdown) to the SPDK vhost-target implementation following the conventional vhost-target protocol.

4.4 Back-end: FVM-Engine-to-SSD

Physical SQ/CQ remapping. To allow FVM-engine to interact with physical NVMe devices directly, host software remaps their NVMe I/O queues onto FVM-engine's PCIe BAR regions. At the installation time, the host FVM-engine driver provides the memory-mapped region's address to the physical NVMe devices. The NVM devices are unaware of FVM-engine, but a PCIe switch delivers DMA transactions to FVM-engine seamlessly. Also, our experimental result demonstrates that FVM-engine can fully utilize a single Intel Optane SSD with eight SQ/CQ pairs (4KB each queue). Thus, FVM-engine can nicely scale with a large number of physical devices and VMs without any on-chip memory space issue for these remapped queues.

Direct NVMe device-control mechanism. FVM-engine incorporates standard NVMe interfaces to implement a direct device-control mechanism. (1) FVM-engine moves the NVMe commands to the submission queue in the FVM-engine on-chip memory. (2) FVM-engine then rings doorbell registers located in the NVMe device to notify the number of newly submitted commands. (3) The NVMe controller fetches the NVMe commands through PCIe P2P communications (Figure 8–④). (4) After the NVMe device processes the commands (Figure 8–⑤), it writes the command completions

to the FVM-engine address space (Figure 8–⑥). (5) FVM-engine processes them and (6) rings doorbell registers located in the NVMe device.

Polling CQs. To immediately handle completions from physical devices, an NVMe interface polls its CQ memory space. Algorithm 2 shows its polling function. First, the NVMe interface handles a CQ entry pointed by its *head* pointer (line 7) and compares its *phase* bit with the current round (line 9). This enables the NVMe interface to determine whether a new entry was posted as a part of the previous or current round of completion notifications. After that, it processes the completion entries (line 10) and forwards them to the front-end (line 11). The FVM core then writes completion messages to the guest CQ memory space. Since FVM-engine manages all SQ/CQ pairs using the on-chip memory, its polling routine does not incur any performance overhead.

Algorithm 2: Polling function in the back-end for I/O completion

```

1 fvm_nvme_complete (devicesphysical);
2 while true do
3     /* Iterate over the assigned physical
4        devices and their CQs */
5     foreach pdev ∈ devicesphysical do
6         foreach cq ∈ available_cqs(pdev) do
7             head = get_head(cq)
8             cq_phase = get_cq_phase(cq)
9             /* Poll the completion entries mapped
10                in FVM-engine */
11             cpl = get_cpl(cq, head)
12             cpl_phase = get_cpl_phase(cpl)
13             /* Find newly added NVMe completions
14                from the physical device */
15             while cpl_phase == cq_phase do
16                 cpl = manipulate_cpl(cpl)
17                 forward_cpl(cpl)
18                 head = (head + 1) % CQ_SIZE
19                 if head == 0 then
20                     cq_phase = invert_phase(cq_phase)
21                 end
22                 cpl = get_cpl(cq, head)
23                 cpl_phase = get_cpl_phase(cpl)
24             end
25             set_head(cq, head)
26             set_cq_phase(cq, cq_phase)
27         end
28     end
29 end

```

4.5 FVM Core Design

FVM maximizes the opportunities of its hardware-level virtualization mechanism by instantiating multiple FVM cores to poll and emulate guest I/O. This design choice can offer more

Figure 9: Performance comparison of different virtualization processing core implementations

Figure 10: Multiple FVM cores with crossbar interconnect

scalable performance than an on-device SoC core as it replaces the general-purpose sidecores with the customized hardware units. By doing so, FVM can address the performance bottleneck in the processing cores. Figure 9 shows the performance difference between *single-core* SoC and *single-FVM core* implementations. To measure the performance bottleneck on the SoC cores, we implemented runtime software on Microblaze softcores [24] and ran FIO random read benchmarks with the increasing number of threads. We projected this performance result for the higher clock speed (400 MHz) to fairly compare it with our FVM core implementation running at the same clock frequency. Our experimental result demonstrates that the current FVM core implementation achieves $8\times$ higher throughput than the softcore implementations.

Figure 10 shows an example system architecture using multiple FVM cores for storage virtualization. First, to reduce the burden on users in building and integrating system functions required for interacting between VMs and NVMe devices, we separate the virtualization logic (storage service) from the common I/O (BRAM, crossbar) and the board-specific logic (DRAM, PCIe). Second, by interconnecting them with crossbars, FVM-engine can be extended to support a multi-core

Figure 11: Multi-VM and multi-SSD support with FVM cores

Designs	LUTs	Registers	BRAMs	Clock speed
1 core	4682 (0.36%)	7528 (0.29%)	5.5 (0.29%)	400 MHz
1 VM - 6 cores (5 SSDs)	106809 (8.19%)	130064 (4.99%)	362.5 (17.98%)	400 MHz
4 VMs - 6 cores (4 SSDs)	103539 (7.94%)	131394 (5.04%)	359.5 (17.83%)	400 MHz
4 VMs - 2 cores (1 SSD)	80259 (6.16%)	93997 (3.61%)	321.5 (15.95%)	400 MHz

Table 3: FPGA resource utilization for different FVM configurations

design. Our crossbar interconnection can have 16 input/output ports and can be connected with other switches for higher scalability. As each crossbar switch takes tens of nanoseconds, the overall switching latency is negligible compared to modern SSD’s microsecond-scale access latency.

In addition, FVM-engine can be configured to support various FVM core mapping strategies. For example, Figure 11 shows two different mapping strategies. Figure 11a demonstrates that a single FVM core is shared by multiple VMs, while it is dedicated to a single NVMe device. This design can easily cover an increasing number of VMs. On the other hand, Figure 11b shows that an FVM core is dedicated to a single VM, while it covers multiple physical NVMe devices. With this mapping strategy, we can allocate more virtualization resources to more performance-critical VMs.

As Table 3 shows, FVM can cost-effectively scale with multiple FVM cores without sacrificing its clock speed. We implemented three different FVM configurations depending on the number of VMs and SSDs that can be supported. The 1-VM and 6-FVM-core implementation supports five NVMe SSDs and utilizes 8.19% LUTs, 4.99% registers, and 17.98% BRAMs in the FPGA chip. Also, its light resource usage ($< 0.5\%$ for a single FVM core) provides opportunities to utilize the remaining resources to implement more FVM cores, and/or deploy much cheaper FPGA boards to minimize the FPGA costs. In addition, FPGAs and FVM cores can be more easily added/upgraded on servers, which provides higher scalability using expandable slots than CPU cores requiring extra sockets.

4.6 HLS

FVM enables flexible and easily programmable implementations through its high-level synthesis (HLS)-based design flow. Modern HLS supports high-level languages and has become a standard hardware design flow for FPGAs. Our HLS-based FVM implementation allows users to extend their designs easily.

In this work, we implemented five different storage functions on FVM-engine. First, we implemented device sharing, which allows multiple VMs to share a single NVMe device. Second, we designed a token-based throttling mechanism to effectively manage guest I/O operations. Third, we implemented replication to achieve fault tolerance. Fourth, we

Figure 12: FVM hardware prototype

implemented server-side caching to accelerate storage accesses from VMs. Fifth, we designed direct copying in which a guest OS moves data between two different storage devices using FVM-engine. For this purpose, the VM utilizes FVM-engine’s internal memory space as an intermediate buffer, while bypassing the entire software stacks.

5 Evaluation

In this section, we evaluate our FVM implementation and compare its random I/O and RocksDB performance with other storage virtualization schemes. We also present five example VM management features implemented through our HLS-based design flow.

5.1 Experimental Setup

To evaluate FVM, we ran FIO [5] random I/O benchmarks and RocksDB [16] workloads on VMs. We evaluated our FVM implementation against its native execution and existing virtualization mechanisms including SPDK vhost-nvme v20.01 [21] (configured with the option `-with-internal-vhost-lib`) and *passthrough*. Since the passthrough technique avoids most of the virtualization software stack and directly assigns the device to the VM, it can provide the near-native execution performance. As FVM’s use cases, we also implemented five different storage services (device sharing, throttling, replication, caching, and direct copy) based on our HLS-based design flow, and validated them with respect to the software reference implementations.

Figure 12 shows our hardware FVM prototype. We built this prototype on a host machine (Super Micro SuperServer 4029GP-TRT2) with two 12-core Intel Xeon Gold 5118 CPUs running at 2.3GHz, 256GB DDR4 DRAM, and five 480GB Intel Optane 900P NVMe SSDs. The Optane SSD (based on the 3D XPoint NVM technology) can support up to 550k IOPS in random-read and 500k IOPS in random-write with 10 μ s latency [7]. We implemented FVM-engine on a Xilinx Alveo U280 Data Center Accelerator Card using Vivado and Vivado HLS v2019.2 EDA tools. We configured the PCIe

Figure 13: Random I/O throughput with two NVMe SSDs

IP block to meet the PCIe Gen3 x4 specification and connected it with other NVMe SSDs through PCIe Gen3 x16 lanes. For accurate performance measurements, we disabled hyperthreading and dynamic voltage and frequency scaling (DVFS).

On the software side, we installed 64-bit Ubuntu 18.04 with the Linux kernel version 5.3.0 and QEMU emulator version 3.0.0 on the host machine. We installed the same OS and Linux kernel versions on VMs, and implemented an FVM-engine Linux device driver. We modified an SPDK vhost-target implementation and applied FVM to an existing QEMU/KVM virtualization system.

5.2 Performance

5.2.1 Random I/O Benchmark

To evaluate the random I/O performance, we ran FIO with two SSDs and measured (1) the maximum achievable throughput, (2) latency, and (3) CPU utilization. For passthrough and FVM, we allocated four CPU cores and 1GB system memory per VM. To show the performance impact due to the lack of host resources in vhost-nvme, we allocated one CPU core for the vhost-nvme virtualization layer and three cores for the VM.

Figure 13 shows the relative throughput of 4KB random read, write and read/write (50% of read and write each) for native, SPDK vhost-nvme, passthrough, and FVM. For all three random I/O benchmarks, passthrough and FVM can achieve about 79% (2.65GB/s on average) of native performance (3.36GB/s on average). However, SPDK vhost-nvme achieves about 58% (1.95GB/s on average) due to the CPU resource competition between VMs and the vhost-nvme virtualization layer.

In this experiment, we observed that other virtualization overheads still prevent even the passthrough and FVM from achieving the full native performance. First, passthrough and FVM include VM exits caused by MSR_WRITE and HLT instructions to manage timer interrupts and to yield CPU resources to a host machine. Second, they involve IOMMU’s address translation to transfer data to and from NVMe storage directly (passthrough) or to manage guest OSes’ SQ/CQ pairs from FVM-engine (FVM). There have been efforts to mini-

Figure 14: Random I/O latency with two NVMe SSDs

Figure 15: RocksDB throughput with FVM (normalized to SPDK vhost-nvme)

mize the overheads [34, 57]. In this work, we do not address the overhead as they are orthogonal to our work.

In addition, we can see that FVM performs better than passthrough in some cases. Our current FVM-engine implementation aggregates completions from those two SSDs and delivers the smaller number of interrupts to the VM, which provides more CPU resources to random I/O operations.

Figure 14 shows the average latency normalized to that of the native execution for the FIO experiments. For all three workloads, FVM outperforms vhost-nvme and passthrough thanks to the fast FVM core design and the direct device-control mechanism through PCIe P2P communications.

5.2.2 RocksDB

To evaluate a server workload on FVM, we ran RocksDB [16] on the EXT4 file system and YCSB [38] to generate workloads. We configured YCSB to generate the workloads as follows: (A) 50% of read and write each, (B) 95% of read and 5% of write, (C) read-only, (D) read-latest (most reads access the last write), (E) short-ranges (most reads access recent writes), and (F) read-modify-writes. We scaled up RocksDB’s recordcount and operationcount parameters to highlight its I/O activities.

For SPDK vhost-nvme, we considered various CPU allocation scenarios and increased the portion of dedicated sidecores up to 50% to emulate future high-performance NVMe devices. For this purpose, we assigned 1 – 4 CPU cores (out of 4 or 8) for SPDK vhost-target and the remaining CPU cores for the VM. For FVM, we assigned four or eight CPU cores for the VM.

Figure 16: I/O throughput with multiple SSDs

Figure 17: Multi-VM throughput with multiple SSDs

Figure 15 shows the operation throughput of FVM, normalized to that of SPDK vhost-nvme. Since FVM saves host CPU resources to provide more computing power to VMs, it obtains $1.20\times$ (average) higher and $1.33\times$ (maximum) higher throughput than vhost-nvme with four CPU cores. On the other hand, with eight total CPU cores, FVM achieves $1.15\times$ (average) higher and $1.71\times$ (maximum) higher throughput than vhost-nvme. With these trends, FVM will become more promising as the storage devices get faster in future.

5.3 Scalability

For the scalability test, we installed one VM with 18 CPU cores to fully utilize five NVMe SSDs and measured the aggregate throughput. For vhost-nvme, we assigned four cores to SPDK vhost-target and 14 cores to the VM. Figure 16 shows the total throughput that a single VM can achieve with the given number of SSDs. As the number of SSDs increases, both passthrough and FVM scale nicely, while vhost-nvme does not scale well due to its excessive CPU usage to emulate the guest I/O operations in the hypervisor.

When the VM utilizes more than four SSDs, FVM’s total throughput is 7% lower compared to that of passthrough. Because the current PCIe IP core [25] supports only eight interrupt vectors per VF, the FVM-engine device driver installed in the guest OS should make the interrupt vectors shared by many SQ/CQ pairs and look up multiple CQs to identify completion messages.

Next, we assigned four CPU cores and one SSD to each VM and ran four VMs concurrently. For vhost-nvme, we assigned one CPU core to SPDK vhost-target and three cores to the VM. Figure 17 shows the total achievable throughput of each virtualization implementation as the number of VMs increases. The results show that FVM scales well as the number of VM increases. With four VMs, FVM achieves up to 9.5

Figure 18: Device sharing with balanced allocation

Figure 19: SSD throughput trace with token-based throttling

GB/s by processing on FVM-engine. However, vhost-nvme fails to achieve the full native throughput, due to its software overhead.

5.4 Programming Example Functions

To evaluate FVM’s flexibility, we implemented five example storage functions in FVM’s hardware-level virtualization layer: (1) device sharing, (2) throttling, (3) replication, (4) caching, and (5) direct copy. To implement these functions, we added and modified only 10s-100s of C++ code lines (i.e., device sharing: 40 LOC, throttling: 70 LOC, replication: 15 LOC, caching: 220 LOC, direct copy: 570 LOC).

Device sharing. To implement the device sharing functionality, we mapped multiple virtual I/O queue pairs from different VMs to a single physical NVMe queue pair (similar to SPDK vhost-nvme implementations). To correctly arbitrate completion messages from the physical device, we made an additional data structure to keep track of the virtual device identifications of the submitted NVMe commands which requires 64 bytes for each physical I/O queue. We also deployed a round-robin method between virtual I/O queues as the vhost-nvme implementation does. Figure 18 shows the FIO throughput results of FVM when running multiple VMs on a single NVMe SSD. FVM achieves the perfectly balanced throughput allocation among VMs without any performance loss.

Throttling. We implemented a token-based throttling algorithm on FVM, which can limit the bandwidth with periodically refilled tokens and a bucket which can save a certain amount of tokens. The FVM-engine driver configures the period of `refill_token` signal, the amount of tokens to be refilled in a period, and the size of the bucket. An FVM core periodically polls the `refill_token` signal and filters every command by checking the size of the request and the amount of remaining tokens. If the command is issued, a proper amount of tokens are removed from the bucket. Fig-

(a) Replication - write

(b) Cache - read

Figure 20: Tail latency of replication and caching

ure 19 shows the aggregate bandwidth within a time interval of the FIO benchmark while throttling the I/O operations on FVM-engine. We configured the FIO benchmark to achieve the maximum bandwidth of an SSD (2GB/s), and we throttled the I/O from 100MB/s to 400MB/s. The figure shows that the bandwidth is stable and limited as configured.

Replication. By seamlessly replicating I/O operations from VMs, a server with FVM-engine can achieve fault tolerance. To enable this feature, we assigned multiple physical NVMe SSDs to a single virtual storage device. When an FVM core receives a write command from a VM, it replicates the commands and broadcasts them to the physical devices. The FVM core then waits for completion messages from all physical storage devices assigned to the virtual device before sending corresponding completions to the target VM. Figure 20a shows its tail latency results of 4KB random writes through FVM. As an FVM core should replicate NVMe commands and wait completions from all the NVMe SSDs, the replication feature adds the extra latency compared to the baseline FVM implementation.

Caching. To enable caching, we implemented a hash table that has 256k entries in the FPGA’s 4MB on-chip memory space. Each table entry contains a start logical block address (SLBA) and a corresponding cached block address (CBA). If an FVM core finds a valid entry in the hash table, it replaces the received SLBAs with CBAs and submits them to the NVMe devices. We measured the tail latency of 4KB random reads with FVM and its caching mechanism, while emulating a perfect cache hit ratio. Figure 20b shows that the caching mechanism increases the tail latency due to the increased number of contentions on FVM-engine’s interconnection resources for the hash table accesses.

Direct copy. FVM can enable a direct device-to-device (D2D) data copy feature, while bypassing the host CPU and memory. Using the feature, a server with FVM-engine can perform intra-VM or inter-VM data transfers efficiently. We implemented a direct-copy feature on FVM leveraging its hardware-based device-control mechanism. When FVM-engine receives a request, it splits the bulk data transfer into multiple smaller-sized requests. It then generates NVMe commands for each

Figure 21: Resource usage of direct copying

split request and submits them using FVM-engine’s NVMe interface. To bypass the host memory, the NVMe commands utilize the FPGA’s on-chip memory as an intermediate data buffer. Figure 21 shows the CPU usage, host memory bandwidth, and PCIe root complex (RC) bandwidth usage while performing a 32GB inter-SSD bulk data transfer. This figure shows that the data transfer controlled by FVM provides high bandwidth without consuming the host resources.

6 Discussion

Cost analysis. FVM can be used for the cost saving, as it minimizes the number of the required CPUs and servers for the target storage virtualization. For example, for a server with 24 NVMe devices, FVM can reduce the CPU core usage by up to 30% (i.e., saving 20 cores in a 64-core machine). Based on the current prices on major online stores (e.g., Amazon) and vendor websites, FVM can save \$2000–\$6400 (\$100–\$320 per core [9, 10]) for 64-core machines. If we consider the trend of increasing the number and performance of storage devices per server, the cost saving will be even more significant. In addition, as our wimpy FVM core uses very small FPGA resources (< 0.5%), we can implement FVM on the cost-effective FPGA boards (e.g., \$3000 for Alveo U50 [3], \$1500–\$3500 for evaluation boards).

FVM-engine scalability. The scalability bottleneck can occur if an FPGA is short of resources and/or communication takes too long. On our FPGA, we can implement around 140 wimpy FVM cores (0.5% per FVM core) including multi-level crossbar networks (2.5% per crossbar module) and hundreds of SQ/CQ pairs (5KB per pair). Our crossbar switch can have 16 input/output ports and can be connected with other switches. As each crossbar switch takes 24 ns (6 cycles, 250MHz), the overall switching latency is negligible compared to modern SSD’s tens of microsecond access latency.

Supporting other storage protocols. One of the biggest benefits of using programmable FPGAs is to provide various storage protocols as needed. The FPGA-based virtualization layer can easily implement a new interface to activate advanced features in modern storage devices. For example, it can easily support standardized key-value store (KV) acceleration extensions [43] by reprogramming the FPGA according to their

interface specifications.

7 Related Work

NVMe virtualization. NVMe virtualization requires a special mechanism to make full use of its parallel and high-performance storage protocol. SPDK [20] is a user-space library for high-performance and scalable storage applications. It integrates all the necessary drivers into the user space to avoid system calls and enable zero-copy access from the applications. In addition, it adopts polling to monitor I/O completions instead of relying on interrupts. Specifically, SPDK vhost-nvme [69] extends the SPDK library to provide virtual NVMe controllers to QEMU-based VMs. Similarly, MDev-NVMe [59] provides a mediated passthrough mechanism in kernel space with an active polling mode.

Direct device-control mechanism. A direct device-control mechanism at the hardware level provides fast and resource-efficient I/O paths. For example, device-centric server (DCS) and its direct device-control method [32, 49] implement a device orchestration scheme on an FPGA to enable fast device-to-device direct data communications. In this way, DCS can enable hardware-offloaded direct data transfers between NVMe SSDs and network adapters through PCIe P2P. As another example, GPUDirect Async [31] enables a direct data transfer between GPUs and NICs to free CPUs from the control path, while moving data between GPUs and NICs. Lynx [64] offloads the server data and control planes to a SmartNIC, and enables direct networking from accelerators via a lightweight hardware-friendly I/O mechanism. It enables to develop hardware-accelerated network servers which do not require much CPU involvement.

8 Conclusion

In this work, we present FVM, a new hardware-assisted storage virtualization mechanism. The key idea is to implement (1) a storage virtualization layer on an FPGA card (FVM-engine) decoupled from the host resources and (2) a device-control method to have the card directly manage the physical storage devices. In this way, a server equipped with FVM-engine achieves high performance, scalability, and flexibility by saving the invaluable host-side resources and by adding the decoupled VM management-efficient FPGA cards as needed.

Abstract

FPGA accelerators on the NIC enable the offloading of expensive packet processing tasks from the CPU. However, FPGAs have limited resources that may need to be shared among diverse applications, and programming them is difficult.

We present a solution to run Linux's eXpress Data Path programs written in eBPF on FPGAs, using only a fraction of the available hardware resources while matching the performance of high-end CPUs. The iterative execution model of eBPF is not a good fit for FPGA accelerators. Nonetheless, we show that many of the instructions of an eBPF program can be compressed, parallelized or completely removed, when targeting a purpose-built FPGA executor, thereby significantly improving performance. We leverage that to design hXDP, which includes (i) an optimizing-compiler that parallelizes and translates eBPF bytecode to an extended eBPF Instruction-set Architecture defined by us; a (ii) soft-CPU to execute such instructions on FPGA; and (iii) an FPGA-based infrastructure to provide XDP's maps and helper functions as defined within the Linux kernel.

We implement hXDP on an FPGA NIC and evaluate it running real-world unmodified eBPF programs. Our implementation is clocked at 156.25MHz, uses about 15% of the FPGA resources, and can run dynamically loaded programs. Despite these modest requirements, it achieves the packet processing throughput of a high-end CPU core and provides a 10x lower packet forwarding latency.

1 Introduction

FPGA-based NICs have recently emerged as a valid option to offload CPUs from packet processing tasks, due to their good performance and re-programmability. Compared to other NIC-based accelerators, such as network processing ASICs [8] or many-core System-on-Chip SmartNICs [40], FPGA NICs provide the additional benefit of supporting diverse accelerators for a wider set of applications [42], thanks to their embedded hardware re-programmability. Notably, Microsoft has been

advocating for the introduction of FPGA NICs, because of their ability to use the FPGAs also for tasks such as machine learning [13, 14]. FPGA NICs play another important role in 5G telecommunication networks, where they are used for the acceleration of radio access network functions [11, 28, 39, 58]. In these deployments, the FPGAs could host multiple functions to provide higher levels of infrastructure consolidation, since physical space availability may be limited. For instance, this is the case in smart cities [55], 5G local deployments, e.g., in factories [44, 47], and for edge computing in general [6, 30]. Nonetheless, programming FPGAs is difficult, often requiring the establishment of a dedicated team composed of hardware specialists [18], which interacts with software and operating system developers to integrate the offloading solution with the system. Furthermore, previous work that simplifies network functions programming on FPGAs assumes that a large share of the FPGA is dedicated to packet processing [1, 45, 56], reducing the ability to share the FPGA with other accelerators.

In this paper, our goal is to provide a more general and easy-to-use solution to program packet processing on FPGA NICs, using little FPGA resources, while seamlessly integrating with existing operating systems. We build towards this goal by presenting hXDP, a set of technologies that enables the efficient execution of the Linux's eXpress Data Path (XDP) [27] on FPGA. XDP leverages the eBPF technology to provide secure programmable packet processing within the Linux kernel, and it is widely used by the Linux's community in productive environments. hXDP provides full XDP support, allowing users to dynamically load and run their unmodified XDP programs on the FPGA.

The eBPF technology is originally designed for sequential execution on a high-performance RISC-like register machine, which makes it challenging to run XDP programs effectively on FPGA. That is, eBPF is designed for server CPUs with high clock frequency and the ability to execute many of the sequential eBPF instructions per second. Instead, FPGAs favor a widely parallel execution model with clock frequencies that are 5-10x lower than those of high-end CPUs. As such, a straightforward implementation of the eBPF iterative exe-

cution model on FPGA is likely to provide low packet forwarding performance. Furthermore, the hXDP design should implement arbitrary XDP programs while using little hardware resources, in order to keep FPGA's resources free for other accelerators.

We address the challenge performing a detailed analysis of the eBPF Instruction Set Architecture (ISA) and of the existing XDP programs, to reveal and take advantage of opportunities for optimization. First, we identify eBPF instructions that can be safely removed, when not running in the Linux kernel context. For instance, we remove data boundary checks and variable zero-ing instructions by providing targeted hardware support. Second, we define extensions to the eBPF ISA to introduce 3-operand instructions, new 6B load/store instructions and a new parametrized program exit instruction. Finally, we leverage eBPF instruction-level parallelism, performing a static analysis of the programs at compile time, which allows us to execute several eBPF instructions in parallel. We design hXDP to implement these optimizations, and to take full advantage of the on-NIC execution environment, e.g., avoiding unnecessary PCIe transfers. Our design includes: (i) a compiler to translate XDP programs' bytecode to the extended hXDP ISA; (ii) a self-contained FPGA IP Core module that implements the extended ISA alongside several other low-level optimizations; (iii) and the toolchain required to dynamically load and interact with XDP programs running on the FPGA NIC.

To evaluate hXDP we provide an open source implementation for the NetFPGA [60]. We test our implementation using the XDP example programs provided by the Linux source code, and using two real-world applications: a simple stateful firewall; and Facebook's Katran load balancer. hXDP can match the packet forwarding throughput of a multi-GHz server CPU core, while providing a much lower forwarding latency. This is achieved despite the low clock frequency of our prototype (156MHz) and using less than 15% of the FPGA resources. In summary, we contribute:

- the design of hXDP including: the hardware design; the companion compiler; and the software toolchain;
- the implementation of a hXDP IP core for the NetFPGA
- a comprehensive evaluation of hXDP when running real-world use cases, comparing it with an x86 Linux server.
- a microbenchmark-based comparison of the hXDP implementation with a Netronome NFP4000 SmartNIC, which provides partial eBPF offloading support.

2 Concept and overview

In this section we discuss hXDP goals, scope and requirements, we provide background information about XDP, and finally we present an overview of the hXDP design.

Figure 1: The hXDP concept. hXDP provides an easy-to-use network accelerator that shares the FPGA NIC resources with other application-specific accelerators.

2.1 Goals and Requirements

Goals Our main goal is to provide the ability to run XDP programs efficiently on FPGA NICs, while using little FPGA's hardware resources (See Figure 1).

A little use of the FPGA resources is especially important, since it enables extra consolidation by packing different application-specific accelerators on the same FPGA.

The choice of supporting XDP is instead motivated by a twofold benefit brought by the technology: it readily enables NIC offloading for already deployed XDP programs; it provides an on-NIC programming model that is already familiar to a large community of Linux programmers. Enabling such a wider access to the technology is important since many of the mentioned edge deployments are not necessarily handled by hyperscale companies. Thus, the companies developing and deploying applications may not have resources to invest in highly specialized and diverse professional teams of developers, while still needing some level of customization to achieve challenging service quality and performance levels. In this sense, hXDP provides a familiar programming model that does not require developers to learn new programming paradigms, such as those introduced by devices that support P4 [7] or FlowBlaze [45].

Non-Goals Unlike previous work targeting FPGA NICs [1, 45, 56], hXDP does not assume the FPGA to be dedicated to network processing tasks. Because of that, hXDP adopts an iterative processing model, which is in stark contrast with the pipelined processing model supported by previous work. The iterative model requires a fixed amount of resources, no matter the complexity of the program being implemented. Instead, in the pipeline model the resource requirement is dependent on the implemented program complexity, since programs are effectively "unrolled" in the FPGA. In fact, hXDP provides dynamic runtime loading of XDP programs, whereas solutions like P4->NetFPGA [56] or FlowBlaze need to often load a new FPGA bitstream when changing application. As such, hXDP is not designed to be faster at processing packets than those designs. Instead, hXDP aims at freeing precious CPU resources, which can then be dedicated to workloads that cannot run elsewhere, while providing similar or better performance than the CPU.

Likewise, hXDP cannot be directly compared to SmartNICs dedicated to network processing. Such NICs' resources

are largely, often exclusively, devoted to network packet processing. Instead, hXDP leverages only a fraction of an FPGA resources to add packet processing with good performance, alongside other application-specific accelerators, which share the same chip's resources.

Finally, hXDP is not providing a transparent offloading solution.¹ While the programming model and the support for XDP are unchanged compared to the Linux implementation, programmers should be aware of which device runs their XDP programs. This is akin to programming for NUMA systems, in which accessing given memory areas may incur additional overheads.

Requirements Given the above discussion, we can derive three high-level requirements for hXDP:

1. it should execute unmodified compiled XDP programs, and support the XDP frameworks' toolchain, e.g., dynamic program loading and userspace access to maps;
2. it should provide packet processing performance at least comparable to that of a high-end CPU core;
3. it should require a small amount of the FPGA's hardware resources.

Before presenting a more detailed description of the hXDP concept, we now give a brief background about XDP.

2.2 XDP Primer

XDP allows programmers to inject programs at the NIC driver level, so that such programs are executed before a network packet is passed to the Linux's network stack. This provides an opportunity to perform custom packet processing at a very early stage of the packet handling, limiting overheads and thus providing high-performance. At the same time, XDP allows programmers to leverage the Linux's kernel, e.g., selecting a subset of packets that should be processed by its network stack, which helps with compatibility and ease of development. XDP is part of the Linux kernel since release 4.18, and it is widely used in production environments [4, 17, 54]. In most of these use cases, e.g., load balancing [17] and packet filtering [4], a majority of the received network packets is processed entirely within XDP. The production deployments of XDP have also pushed developers to optimize and minimize the XDP overheads, which now appear to be mainly related to the Linux driver model, as thoroughly discussed in [27].

XDP programs are based on the Linux's eBPF technology. eBPF provides an in-kernel virtual machine for the sandboxed execution of small programs within the kernel context. An overview of the eBPF architecture and workflow is provided in Figure 2. In its current version, the eBPF virtual machine has 11 64b registers: *r0* holds the return value from in-kernel functions and programs, *r1* – *r5* are used to store arguments that are passed to in-kernel functions, *r6* – *r9* are registers

¹ Here, previous complementary work may be applied to help the automatic offloading of network processing tasks [43].

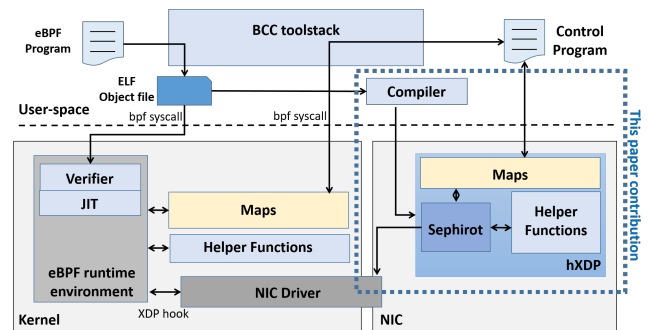

Figure 2: An overview of the XDP workflow and architecture, including the contribution of this paper.

that are preserved during function calls and *r10* stores the frame pointer to access the stack. The eBPF virtual machine has a well-defined ISA composed of more than 100 fixed length instructions (64b). The instructions give access to different functional units, such as ALU32, ALU64, branch and memory. Programmers usually write an eBPF program using the C language with some restrictions, which simplify the static verification of the program. Examples of restrictions include forbidden unbounded cycles, limited stack size, lack of dynamic memory allocation, etc.

To overcome some of these limitations, eBPF programs can use helper functions that implement some common operations, such as checksum computations, and provide access to protected operations, e.g., reading certain kernel memory areas. eBPF programs can also access kernel memory areas called maps, i.e., kernel memory locations that essentially resemble tables. Maps are declared and configured at compile time to implement different data structures, specifying the type, size and an ID. For instance, eBPF programs can use maps to implement arrays and hash tables. An eBPF program can interact with map's locations by means of pointer deference, for un-structured data access, or by invoking specific helper functions for structured data access, e.g., a lookup on a map configured as a hash table. Maps are especially important since they are the only mean to keep state across program executions, and to share information with other eBPF programs and with programs running in user space. In fact, a map can be accessed using its ID by any other running eBPF program and by the control application running in user space. User space programs can load eBPF programs and read/write maps either using the `libbpf` library or frontends such as the BCC toolstack.

XDP programs are compiled using LLVM or GCC, and the generated ELF object file is loaded through the `bpf` syscall, specifying the XDP hook. Before the actual loading of a program, the kernel verifier checks if it is safe, then the program is attached to the hook, at the network driver level. Whenever the network driver receives a packet, it triggers the execution of the registered programs, which starts from a clean context.

2.3 Challenges

To grasp an intuitive understanding of the design challenge involved in supporting XDP on FPGA, we now consider the example of an XDP program that implements a simple stateful firewall for checking the establishment of bi-directional TCP or UDP flows, and to drop flows initiated from an external location. We will use this function as a running example throughout the paper, since despite its simplicity, it is a realistic and widely deployed function.

The simple firewall first performs a parsing of the Ethernet, IP and Transport protocol headers to extract the flow's 5-tuple (IP addresses, port numbers, protocol). Then, depending on the input port of the packet (i.e., external or internal) it either looks up an entry in a hashmap, or creates it. The hashmap key is created using an absolute ordering of the 5 tuple values, so that the two directions of the flow will map to the same hash. Finally, the function forwards the packet if the input port is internal or if the hashmap lookup retrieved an entry, otherwise the packet is dropped. A C program describing this simple firewall function is compiled to 71 eBPF instructions.

We can build a rough idea of the potential best-case speed of this function running on an FPGA-based eBPF executor, assuming that each eBPF instruction requires 1 clock cycle to be executed, that clock cycles are not spent for any other operation, and that the FPGA has a 156MHz clock rate, which is common in FPGA NICs [60]. In such a case, a naive FPGA implementation that implements the sequential eBPF executor would provide a maximum throughput of 2.8 Million packets per second (Mpps).² Notice that this is a very optimistic upper-bound performance, which does not take into account other, often unavoidable, potential sources of overhead, such as memory access, queue management, etc. For comparison, when running on a single core of a high-end server CPU clocked at 3.7GHz, and including also operating system overhead and the PCIe transfer costs, the XDP simple firewall program achieves a throughput of 7.4 Million packets per second (Mpps).³ Since it is often undesired or not possible to increase the FPGA clock rate, e.g., due to power constraints, in the lack of other solutions the FPGA-based executor would be 2-3x slower than the CPU core.

Furthermore, existing solutions to speed-up sequential code execution, e.g., superscalar architectures, are too expensive in terms of hardware resources to be adopted in this case. In fact, in a superscalar architecture the speed-up is achieved leveraging instruction-level parallelism at runtime. However, the complexity of the hardware required to do so grows exponentially with the number of instructions being checked for parallel execution. This rules out re-using general purpose

²I.e., the FPGA can run 156M instructions per second, which divided by the 55 instructions of the program's expected execution path gives a 2.8M program executions per second. Here, notice that the execution path comprises less instructions than the overall program, since not all the program's instructions are executed at runtime due to if-statements.

³Intel Xeon E5-1630v3, Linux kernel v.5.6.4.

soft-core designs, such as those based on RISC-V [22, 25].

2.4 hXDP Overview

hXDP addresses the outlined challenge by taking a software-hardware co-design approach. In particular, hXDP provides both a compiler and the corresponding hardware module. The compiler takes advantage of eBPF ISA optimization opportunities, leveraging hXDP's hardware module features that are introduced to simplify the exploitation of such opportunities. Effectively, we design a new ISA that extends the eBPF ISA, specifically targeting the execution of XDP programs.

The compiler optimizations perform transformations at the eBPF instruction level: remove unnecessary instructions; replace instructions with newly defined more concise instructions; and parallelize instructions execution. All the optimizations are performed at compile-time, moving most of the complexity to the software compiler, thereby reducing the target hardware complexity. We describe the optimizations and the compiler in Section 3. Accordingly, the hXDP hardware module implements an infrastructure to run up to 4 instructions in parallel, implementing a Very Long Instruction Word (VLIW) soft-processor. The VLIW soft-processor does not provide any runtime program optimization, e.g., branch prediction, instruction re-ordering, etc. We rely entirely on the compiler to optimize XDP programs for high-performance execution, thereby freeing the hardware module of complex mechanisms that would use more hardware resources. We describe the hXDP hardware design in Section 4.

Ultimately, the hXDP hardware component is deployed as a self-contained IP core module to the FPGA. The module can be interfaced with other processing modules if needed, or just placed as a bump-in-the-wire between the NIC's port and its PCIe driver towards the host system. The hXDP software toolchain, which includes the compiler, provides all the machinery to use hXDP within a Linux operating system.

From a programmer perspective, a compiled eBPF program could be therefore interchangeably executed in-kernel or on the FPGA, as shown in Figure 2.⁴

3 hXDP Compiler

In this section we describe the hXDP instruction-level optimizations, and the compiler design to implement them.

3.1 Instructions reduction

The eBPF technology is designed to enable execution within the Linux kernel, for which it requires programs to include a number of extra instructions, which are then checked by the kernel's verifier. When targeting a dedicated eBPF executor implemented on FPGA, most such instructions could be

⁴The choice of where to run an XDP program should be explicitly taken by the user, or by an automated control and orchestration system, if available.

Figure 3: Examples of instructions removed by hXDP

Figure 4: Examples of hXDP ISA extensions

safely removed, or they can be replaced by cheaper embedded hardware checks. Two relevant examples are instructions for memory boundary checks and memory zero-ing.

Boundary checks are required by the eBPF verifier to ensure that programs only read valid memory locations, whenever a pointer operation is involved. For instance, this is relevant for accessing the socket buffer containing the packet data, during parsing. Here, a required check is to verify that the packet is large enough to host the expected packet header. As shown in Figure 3, a single check like this may cost 3 instructions, and it is likely that such checks are repeated multiple times. In the simple firewall case, for instance, there are three such checks for the Ethernet, IP and L4 headers. In hXDP we can safely remove these instructions, implementing the check directly in hardware.

Zero-ing is the process of setting a newly created variable to zero, and it is a common operation performed by programmers both for safety and for ensuring correct execution of their programs. A dedicated FPGA executor can provide hard guarantees that all relevant memory areas are zero-ed at program start, therefore making the explicit zero-ing of variables during initialization redundant. In the simple firewall function zero-ing requires 4 instructions, as shown in Figure 3.

3.2 ISA extension

To effectively reduce the number of instructions we define an ISA that enables a more concise description of the program. Here, there are two factors at play to our advantage. First, we can extend the ISA without accounting for constraints related to the need to support efficient Just-In-Time compilation. Second, our eBPF programs are part of XDP applications, and as such we can expect packet processing as the main program task. Leveraging these two facts we define a new ISA that changes in three main ways the original eBPF ISA.

Operands number. The first significant change has to deal with the inclusion of three-operand operations, in place of eBPF’s two-operand ones. Here, we believe that the eBPF’s ISA selection of two-operand operations was mainly dictated

by the assumption that an x86 ISA would be the final compilation target. Instead, using three-operand instructions allows us to implement an operation that would normally need two instructions with just a single instruction, as shown in Figure 4.

Load/store size. The eBPF ISA includes byte-aligned memory load/store operations, with sizes of 1B, 2B, 4B and 8B. While these instructions are effective for most cases, we noticed that during packet processing the use of 6B load/store can reduce the number of instructions in common cases. In fact, 6B is the size of an Ethernet MAC address, which is a commonly accessed field both to check the packet destination or to set a new one. Extending the eBPF ISA with 6B load/store instructions often halves the required instructions.

Parametrized exit. The end of an eBPF program is marked by the exit instruction. In XDP, programs set the *r0* to a value corresponding to the desired forwarding action (e.g., DROP, TX, etc), then, when a program exits the framework checks the *r0* register to finally perform the forwarding action (see listing 4). While this extension of the ISA only saves one (runtime) instruction per program, as we will see in Section 4, it will also enable more significant hardware optimizations.

3.3 Instruction Parallelism

Finally, we explore the opportunity to perform parallel processing of an eBPF program’s instructions. Here, it is important to notice that high-end *superscalar* CPUs are usually capable to execute multiple instructions in parallel, using a number of complex mechanisms such as speculative execution or out-of-order execution. However, on FPGAs the introduction of such mechanisms could incur significant hardware resources overheads. Therefore, we perform only a static analysis of the instruction-level parallelism of eBPF programs.

To determine if two or more instructions can be parallelized, the three Bernstein conditions have to be checked [3]. Simplifying the discussion to the case of two instructions P_1, P_2 :

$$I_1 \cap O_2 = \emptyset; O_1 \cap I_2 = \emptyset; O_2 \cap O_1 = \emptyset; \quad (1)$$

Where I_1, I_2 are the instructions’ input sets (e.g. source operands and memory locations) and O_1, O_2 are their output sets. The first two conditions imply that if any of the two instructions depends on the results of the computation of the other, those two instructions cannot be executed in parallel. The last condition implies that if both instructions are storing the results on the same location, again they cannot be parallelized. Verifying the Bernstein conditions and parallelizing instructions requires the design of a suitable compiler, which we describe next.

3.4 Compiler design

We design a custom compiler to implement the optimizations outlined in this section and to transform XDP programs into

a schedule of parallel instructions that can run with hXDP. The schedule can be visualized as a virtually infinite set of rows, each with multiple available spots, which need to be filled with instructions. The number of spots corresponds to the number of execution lanes of the target executor. The final objective of the compiler is to fit the given XDP program's instructions in the smallest number of rows. To do so, the compiler performs five steps.

Control Flow Graph construction First, the compiler performs a forward scan of the eBPF bytecode to identify the program's *basic blocks*, i.e., sequences of instructions that are always executed together. The compiler identifies the first and last instructions of a block, and the control flow between blocks, by looking at branching instructions and jump destinations. With this information it can finally build the *Control Flow Graph* (CFG), which represents the basic blocks as nodes and the control flow as directed edges connecting them.

Peephole optimizations Second, for each basic block the compiler performs the removal of unnecessary instructions (cf. Section 3.1), and the substitution of groups of eBPF instructions with an equivalent instruction of our extended ISA (cf. Section 3.2).

Data Flow dependencies Third, the compiler discovers *Data Flow dependencies*. This is done by implementing an iterative algorithm to analyze the CFG. The algorithm analyzes each block, building a data structure containing the block's input, output, defined, and used symbols. Here, a symbol is any distinct data value defined (and used) by the program. Once each block has its associated set of symbols, the compiler can use the CFG to compute data flow dependencies between instructions. This information is captured in per-instruction *data dependency graphs* (DDG).

Instruction scheduling Fourth, the compiler uses the CFG and the learned DDGs to define an instruction schedule that meets the first two Bernstein conditions. Here, the compiler takes as input the maximum number of parallel instructions the target hardware can execute, and potential hardware constraints it needs to account for. For example, as we will see in Section 4, the hXDP executor has 4 parallel execution lanes, but helper function calls cannot be parallelized.

To build the instructions schedule, the compiler considers one basic block at a time, in their original order in the CFG. For each block, the compiler assigns the instructions to the current schedule's row, starting from the first instruction in the block and then searching for any other *enabled* instruction. An instruction is enabled for a given row when its data dependencies are met, and when the potential hardware constraints are respected. E.g., an instruction that calls a helper function is not enabled for a row that contains another such instruction. If the compiler cannot find any enabled instruction for the current row, it creates a new row. The algorithm continues until all the block's instructions are assigned to a row.

At this point, the compiler uses the CFG to identify potential candidate blocks whose instructions may be added to

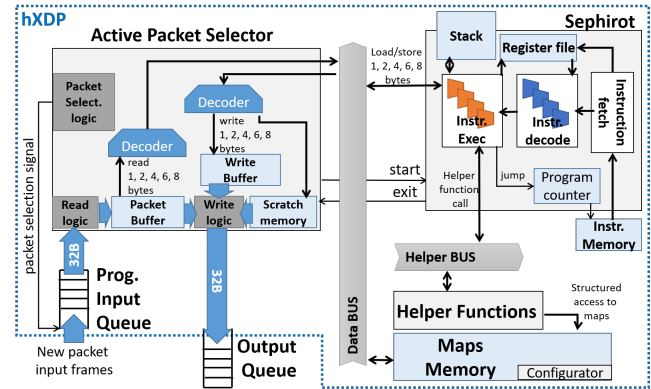

Figure 5: The logic architecture of the hXDP hardware design.

the schedule being built for the current block. That is, such block's instructions may be used to fill gaps in the current schedule's rows. The compiler considers as candidate blocks the current block's *control equivalent blocks*. I.e, those blocks that are surely going to be executed if the current block is executed. Instructions from such blocks are checked and, if enabled, they are added to the currently existing schedule's rows. This allows the compiler to move in the current block's schedule also a series of branching instructions that are immediately following the current block, enabling a *parallel branching* optimization in hardware (cf. Section 4.2).

When the current block's and its candidate blocks' enabled instructions are all assigned, the algorithm moves to the next block with instructions not yet scheduled, re-applying the above steps. The algorithm terminates once all the instructions have been assigned to the schedule.

Physical register assignment Finally, in the last step the compiler assigns physical registers to the program's symbols. First, the compilers assigns registers that have a precise semantic, such as `r0` for the exit code, `r1-r5` for helper function argument passing, and `r10` for the frame pointer. After these fixed assignment, the compiler checks if for every row also the third Bernstein condition is met, otherwise it renames the registers of one of the conflicting instructions, and propagates the renaming on the following dependant instructions.

4 Hardware Module

We design hXDP as an independent IP core, which can be added to a larger FPGA design as needed. Our IP core comprises the elements to execute all the XDP functional blocks on the NIC, including helper functions and maps. This enables the execution of a program entirely on the FPGA NIC and therefore it avoids as much as possible PCIe transfers.

4.1 Architecture and components

The hXDP hardware design includes five components (see Figure 5): the Programmable Input Queue (PIQ); the Ac-

tive Packet Selector (APS); the `Sephirot` processing core; the Helper Functions Module (HF); and the Memory Maps Module (MM). All the modules work in the same clock frequency domain. Incoming data is received by the PIQ. The APS reads a new packet from the PIQ into its internal packet buffer. In doing so, the APS provides a byte-aligned access to the packet data through a *data bus*, which `Sephirot` uses to selectively read/write the packet content. When the APS makes a packet available to the `Sephirot` core, the execution of a loaded eBPF program starts. Instructions are entirely executed within `Sephirot`, using 4 parallel execution lanes, unless they call a helper function or read/write to maps. In such cases, the corresponding modules are accessed using the *helper bus* and the *data bus*, respectively. We detail each component next.

4.1.1 Programmable Input queue

When a packet is received, it enters the Programmable Input Queue (PIQ), which works as an interface with the NIC input bus. Thus, a packet is usually received divided into *frames*, received at each clock cycle. The PIQ holds the packet's frames maintaining a *head frame pointer*. The frames of a given packet can be therefore read from the queue independently from the reception order.

4.1.2 Active Packet Selector

The APS implements a finite-state machine to handle the transfer of a selected packet's frames from the PIQ to an APS' internal buffer.⁵ The internal buffer is large enough to hold a full-sized packet.

While the packet is stored divided in frames, the APS provides a byte-aligned read/write access to the data, as required by the eBPF ISA. I.e., the APS implements an eBPF program's *packet buffer*, and builds the hardware-equivalent of the `xdp_md` struct that is passed as argument to XDP programs. `Sephirot` accesses such data structure using the main `hXDP`'s data bus. Since `Sephirot` has four parallel execution lanes, the APS provides four parallel read/write memory accesses through the data bus.

Storing the packet data in frames simplifies the buffer implementation. Nonetheless, this also makes the writing of specific bytes in the packet more complex. In particular, since only a frame-size number of bytes can be written to the buffer, the writing of single bytes would need to first read the entire frame, apply the single-byte modification, and then re-write to the buffer the entire modified frame. This is a complex operation, which would impact the maximum achievable clock rate if implemented in this way, or it would alternatively require multiple clock cycles to be completed. We instead use a *difference buffer* to handle writes, trading off some memory space

for hardware complexity. That is, modifications to the packet data are stored in a difference buffer that is byte addressed. As we will see next, the difference buffer allows us to separate the reading of certain packet data, which can be pre-fetched by `Sephirot` during the decoding of an instruction, from the actual writing of new data in the packet, which can be performed during packet emission. In fact, the APS contains also a scratch memory to handle modifications to the packet that are applied before the current packet head. This is usually required by applications that use the `bpf_adjust_head` helper.

The scratch memory, the difference buffer, and the packet buffer are combined when `Sephirot` performs a read of the packet data, and at the end of the program execution, during packet emission. Packet emission is the process of moving the modified packet data to the output queue. The entire process is handled by a dedicated finite-state machine, which is started by `Sephirot` when an *exit* instruction is executed. The emission of a packet happens in parallel with the reading of the next packet.

4.1.3 Sephirot

`Sephirot` is a VLIW processor with 4 parallel lanes that execute eBPF instructions. `Sephirot` is designed as a pipeline of four stages: instruction fetch (IF); instruction decode (ID); instruction execute (IE); and commit. A program is stored in a dedicated instruction memory, from which `Sephirot` fetches the instructions in order. The processor has another dedicated memory area to implement the program's stack, which is 512B in size, and 11 64b registers stored in the register file. These memory and register locations match one-to-one the eBPF virtual machine specification. `Sephirot` begins execution when the APS has a new packet ready for processing, and it gives the processor *start* signal.

On processor start (IF stage) a VLIW instruction is read and the 4 extended eBPF instructions that compose it are statically assigned to their respective execution lanes. In this stage, the operands of the instructions are pre-fetched from the register file. The remaining 3 pipeline stages are performed in parallel by the four execution lanes. During ID, memory locations are pre-fetched, if any of the eBPF instructions is a *load*, while at the IE stage the relevant sub-unit are activated, using the relevant pre-fetched values. The sub-units are the Arithmetic and Logic Unit (ALU), the Memory Access Unit and the Control Unit. The ALU implements all the operations described by the eBPF ISA, with the notable difference that it is capable of performing operations on three operands. The memory access unit abstracts the access to the different memory areas, i.e., the stack, the packet data stored in the APS, and the maps memory. The control unit provides the logic to modify the program counter, e.g., to perform a *jump*, and to invoke helper functions. Finally, during the commit stage the results of the IE phase are stored back to the register file, or to one of the

⁵The policy for selecting a given packet from the PIQ is by default FIFO, although this can be changed to implement more complex mechanisms.

memory areas. *Sephirot* terminates execution when it finds an exit instruction, in which case it signals to the APS the packet forwarding decision.

4.1.4 Helper Functions

hXDP implements the XDP helper functions in a dedicated sub-module. We decided to provide a dedicated hardware implementation for the helper functions since their definition is rather static, and it changes seldom when new versions of the XDP technology are released. This also allows us to leverage at full the FPGA hardware parallelism to implement some more expensive functions, such as checksum computations. In terms of interface, the helper function sub-module offers the same interface provided by eBPF, i.e., helper functions arguments are read from registers r1-r5, and the return value is provided in r0. All values are exchanged using the dedicated helper data bus. Here, it is worth noticing that there is a single helper functions sub-module, and as such only one instruction per cycle can invoke a helper function.⁶ Among the helper functions there are the map lookup functions, which are used to implement hashmap and other data structures on top of the maps memory. Because of that, the helper functions sub-module has a direct access to the maps module.

4.1.5 Maps

The maps subsystem main function is to decode memory addresses, i.e., map id and row, to access the corresponding map's memory location. Here, one complication is that eBPF maps can be freely specified by a program, which defines the map's type and size for as many maps as needed. To replicate this feature in the hardware, the maps subsystem implements a *configurator* which is instructed at program's load time. In fact, all the maps share the same FPGA memory area, which is then shaped by the configurator according to the maps section of the eBPF program, which (virtually) creates the appropriate number of maps with their row sizes, width and hash functions, e.g., for implementing hashmaps.

Since in eBPF single maps entries can be accessed directly using their address, the maps subsystem is connected via the data bus to *Sephirot*, in addition to the direct connection to the helper function sub-module, which is instead used for structured map access. To enable parallel access to the *Sephirot*'s execution lanes, like in the case of the APS, the maps modules provides up to 4 read/write parallel accesses.

4.2 Pipeline Optimizations

Early processor start The packet content is transferred one frame per clock cycle from the PIQ to the APS. Starting pro-

⁶Adding more sub-modules would not be sufficient to improve parallelism in this case, since we would need to also define additional registers to hold arguments/return values and include register renaming schemes. Adding sub-modules proved to be not helpful for most use cases.

Figure 6: Example of a switch statement

gram execution without waiting the full transfer of the packet may trigger the reading of parts of it that are not yet transferred. However, handling such an exception requires only little additional logic to pause the *Sephirot* pipeline, when the exception happens. In practice, XDP programs usually start reading the beginning of a packet, in fact in our tests we never experienced a case in which we had to pause *Sephirot*. This provides significant benefits with packets of larger sizes, effectively masking the *Sephirot* execution time.

Program state self-reset As we have seen in Section 3, eBPF programs may perform zero-ing of the variables they are going to use. We provide automatic reset of the stack and of the registers at program initialization. This is an inexpensive feature in hardware, which improves security [15] and allows us to remove any such zero-ing instruction from the program.

Data hazards reduction One of the issues of pipelined execution is that two instructions executed back-to-back may cause a race condition. If the first instruction produces a result needed by the second one, the value read by the second instruction will be stale, because of the operand/memory pre-tecthing performed by *Sephirot*. Stalling the pipeline would avoid such race conditions at the cost of performance. Instead, we perform result forwarding on a per-lane basis. This allows the scheduling back-to-back of instructions on a single lane, even if the result of the first instruction is needed by the second one.⁷ The compiler is in charge of checking such cases and ensure that the instructions that have such dependencies are always scheduled on the same lane.

Parallel branching The presence of branch instructions may cause performance problems with architectures that lack branch prediction, speculative and out of order execution. In the case of *Sephirot*, this forces a serialization of the branch instructions. However, in XDP programs there are often series of branches in close sequence, especially during header parsing (see Figure 6). We enabled the parallel execution of such branches, establishing a priority ordering of the *Sephirot*'s lanes. That is, all the branch instructions are executed in parallel by the VLIW's lanes. If more than one branch is taken, the highest priority one is selected to update the program counter. The compiler takes that into account when scheduling instructions, ordering the branch instructions accordingly.⁸

Early processor exit The processor stops when an exit instruction is executed. The exit instruction is recognized during the IF phase, which allows us to stop the processor pipeline early, and save the 3 remaining clock cycles. This optimization

⁷We empirically tested that a more complex intra-lane result forwarding does not provide measurable benefits.

⁸This applies equally to a sequence of `if...else` or `goto` statements.

improves also the performance gain obtained by extending the ISA with parametrized exit instructions, as described in Section 3. In fact, XDP programs usually perform a move of a value to $r0$, to define the forwarding action, before calling an exit. Setting a value to a register always needs to traverse the entire Sephirot pipeline. Instead, with a parametrized exit we remove the need to assign a value to $r0$, since the value is embedded in a newly defined exit instruction.

4.3 Implementation

We prototyped hXDP using the NetFPGA [60], a board embedding 4 10Gb ports and a Xilinx Virtex7 FPGA. The hXDP implementation uses a frame size of 32B and is clocked at 156.25MHz. Both settings come from the standard configuration of the NetFPGA reference NIC design.

The hXDP FPGA IP core takes 9.91% of the FPGA logic resources, 2.09% of the register resources and 3.4% of the FPGA’s available BRAM. The considered BRAM memory does not account for the variable amount of memory required to implement maps. A per-component breakdown of the required resources is presented in Table 1, where for reference we show also the resources needed to implement a map with 64 rows of 64B each. As expected, the APS and Sephirot are the components that need more logic resources, since they are the most complex ones. Interestingly, even somewhat complex helper functions, e.g., a helper function to implement a hashmap lookup (HF Map Access), have just a minor contribution in terms of required logic, which confirms that including them in the hardware design comes at little cost while providing good performance benefits, as we will see in Section 5. When including the NetFPGA’s reference NIC design, i.e., to build a fully functional FPGA-based NIC, the overall occupation of resources grows to 18.53%, 7.3% and 14.63% for logic, registers and BRAM, respectively. This is a relatively low occupation level, which enables the use of the largest share of the FPGA for other accelerators.

Program	Description
xdp1	parse pkt headers up to IP, and XDP_DROP
xdp2	parse pkt headers up to IP, and XDP_TX
xdp_adjust_tail	receive pkt, modify pkt into ICMP pkt and XDP_TX
router_ipv4	parse pkt headers up to IP, look up in routing table and forward (redirect)
rxq_info (drop)	increment counter and XDP_DROP
rxq_info (tx)	increment counter and XDP_TX
tx_ip_tunnel	parse pkt up to L4, encapsulate and XDP_TX
redirect_map	output pkt from a specified interface (redirect)

Table 2: Tested Linux XDP example programs.

5 Evaluation

We use a selection of the Linux’s XDP example applications and two real world applications to perform the hXDP evaluation. The Linux examples are described in Table 2. The real-world applications are the simple firewall we used as running example, and the Facebook’s Katran server load balancer [17]. Katran is a high performance software load balancer that translates virtual addresses to actual server addresses using a weighted scheduling policy, and providing per-flow consistency. Furthermore, Katran collects several flow metrics, and performs IPinIP packet encapsulation.

Using these applications, we perform an evaluation of the impact of the compiler optimizations on the programs’ number of instructions, and the achieved level of parallelism. Then, we evaluate the performance of our NetFPGA implementation. In addition, we run a large set of micro-benchmarks to highlight features and limitations of hXDP. We use the microbenchmarks also to compare the hXDP prototype performance with a Netronome NFP4000 SmartNIC. Although the two devices target different deployment scenarios, this can provide further insights on the effect of the hXDP design choices. Unfortunately, the NFP4000 offers only limited eBPF support, which does not allow us to run a complete evaluation. We further include a comparison of hXDP to other FPGA NIC programming solutions, before concluding the section with a brief discussion of the evaluation results.

5.1 Compiler

Instruction-level optimizations We evaluate the instruction-level optimizations described in Section 3, by activating selectively each of them in the hXDP compiler. Figure 7 shows the reduction of eBPF instructions for a program, relative to its original number of instructions. We can observe that the contribution of each optimization largely depends on the program. For instance, the `xdp_adjust_tail` performs several operations that need to read/write 6B of data, which in turn makes the 6B load/store instructions of our extended ISA particularly effective, providing a 18% reduction in the number of instructions. Likewise, the `simple_firewall` performs several bound checks, which account for 19% of the program’s instructions. The parametrized exit reduces the

Figure 7: Reduction of instructions due to compiler optimizations, relative to the original number of instructions.

Figure 8: Number of VLIW instructions when varying the available number of execution lanes.

number of instructions by up to 5-10%. However, it should be noted that this reduction has limited impact on the number of instructions executed at runtime, since only one exit instruction is actually executed.

Instructions parallelization We configure the compiler to consider from 2 to 8 parallel execution lanes, and count the number of generated VLIW instructions. A VLIW instruction corresponds to a schedule's row (cf. Section 3.4), and it can therefore contain from 2 to 8 eBPF instructions in this test. Figure 8 shows that the number of VLIW instructions is reduced significantly as we add parallel execution lanes up to 3, in all the cases. Adding a fourth execution lane reduces the VLIW instructions by an additional 5%, and additional lanes provide only marginal benefits. Another important observation is that the compiler's physical register assignment

Figure 9: Number of VLIW instructions, and impact of optimizations on its reduction.

step becomes more complex when growing the number of lanes, since there may not be enough registers to hold all the symbols being processed by a larger number of instructions.⁹ Given the relatively low gain when growing to more than four parallel lanes, we decided use four parallel lanes in hXDP.

Combined optimizations Figure 9 shows the final number of VLIW instructions produced by the compiler. We show the reduction provided by each optimization as a stacked column, and report also the number of x86 instructions, which result as output of the Linux's eBPF JIT compiler. In Figure, we report the gain for instruction parallelization, and the additional gain from *code movement*, which is the gain obtained by anticipating instructions from control equivalent blocks (cf. Section 3.4). As we can see, when combined, the optimizations do not provide a simple sum of their gains, since each optimization affects also the instructions touched by the other optimizations. Overall, the compiler is capable of providing a number of VLIW instructions that is often 2-3x smaller than the original program's number of instructions. Notice that, by contrast, the output of the JIT compiler for x86 usually grows the number of instructions.¹⁰

5.2 Hardware performance

We compare hXDP with XDP running on a server machine, and with the XDP offloading implementation provided by a SoC-based Netronome NFP 4000 SmartNIC. The NFP4000 has 60 programmable network processing cores (called *micro-engines*), clocked at 800MHz. The server machine is equipped with an Intel Xeon E5-1630 v3 @3.70GHz, an Intel XL710 40GbE NIC, and running Linux v.5.6.4 with the i40e Intel

⁹This would ultimately require adding more registers, or the introduction of instructions to handle register spilling.

¹⁰This is also due to the overhead of running on a shared executor, e.g., calling helper functions requires several instructions.

NIC drivers. During the tests we use different CPU frequencies, i.e., 1.2GHz, 2.1GHz and 3.7GHz, to cover a larger spectrum of deployment scenarios. In fact, many deployments favor CPUs with lower frequencies and a higher number of cores [24]. We use a DPDK packet generator to perform throughput and latency measurements. The packet generator is capable of generating a 40Gbps throughput with any packet size and it is connected back-to-back with the system-under-test, i.e., the hXDP prototype running on the NetFPGA, the Netronome SmartNIC or the Linux server running XDP. Delay measurements are performed using hardware packet timestamping at the traffic generator's NIC, and measure the round-trip time. Unless differently stated, all the tests are performed using packets with size 64B belonging to a single network flow. This is a challenging workload for the systems under test. Since we are interested in measuring the hXDP hardware implementation performance, we do not perform tests that require moving packets to the host system. In such cases the packet processing performance would be largely affected by the PCIe and Linux drivers implementations, which are out-of-scope for this paper. We use a similar approach when running tests with the Netronome SmartNIC. As already mentioned, in this case we are only able to run a subset of the evaluation, i.e., some microbenchmarks, due to the limited eBPF support implemented by the Netronome SmartNICs.

5.2.1 Applications performance

Simple firewall In Section 2 we mentioned that an optimistic upper-bound for the hardware performance would have been 2.8Mpps. When using hXDP with all the compiler and hardware optimizations described in this paper, the same application achieves a throughput of 6.53Mpps, as shown in Figure 10. This is only 12% slower than the same application running on a powerful x86 CPU core clocked at 3.7GHz, and 55% faster than the same CPU core clocked at 2.1GHz. In terms of latency, hXDP provides about 10x lower packet processing latency, for all packet sizes (see Figure 11). This is the case since hXDP avoids crossing the PCIe bus and has no software-related overheads. We omit latency results for the remaining applications, since they are not significantly different.¹¹ While we are unable to run the simple firewall application using the Netronome's eBPF implementation, Figure 11 shows also the forwarding latency of the Netronome NFP4000 (nfp label) when programmed with an XDP program that only performs packet forwarding. Even in this case, we can see that hXDP provides a lower forwarding latency, especially for packets of smaller sizes.

Katran When measuring Katran we find that hXDP is in-

¹¹The impact of different programs is especially significant with small packet sizes. However, even in such cases we cannot observe significant differences. In fact each VLIW instruction takes about 7 nanoseconds to be executed, thus, differences of tens of instructions among programs change the processing latency by far less than a microsecond.

stead 38% slower than the x86 core at 3.7GHz, and only 8% faster than the same core clocked at 2.1GHz. The reason for this relatively worse hXDP performance is the overall program length. Katran's program has many instructions, as such executors with a very high clock frequency are advantaged, since they can run more instructions per second. However, notice the clock frequencies of the CPUs deployed at Facebook's datacenters [24] have frequencies close to 2.1GHz, favoring many-core deployments in place of high-frequency ones. hXDP clocked at 156MHz is still capable of outperforming a CPU core clocked at that frequency.

Linux examples We finally measure the performance of the Linux's XDP examples listed in Table 2. These applications allow us to better understand the hXDP performance with programs of different types (see Figure 12). We can identify three categories of programs. First, programs that forward packets to the NIC interfaces are faster when running on hXDP. These programs do not pass packets to the host system, and thus they can live entirely in the NIC. For such programs, hXDP usually performs at least as good as a single x86 core clocked at 2.1GHz. In fact, processing XDP on the host system incurs the additional PCIe transfer overhead to send the packet back to the NIC. Second, programs that always drop packets are usually faster on x86, unless the processor has a low frequency, such as 1.2GHz. Here, it should be noted that such programs are rather uncommon, e.g., programs used to gather network traffic statistics receiving packets from a network tap. Finally, programs that are long, e.g., `tx_ip_tunnel` has 283 instructions, are faster on x86. Like we noticed in the case of Katran, with longer programs the hXDP's implementation low clock frequency can become problematic.

5.2.2 Microbenchmarks

Baseline We measure the baseline packet processing performance using three simple programs: `XDP_DROP` drops the packet as soon as it is received; `XDP_TX` parses the Ethernet header and swaps MAC addresses before sending the packet out to the port from which it was received; `redirect` is like `XDP_TX`, but sends the packet out to a different port, which requires calling a specific XDP helper function. The performance results clearly show the advantage of running on the NIC and avoiding PCIe transfers when processing small programs (see Figure 13). hXDP can drop 52Mpps vs the 38Mpps of the x86 CPU core@3.7GHz, and 32Mpps of the Netronome NFP4000. Here, the very high performance of hXDP is due to the parametrized exit/early exit optimizations mentioned in Section 4. Disabling the optimization brings down the hXDP performance to 22Mpps. In the case of `XDP_TX`, instead, hXDP forwards 22.5Mpps while x86 can forward 12Mpps. The NFP4000 is the fastest device in this test, forwarding over 28Mpps. In the case of `redirect`, hXDP provides 15Mpps, while x86 can only forward 11Mpps when running at 3.7GHz. Here, the `redirect` has lower performance because eBPF im-

Figure 10: Throughput for real-world applications. hXDP is faster than a high-end CPU core clocked at over 2GHz.

Figure 14: Impact on forwarding throughput of map accesses.

Figure 15: Forwarding tput when calling a helper function.

plements it with a helper. Results for the NFP4000 are not available since the it does not support the redirect action.

Maps access Accessing eBPF maps affects the performance of XDP programs that need to read and keep state. In this test we measure the performance variation when accessing a map with a variable key size ranging between 1-16B. Accessing the map is performed calling a helper function that performs a hash of the key and then retrieves the value from memory. In the x86 tests we ensure that the accessed entry is in the CPU cache. Figure 14 shows that the hXDP prototype has constant access performance, independently from the key size. This is the result of the wider memory data buses, which can in fact accomodate a memory access in a single clock cycle for keys of up to 32B in size. The NFP4000, like hXDP, shows no performance drop when increasing the key size. Instead, in the x86 case the performance drops when the key size grows from 8B to 16B, we believe this is due to the need to perform multiple loads.

Helper functions In this micro-benchmark we measure throughput performance when calling from 1 to 40 times a helper function that performs an incremental checksum calculation. Since helper functions are implemented as dedicated hardware functions in hXDP, we expect our prototype to exhibit better performance than x86, which is confirmed by our results (see Figure 15). I.e., hXDP may provide significant benefits when offloading programs that need complex computations captured in helper functions. Also, the hXDP's helper function machinery may be used to eventually replace sets

Program	# instr.	x86 IPC	hXDP IPC
xdp1	61	2.20	1.70
xdp2	78	2.19	1.81
xdp_adjust_tail	117	2.37	2.72
router_ipv4	119	2.38	2.38
rxq_info	81	2.81	1.76
tx_ip_tunnel	283	2.24	2.83
simple_firewall	72	2.16	2.66
Katran	268	2.32	2.62

Table 3: Programs' number of instructions, x86 runtime instruction-per-cycle (IPC) and hXDP static IPC mean rates.

of common instructions with more efficient dedicated hardware implementations, providing an easier pathway for future extensions of the hardware implementation.

Instructions per cycle We compare the parallelization level obtained at compile time by hXDP, with the runtime parallelization performed by the x86 CPU core. Table 3 shows that the static hXDP parallelization achieves often a parallelization level as good as the one achieved by the complex x86 runtime machinery.¹²

5.2.3 Comparison to other FPGA solutions

hXDP provides a more flexible programming model than

¹²The x86 IPC should be understood as a coarse-grained estimation of the XDP instruction-level parallelism since, despite being isolated, the CPU runs also the operating system services related to the eBPF virtual machine, and its IPC is also affected by memory access latencies, which more significantly impact the IPC for high clock frequencies.

previous work for FPGA NIC programming. However, in some cases, simpler network functions implemented with hXDP could be also implemented using other programming approaches for FPGA NICs, while keeping functional equivalence. One such example is the simple firewall presented in this paper, which is supported also by FlowBlaze [45].

Throughput Leaving aside the cost of re-implementing the function using the FlowBlaze abstraction, we can generally expect hXDP to be slower than FlowBlaze at processing packets. In fact, in the simple firewall case, FlowBlaze can forward about 60Mpps, vs the 6.5Mpps of hXDP. The FlowBlaze design is clocked at 156MHz, like hXDP, and its better performance is due to the high-level of specialization. FlowBlaze is optimized to process only packet headers, using statically-defined functions. This requires loading a new bitstream on the FPGA when the function changes, but it enables the system to achieve the reported high performance.¹³ Conversely, hXDP has to pay a significant cost to provide full XDP compatibility, including dynamic network function programmability and processing of both packet headers and payloads.

Hardware resources A second important difference is the amount of hardware resources required by the two approaches. hXDP needs about 18% of the NetFPGA logic resources, independently from the particular network function being implemented. Conversely, FlowBlaze implements a packet processing pipeline, with each pipeline's stage requiring about 16% of the NetFPGA's logic resources. For example, the simple firewall function implementation requires two FlowBlaze pipeline's stages. More complex functions, such as a load balancer, may require 4 or 5 stages, depending on the implemented load balancing logic [19].

In summary, the FlowBlaze's pipeline leverages hardware parallelism to achieve high performance. However, it has the disadvantage of often requiring more hardware resources than a sequential executor, like the one implemented by hXDP. Because of that, hXDP is especially helpful in scenarios where a small amount of FPGA resources is available, e.g., when sharing the FPGA among different accelerators.

5.3 Discussion

Suitable applications hXDP can run XDP programs with no modifications, however, the results presented in this section show that hXDP is especially suitable for programs that can process packets entirely on the NIC, and which are no more than a few 10s of VLIW instructions long. This is a common observation made also for other offloading solutions [26].

FPGA Sharing At the same time, hXDP succeeds in using little FPGA resources, leaving space for other accelerators. For instance, we could co-locate on the same FPGA several

¹³FlowBlaze allows the programmer to perform some runtime reconfiguration of the functions, however this a limited feature. For instance, packet parsers are statically defined.

instances of the VLDA accelerator design for neural networks presented in [12]. Here, one important note is about the use of memory resources (BRAM). Some XDP programs may need larger map memories. It should be clear that the memory area dedicated to maps reduces the memory resources available to other accelerators on the FPGA. As such, the memory requirements of XDP programs, which are anyway known at compile time, is another important factor to consider when taking program offloading decisions.

6 Future work

While the hXDP performance results are already good to run real-world applications, e.g., Katran, we identified a number of optimization options, as well as avenues for future research.

Compiler First, our compiler can be improved. For instance, we were able to hand-optimize the simple firewall instructions and run it at 7.1Mpps on hXDP. This is almost a 10% improvement over the result presented in Section 5. The applied optimizations had to do with a better organization of the memory accesses, and we believe they could be automated by a smarter compiler.

Hardware parser Second, XDP programs often have large sections dedicated to packet parsing. Identifying them and providing a dedicated programmable parser in hardware [23] may significantly reduce the number of instructions executed by hXDP. However, it is still unclear what would be the best strategy to implement the parser on FPGA and integrate it with hXDP, and the related performance and hardware resources usage trade offs.

Multi-core and memory Third, while in this paper we focused on a single processing core, hXDP can be extended to support two or more Sephirot cores. This would effectively trade off more FPGA resources for higher forwarding performance. For instance, we were able to test an implementation with two cores, and two lanes each, with little effort. This was the case since the two cores shared a common memory area and therefore there were no significant data consistency issues to handle. Extending to more cores (lanes) would instead require the design of a more complex memory access system. Related to this, another interesting extension to our current design would be the support for larger DRAM or HBM memories, to store large memory maps.

ASIC Finally, hXDP targets FPGA platforms, since we assume that FPGAs are already available in current deployments. Nonetheless, hXDP has several fixed design's components, such as the Sephirot core, which suggests that hXDP may be implemented as ASIC. An ASIC could provide a potentially higher clock frequency, and an overall more efficient use of the available silicon resources. Here, in addition to measuring the performance that such a design may achieve, there are additional interesting open questions. For instance evaluating the potential advantages/disadvantages provided by the ability

to change helper functions implemented in the FPGA, when compared to a fixed set of helper functions provided in ASIC.

7 Related Work

NIC Programming AccelNet [18] is a match-action offloading engine used in large cloud datacenters to offload virtual switching and firewalling functions, implemented on top of the Catapult FPGA NIC [10]. FlexNIC [32] is a design based on the RMT [8] architecture, which provides a flexible network DMA interface used by operating systems and applications to offload stateless packet parsing and classification. P4->NetFPGA [1] and P4FPGA [56] provide high-level synthesis from the P4 [7] domain-specific language to an FPGA NIC platform. FlowBlaze [45] implements a finite-state machine abstraction using match-action tables on an FPGA NIC, to implement simple but high-performance network functions. Emu [50] uses high level synthesis to implement functions described in C# on the NetFPGA. Compared to these works, instead of match-action or higher-level abstractions, hXDP leverages abstractions defined by the Linux's kernel, and implements network functions described using the eBPF ISA.

The Netronome SmartNICs implement a limited form of eBPF/XDP offloading [33]. Unlike hXDP that implements a solution specifically targeted to XDP programs, the Netronome solution is added on top of their network processor as an afterthought, and therefore it is not specialized for the execution of XDP programs.

Application frameworks AccelTCP [38], Tonic [2] and Xtra [5] present abstractions, hardware architectures and prototypes to offload the transport protocol tasks to the NIC. We have not investigated the feasibility of using hXDP for a similar task, which is part of our future work. NICA [16] and ClickNP [36] are software/hardware frameworks that introduce specific software abstractions that connect FPGA blocks with an user program running on a general purpose CPU. In both cases, applications can only be designed composing the provided hardware blocks. hXDP provides instead an ISA that can be flexibly programmed, e.g., using higher level languages such as C.

Applications Examples of applications implemented on NICs include: DNS resolver [57]; the paxos protocol [51]; network slicing [59]; Key-value stores [34, 35, 49, 52]; Machine Learning [14, 21, 41]; and generic cloud services as proposed in [10, 46, 48]. [37] uses SmartNICs to provide a microservice-based platform to run different services. In this case, SoC-based NICs are used, e.g., based on Arm processing cores. Lynx [53] provides a system to implement network-facing services that need access to accelerators, such as GPUs, without involving the host system's CPU. Floem [43] is a framework to simplify the design of applications that leverage offloading to SoC-based SmartNICs. hXDP provides an XDP programming model that can be used to implement and extend these

applications.

NIC Hardware Previous work presenting VLIW core designs for FPGAs did not focus on network processing [29, 31]. [9] is the closest to hXDP. It employs a non-specialized MIPS-based ISA and a VLIW architecture for packet processing. hXDP has an ISA design specifically targeted to network processing using the XDP abstractions. [20] presents an open-source 100-Gbps FPGA NIC design. hXDP can be integrated in such design to implement an open source FPGA NIC with XDP offloading support.

8 Conclusion

This paper presented the design and implementation of hXDP, a system to run Linux's XDP programs on FPGA NICs. hXDP can run unmodified XDP programs on FPGA matching the performance of a high-end x86 CPU core clocked at more than 2GHz. Designing and implementing hXDP required a significant research and engineering effort, which involved the design of a processor and its compiler, and while we believe that the performance results for a design running at 156MHz are already remarkable, we also identified several areas for future improvements. In fact, we consider hXDP a starting point and a tool to design future interfaces between operating systems/applications and network interface cards/accelerators. To foster work in this direction, we make our implementations available to the research community.¹⁴

Do OS abstractions make sense on FPGAs?

Abstract

Hybrid computing systems, consisting of a CPU server coupled with a Field-Programmable Gate Array (FPGA) for application acceleration, are today a common facility in datacenters and clouds. FPGAs can deliver tremendous improvements in performance and energy efficiency for a range of workloads, but development and deployment of FPGA-based applications remains cumbersome, leading to recent work which replicates subsets of the traditional OS execution environment (virtual memory, processes, etc.) on the FPGA.

In this paper we ask a different question: to what extent do traditional OS abstractions make sense in the context of an FPGA as part of a hybrid system, particularly when taken as a *complete package*, as they would be in an OS? To answer this, we built and evaluated Coyote, an open source, portable, configurable “shell” for FPGAs which provides a full suite of OS abstractions, working with the host OS. Coyote supports secure spatial and temporal multiplexing of the FPGA between tenants, virtual memory, communication, and memory management inside a uniform execution environment. The overhead of Coyote is small and the performance benefit is significant, but more importantly it allows us to reflect on whether importing OS abstractions wholesale to FPGAs is the best way forward.

1 Introduction

Field-Programmable Gate Arrays (FPGAs) are now standard in datacenters and cloud providers [1, 3, 12], providing more flexibility at lower power than ASICs or GPUs for many applications (e.g. [5, 19, 25, 29, 30, 41, 53]) despite (due to their heritage in embedded systems and prototyping) remaining difficult to program, deploy, and securely manage. As a result, along with much research into making FPGAs easier to program [7, 8, 36, 45, 51, 54, 58], considerable recent work applied ideas from operating systems design and implementation to resource allocation, sharing, isolation, and management of an FPGA-centric computer.

So far, this work has been piecemeal, focusing on a particular aspect of functionality, e.g. Feniks [63] targets FPGA access to peripherals, Optimus [32] provides access to a host’s virtual memory via address translation, etc. These yield substantial incremental improvements over the state of the art.

At the same time, what makes good OS design so challenging is the close interaction in the kernel between *all* the functionality. Virtual memory without support for multiple applications (multi-tenancy) or strong isolation between them is of limited use. Virtualizing hardware devices without providing virtual addressing and creating a common execution environment that abstracts the hardware leaves most of the problem unsolved. An FPGA scheduler that cannot exploit the ability to dynamically reconfigure parts of the chip has a limited shelf-life, and so on.

Therefore, we step back to ask the question: to what extent can (or should) traditional OS concepts (processes, virtual memory, etc.) be usefully translated to an FPGA? What happens when they are? To answer this question, we need to adopt a comprehensive, holistic approach and think about complete functionality, rather than sticking to particular aspects of an OS or supporting only limited FPGA features.

To this end, we have built Coyote, combining a coherent set of OS abstractions in a single unified runtime for FPGA-based applications. Like a microkernel, Coyote provides the core set of essential functions on which other services can be based: a uniform execution environment and portability layer, virtual memory, physical memory management, communication, spatial and temporal scheduling, networking, and an analog of software processes or tasks for user logic. It achieves this with minimal overhead (less than 15% of a commodity FPGA). Our contributions in this paper are therefore:

1. For a range of OS abstractions, a critical assessment of how each might map to an FPGA, in the context of its interaction with the others,
2. An implementation of the complete ensemble in Coyote, a configurable FPGA “OS” for hybrid compute servers.

3. A quantitative evaluation of Coyote using both microbenchmarks and 5 real applications.
4. A qualitative discussion of the implications of the work for future FPGA and OS designs.

We start with the basic hardware that any FPGA OS must handle. This determines the high-level structure of Coyote.

2 Foundations

Coyote targets hybrid systems, combining a conventional CPU with an FPGA either over a peripheral bus like PCIe, CXL [16], CCIX [13] or OpenCAPI [49], or instead a native coherency protocol as with Intel HARP [39] or ETH Enzian [2, 21]. Coyote runs today on PCs with Xilinx VCU118 [56], Alveo U250 [59] and Alveo U280 [60] cards. The port to Enzian is under way. We avoid any design decisions that might prevent the use of modern FPGA features like dynamic partial reconfiguration of multiple regions, or useful “hard” on-chip functions.

This naturally splits any design into a “hardware” component running on the FPGA and a software component running on the host CPU as part of the OS and support libraries.

Furthermore, dynamic reconfiguration of the FPGA induces a further split of the hardware component into a “static region”, configured at boot, and a “dynamic region”, containing subregions (vFPGAs), each of which may be changed on the fly. This split exists (often in simplified form) in all FPGA datacenter deployments. Within and between regions, hardware components interact via standard interconnects like AXI [31].

2.1 The static region

The FPGA static region must contain the functionality required to reconfigure the dynamic region and communicate with the CPU’s OS. However, its contents should not be fixed for all time. Space (chip area, logic blocks, wires, etc.) remains a scarce resource on FPGAs, and unlike OS resources such as CPU time and virtual memory, it is hard to make it “elastic” through virtualization. Moreover, different models of FPGAs show very different tradeoffs. In the medium term, it is important to make some static region components (for example, the TCP/IP stack) optional so they can be omitted if the space is better used for user logic.

In Coyote, the static region always contains logic to partially reconfigure the dynamic region, communicate with the host machine (an xDMA copy engine [57]), and to divide the dynamic region into a set of *virtual FPGAs* (“vFPGAs”), each of which has an interface mapped into the physical address space of the host CPU (described below).

The static region can also contain optional logic shared between all applications running in vFPGAs, the most basic

being memory controllers (for RAM directly connected to the FPGA) and networking (at present, TCP and RDMA).

2.2 The dynamic region

The dynamic region is the basic mechanism for time-division multiplexing of the FPGA resources. Modern FPGAs allow selective portions of this region to be reconfigured independently at any time. Most deployed systems (e.g. F1 [3] and Intel’s HARP [39]) dedicate this region to a single application, and reprogram it only rarely (e.g. when an associated virtual machine on the host is booted up).

Coyote, like other recent systems [14, 17, 62, 63], provides flexible spatial and temporal multiplexing. The dynamic region is partitioned into independent vFPGAs. Their number is wired into the static region, which allows multiple applications to run concurrently and be switched in and out.

A novel feature of Coyote is that each vFPGA is further divided into *user logic* and a *wrapper*. The former is a bitstream entirely synthesized by a Coyote user and validated by the system. This allows great flexibility in programming models: Coyote applications can be written in HLS, Verilog, VHDL, OpenCL, or some combination of these or other languages.

The wrapper is part of Coyote, and both sandboxes user logic and provides a standard interface to the rest of the system (in FPGA terms, partition pins are inserted by the reconfiguration tool locking all the boundary interface signals in the fabric). This incurs a cost in chip area usage, but the benefit is that Coyote pushes the “portability layer” for FPGA applications up to the language level: an application written for Coyote can, given sufficient resources, be synthesized to run on any Coyote FPGA. In contrast, with native FPGA development at present code is rarely portable between device models (or even, in some cases, revisions of the same model).

It is tempting to draw an analogy between the structure of Coyote and a microkernel model of an OS, consisting of the kernel (the static region), services (optional static components), system libraries (dynamic wrappers), and applications code (user logic). However, this would be an error. For example, the dynamic wrappers form part of a trusted computing base (TCB), whereas system libraries in a microkernel do not.

2.3 The software component

In a hybrid system, the host OS must clearly be aware of the FPGA environment, and also provide suitable and safe abstractions to user application code running on the CPU for interacting with user logic on the FPGA.

Beyond this, however, there is a fundamental tradeoff between how much management of FPGA resources is performed on the FPGA itself (by a combination of static region logic and dynamic functionality) and how much is implemented by system software on the CPU. Offloading FPGA

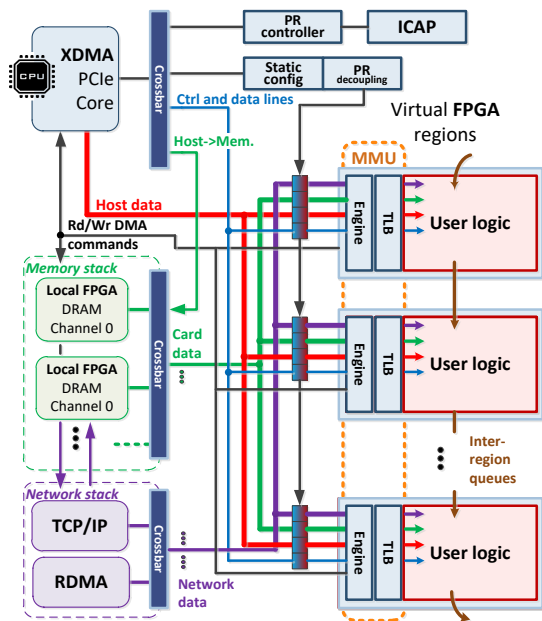

Figure 1: Coyote structure

management functionality to the CPU and OS frees up valuable space on the FPGA, and allows much more policy flexibility than could be reasonably implemented in logic. However a functionality that is on a critical path can lead to degraded performance and/or loss of predictability in response time (often a key attribute of hardware solutions). In some ways this mirrors the traditional OS tradeoff between kernel-mode and user-space implementation, but the contrast is more stark.

Coyote maximises the FPGA area available to user logic, moving much functionality not on the fast path into the host CPU’s OS. The software part of Coyote consists of a kernel driver (currently for Linux), a *runtime manager* process, and user application code.

At startup, the driver reads the configuration of the static region from the FPGA and sets up data structures for the set of vFPGAs to be supported. Thereafter, it is responsible for “control plane” communication with the FPGA (such as reconfiguring a vFPGA) and creating memory mappings for application code to interact directly with a vFPGA. The driver also handles dynamic memory allocation for the FPGA, and services TLB misses on the FPGA (see below).

Figure 1 shows the components of Coyote. The host CPU is connected to the PCIe core at top left.

3 OS abstractions on an FPGA

In this section, for each considered OS abstraction we first review its role in a conventional OS for a homogeneous multicore machine. We then discuss what is fundamentally dif-

ferent in an FPGA environment, and the impact this has on design decisions when creating an analog of the abstraction on the FPGA. Following this, we discuss our own implementation, and discuss our experience with building and using the approach. A quantitative evaluation of the whole of Coyote is given in Section 4.

3.1 Processes, tasks, and threads

The basic abstractions most OSes provide for multiplexing and virtualizing processor resources are based on processes, threads, and/or tasks. Definitions vary from OS to OS, but a thread is generally an open-ended execution of a sequence of instructions on a single virtual processor, a task is a unit of computational work to be dispatched to a CPU core, and a process is some combination of threads sharing an address space, to which CPU resources are allocated.

The hardware mechanisms underlying these abstractions are basically the ability of the processor to context switch, and be preempted by an interrupt or trap.

Such abstractions can be readily adapted to architectures like GPUs, which retain the notion of a hardware thread, albeit with a very different degree of parallelism. GPU drivers for modern OSes attempt to extend the process abstraction of the host CPU to the GPU, although in a somewhat limited form [9], and this is the foundation for programming models like CUDA and OpenCL. The task abstraction has also been successfully deployed on GPUs [44].

What’s different on an FPGA? Resource multiplexing on FPGAs is fundamentally different, since there is no hardware corresponding to a “processor”, “core”, or “hardware thread” on which to base an abstraction aimed at multiplexing processing resources. Instead, the basic mechanisms available on the FPGA for multiplexing compute resources between principals are partial reconfiguration of areas of the FPGA logic at runtime, and spatial partitioning of application logic across different areas of the chip.

While it is true that a popular programming technique for FPGAs involves implementing a custom application-specific processor (typically some VLIW-based architecture), this is not intended to be multiplexed or scheduled. The analogue of these custom cores in the software world is more that of a library or bytecode interpreter that lives entirely within the process abstraction.

The trivial approach here is to dedicate the entire FPGA to a single application, and indeed in embedded systems this is the norm. A more flexible approach allows more than one application to use the FPGA at a time. The static region of the FPGA contains enough logic to swap one application out for another, but otherwise the chip is dedicated to an application for long periods. This is the model adopted by Amazon F1 and, indeed, almost all other commercially deployed systems.

An alternative proposed in research systems (e.g. [32, 62, 63] and others) is to partition the FPGA resources statically

between applications. Spatial partitioning also raises further questions. For example, when multiple applications share the FPGA, should they be allowed to communicate, as processes do with IPC, and if so, how?

Coyote approach: Coyote combines both approaches, providing a cooperative multitasking abstraction of a set of virtual FPGAs, each of which is timeshared between applications. A Coyote platform is configured at boot time with a fixed number (e.g. 2-8) of vFPGAs, which are a spatial partition of the dynamic region of the chip. Each of these regions are, for the purposes of executing user logic, equivalent (much like cores in a symmetric multiprocessor), and are time-shared between applications. Ideally, a single application bitstream could be loaded into any available “slot” to be executed. Although some research in this direction exists [20], this is difficult with current levels of heterogeneity in FPGAs, which means that (at present) each application has to be (automatically) synthesized in advance for each vFPGA slot, akin to compiling “fat binaries” for multiple architectures. We discuss specific spatial and temporal scheduling questions below, along with the execution environment provided to user logic.

Discussion: A scheme with this generality requires care to implement. When timesharing vFPGAs, it is important that the context switch overhead does not outweigh the performance benefits of using a circuit in the first place. Dynamic partial reconfiguration of an FPGA is a relatively slow process and may remain so for the foreseeable future. In 4.3 we measure this cost.

Moreover, the logic required to implement multiple vFPGAs, and allow them to communicate and share services in the static region of the chip, must come with an acceptably-small cost in chip resources. We evaluate this in Section 4.2. So far our experience has been good: we can comfortably run multiple useful applications on a single FPGA today, and hardware trends are in our favour as the parts become larger.

3.2 Execution environment

The process abstraction also serves the purpose of providing a standard *execution environment* for a program. A program compiled to run in a process can, in principle, execute in any process on any machine implementing the same process environment. For example, in Unix, a process’s execution environment consists of a virtual address space, one or more threads, a set of file descriptors, the system call interface, etc.

What’s different on an FPGA? To date, there are almost no attempts to define a process-like execution environment for an FPGA. Most FPGA application development targets a specific model of FPGA. Porting the same logic to a different chip is often a non-trivial programming problem.

The heterogeneous nature of hybrid platforms complicates this question further. In addition to the environment in which user logic executes, a process abstraction must also address how software processes and FPGA-based logic “processes”

Figure 2: User logic interface

interact across the hardware/software interface.

In GPUs, programming models like OpenCL and CUDA are the solution. Portability is raised to the compiler, and the execution environment is defined by the language in which the GPU code is written. This works well for GPUs because they function as pure accelerators. The same model has been implemented for FPGAs [51, 58].

However, hybrid FPGA-based systems are not pure computational devices - for example, they perform I/O through network and storage interfaces; indeed, this ability to interface externally is a major selling point. Rolling this functionality entirely into a compiler has not worked in conventional machines, and is unlikely to do so here. Instead, runtime interfaces are needed. Perhaps the closest GPU analogy here is tasks [44], which present the GPU as a task-based runtime as opposed to a language-level OpenCL interpreter.

Coyote approach: Coyote defines a single *user logic interface* (ULI) for every application, which is the hardware analog of an ABI, and is illustrated in Figure 2. It uses the streaming AXI4 protocol for transferring bulk data between the host, memory stack, other services like the network stack, and the user logic. The same interface is used for inter-region communication, with a control plane over an AXI4-light bus.

This interface is provided by the dynamic wrapper in each vFPGA, and effectively sandboxes the user logic while providing communication with system services and memory – effectively combining functions of an address space and system call ABI in a software process.

Access to the ULI interface is exposed to user logic at a fairly low level, allowing read and write descriptors to be generated directly from the user logic in the FPGA fabric, and host software access (including by high-bandwidth SIMD instructions) to be routed directly to the user logic.

User software on the CPU interacts with the FPGA by creating a *job object*, essentially a closure consisting of user logic and other parameters and data. This is passed to the runtime manager for installation on the FPGA.

Once functional, the user logic exposes a register interface in physical memory to the CPU, and the runtime manager maps this into the calling process’ address space. Thereafter, the interaction between application software and user logic

completely bypasses the kernel and runtime manager.

Discussion: The ULI in Coyote incurs minimal overhead, but delivers considerable benefits, some of which might be surprising to those familiar with software development. It enables an approach analogous to microkernels, with common services provided to multiple vFPGAs over the AXI interconnect. For example, we ported publicly-available TCP and RoCE stacks [46, 48] to Coyote, and they became immediately usable to our existing applications without the extensive hardware-specific modifications usually required in FPGA development.

As with conventional OSes, the Coyote execution environment also provides a way to deal with the evolution of hardware. The FPGA design space is changing rapidly. To take one example: in most FPGAs deployed in data centers today, the memory controllers and network stack (aside from PHY and MAC) are still instantiated as reconfigurable logic. However, both are becoming an almost universal requirement for cloud FPGA applications, which makes a strong case for building “hard” IP into future FPGAs to provide this functionality with less penalty in chip area - indeed, the latest design of Microsoft’s Catapult platform offloads the network stack to an ASIC (albeit off-chip). Intel’s Embedded Multi-Die Interconnect Bridge (EMIB) is intended to extend FPGAs with new hardware, for example machine learning accelerators [37]. Recent Xilinx Versal cards also provide numerous off-chip hardware functions.

These trends make it even more difficult to achieve portability without a uniform execution environment like Coyote’s to abstract these features behind a clean interface.

3.3 Scheduling

Scheduling on conventional machines is a complex topic with a history older than computers themselves. In this paper we focus on factors affecting scheduling mechanisms rather than specific policies.

What’s different on an FPGA? CPU scheduling can be preemptive or non-preemptive. Preemptive scheduling on CPUs requires a mechanism to interrupt a running process, save its state, and context switch to another, without any co-operation from the process or user program itself.

On an FPGA, such interrupt mechanisms are not supported by any of the mainstream toolchains. Some progress in this direction has been made in academia [27], but with significant performance penalties and implementation difficulties. Furthermore, the “state” of executing user logic potentially includes any stateful logic block (block RAM, flip-flops, DSPs) in the region of the FPGA used by the application, making the state capture all the more complex. For this reason, mechanisms for preempting arbitrary FPGA applications so that they can be reliably resumed later are not clear.

Instead, existing approaches to timeshare an FPGA avoid preemption [50] and rely on two techniques. The first is a

Figure 3: Coyote scheduling

“task-based” approach where work units are submitted to the FPGA and run to completion much like Ptasks [44]. Secondly, as a last resort a badly-behaved piece of user logic can simply be deconfigured by the OS, in a manner analogous to killing a misbehaving process. The scheduling problem then becomes one of dispatching tasks to the FPGA.

The key *quantitative* difference with FPGA scheduling is that context switch time is much higher: reconfiguring a dynamic region can take many milliseconds. Moreover, only one region of the FPGA can be reconfigured at a time. If not addressed, these limitations can lead to unacceptably high scheduling overhead.

Coyote approach: Coyote adopts the task-based technique, with tasks being described by job objects. Tasks are not scheduled by the FPGA itself, instead the runtime manager on the host CPU schedules them spatially (across vFPGAs) and temporally (by reconfiguring a vFPGA if required, and serializing such reconfigurations).

The current version of Coyote adopts a modified priority-based queue scheme for tasks (Figure 3). Application software submits a task to a per-application queue in the runtime monitor. These are serviced in a round-robin fashion, and dispatched to a priority queue for one of the fixed number of vFPGA instances. Each of these queues is sorted first by priority and, then, by the bitstream image that the task requires.

This heuristic provides a degree of fairness between applications (though it could certainly be improved with better protection against starvation in a few pathological cases), but more importantly groups together tasks that can run in a sequence without intervening reconfigurations of their vFPGA. This approximates some of the benefits of Optimus [32], which employs a more static assignment of logic to vFPGAs but shares this between applications. Note that it also makes the scheduler non-work-conserving.

Discussion: For the 5 applications we evaluate in Section 4, the reduction in the number of required reconfigurations substantially improves efficiency, to the extent that, with current hardware, it probably dominates other aspects of the scheduling algorithm. However, we feel there is still important work

to be done in improving fairness, starvation-freedom, and predictability of the scheduler.

Coyote deliberately avoids any question of preempting applications running in vFPGAs, except *in extremis* to “kill” badly behaving user logic. This decision is worth discussing in more detail, since other approaches [26,32] provide explicit preemption interfaces. Applications can use these interfaces to implement user logic to save and restore their state in response to a preemption request from the scheduler.

The first reason for this decision is from an OS designer’s perspective: the classical OS design principles adopted in Coyote strongly argue against this approach to preemption. Traditionally, user applications are not trusted to behave nicely by the OS, and so implementations take great care to ensure that preemption never requires cooperation from the application – even in cases where it is explicitly visible to user threads, as in Psyche [33]. So-called “cooperative multi-tasking systems” (for example, early versions of the Apple Macintosh OS) do require application cooperation for context switching, but are generally not preemptive and, as history shows, are invariably supplanted by preemptive scheduling that does not require participation by the application.

The second reason is that the nature of “services” (e.g. networking) on an FPGA is different from that on a CPU. FPGAs emphasize spatial multiplexing and extreme concurrency. This means that services like the network stack (Section 3.6) and physical memory management (Section 3.5) do not need to be scheduled in Coyote: they are separate circuits and so inherently run all the time. A user-supplied preemption implementation may appear sufficient where these OS facilities are absent, but their presence means that user-implemented preemption has to also save and restore state (such as network flows) in each of these services. This capture of system-wide state cannot yet be done efficiently in current FPGAs.

3.4 Virtual memory

In a conventional OS, virtual memory provides a potentially unlimited number of “virtual address spaces” to software processes. By default, a virtual address space provides a sandbox of private memory, but segments of memory can be selectively shared between address spaces by the OS.

Virtual address spaces solve several crucial problems in computer systems: code and data does not need to be relocated at runtime, since it can be compiled and linked to run at a fixed address. Demand paging to a disk or SSD allows the amount of memory seemingly available to all applications to exceed the total real memory in the system.

Fragmentation of physical memory is avoided at anything coarser than page granularity. Physical locations for data can be chosen carefully to provide cache-coloring transparently to user code. Accesses to memory regions can be tracked via a “protect-and-trap” technique, with applications ranging from garbage collection [4], copy-on-write, and transaction

management [35] to dynamic binary translation [10].

Hardware support for the abstraction of virtual memory is traditionally provided by the MMU, by way of three key functions: *address translation* from a virtual to a physical address space, *protection* of memory pages, and a mechanism to *trap* to the OS on certain memory accesses (i.e. a page or protection fault).

What’s different on an FPGA? Some uses of virtual memory do not make sense on an FPGA, such as trapping on particular instructions or memory addresses. However, others (demand paging, relocation, etc.) are highly relevant.

Existing approaches to programming FPGAs generally ignore virtual memory, or handle address translation solely in the host OS kernel [11, 14, 17, 26, 27, 39, 62, 63]. Pinned physical buffers are allocated and shared between FPGA user logic and software, which (when the data is not simply copied *en masse* between host memory and the FPGA) entails either the use of offsets to implement pointer-rich data structures, or cumbersome “pointer swizzling” when passing ownership of regions between devices. In both cases, one cannot simply pass a pointer from software to user logic without some mediation, typically by the OS kernel, or a runtime specific to a programming model like OpenCL [55].

One approach to accessing host virtual memory from the FPGA is via the host platform’s IOMMU. However, IOMMUs are not well-suited to a dynamic set of FPGA applications, even the subset that only use PCIe as an interconnect. Optimus [32] has a good explanation of the limitations of IOMMUs, and employs an ingenious “page table slicing” technique to work around them. Other recent work also implements some form of translation on the FPGA from user logic to host-physical addresses [6, 15, 42, 52], .

These approaches, however, are limited to one special case: user logic accessing data on the host CPU memory in a software virtual address space. Modern FPGA platforms, however, have additional extensive memory closely coupled to the chip (for example, Enzian’s FPGA has 512 GiB of DDR4), and also devices (such as network or storage controllers). To interact correctly with other OS abstractions (such as device virtualization, isolation, or even simply access to FPGA resources from the CPU), a virtual memory abstraction for multi-tenant FPGAs must thus be extended to these resources as well. It must enable safe and secure access to memory both on the FPGA itself, and on memory and devices directly attached to the FPGA, from user logic *and* software.

An approach satisfying these requirements is present in modern GPUs [38] where a unified memory abstraction of GPU and host memory is implemented. This abstraction provides primarily increased programmability which removes the need for explicit memory management and data movement from the software side.

FPGAs also differ fundamentally from GPUs or other accelerators in that they are reconfigurable. In a CPU or, indeed, a conventional IOMMU or SMMU, parameters such as TLB

size, associativity, coverage, etc. are fixed when the chip is laid out. They represent a careful, “one-size-fits-all” compromise intended to run most workloads reasonably well.

In contrast, with an FPGA TLB parameters can be changed on the fly to handle specific workloads more efficiently. Moreover, many accelerator workloads which deal with large data volumes benefit greatly from larger page sizes – this motivates Optimus [32] to use 2MiB pages exclusively, for example. These factors, combined with the lower clock speed at which FPGAs run (typically about 10% of CPU clock speed), make a *software loaded TLB* more attractive as a design option.

Coyote approach: Rather than relying on a single shared FPGA MMU, and/or relying on an IOMMU, Coyote includes TLBs in the wrapper of each vFPGA. This not only allows TLB dimensions to be decided based on the application, but also provides sandboxing of user logic regardless of whether it is accessing off-chip DRAM attached to the FPGA’s memory controllers, or host CPU DRAM using the xDMA engines in the static region. It also makes floorplanning and routing easier on the chip by reducing fanout.

Moreover, the TLBs are positioned in each dynamic region so as to mediate *all* accesses to FPGA-attached devices and RAM, and the entire host CPU’s physical address space, something not possible with a conventional IOMMU.

The operation of TLBs in Coyote is best described in two parts: first, the underlying mechanism, and second, the different memory usage models it supports.

Mechanism: Coyote actually provides two TLBs per vFPGA, one for 4KiB pages and one for 2MiB large pages. The TLBs are fairly straightforward caches (see Figure 4); associativity and number of sets are determined at build time for the application. A TLB miss causes an interrupt to the host CPU, whereupon the driver identifies the faulting vFPGA and either loads the TLB with a valid mapping or signals a page fault, which would be handled in software on the host.

All accesses to both FPGA and host DRAM *from user logic* use the same unified TLB interface. User logic can therefore access any host memory, if the TLB allows. Accesses to host and FPGA memory use different paths to proceed in parallel.

Meanwhile, on the *host* side, the CPU’s physical address space contains a region for each vFPGA, each of which is further subdivided into three parts:

1. The TLB contents and other privileged configuration values. This subregion may only be mapped by the privileged Coyote device driver.
2. Dynamic wrapper registers accessible to user software, e.g. for setting up DMA copies.
3. Direct access to user logic. CPU-initiated accesses are presented to user logic as AXI4 transactions (see Figure 2) to be interpreted as the user logic sees fit.

Usage models: The most common way of using this facility is to provide GPU-style “Unified Memory”, which is

Figure 4: Coyote per-application TLBs

essentially a form of local distributed shared virtual memory: pages are copied (faulted in) on demand between FPGA and host memory via DMA with coherence managed by a combination of driver software and dedicated “page fault” units in the secure wrappers. Coyote can thus handle multiple application contexts maintaining different shared virtual address spaces. It is the job of the software component of Coyote to ensure that address mappings are consistent between the vFPGA TLBs and the virtual address space of the corresponding software processes. Though there is no fundamental need for them to be so, it allows direct sharing of pointer-rich data structures between application software and user logic.

Alternatively, TLB entries can indicate that, when a corresponding virtual address is requested, the physical access is directly routed to either host or FPGA memory without any copying of pages. For efficient random access (such as pointer-chasing) this may be much more faster to program and execute than “unified memory”.

Finally, it is also possible to route CPU accesses to addresses on the FPGA back through the vFPGA wrapper’s TLBs and into FPGA (or, indeed, host) memory. While quite slow on PCIe-based systems, it might be an attractive option on a fully-coherent non-PCIe system like Enzian.

Discussion: As we show in Section 4, the TLBs impose very little space overhead in a vFPGA, and deliver in return considerable simplicity in programming applications.

The partitioning of TLB functionality across vFPGAs brings a degree of performance isolation to vFPGA applications: one vFPGA cannot pollute the TLB contents of another region and thereby impact performance, an important consideration for a multi-tenant environment.

Note also that the area occupied by TLBs can be traded off against performance in an application-specific manner. This would not be possible with conventional IOMMUs situated on the PCIe bus, and would be hard to achieve with a

single IOMMU shared between applications. Partly as a consequence, we have yet to see serious performance overheads due to the software-loaded TLBs.

3.5 Memory management

In addition to virtual memory, a traditional OS provides facilities for managing *physical* memory. As hardware has become more complex, this has become more important for performance. E.g. an application might request regions of contiguous RAM to optimize sequential access and/or TLB coverage via superpages, or memory on specific NUMA nodes, explicitly (e.g. via `libnuma` on Linux) or implicitly (e.g. using Linux’ “first-touch” allocation policy).

These abstractions more concern performance than correctness. However, in the case of peripherals and heterogeneous accelerators it may be a requirement for software to work. A CUDA application may need to allocate GDDR memory on a GPU which is accessible (over PCIe) to CPU code. Alternatively, a device might only be able to DMA to and from a subset of the CPU-attached physical RAM.

In a software OS, however, there is a *single* mechanism available to allocate memory with the right characteristics: choosing an appropriate range of physical addresses. The physical address functions as a proxy for all kinds of features of the hardware interconnect, memory controllers, DMA capabilities, and (in the case of cache coloring) the processor’s cache architecture and placement policies.

What’s different on an FPGA? Since FPGAs are much closer to the hardware, the situation is very different. Code running on FPGAs can access memory controllers directly. Data paths are not limited in size to cache lines, machine words, or MMU pages. SDAccel [58] exposes memory controllers explicitly to the programmer, providing flexibility but sacrificing simplicity and portability across FPGA devices.

The memory potentially visible to FPGA user logic is much more diverse than in software (and there are no caches). Block RAM (BRAM) is fast but scarce, DRAM is slower but there is typically much more of it, many systems have extensive off-chip DRAM available, and newer FPGAs incorporate High-Bandwidth Memory (HBM) as well.

Moreover, as with servicing TLB misses, it may be useful to offload the dynamic allocation of FPGA memory to software, although hardware allocators have been developed [61].

Coyote approach: Allocation of physical memory both within and between vFPGAs in Coyote is handled by software, in the kernel driver, which also takes care of creating virtual memory mappings both for the user logic and application CPU code. A variety of physical memory types can be used (off-chip DRAM, host DRAM, HBM, etc.).

Accessing memory is similarly different. Whereas software deals with register loads and stores or cacheline fills and write-backs, *any* memory access in FPGA user logic is inherently, and explicitly, a copy operation from one location to another.

Figure 5: Read/Write engine

On current PCIe-based systems, user logic can access the entire host CPU’s physical address space (albeit subject to memory protection) by transparently using xDMA copy engines. The complexity of routing memory accesses originating from both user logic and host software, and destined for host memory or FPGA resources, is handled by a *read/write engine* in each vFPGA wrapper (Figure 5), which provides this flexibility in access. Requests are submitted to the read/write engine using base/length descriptors; accesses from host software to FPGA memory are translated into these descriptors by the interface logic whereas the user logic issues them directly. This results in low overhead operations in the ULI entirely on virtual addresses. On fully coherent systems like Enzian, the read/write engines would be replaced with the interface Coyote provides to the CPU’s native cache-coherence protocol.

In contrast to approaches like SDAccel (but more in line with a software environment), Coyote hides the presence of individual on-board DRAM controllers from user logic. On-board DRAM is the most commonly used way to hold bulk data in most FPGA acceleration algorithms, since it is higher capacity than BRAM. Coyote aims simply to maximize the bandwidth of bulk sequential access to this resource for user logic running in a vFPGA.

Coyote *stripes* DRAM access across all available controllers via careful allocation of pages. Coupled DRAM is allocated in 2MiB superpages. Each page is then striped across channels – e.g. if the FPGA has two physical DRAM channels, the first 1MiB of each page will access one DRAM channel, and the second half will use the second channel. This permits bandwidth optimization when performing rapid accesses with multiple channels present, and (as we show in Section 4.5) results in considerable performance gains over the naive approach. Accesses from different vFPGAs are still interleaved at each memory controller, as shown in Figure 6.

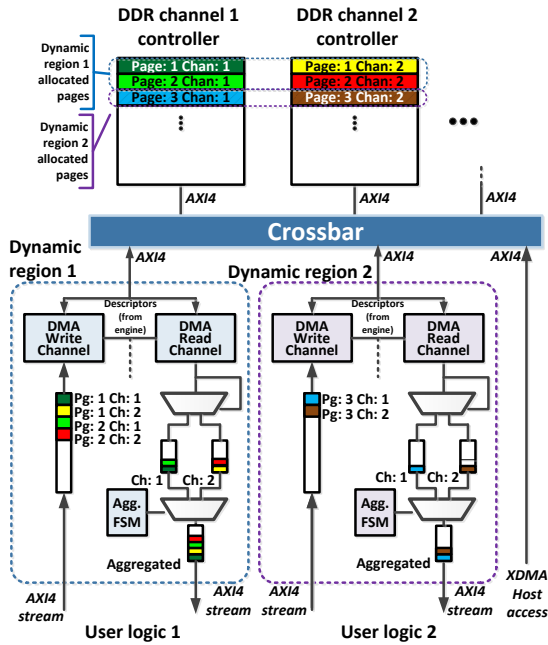

Figure 6: Multi-channel striping

Discussion: User logic is rarely as “memory-allocation intensive” as software, and so the kernel memory allocation code is rarely on the critical path.

By abstracting away on-chip DRAM controllers, Coyote makes a tradeoff in favour of portability and ease of programming, which we argue (based on our experiments) is appropriate. Moreover, Coyote applications can directly run on future FPGA designs which entirely offload memory controllers to dedicated hardware (as we discussed in Section 3.2).

In this context, striping provides more than just faster sequential access: it is vital for abstracting and sharing memory controllers since it allows the DRAM controllers to enforce fair sharing of bandwidth between vFPGAs.

3.6 IPC, I/O, and other services

A traditional OS provides a number of abstractions beyond those we have covered here. The most fundamental, at the heart even of microkernel architectures, is inter-process communication (IPC). We have already described how Coyote provides communication between vFPGAs and CPU-based software processes, but it also allows optional hardware queues between vFPGAs by analogy with IPC channels, pipes, etc., in a manner reminiscent of Centaur [42]. This allows users e.g. to chain dataflow operators running in different vFPGAs together while preserving the isolation between them.

While inter-vFPGA queues (and shared locations in FPGA virtual memory) can be used for inter-application commu-

nication, we find they are rarely used as such. As with containers, in our experience inter-vFPGA communication, when it happens at all, is coarse-grained and benefits from being independent of whether the vFPGAs share the same FPGA.

Instead, the main use for such queues is communication with *services* provided by Coyote.

For example, Coyote provides an optional, but fully integrated, high-performance *multi-tenant* network stack based on our open-source TCP/IP and RDMA engine for FPGAs [46, 47]. Like the memory stack described in Section 3.5, the network stack abstracts away the details of the physical network interfaces present and exposes a portable, standard interface, and can be shared between all vFPGAs present.

Further services can be similarly implemented and configured into the static region at startup, for example a storage stack (perhaps driving directly attached Flash memory). The microkernel analogy applies here: Coyote provides a basic framework where such services can be added in the future based on use-case requirements.

Unlike in a software-based OS, Coyote “services” like the network stacks do not need to be scheduled, since they are always present on the FPGA – the FPGA is being spatially rather than temporally shared between services and user logic.

4 Evaluation

We focus on the question of whether the qualitative benefits of using Coyote’s OS-style abstractions (scheduling, virtual memory, etc.) incur an acceptable quantitative cost in performance or efficiency. We look at overhead and space costs, as well as fairness in sharing resources, and the benefits of some of the optimizations in Section 3.

The hardware used for the results we report on here is a Xilinx VCU118 board [56] with an Ultrascale+ VU9P FPGA, attached to a host PC via PCIe x16. This interface provides a maximum theoretical bidirectional bandwidth of 16GiB/s. The board has 2 external DDR4 banks connected to the FPGA. Each DDR channel has a soft core DRAM controller instantiated in the FPGA fabric providing a total theoretical bandwidth of 18GiB/s. The host PC is a quad-core Intel i5-4590 at 3.3 GHz with 8GiB of RAM running at 1600MHz.

Unless stated otherwise, the system frequency used on the FPGA is 250 MHz. While each Coyote vFPGA has a separate PLL-generated clock, all the experiments reported here used the same frequency for the vFPGAs.

4.1 Macro-benchmark: decision trees

We first compare the performance of a complete, mature application running on Coyote with that obtained on Amazon F1 instances with the Xilinx SDAccel programming framework [58] and the Intel HARP environment [39]. It is hard to draw detailed conclusions from such a coarse-grained comparison, but we aim to show that (1) Coyote is a viable platform

Figure 7: Performance of decision trees.

for real applications, and (2) the portability and programming features of Coyote come with negligible performance cost. The application is an open-source implementation [40, 41] of Gradient Boosting Decision Trees [34], focussing here exclusively on inference over decision tree ensembles.

Decision trees are a popular form of supervised machine learning for widely used tasks like classification and regression. They are constructed by recursively splitting the data into multiple groups. Using a cost function splits are evaluated and a greedy algorithm decides which split is the best candidate. Recursive splitting terminates at a pre-determined tree depth to prevent overfitting.

To do inference on the FPGA, the tree model is first loaded into FPGA on-chip memory. Data is then fetched from the host, inference performed, and the results copied back to host memory. All three phases are overlapped, allowing computation latency to be hidden behind memory operations.

We compare inference throughput (scored tuples per second) over Coyote with the same application on F1, and with a port running on Intel’s hybrid CPU-FPGA HARP v2 platform. The latter is a rather different platform and the FPGA is clocked at 200MHz instead of 250MHz. Since F1 targets OpenCL applications, the SDAccel port employs a strict GPU-based compute model which incurs high data transfer overhead. In all cases, we measure throughput with both one and two instances of the application running on the FPGA with the data size of 4k tuples. On all platforms, the inference engine is compute-bound and requires only 4 GiB/s of memory bandwidth, allowing two instances to operate at full capacity.

The results are shown in Figure 7. Coyote provides comparable or better performance to that of the two commercial baselines. In the case of F1, this is despite Coyote providing portability and supporting multiple vFPGAs (SDAccel only allows a single dynamic region on the FPGA). True comparison with HARP is more tentative, given the lower clock frequency and very different hardware.

Nevertheless, we can conclude that, at the very least, there is no performance penalty in using Coyote in this case, and benefiting from the qualitative value it brings.

# vFPGAs	Stacks	LUTs	BRAM	Regs
1	✗	4%	4%	2%
2	✗	5%	5%	3%
4	✗	6%	7%	4%
1	✓	9%	10%	6%
2	✓	11%	12%	7%
4	✓	14%	14%	9%

Table 1: Resource overhead

Figure 8: Time to load the operator and provide the view.

4.2 Space overhead

Raw performance is not the only consideration when comparing FPGA implementations, however. The space overhead (more precisely, the various resources on the chip used for the framework) can be just as important.

In this regard, Coyote (or any such set of abstractions) is strictly worse than a custom, native implementation of an application that takes over the whole FPGA, just as a bare-metal program is likely to use fewer resources than one running on top of Linux or Windows.

The space overhead of the framework for varying numbers of virtual FPGA regions and configurations with and without memory and network stacks are shown in Table 1. We give figures for the principal logic resources on the FPGA: lookup tables (LUTs), block RAM (BRAM), and registers (Regs).

On the VU9P, Coyote incurs a base overhead of 2-4%, increasing by < 1% for each additional vFPGA. Adding network and memory stacks roughly doubles this, incurring at most 14% for a full-featured Coyote install with 4 vFPGAs.

Larger future FPGAs and migration of often-used functionality into hard IP are likely to reduce this overhead still further. We therefore consider this to be a modest penalty in return for the benefits Coyote offers.

4.3 Micro-benchmark: context switching

We next measure the performance penalty in context switching a vFPGA from one application to another.

Figure 9: Scheduling performance.

Partial reconfiguration is still relatively slow on FPGAs, despite recent improvements. Figure 8 shows partial reconfiguration latency of the Xilinx VU9P as a function of the chip area to be reconfigured; Coyote with 4 vFPGAs would correspond to roughly 20%, or 20ms, per vFPGA.

We note that achieving even this performance is non-trivial. Coyote’s implementation uses a fast data stream to the ICAP (the FPGA unit handling partial reconfiguration) which can saturate its bandwidth of about 800MiB/s. In contrast, SDAccel achieves a mere 19MiB/s over a slow AXI4-Lite link.

As mentioned in Section 3.3, this overhead can be reduced substantially by sharing the same vFPGA logic between successive tasks targeting the same partial bitstream (compute operator). We illustrate this with a simple example by scheduling queues of tasks from the four applications used in Section 4.4, all with small transfers of 4KiB each and all with the same priority. We configure Coyote here with 3 vFPGAs.

We dispatch jobs in three ways: *no-sched* is round-robin in both queues and vFPGAs. This causes a reconfiguration for each job and is the worst-case scenario. *rand* picks the next job from a random queue each time, and so has a 1-in-3 chance of needing a reconfiguration, and *sched* uses Coyote’s heuristic of grouping jobs which share the same user logic.

Figure 9 shows total turnaround time for 10, 50, and 100 jobs of each type. Unsurprisingly, minimizing the number of partial reconfigurations has a dominating effect on total system throughput. Clearly there is room here for much more sophisticated job scheduling, beyond the scope of this paper.

4.4 Resource sharing

We now evaluate how the OS-like features of Coyote can provide fair sharing of resources across multiple vFPGAs simultaneously. In cloud deployments, stable and predictable distribution of resources is a key requirement.

We run four different applications on Coyote: AES encryption, sha256 hash computation, HyperLogLog multiset cardinality estimation [18, 28] and k-means calculation [22]. In each experiment we run an application with one or more

simultaneous vFPGA instances at a time. All tests except the k-means are using the host memory and direct streaming. Due to the iterative nature, the k-means utilizes accesses to the local FPGA memory.

We measure per-application round-trip throughput vs. transfer size, including the transfer of the plain data to the FPGA user logic, pipeline computation, and simultaneous transfer of the computed results back to the memory. We use hardware counters in the FPGA fabric and so incur no overhead.

When multiple applications are running concurrently, we also calculate mean absolute deviation (MAD) of the instances from the average performance results, to give a quantitative measure of (un)fairness in resource allocation.

Results are shown in Figure 10. sha256 (Figure 10.a) is compute bound, and performance scales perfectly as long as all the vFPGAs fit in the FPGA.

More interesting is AES (Figure 10.b) which is memory-bound. Here multiple AES vFPGAs are competing for PCIe bandwidth, which is saturated in all cases due to the AES implementation being heavily pipelined. We observe that, firstly, throughput of an AES instance is inversely proportional to the number of peers in the system, showing that the scarce resource of PCIe bandwidth is being shared between them, and also the MAD is very low compared with total bandwidth, suggesting that sharing is fair.

The HyperLogLog implementation uses 16 parallel pipelines that are able to compute on a single cache-line at a time. The module is thus able to sustain processing at line rate for larger transfers (as are mostly present during cardinality estimation). For smaller transfers processing latency is the domineering factor. The results are shown in the Figure 10.c.

The final results (Figure 10.d) show the throughput of the k-means clustering operator during the single computation iteration. This is an iterative algorithm, where data is first offloaded from the host to the local FPGA memory. The data is then streamed to the user logic in each iteration and dispatched to 16 parallel pipelines on the FPGA to compute centroids, the results of which are then transferred back.

In summary, these results validate our goals of sharing scarce bandwidth on the FPGA between multiple tenants.

4.5 Striping

We evaluate the impact of Coyote hiding individual DRAM channels behind a single abstraction that stripes each 2MiB page across all channels on the FPGA for portability.

The benchmark is a simple DRAM to DRAM copy, implemented entirely on the FPGA and measuring throughput for transfers ranging from 4KiB to 1MiB. We measure bandwidth for three scenarios. First, *1-channel* copies memory using on a single channel, and is the baseline for performance. Second, *2-channel* reads from one channel and writes to another. This is the best case and requires knowledge of all the channels in the FPGA. It could be achieved in, for example,

(a) sha256 round throughput for different number of concurrent applications in dynamic regions.

(c) HyperLogLog throughput.

(b) AES round throughput for different number of concurrent applications in dynamic regions.

(d) k-means single iteration throughput.

Figure 10: Performance benchmarks for example applications running in Coyote showing fair sharing of the bandwidth.

Figure 11: Striping performance.

SDAccel by explicit placement of data on the channels and careful FPGA-specific code. Finally, **striping** shows Coyote’s performance when oblivious to channels and placement, and each data page is striped across channels.

Figure 11 shows the results. For small transfers, setup costs dominate, but a single channel becomes saturated at 16KiB and two channels at about 128KiB. Coyote incurs an overhead of about 10%, which is competitive with many cases of hand-optimized vs. compiler generated software code, and leads

us to conclude that abstracting the DRAM controllers is a worthwhile trade-off for performance isolation and portability.

4.6 Demand paging

GPU-style “unified memory” implements a form of distributed shared virtual memory between the host and FPGA, largely abstracting memory management and explicit data movement from the users. When a vFPGAs tries to access virtual locations on the local FPGA memory which are not present in the physical memory, a page fault is generated and the driver initiates a copy from host to FPGA memory, then adjusts page tables on both sides, before signalling the vFPGA that it can proceed.

Without this model, explicit copying of data would be required, as illustrated by this pseudocode:

```
void* host_d = malloc(size);
void* fpga_d = getFpgaMem(size);
offloadMemCpy(host_d, fpga_d, size);
executeOperator(fpga_d, size);
free(host_d);
freeFpgaMem(fpga_d);
```

The demand paging provided by “unified memory” allows a simpler (for the programmer) model, resulting in code like this:

Figure 12: Unified memory overhead.

```
void* host_d = malloc(size);
executeOperator(host_d, size);
free(host_d);
```

In a fully cache-coherent system like Enzian [21] this code would not require copies at all, but in PCIe-based systems they are needed in both directions: after the computation has completed, the pages holding the computation results must also be copied back to the host physical memory.

The cost, therefore, of the unified memory abstraction stems from page faults on both sides, remapping pages by modifying page tables, and copying the data between host and FPGA. In practice, this cost is amortized over the number of iterations (for example) that the computation performs for each transfer.

Figure 12 shows this overhead in the context of the whole computation. The workload represents kmeans iterating over 1MiB of data which has to be moved from the host to local FPGA memory. We vary the number of iterations and measure the impact of the page fault overhead and initial copy.

For a single iteration the overhead is high (95%), reflecting the fact that an iteration executes extremely quickly on the FPGA and is comparable in time to the copy, and suggesting that this model of memory usage is not ideal for streaming applications. However, as the iteration count reaches 500, the overhead has reduced to 2% and is likely to be an acceptable price to pay for programming convenience.

5 Related work

The FPGA community has generated a tremendous amount of work in recent years on programming and managing FPGAs. We have compared Coyote with many examples already in Section 3, and two recent surveys [24, 50] give an excellent overview. In this section, therefore, we focus on a few important recent systems.

The initial version of Microsoft’s Catapult [12, 43] environment offers a reusable, static portion of programmable logic accessible through a high level API. Configurability for the (single) application is possible for modules like the network (recently offloaded to a sophisticated ASIC) and memory. The

accelerator/smartNIC usage model means there is no support for virtualization nor partial reconfiguration.

Intel’s hybrid CPU-FPGA HARP design [39] turns the FPGA into one more processor. Intel implements its own QuickPath interconnect [23] supporting full cache-coherent memory access, but only to external memory on the CPU side. Usage model and management is similar to Catapult. Partial reconfiguration is possible but there is no option to include local on-board memory or network modules on the FPGA.

Xilinx SDAccel [58], used by Amazon [3] and Alibaba [1] in their cloud deployments, also divides the FPGA into a static “shell” and dynamic user regions. One application can run at a time, but the user logic can be exchanged at run time with the help of partial reconfiguration. To date, there is no support for I/O devices or network.

All these deployed systems support only a single application at a time, and also do not try to provide a shared virtual address space between host software and user logic. Systems in the research literature are rather more ambitious in adopting one or more ideas from traditional operating systems:

AmorphOS [26] aims to increase FPGA utilization by placing multiple applications on the FPGA. It provides protection on FPGA-attached memory, but no access to host memory. Protection is based on segments set up by the host OS. AmorphOS can operate in “low-latency mode”, where applications occupy different parts of the dynamic region, and “high-throughput” mode, where everything is synthesized into a single bitstream. Time-division multiplexing in low-latency mode is achieved by requiring applications to implement correct checkpoint and resume.

AmorphOS can be seen as pushing many traditional OS problems into the synthesis pipeline, and compiling many different bitstreams for configurations which, in Coyote, are handled at runtime by the same image. Since it provides no integration with the host memory system, and applications are directly compiled to the FPGA, AmorphOS provides no virtual memory facilities beyond segmented addressing of FPGA memory. Scheduling is simplified by not partially reconfiguring the FPGA, which also obviates the need to provide a uniform network interface.

AmorphOS optimizes how many applications can fit on one FPGA, at the cost of compilation and deployment overheads, by delegating OS functionality to synthesis tools. In contrast, Coyote’s OS-centric approach standardizes the execution environment, allowing applications to be flexibly deployed, and evaluates the cost of this generality.

Optimus [32] provides FPGA user logic with access to host memory via a per-application virtual address space. It partitions the dynamic region into application containers which appear not to be partially reconfigurable, but which can run the same user logic on behalf of multiple applications. As in AmorphOS, user logic implements checkpoint and restore to allow time-division multiplexing of resources. Optimus allows the host address space to be shared, but does not give

a host process access to the address space of a vFPGA.

Optimus has many similarities with Coyote, but focuses on a subset of OS functionality. By avoiding dynamically reconfiguring vFPGAs, scheduling is simplified relative to Coyote. Optimus provides address translation, but only for vFPGA-to-host access, whereas Coyote provides a true unified virtual address space shared between host process and user logic. This in turn allows Coyote to virtualize services like the network stack, something Optimus does not do. Optimus therefore does not provide a standard execution environment for bitstreams, since the functionality it does provide would not benefit from such an environment.

ViTAL [62] focusses on clusters of FPGAs and, unlike Coyote, addresses distributing applications across a cluster. While it provides a network device, and flexible multiplexing, it does not target hybrid CPU/FPGA systems, and provides neither unified memory, nor (e.g.) a shared network *stack* between vFPGAs.

ViTAL virtualizes access to the FPGA memory (like AmorphOS) and the network *device* (as a simple point-to-point communication link). As with Coyote, it uses a fixed partition of the dynamic region in reusable vFPGA which are allocated to applications when they are deployed. A key feature of ViTAL is being able to partition applications and compile them into multiple vFPGAs; these can then be deployed on the same FPGA or several connected by point-to-point links.

By not supporting host memory access nor virtualizing a high-level service like TCP or RDMA, ViTAL is relieved of the need for a virtual memory system. Moreover, by using the compiler to turning a set of physical FPGAs into one large logical FPGA by application partitioning, it obviates the need for a standard execution environment.

To greater or lesser degrees, all these systems focus on optimizing one or another metric and implement a subset of the critical functionality of a classical OS.

In contrast, Coyote investigates the consequences of a complete, general-purpose approach: putting a general OS feature set together (multi-user TCP/IP stack, unified memory translation/protection across CPU and FPGA, inter-application communication, standardized execution environment, etc.). Uniquely, this combination is what allows Coyote to provide shared high-level OS services like networking.

It also demonstrates that a full set of combined OS features fundamentally changes how a system like Coyote is designed, and this is where it differs most from prior work while still reusing a number of ideas from such systems. We return to this point in our conclusion.

6 Conclusion

Coyote approaches the FPGA shell as an *operating system design problem*. While putting individual OS features on an FPGA has value, taking a holistic view allows us to identify how things fit together. The design of virtual memory on an

FPGA changes radically when one takes into account e.g. FPGA-local devices, or the need to abstract local DRAM controllers. Conversely, abstracting such controllers only works when one has the right MMU design in place.

For example, allowing both software and hardware applications to initiate virtual memory accesses to both host and FPGA memory resources enables a uniform execution environment and portability across different memory systems, but may rule out the application-implemented checkpoint-and-restore approaches ViTAL and Optimus use for cooperative "preemption", since there is now per-application state (TLBs, etc.) not accessible to user logic.

As FPGAs become larger, the demand for the traditional OS functions of secure multiplexing, sharing, and abstraction will grow. At the same time, so will the opportunity to provide more OS-like functions on the FPGA. It is important that these functions work together. Our evaluation shows that the price of this complete OS functionality is more than acceptable in throughput, space efficiency, scheduling overhead, and memory bandwidth.

A further hardware trend, moreover, is the migration of commonly-used functions out of synthesized logic and into hard IP cores on the FPGA. In this rapidly-changing landscape, the right set of abstractions can prevent hard-to-develop OS-style logic from becoming rapidly obsolete.

Experience with software also suggests that OS abstractions are "sticky": once decided, they alter very slowly over time even when the underlying hardware changes radically, to the detriment of performance and security. This suggests that it is vitally important to get things "right" as early as possible.

Coyote is a small step in this direction, and shows that a coherent and reasonably complete set of OS abstractions, suitably modified, can map well onto an FPGA, deliver both immediate and longer-term benefits, and impose only a modest overhead on today's hardware.

Coyote can be downloaded at <https://github.com/fpgasystems/Coyote>.

Acknowledgements

This work has been made possible through a generous equipment donation from Xilinx and through access to the Xilinx Adaptive Compute Cluster (XACC) Program. The research of Dario Korolija is funded in part by a grant from HPE. We would like to thank Mohsen Ewaida, Zhenhao He and Amit Kulkarni for some of the use cases and designs, David Sidler for feedback and help with the network stack, the anonymous reviewers for their helpful comments and questions, and our shepherd Baris Kasikci for feedback and guidance.

A Artifact Appendix

A.1 Abstract

Coyote brings operating system abstractions to reconfigurable heterogeneous architectures. It provides a range of abstractions which ease the interaction between the host, the FPGA, the memory and the network. The following sections will describe the process of obtaining the framework resources and building them. The application deployment procedure is shown as well.

A.2 Artifact check-list

- **Compilation:** HLS, CMake, C++, Boost.
- **Run-time environment:** Vivado, Linux.
- **Hardware:** Xilinx.
- **Metrics:** Throughput, latency, resources, reconfiguration.
- **Experiments:** HyperLogLog, kmeans, AES, sha256, decision trees, microbenchmarks.
- **Required disk space:** 4MiB.
- **Expected experiment run time:** 2 hours.
- **Public link:** <https://github.com/fpgasystems/Coyote>.

A.3 Description

A.3.1 How to access

The open-source version of the Coyote framework can be found on Github at the following address:

<https://github.com/fpgasystems/Coyote>.

A.3.2 Hardware dependencies

The framework targets a variety of Xilinx data center and development boards. At this point full support for the following boards is provided: Alveo U250, Alveo U280, VCU118. The boards have to be attached to the host system over the PCIe. If available, the framework takes advantage of the AVX2 (*Advanced Vector Extensions*) instruction set. Legacy support is also provided.

The hardware build process relies on the Vivado toolchain and its high-level synthesis extension. Versions 2019.2 and 2020.1 have been officially tested. The toolchain is used for the compilation of the full and partial bitstreams. It also handles the deployment of the full bitstreams. The automation of the hardware build process is done with CMake. Minimum required version is 3.0.

A.3.3 Software dependencies

The software build process is split between the low level Linux kernel driver and the high level user application layers.

The driver code was tested on the machine with the Linux kernel version 5.4. This code is built with Makefile.

The user application layer is fully written in C++11. The Boost libraries (<https://www.boost.org/>) are used for the parsing of the command line arguments. As with hardware, CMake with a minimum version of 3.0 is required for the software build automation.

A.4 Installation

Pull the newest version of the repository:

```
$ git clone https://github.com/fpgasystems/Coyote
$ cd Coyote
```

The network stack submodule and the correct branch can then be initialized:

```
$ git submodule update --init --recursive
```

At this point all the necessary resources are available locally. Further build is split into separate hardware and software processes.

A.4.1 Hardware build

This section explains the process of creating the custom hardware design, the integration of the arbitrary user logic and finally the formation of the valid FPGA bitstreams.

First create the build directory inside the hw directory:

```
$ cd hw
$ mkdir build
$ cd build
```

Enter a valid chosen system configuration:

```
$ cmake .. -DFDEV_NAME=u250 <params...>
```

Large level of configuration flexibility for the framework is available. This allows the framework to adapt to a variety of processing scenarios. The following parameters can be chosen (bolded parameters are passed by default):

- **FDEV_NAME:** This is the name of the target device. Supported parameters are **<u280, u250, vcu118>**.
- **N_REGIONS:** This is the number of concurrent vFPGAs (independent regions). The maximum of 16 regions per FPGA is supported at the moment **<1:16>**.
- **EN_STRM:** Enables the direct host-FPGA streaming over PCIe lanes **<0, 1>**.
- **EN_DRAM:** Enables the local FPGA memory stack **<0, 1>**. It can work in conjunction with the streaming.
- **N_DRAM_CHAN:** The number of the chosen DRAM channels. The maximum available number depends on the target board. **<1:4>**.

- **EN_PR:** Enables the partial reconfiguration flow <0, 1>. This partitions the FPGA fabric into multiple dynamic regions. The number depends on the amount of vFPGAs present. A separate partial bitstream will be generated for each dynamic region. Manual floorplanning of dynamic regions is advised.
- **EN_TCP:** Enables the 100G TCP/IP stack <0, 1>. This integrates a TCP/IP network stack and exposes its communication interface to every vFPGA.
- **EN_RDMA:** Enables the 100G RDMA stack <0, 1>. This integrates a full RDMA network stack with reliable communication protocol (RC) built on top of RoCE v2. Interface is exposed to every vFPGA.

The build directory with the chosen configuration is initiated once the previous command completes. Now referenced high-level synthesis cores can be built:

```
$ make installip
```

The hardware project can then be created:

```
$ make shell
```

Once this command completes, the project with one static and initial vFPGA regions is created (config 0). If partial reconfiguration flow is enabled, additional sets of partial bitstreams (new logic for each vFPGA) can be created:

```
$ make dynamic
```

This command can be executed multiple times to create multiple sets of partial bitstreams (config 1, 2, 3, ...).

At this point the user logic can be inserted into vFPGAs. Wrappers can be found under build project directory in the hdl/config_X. Once the user design is ready to be compiled, run the following command:

```
$ make compile
```

When the compilation finishes, the initial bitstream with the static region can be loaded to the FPGA via JTAG. This can be done in Vivado's programming utility. At any point during the compilation, the status can be checked by opening the project in Vivado (`start_gui` command).

All compiled bitstreams, including partial ones, can be found in the build directory under bitstreams.

A.4.2 Driver

The driver can be compiled on the host machine:

```
$ cd driver
$ make
```

Once the bitstream is loaded on to the target FPGA, the rescan of the PCIe can be executed with the utility script:

```
$ ./util/hot_reset.sh
```

If during this card detection fails, warm reboot of the host machine has to be completed. The driver can then be inserted into the kernel:

```
$ insmod fpga_drv.ko
```

The software applications can now be executed.

A.4.3 Software build

This section explains the process of building the user applications that utilize the provided high-level API. Additionally, the scheduling example provides the runtime manager which abstracts the application deployment.

First create the build directory inside the directory of the chosen software project:

```
$ cd sw/<project>
$ mkdir build
$ cd build
```

Initiate the build configuration and compile the executable:

```
$ cmake ..
$ make main
```

System permissions need to be assigned to the executable.

A.4.4 Simulation

The user logic hardware can be simulated in Vivado:

```
$ cd hw/sim/scripts/sim
$ vivado -mode tcl -source tb.tcl
```

At this point any user logic can be inserted and arbitrary stimulus applied. The signal behaviour can then be observed.

A.5 Evaluation and expected result

The user logic for hardware applications (HyperLogLog, kmeans, AES, decision trees, sha256) and all microbenchmarks can be found under hw/hdl/operators. Examples of specific network operators are supplied as well. Default configurations of every operator coincide with ones used to obtain the results in the paper.

The code in sw/base is used for the tests where no explicit operator control is needed (AES, HyperLogLog, sha256). The code in sw/scheduling is used for the measurements of the reconfiguration time. Separate code for the operators requiring more control is provided (kmeans and decision trees).

A.6 Experiment customization

A wide variety of test cases and customization is available through different system configurations. The users can create different versions of the system through combinations of vFPGAs, network and memory stacks.

A.7 AE Methodology

Submission, reviewing and badging methodology:

Abstract

The adoption of low latency persistent memory modules (PMMs) upends the long-established model of remote storage for distributed file systems. Instead, by colocating computation with PMM storage, we can provide applications with much higher IO performance, sub-second application failover, and strong consistency. To demonstrate this, we built the Assise distributed file system, based on a persistent, replicated coherence protocol that manages client-local PMM as a *linearizable* and *crash-recoverable* cache between applications and slower (and possibly remote) storage. Assise maximizes locality for all file IO by carrying out IO on process-local, socket-local, and client-local PMM whenever possible. Assise minimizes coherence overhead by maintaining consistency at IO operation granularity, rather than at fixed block sizes.

We compare Assise to Ceph/BlueStore, NFS, and Octopus on a cluster with Intel Optane DC PMMs and SSDs for common cloud applications and benchmarks, such as LevelDB, Postfix, and FileBench. We find that Assise improves write latency up to 22×, throughput up to 56×, fail-over time up to 103×, and scales up to 6× better than its counterparts, while providing stronger consistency semantics.

1 Introduction

Byte-addressable non-volatile memory (NVM), such as Intel's Optane DC persistent memory module (PMM) [14], is now commercially available as main memory. NVM provides high-capacity persistent memory with near-DRAM performance at lower cost. The promise of NVM as a low-cost main memory add-on is driving the adoption of node-local NVM at scale [43, 86, 87]. Remote direct memory access (RDMA) allows NVM access across the network without CPU overhead, raising interest in NVM for high-performance distributed storage.

A common paradigm in distributed file systems, like Amazon EFS [2], NFS [39], Ceph [82], Colossus/GFS [37], and NVM re-designs, like Octopus [58] and Orion [85], is to separate storage servers from clients. In this server-client design, files are stored by servers on machines physically separated from clients running applications. Client main memory is treated as a volatile block cache managed by the client's OS

kernel. This design simplifies resource pooling by physically separating application from storage concerns with simple, server-managed data consistency mechanisms.

This simplicity comes at a cost, which becomes apparent as we move from SSD/HDD to NVM storage. In steady state, application performance is limited by the overhead to access kernel-level client caches. Upon a cache miss, multiple network round trips are needed to consult remote metadata servers and to fetch the actual data. On failure, client-server file systems must rebuild caches of failed clients from scratch, involving long fail-over times to re-establish application-level service and necessitating high network utilization during recovery. Third, managing client caches at fixed page-block granularity amplifies the small IO operations typical of many distributed applications and increases cache coherence overhead when IO is larger than the block size. These costs prevent NVM from reaching its performance potential and have led some within the storage community to advocate for a complete redesign of the file system API [54, 72, 73, 88].

We present Assise, a distributed file system designed to maximize the use of *client-local* NVM without requiring a new API for high performance. Assise unleashes the performance of NVM via pervasive and persistent caching in process-local, socket-local, and node-local NVM. Assise accelerates POSIX file IO by orders of magnitude by leveraging client-local NVM without kernel involvement, block amplification, or unnecessary coherence overheads. Assise provides near-instantaneous application fail-over onto a *hot replica* that mirrors an application's local file system cache in the replica's local NVM. Assise reduces node recovery time by orders of magnitude by locally recovering NVM caches with strong consistency semantics. Finally, Assise leverages cluster-wide NVM via *warm replicas* that provide lower latency reads than slower storage media, such as SSDs. In cascaded hot replica failure scenarios, warm replicas can become hot replicas to preserve near-instantaneous fail-over.

To enable these properties, we design and build to our knowledge the first crash consistent distributed file system cache coherence layer for replicated NVM (CC-NVM). CC-NVM serves cached file system state in Assise with strong consistency guarantees and locality. CC-NVM provides prefix crash consistency [80] by enforcing write order to local

†Co-student authors.

NVM via logging and to cross-socket and remote NVM by leveraging the write order of DMA and RDMA, respectively. CC-NVM provides linearizability for all IO operations via leases [38] that can be delegated among nodes, sockets, and processes for local management of file system state. CC-NVM consistently chain-replicates [77] all file system updates to a configurable set of hot and warm replicas for availability.

Using CC-NVM, Assise achieves the following goals:

- **Simple programming model.** Assise supports unmodified applications using the familiar POSIX API with strong linearizability and crash consistency [80].
- **Scalability.** Unlike NVM-aware distributed file systems that are limited to rack-scale [71, 85], Assise provides strong consistency but remains scalable using dynamic delegation of leases to nodes, sockets, and processes; local sharing uses CC-NVM for consistency without network, cross-socket, or kernel communication.
- **Low IO tail latency.** To efficiently support applications with low tail latency requirements, Assise allows kernel-bypass access to authorized local and remote NVM areas. To reduce write latency with replicated persistence, Assise provides an optimistic mode using asynchronous chain replication with prefix crash consistency.
- **High availability.** Assise provides near-instantaneous fail-over to a configurable number of replicas and minimizes the time to restore the replication factor after failure.
- **Efficient bandwidth use.** The high bandwidth provided by NVM means that communication can be a throughput bottleneck (cf. Table 1). Assise minimizes communication by eliminating redundant writes [52] and reducing coherence protocol overhead via logging.

We make the following contributions:

- We present the design (§3) and implementation (§4) of Assise, a distributed file system that fully utilizes NVM by persistent caching in client-local NVM as a primary design principle. Assise uses client-local NVM to recover the file system cache for fast fail-over and locally synchronizes reads and writes to file system state.
- We present CC-NVM (§3.3), the first persistent and available distributed cache coherence layer. CC-NVM provides locality for data and metadata access, replicates for availability, and provides linearizability and prefix crash consistency for all file system IO.
- We quantify the performance benefits of using local NVM versus remote NVM for distributed file systems (§5). We compare Assise’s steady-state and fail-over behavior to RDMA-accelerated versions of Ceph with BlueStore [21] and NFS, as well as Octopus [58], a distributed file system designed for RDMA and NVM, using common cloud applications and benchmarks, such as LevelDB, Postfix, MinuteSort, and FileBench.

Our evaluation shows that Assise provides up to $22\times$ lower write latency and up to $56\times$ higher throughput than NFS and Ceph/BlueStore. Assise outperforms Octopus by up to an

Memory	R/W Latency	Seq. R/W GB/s	\$/GB
DDR4 DRAM	82 ns	107 / 80	9.77 [19]
NVM (local)	175 / 94 ns	32 / 11.2	3.83 [20]
NVM-NUMA	230 ns	4.8 / 7.4	-
NVM-kernel	0.6 / 1 μ s	-	-
NVM-RDMA	3 / 8 μ s	3.8	-
SSD (local)	10 μ s	2.4 / 2.0	0.32 [15]

Table 1: Memory & storage price/performance (October 2020).

order of magnitude. Assise scales better than Ceph, providing $6\times$ throughput for Postfix with 48 processes over 3 nodes. Assise is more available than Ceph, returning a recovering LevelDB store to full performance up to $103\times$ faster. Demonstrating that strong consistency with the familiar POSIX API and high performance are not mutually exclusive, Assise finishes a local external sort 3% faster than a hand-tuned implementation using processor loads and stores to memory mapped NVM. Finally, Assise finishes the MinuteSort distributed sorting benchmark up to $2.2\times$ faster than a parallel NFS installation.

Assise supports networked access to remote storage where it makes sense. Assise can automatically migrate cold data that does not fit in NVM to slower, network-attached storage devices, such as SSDs and HDDs. To do so, Assise’s implementation builds on Strata [52] as its node-local store.

2 Background

Distributed applications have diverse workloads, with IO granularities large and small [56], different sharding patterns, and consistency requirements. All demand high availability and scalability. Supporting these properties simultaneously has been the focus of decades of distributed storage research [23, 39, 41, 58, 81, 82, 85]. Before NVM, trade-offs had to be made. For example, by favoring large transfers ahead of small IO, or steady-state performance ahead of crash consistency and fast recovery, leading to the common idiom of remote-storage file system design. We argue that with the arrival of fast NVM, these trade-offs need to be re-evaluated.

The opportunity posed by NVM is two-fold:

Cost/performance. Table 1 shows measured access latency, bandwidth, and cost for modern server memory and storage technologies, including Optane DC PMM (measurement details in §5). We can see that local NVM access latency and bandwidth are close to DRAM, up to two orders of magnitude better than SSD. At the same time, NVM’s per-GB cost is only 39% that of DRAM. NVM’s unique characteristics allow it to be used as the top layer in the storage hierarchy, as well as the bottom layer in a server’s memory hierarchy.

Fast recovery. Persistent local storage with near-DRAM performance can provide a *recoverable* cache for hot file system data that can persist across reboots. The vast majority of system failures are due to software crashes that simply require rebooting [25, 36, 40]. Caching hot file system data in NVM allows for quick recovery from these common failures.

For these reasons, data center operators are deploying NVM

at scale [43, 86, 87]. However, to fully realize its potential, we have to efficiently use local NVM. NVM accessed via RDMA (NVM-RDMA), via loads and stores to another CPU socket (NVM-NUMA), or via the kernel on the same socket (NVM-kernel) can be an order of magnitude slower in terms of latency and bandwidth.

2.1 Related Work

We survey the existing work in distributed storage and highlight why it cannot fully utilize the storage system performance offered by local NVM.

Block and object stores, such as Amazon’s EBS [1], S3 [3], and Ursa [56], provide a new API to a multi-layer storage hierarchy that can provide cheap, fault-tolerant access to vast amounts of data. However, block stores have a minimum IO granularity (16KB for EBS) and IO smaller than the block size suffers performance degradation from write amplification [56, 69]. For this reason, Dropbox uses Amazon S3 for data blocks, but keeps small metadata in DRAM for fast access, backed by an SSD [62]. Apache Crail [4] and Blizzard [63] provide file system APIs on top of block stores, but both focus on parallel throughput of large data streams, rather than small IO.

To realize the performance benefits of NVM for all IO, we need to abandon fixed block sizes and instead persist and track IO at its original operation granularity. Hence, Assise leverages logging to persist writes at their original granularity in NVM. A similar model is realized in the RAMcloud [66] key-value store. RAMcloud maintains data in DRAM for performance, using SSDs for asynchronous persistence. However, the capacity limits of DRAM mean that many RAMcloud operations still involve the network, and because DRAM state cannot be recovered after a crash, it is vulnerable to cascading node failures. Even after single node failures, state must be restored from remote nodes and RAMcloud requires a full-bisection bandwidth network for fast recovery. Assise leverages local NVM for recovery and does not require full-bisection bandwidth or asynchronous backup storage.

Client-server file systems, like Ceph [82], use distributed hashing over nodes to provide scalable file service for cloud applications. However, network and system call latency harms file IO latency, as shown in Table 1. Typical network access bandwidth to NVM is similarly surpassed by the higher bandwidth of local NVM.

To combat network overheads, several file systems have been built [58, 85] or retrofitted [13, 39, 44] to use RDMA. Octopus [58] and Orion [85] are redesigns that use RDMA for high performance access to NVM. Still, neither leverages kernel-bypass for low-latency IO (Octopus uses FUSE, Orion runs in the kernel) and both pool storage remotely. Like Ceph, Octopus uses distributed hashing to place files on nodes (Octopus does not replicate). Orion can store data locally via “internal clients,” but uses a metadata server. Clover [76] is a key-value store that takes the opposite approach, locating metadata with applications, but storing data remotely. All

Concept	Explanation
LibFS	Per-process, user-level file system library
SharedFS	Per-socket system daemon; manages local leases
CC-NVM	Crash-consistent cache coherence with linearizability
Hot replica	Cache-hot replica for fast failover
Warm replica	Provides NVM for low-latency, remote, warm reads
Cluster manager	Fault-tolerant service for membership & leases

Table 2: Concepts used in Assise.

systems perform remote operations in the common case to update data and/or metadata, increasing IO latency.

Network latency and limited bandwidth increase operation latency, reduce throughput, and limit scalability. For example, due to update contention at a central metadata server, Orion scales only to a small number of clients. Orion omits an evaluation of server fail-over and recovery (Assise’s is in §5.4). Tachyon [55] aims to circumvent replication overhead by leveraging the concept of *lineage*, where lost output is recovered by re-executing application code that created the output. However, to do so, Tachyon requires applications to use a complex data lineage tracking API.

To maximize NVM utility, we need to design for a scenario where kernel and networking overheads are high compared to storage access. Hence, Assise eliminates kernel overhead for local IO operations and remote IO incurs a single operation to the nearest replica in the common case, without requiring dedicated metadata servers or a distributed hash to balance load. For scalability, we need to enforce data and metadata consistency locally, which CC-NVM tackles with the help of leases. Unlike Tachyon, Assise supports the classic POSIX file API and is fully compatible with existing applications.

Leases [38, 57] have long been integral to performance in distributed file systems, by allowing local operations to leased portions of the file system name space, with linearizability. Read-only leases are a common design pattern [12, 27, 39, 42], but some research systems have explored using both read and write leases in a similar manner to Assise. A prominent example is Berkeley xFS [23], which maintained a local block-level update log at each node, written as a software RAID 5/6 partitioned across other nodes. Assise differs from xFS by using an operational log, replicating rather than striping the log, and by doing update coalescing.

2.2 Remote Storage versus Local NVM

Figure 1 contrasts the IO architecture of traditional client-server file systems and Assise. Each subfigure shows two dual-socket nodes executing a number of application processes sharing a distributed file system. Both designs use a replicated cluster manager for membership management and failure detection, but they diverge in all other respects.

Traditional distributed file systems first partition available cluster nodes into clients and servers. Clients cache file system state in a volatile kernel buffer cache that is shared by processors across sockets (NVM-NUMA) and accessed via expensive system calls (NVM-kernel). Persistent file system state is stored in NVM on remote servers. For persistence and

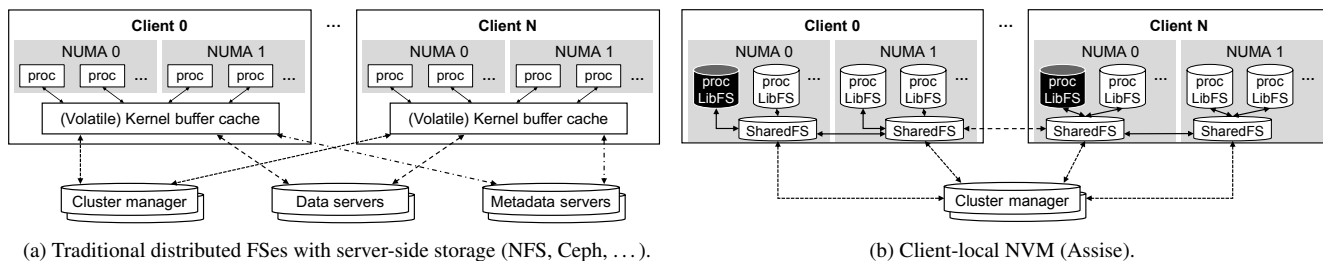

Figure 1: Distributed file system IO architectures. Arrow = RPC/system call. Cylinder = persistence. Black = hot replica.

consistency, clients thus have to coordinate updates with replicated storage and metadata servers via the network (NVM-RDMA) with higher latency than local NVM. The cluster manager is not involved in IO. Data is typically distributed at random over replicated storage servers for simplicity and load balance [82]. The overhead of updating a large set of storage nodes atomically means that (crash) consistency is often provided only for metadata, which is centralized.

3 Assise Design

Assise avoids remote storage servers and instead uses CC-NVM to coordinate linearizable state among processes. Processes access cached file system state in local NVM directly via a library file system (LibFS), which may be replicated for fail-over (two LibFS hot replicas shown in black in Figure 1). CC-NVM coordinates LibFSes hierarchically via per-socket daemons (SharedFS) and the cluster manager. Table 2 explains several Assise-related concepts.

Crash consistency modes. Assise supports two crash consistency modes: optimistic or pessimistic [30]. Mount options specify the chosen crash consistency mode. When pessimistic, `fsync` forces immediate, synchronous replication and all writes prior to an `fsync` persist across failures. When optimistic, Assise commits all operations in order, but it is free to delay replication until the application forces it with a `dsync` call [30]. Optimistic mode provides lower latency persistence with higher throughput, but risks data loss after crashes that cannot recover locally (§3.4). In either mode, Assise guarantees a prefix crash-consistent file system [80]—all recoverable writes are in order and no parts of a prefix of the write history are missing.

We now describe cluster coordination and membership management in Assise (§3.1). We then detail the IO paths (§3.2) and show how CC-NVM interacts with them to provide linearizability and prefix crash consistency (§3.3). Finally, we describe recovery (§3.4) and warm replicas (§3.5). We close with a discussion of connected design questions (§3.6).

3.1 Cluster Coordination and Failure Detection

Like other distributed file systems, Assise leverages a replicated cluster manager for storing the cluster configuration and detecting node failures. Assise uses the ZooKeeper [10] distributed coordination service as its cluster manager.

Cluster coordination. Each SharedFS in Assise registers with the cluster manager. In our prototype, the system admin-

istrator decides which SharedFS replicates which parts of the cached file system namespace and the caching policy (hot or warm replica) for arbitrary subtrees; the cluster manager records this mapping. When a subtree is first accessed, LibFSes contact their local SharedFS, which consults the cluster configuration and sets up an RDMA replication chain from LibFS through the subtree’s hot replicas. For each chain, hot replicas preallocate a configurable amount of NVM for replication (sensitivity evaluated in §5.2). It is future work to implement a distributed replica discovery service (e.g., using CC-NVM). LibFSes on any node are already able to cache any (meta-)data with linearizability.

Failure detection. The cluster manager sends heartbeat messages to each active SharedFS once every second. If no response is received after a timeout, the node is marked failed and all connected SharedFS are notified. When the node comes back online, it contacts the cluster manager and initiates recovery (§3.4).

3.2 IO Paths

Application IO interacts first with Assise caches. To keep tail latency low, Assise does not use a shared kernel buffer cache. Instead, LibFS caches file system state first in process-local memory. The LibFS cache uses both NVM and DRAM. NVM stores updates, while DRAM caches reads. LibFS implements the POSIX API at user-level. We now discuss cache operation upon IO, including replication, eviction, and access permissions. Figure 2 shows these mechanisms for two hot replicas and one warm replica, using SSDs for cold storage. Cache coherence is discussed in §3.3.

3.2.1 Write Path

Writes in Assise involve three mechanisms that operate on different time scales:

1. To allow for persistence with low latency, LibFS directly writes into a process-local cache in NVM (W). To efficiently support writes of any granularity, the write cache is an *update log*, rather than a block cache.
2. To outlive node failures, the update log is chain-replicated, with kernel-bypass, by LibFS (S1, S2).
3. When update logs fill beyond a threshold, evictions are initiated (E2), moving their contents to SharedFS. We describe replication and eviction next.

Replication and crash consistency. When pessimistic, `fsync` forces immediate, synchronous replication. The caller

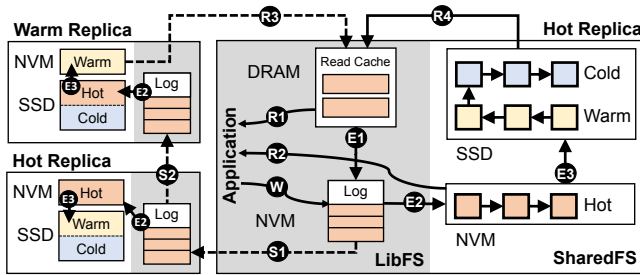

Figure 2: Assise IO paths. Dashed line = RDMA operation, solid line = local operation. Shaded areas are per process.

is blocked until all writes up to the `fsync` have been replicated. Thus, all writes prior to an `fsync` outlive node failures.

When optimistic, Assise is free to delay replication. This provides Assise with an opportunity to *coalesce* [52] temporary durable writes (i.e., overwritten or deleted files), a workload pattern seen in application-level commit protocols [67]. Eliminating these writes allows Assise to conserve network bandwidth. In optimistic mode, Assise initiates replication on `dsync` or upon log eviction.

In both cases, the local update log contents are written to preallocated NVM on the first replica along the replication chain via RDMA (S1). The replica continues chain replication to the next replica (S2), and so on. The final replica in the chain sends an acknowledgment back along the chain to indicate that the chain completed successfully.

Cache eviction. When a LibFS update log fills, it replicates any unreplicated writes and initiates eviction. Eviction is done in least-recently-used (LRU) fashion through the SharedFS shared caches to cold storage (E2, E3). Hot replicas keep *hot* data in NVM, while moving *warm* and *cold* data to cold storage. Warm replicas (§3.5) keep hot and cold data in cold storage, while warm data resides in NVM to accelerate warm reads (§3.5). Cold storage may be remote (e.g., via NVMe-over-Fabrics [17]). Each replica along the chain evicts in parallel and acknowledges when eviction is finished. This ensures that all replicas cache identical state for fast failover.

For log eviction (E2), issuing direct stores to NVM shared caches on another socket has overhead due to cross-socket hardware cache coherence, limiting throughput [83]. Since CC-NVM provides cache coherence, Assise can bypass hardware cache coherence by using DMA [53] when evicting to NVM-NUMA. This yields up to 30% improvement in cross-socket file system write throughput (§5.5).

3.2.2 Read Path

LRU cache eviction guarantees that the latest version of all data is always available in the fastest cache. Thus, upon a read, LibFS (1) checks the process-private write and read caches (via a *log hashtable* and *read cache*, shown in Figure 2) for the requested data (R1). If not found, LibFS (2) checks the node-local hot SharedFS cache (R2) (via an *extent tree* used to index the SharedFS cache [52]). If the data was found in either of these areas, it is read locally. If not found, LibFS (3)

checks the warm replica’s SharedFS cache (R3), if it exists, and, in parallel, checks cold storage (R4).

Read cache management. Recently read data is cached in process-local DRAM, except if it was read from local NVM, where DRAM caching does not provide benefit. LibFS prefetches up to 256KB from cold storage and up to 4KB from remote NVM. For remote NVM reads, LibFS first fetches the requested data and then prefetches the remainder. This minimizes small read latency while improving the performance of workloads with spatial locality. Data from remote NVM and cold storage is evicted from the read cache to the process-local update log (E1).

3.2.3 Permissions and Kernel Bypass

Assise assumes a single administrative domain with UNIX file and directory ownership and permissions. SharedFS enforces that LibFS may access only authorized data, by checking permissions and metadata integrity upon cache eviction and enforcing permissions on reads. To minimize latency of node-local SharedFS cache reads, Assise allows read-only mapping of authorized parts of the SharedFS cache into the LibFS address space. LibFS caches and mappings are invalidated when files or directories are closed and whenever the update log is evicted.

The metadata integrity of the file system is ensured by SharedFS. LibFS operations do not prevent one thread from corrupting another’s data in the process-local update log, but SharedFS verifies that all metadata operations are valid before they become visible to other processes. This implies that processes can corrupt *their* own data in their private update log, even after it was written (memory protection keys can mitigate inter-thread data corruption [34]). However, only process-local writes go to the process-local update logs. Multi-process access to any filesystem object (including a subtree) is linearizable and access-controlled via leases. Processes cannot corrupt shared file system (meta-)data.

3.3 Crash Consistent Cache Coherence with CC-NVM

CC-NVM provides distributed cache coherence with linearizability when sharing file system state among processes; it provides prefix semantics upon a crash.

Prefix crash consistency. To provide prefix crash consistency, CC-NVM tracks write order via the update log in process-local NVM. Each POSIX call that updates state is recorded, in order, in the update log. When chain-replicating, CC-NVM leverages the write ordering guarantees of (R)DMA to write the log in order to replicas. In optimistic mode, CC-NVM wraps coalesced file system operations in a Strata transaction [52]. This ensures that file system updates are persisted and replicated atomically and that a prefix of the write history can be recovered (§3.4).

Sharing with linearizability. CC-NVM serializes concurrent access to shared state by multiple processes and recovers the same serialization after a crash via leases [38]. Leases

provide a simple, fault-tolerant mechanism to delegate access. Leases function similarly to reader-writer locks, but can be revoked (to allow another process access) and expire after a timeout (after which they may be reacquired). In CC-NVM, leases are used to grant shared read or exclusive write access to a set of files and directories—multiple read leases to the same set may be concurrently valid, but write leases are exclusive. Reader/writer semantics efficiently support shared files and directories that are read-mostly and widely used, but also write-intensive files and directories that are not frequently shared. CC-NVM also supports a *subtree lease* that includes all files and directories at or below a particular directory. A subtree lease holder controls access to files and directories within that subtree. For example, a LibFS with an exclusive subtree lease on `/tmp/bwl-ssh/` can recursively create and modify files and directories within this subtree.

Leases must be acquired by LibFS from SharedFS via a system call before LibFS can cache the data covered by the lease. Assise does this upon first IO; leases are kept until they are revoked by SharedFS. This occurs when another LibFS wishes access to a leased file or when a LibFS instance crashes or the lease times out. Lease revocation latency is bounded by a grace period, within which the current lease holder can finish its ongoing IO before releasing contended leases. If LibFS fails to surrender the lease after the grace period, the lease is revoked by SharedFS and any subsequent IO on the leased file is rejected as invalid. SharedFS enforces that the lease holder's read and write caches are cleaned and evicted of the covered data before the lease is transferred. The time taken to do so is bounded by the holder's update log size. SharedFS logs and replicates each lease transfer in NVM for crash consistency. A LibFS may overlap IO with SharedFS lease replication until `fsync/dsync`.

Hierarchical coherence. To localize coherence enforcement, leases are delegated hierarchically. The cluster manager is at the root of the delegation tree, with SharedFSes as children, and LibFSes as leaves (cf. Figure 1b). LibFSes request leases first from their local SharedFS. If the local SharedFS is not the lease holder, it consults the cluster manager. If there is no current lease holder, the cluster manager assigns the lease to the requesting SharedFS, which delegates it to the requesting LibFS and becomes its *lease manager*. If a lease manager already exists, SharedFS forwards the request to the manager and caches the lease manager's information (leased namespace and expiration time of lease). The cluster manager expires lease management from SharedFSes every 5 seconds. This allows CC-NVM to migrate lease management to the local SharedFS, while preventing leases from changing managers too quickly, facilitating scalability.

Hierarchical coherence minimizes network communication and thus lease delegation overhead. LibFSes on the same node or socket require only local SharedFS delegation in the common case. This structure maps well to the data sharding patterns of many distributed applications (§5.5).

3.4 Fail-over and Recovery

Assise caches file system state with persistence in local NVM, which it can use for fast recovery. Assise optimizes recovery performance for the most common crash types.

LibFS recovery. An application process crashing is the most common failure scenario. In this case, the local SharedFS simply evicts the dead LibFS update log, recovering all completed writes (even in optimistic mode) and then expires its leases. Log-based eviction is idempotent [52], ensuring consistency in the face of a system crash during eviction. The crashed process can be restarted on the local node and immediately re-use all file system state. The LibFS DRAM read-only cache has to be rebuilt, with minimal performance impact (§5.4).

SharedFS recovery. Another common failure mode is a reboot due to an OS crash. In this case, we can use NVM to dramatically accelerate OS reboot by storing a checkpoint of a freshly booted OS. After boot, Assise can initiate recovery for all previously running LibFS instances, by examining the SharedFS log stored in NVM.

Cache replica fail-over. To avoid waiting for node recovery after a power failure or hardware problem, we immediately fail-over to a hot replica. The replica's SharedFS takes over lease management from the failed node, using the replicated SharedFS log to re-grant leases to any application replicas. The new instances will see all IO that preceded the most recently completed `fsync/dsync`.

Writes to the file system can invalidate cached data of the failed node during its downtime. To track writes, the cluster manager maintains an epoch number, which it increments on node failure and recovery. All SharedFS instances are notified of epoch updates. All SharedFS instances share a per-epoch bitmap in a sparse file indicating what inodes have been written during each epoch. The bitmaps are deleted at the end of an epoch when all nodes have recovered.

Node recovery. When a node crashes, the cluster manager makes sure that all of the node's leases expire before the node can rejoin. When rejoining, Assise initiates SharedFS recovery. A recovering SharedFS contacts an online SharedFS to collect relevant epoch bitmaps. SharedFS then invalidates every block from every file that has been written since its crash. This simple protocol could be optimized, for instance, by tracking what blocks were written, or checksumming regions of the file to allow a recovering SharedFS to preserve more of its local data. But the table of files written during an epoch is small and quickly updated during file system operation, and our simple policy has been sufficient.

3.5 Warm Replicas

To fully exploit the memory hierarchy presented in Table 1, remote NVM can be used as a third-level cache, below local DRAM and local NVM. To do so, we introduce *warm replicas*. Like hot replicas, warm replicas receive all file system updates via chain-replication, but leverage a different update

log eviction policy. Warm replicas track the LRU chain for a specified portion of “warm data” beyond the LibFS and SharedFS caches. Warm replicas do not impact the latency of replicated writes, but they reduce read latency for warm data by serving these reads from NVM, rather than cold storage.

LibFSes can read from warm replicas via RDMA with lower latency and higher bandwidth than cold storage (NVM-RDMA versus SSD in Table 1). Applications do not run on warm replicas in the common case. In the rare case of a failure cascade crashing all hot replicas, processes can fail-over to warm replicas, albeit with reduced short-term performance. After fail-over, warm replicas become hot replicas and hot data must be migrated back into local NVM.

3.6 Discussion

Assise may be deployed at scale. The use of local NVM together with hierarchical lease delegation aligns well with datacenter server, rack, and pod architecture [22]. We discuss factors of Assise’s design that impact such a deployment. In particular, the memory overhead of per-process and per-replica update logs, the use of NVM and RDMA at scale, and security.

Update log scalability. Assise uses per-process and per-replica update logs for efficient chain-replication with kernel-bypass. These update logs are preallocated on process creation in our prototype. While update logs can support high performance at moderate size (§5.2), a deployment at scale might be concerned with the memory consumption of update logs. In this case, the per-process and per-replica update log size can be adapted dynamically to momentarily available NVM capacity and per-process IO demand. SharedFS can resize logs upon eviction. The most significant overhead for log resizing is memory registration for RDMA. It requires pinning the memory and mapping it in the RDMA NICs. This operation can be overlapped with the log eviction itself. To help reduce the need for frequent resizing, logs can be resized multiplicatively, similar to resizing approaches in prior work [84].

RDMA scalability. Assise uses RDMA reliable connections (RCs) for each process and replica. RCs require the NIC to create and maintain connection state. For larger clusters, maintaining a large number of connections can stress the NIC’s limited memory and degrade performance. Several proposals have been made to reduce NIC cache thrashing [29, 68] and Mellanox introduced dynamically-connected (DC) transports [70], which allows connection-sharing and enables a high degree of scalability. Assise can leverage these approaches to scale the use of RDMA.

NVM wear-out. Assise uses local NVM extensively. This use can lead to the wear-out of NVM. To prevent frequent NVM replacement at scale, it is important to minimize writes to the NVM media. Assise’s update logs minimize write amplification, but update log eviction in causes a 2× write amplification in the worst case. This write amplification can

be partially eliminated via coalescing as seen in workloads, like Varmail (§5.3). To further reduce write amplification, update log pages may be remapped to the SharedFS shared cache, without introducing any additional writes [48]. We leave this as future work.

Security. In a large-scale public cloud scenario, data from each tenant is usually encrypted for security. For this purpose, both NVM and RDMA support encryption of data at rest and in-flight. Intel’s Optane DC PMMs support transparent hardware encryption of data stored in NVM and modern RDMA NICs [61] support transparent encryption of RDMA operations.

4 Implementation

Assise uses *libpmem* [11] for persisting data on NVM and *libibverbs* for RDMA operations in userspace. Assise intercepts POSIX file system calls and invokes the corresponding LibFS implementation of these functions in userspace [8]. The Assise implementation consists of 28,982 lines of C code (LoC), with LibFS and SharedFS using 16,515 and 6,563 LoC, respectively. The remaining 5,904 LoC contain utility code, such as hash tables and linked lists. SharedFS communicates with LibFSes via shared memory [24]. Assise uses Strata code (LoC not counted) for cold storage in SSD and HDD.

Assise uses Intel Optane DC PMM in App-Direct mode. App-Direct exposes NVM as a range of physical memory. It is the most efficient way to access NVM, but it requires OS support. OS-transparent modes have weaker persistence or performance properties [45]. For example, memory mode integrates NVM as *volatile* memory, using DRAM as a hardware-managed level 4 cache. Sector mode exposes NVM as a disk, with attendant IO amplification and disk driver overheads.

4.1 Strata as a Building Block

Assise builds upon Strata’s local file system functionality and augments it with the CC-NVM cache coherence layer and RDMA to create a replicated and highly efficient distributed file system with prefix crash consistency. Assise inherits several components from Strata, including its use of extent trees to index storage managed by SharedFS (in turn based on Ext4 [60]), the LibFS update log, and log coalescing. We enhance Strata’s extent trees to manage directories and Strata’s leases to support delegation.

4.2 Efficient Network IO with RDMA

Assise makes efficient use of RDMA. For lossless, in-order data transfer among nodes, Assise uses RDMA reliable connections (RCs). RCs have low header overhead, improving throughput for small IO [49, 59]. RCs also provide access to one-sided verbs that bypass CPUs on the receiver side, reducing message transfer times [35, 64] and memory copies [74].

Log replication. Logs are naturally suited for one-sided RDMA operations. Replication typically requires only one RDMA write, reducing header and DMA overheads [59]. As-

Assise uses RDMA *write-with-immediate* for log replication. This operation performs a write and also notifies the remote replica to forward the data to the next replica in the chain. The only exceptions are when the remote log wraps around or when the local log is fragmented (due to coalescing), such that it exceeds the NIC’s limit for scatter-gather DMA.

Persistent RDMA writes. The RDMA specification does not define the persistence properties of remote NVM writes via RDMA. In practice, the remote CPU is required to flush any RDMA writes from its cache to NVM. Assise flushes all writes via the CLWB and SFENCE instructions on each replica, before acknowledging successful replication. In the future, it is likely that enhancements to PCIe will allow RDMA NICs to bypass the processor cache and write directly to NVM to provide persistence without CPU support [50].

Remote NVM reads. Assise reads remote data via RPC. To keep the request sizes small, Assise identifies files using their inode numbers instead of their path. As an optimization, DRAM read cache locations are pre-registered with the NIC. This allows the remote node to reply to a read RPC by RDMA writing the data directly to the requester’s cache, obviating the need for an additional data copy.

5 Evaluation

We evaluate Assise’s common-case as well as its recovery performance, and break down the performance benefits attained by each system component. We compare Assise to three state-of-the-art distributed file systems that support NVM and RDMA. Our experiments rely on several microbenchmarks and Filebench [75] profiles, in addition to several real applications, such as LevelDB, Postfix, and MinuteSort. Our evaluation answers the following questions:

- **IO latency and throughput breakdown (§5.2).** What is the hardware IO performance of a storage hierarchy with local NVM (Table 1)? How close to this performance do the file systems operate under various IO patterns? What are the sources of overhead?
- **Cloud application performance (§5.3).** What is the performance of cloud applications with various consistency, latency, throughput, and scalability requirements? What is the overhead of Assise’s POSIX API implementation versus hand-tuned, direct use of local NVM? By how much can a warm replica improve read latency? By how much can optimistic crash consistency improve write throughput for real applications?
- **Availability (§5.4).** How quickly can applications recover from various failure scenarios?
- **Scalability (§5.5).** How well does Assise perform when multiple processes share the file system? By how much can Assise’s hierarchical coherence improve multi-process, multi-socket, and multi-node scalability?

Testbed. Our experimental testbed consists of 5× dual-socket Intel Cascade Lake-SP servers running at 2.2GHz, with a total of 48 cores (96 hyperthreads), 384GB DDR4-2666 DRAM,

Table 3: Features of the evaluated distributed file systems.

6TB Intel Optane DC PMM, 375GB Intel Optane DC P4800X series NVMe-SSD, and a 40GbE ConnectX-3 Mellanox InfiniBand NIC, connected via an InfiniBand switch. Exploiting all 6 memory channels per processor, there are 6 DIMMs of DRAM and NVM per socket. NVM is used in App-Direct mode (§4). All nodes run Fedora 27 with Linux kernel version 4.18.19.

Hardware performance. We first measure the achievable IO latency and throughput for each memory layer in our testbed server. We do this by using sequential IO and as many cores of a single socket as necessary. We measure DRAM and NVM (App-Direct) latency and throughput using Intel’s memory latency checker [5]. NVM-RDMA performance is measured using RDMA read and write-with-immediate (to flush remote processor caches) operations to remote NVM. SSD performance is measured using `/dev/nvme` device files. The IO sizes that yielded maximum performance are 64B for DRAM, 256B for NVM, and 4KB for SSD. Table 1 shows these results. The measured IO performance for DRAM, NVM, and SSD matches the hardware specifications of the corresponding devices and is confirmed by others [45]. NVM-RDMA throughput matches the line rate of the NIC. NVM-RDMA write latency has to invoke the remote CPU (to flush caches) and is thus larger than read latency. We now investigate how close to these limits each file system can operate.

State-of-the-art. Table 3 shows performance-relevant features of the state-of-the-art and Assise. We can see that no open-source distributed file system provides all of Assise’s features. Hence, a direct performance comparison is difficult. We perform comparisons against the Linux kernel-provided NFS version 4 [39] and Ceph version 14.2.1 [82] with BlueStore [21], both retrofitted for RDMA, as well as Octopus [58]. We cannot directly compare with Orion [85] as it is not publicly available, but we emulate its behavior where possible. Only Ceph provides availability via replicated object storage daemons (OSDs), delegating metadata management to a (potentially sharded) metadata server (MDS). Octopus and NFS do not support replication for availability and thus gain an unfair performance advantage over Assise. However, Assise beats them even while replicating for availability, showing that both features can be had when leveraging local NVM.

Other file systems do not support persistent caches and their consistency semantics are often weaker than Assise’s. Assise provides data crash consistency, while both Ceph/BlueStore

and Octopus provide only metadata crash consistency [31]. For NFS, crash consistency is determined by the underlying file system. We use EXT4-DAX [9], which also provides only metadata crash consistency. When sharing data, NFS provides *close-to-open consistency* [39], while Octopus and Ceph provide “stronger consistency than NFS” [28], and Assise provides linearizability, which is stronger than Octopus’ and Ceph’s guarantees. In all performance comparisons, Assise provides stronger consistency than the alternatives. Ceph is the closest comparison point.

File system compliance tests. We tested Assise using xfstests [18] and CrashMonkey [65]. Assise passed all 75 generic xfstests that are recommended for NFS [16]. NFSv4.2 and Ceph v14.2.1 pass only 71 and 69 of these tests, respectively. In part, this is due to their weaker consistency model. Assise also successfully passes CrashMonkey tests, runs all existing Filebench profiles, passes all unit tests for the LevelDB key-value store, and passes MinuteSort validation.

5.1 Experimental Configuration

Machines. Each experiment specifies the number (≥ 2) of testbed machines used. By default, machines are used as hot replicas in Assise, as a pool of storage nodes in Octopus, and as OSD and MDS replicas in Ceph. NFS uses only one machine as server, the rest as clients. We place applications on hot replicas for Assise, on OSD replicas for Ceph, on storage nodes for Octopus, and on clients for NFS. Assise’s and Ceph’s cluster managers run on 2 additional testbed machines (NFS and Octopus do not have cluster managers). The colocated deployment of applications and OSDs for Ceph is due to the small size of our cluster. It gives Ceph a potential performance advantage over an all-remote OSD deployment.

Network. We use RDMA for the NFS client-server connection. Ceph provides its client-side file system via the Ceph kernel driver and uses IP over InfiniBand, which was the fastest configuration (we also tried FUSE and Accelio [13]). Assise and Octopus use RDMA with kernel-bypass.

Storage and caches. For maximum efficiency, all file systems use NVM in App-Direct mode to provide persistence (cylinders in Figure 1) and DRAM when persistence is not needed (e.g., kernel buffer cache). We investigate Ceph and NFS performance using NVM in memory mode for volatile caches and find it to degrade throughput by up to 25% versus DRAM. For efficient access to NVM, Ceph OSDs use BlueStore and NFS servers use EXT4-DAX. Octopus uses FUSE to provide its file system interface to applications in *direct IO* mode to NVM, bypassing the kernel buffer cache [6].

To evaluate a breadth of cache behaviors with limited application data set sizes, we limit the fastest cache size for all file systems to 3GB. For Ceph and NFS, we limit the kernel buffer cache to 3GB. For Assise, we partition the LibFS cache into a 1GB NVM update log and a 2GB DRAM read cache (the SharedFS second-level cache may use all NVM available), and we run Assise in pessimistic mode.

(a) Sequential write. write latency is solid line, fsync is bar height.

(b) Read latencies for cache hits, misses, and remote (RMT) misses.

Figure 3: Avg. and 99%ile (error bar) IO latencies. Log scale.

5.2 Microbenchmarks

Average and tail write latency. We compare unladen synchronous write latencies with 2 machines (except Assise-3r which uses 3 machines). Synchronous writes involve `write` calls (fixed-width font identifies POSIX calls) that operate locally (except for Octopus where `write` may be remote), and `fsync` calls that involve remote nodes for replication (Assise, Ceph) and/or persistence (Ceph, NFS). Each experiment appends 1GB of data into a single file, and we report per-operation latency. In this case, the file size is smaller than each file system’s cache size, so no evictions occur—with gigabytes of cache capacity, this is common for latency-sensitive write bursts.

Figure 3a shows the average and 99th percentile sequential write latencies over various common IO sizes (random write latencies are similar for all file systems). We break writes down into `write` (solid line) and `fsync` call latencies (bar). Octopus’ `fsync` is a no-op. Assise’s local write latencies match that of Strata [52]. Assise’s average write latency for 128B two-node replicated writes is only 8% higher than the aggregate latencies of the required local and NVM-RDMA writes (cf. Table 1). Three replicas (Assise-3r) increase Assise’s overhead to $2.2\times$ due to chain-replication with sequential RPCs. The 99th percentile replicated write latency is up to $2.1\times$ higher than the average for 2 replicas. This is due to Optane PMM write tail-latencies [45]. The tail difference diminishes to 19% for 3 replicas due to the higher average.

Ceph and NFS use the kernel buffer cache and interact at 4KB block granularity with servers. For small writes, the incurred network IO amplification during `fsync` is the main reason for up to an order of magnitude higher aggregate write latency than Assise. In this case, their `write` latency is up

to $3.2\times$ higher than Assise due to kernel crossings and copy overheads. For large writes ($\geq 64\text{KB}$), network IO amplification diminishes but the memory copy required to maintain the kernel buffer cache becomes a major overhead. The latency of large writes is higher than Assise’s replicated write latency (and up to $2.7\times$ higher than Assise’s non-replicated write latency), while aggregate write latency is up to $7.2\times$ higher than Assise. Ceph has higher `fsync` latency than NFS due to replication.

Octopus eliminates the kernel buffer cache and block orientation, which improves its performance drastically versus NFS and Ceph. However, Octopus still treats all NVM as remote and uses FUSE for file IO. Octopus exhibits up to $2.1\times$ higher latency than Assise for small ($< 64\text{KB}$) writes. This overhead stems from FUSE (around $10\mu\text{s}$ [78]) and writing to remote NVM via the network. Large writes ($\geq 64\text{KB}$) amortize Octopus’ write overheads. Assise has up to $1.7\times$ higher write latency due to replication. Octopus does not replicate.

Average and tail read latency. We compare unladen read latencies across different cache configurations. To do this, we read a 1GB file using various IO sizes, once with a warm cache (to report cache hits) and once with a cold cache (to report misses). The results are shown in Figure 3b. Assise has a second-layer cache in SharedFS before going remote, and we report three cases for Assise. Reads in Octopus are always remote.

We first compare cache-hit latencies (HIT), where Assise is up to 40% faster than NFS and 50% faster than Ceph. Assise serves data from the LibFS read cache, while NFS and Ceph use the kernel buffer cache. If Assise misses in the LibFS cache, data may be served from the local SharedFS (MISS). Assise-MISS incurs up to $3.2\times$ higher latency than Assise-HIT due to reading the extent tree index, especially for larger IO sizes that read a greater number of extents. If Assise misses in both caches, it has to read from a remote replica (RMT). Assise-RMT incurs the latency of an RPC using RDMA. When NFS and Ceph miss in the cache, their clients have to fetch from remote servers, which incurs up to orders of magnitude higher average and tail latencies than Assise-RMT and Assise-MISS. Ceph performs worse than NFS due to a more complex OSD read path.

The elimination of a cache hurts Octopus’ read performance, because it has to fetch metadata and data (serially) from remote NVM (RMT). Octopus’ read latency is up to two orders of magnitude higher than the other file systems hitting in the cache, and up to an order of magnitude lower than NFS and Ceph missing in the cache. Octopus does not handle small ($\leq 4\text{KB}$) reads well due to FUSE overheads, with up to $3.54\times$ Assise-RMT read latency. This overhead is amortized for larger reads ($\geq 64\text{KB}$), where Octopus incurs up to $1.46\times$ the read latency of Assise-RMT. By configuring FUSE to use the kernel buffer cache for Octopus, we reduce Octopus’ read hit latency to $1.8\times$ that of Assise-HIT, with the remaining overhead due to FUSE. However, using the kernel

buffer cache inflates write latencies for Octopus by up to an order of magnitude due to additional buffer cache memory copies.

Peak throughput. Figure 4 shows average throughput of sequential and random IO to a 120GB dataset (on the local socket) with 4KB IO size from 24 threads (all cores of one socket). To evaluate a standard replication factor of 3, we use 3 machines for Assise and Ceph. The dataset is sharded over 24 files, and 5GB of data is written per thread. For random writes, a random offset is generated for every IO. `write` calls are not followed by `fsync` and the total amount of accessed data is larger than the cache size, causing cache eviction on write. The cache is initially cold so reads miss in the cache. For Assise, we show cache miss performance from a local and remote SharedFS. Octopus crashes during this experiment and is not shown.

For sequential writes, Assise and NFS achieve 74% and 66% of the NVM-RDMA bandwidth (cf. Table 1), respectively, due to protocol overhead for NFS and log header overhead for Assise. Chain-replication in Assise affects throughput only marginally. Ceph replicates in parallel to 2 remote replicas, consuming $3\times$ the network bandwidth. This reduces its throughput to 31% of Assise and 35% of NFS. Assise achieves similar performance for sequential and random writes, as Assise’s writes are log-structured. NFS and Ceph perform poorly for random writes due to cache block mis-prefetching incurring additional reads from remote servers, causing Assise to achieve $4.8\times$ Ceph’s throughput. NFS throughput is at only 67% that of Ceph, which is due to kernel locking overhead.

To quantify the benefit of bypassing hardware cache coherence for cross-socket writes with DMA, we repeat the benchmark, placing all files on the remote socket. We can see that Assise-DMA attains 44% higher cross-socket throughput than non-temporal processor writes (Assise). Sequential and random writes provide comparable performance. NVM-NUMA writes occur during eviction from the LibFS update log (local socket) to the NVM shared cache (remote socket). When writing to the local socket, Assise-DMA attains identical throughput to Assise, regardless of pattern.

For local sequential and random reads from the local SharedFS cache, Assise achieves 90% and 68%, respectively, of local, sequential NVM bandwidth. The 10% difference for sequential reads to local NVM bandwidth is due to metadata lookups, while random reads additionally suffer PMM buffer misses [45]. Assise remote reads (Assise-RMT) attain full NVM-RDMA bandwidth (3.8GB/s), regardless of access pattern. NFS and Ceph are limited by NVM-RDMA bandwidth for all reads and again have worse random read performance due to prefetching.

Log size sensitivity. To evaluate the impact of log size on write throughput, we conduct a sensitivity analysis. We run a single-process microbenchmark that writes a 1GB file sequentially at 4KB IO granularity. This experiment models a

(a) Write. 3.8GB/s is NVM-RDMA bandwidth.

(b) Read. 32GB/s is NVM read bandwidth.

Figure 4: Average throughput with 24 threads at 4KB IO size.

Figure 5: Worst-case throughput versus update log size, normalized to 2GB.

Figure 6: Average LevelDB benchmark latencies. Log scale.

worst case scenario. In the absence of sharing, processes can quickly fill up their allocated log space. Figure 5 shows the normalized write throughput at different log sizes. Throughput increases with log size, but the performance impact is small. Throughput increases by only 22% when using a 2GB log size versus a 16MB log size, a 128 \times increase in log size. For workloads that share data, we expect this gap to be smaller, as logs are evicted upon lease handoff. With 6TB of NVM per machine, Assise can scale to thousands of processes even with 2GB update logs. At 16MB, 100,000s of processes can be supported.

5.3 Application Benchmarks

We evaluate the performance of a number of common cloud applications, such as the LevelDB key-value store [33], the Fileserver and Varmail profiles of the Filebench [75] benchmarking suite, emulating file and mail servers, and the MinuteSort benchmark. We use 3 machines for LevelDB and Filebench and 5 machines for MinuteSort.

LevelDB. We run a number of single-threaded LevelDB latency benchmarks using LevelDB’s `db_bench`, including sequential and random IO, skewed random reads with 1% of highly accessed keys, and sequential synchronous writes (`fsync` after each write). All benchmarks use a key size of 16B and a value size of 1KB with a working set of 1M KV pairs. Figure 6 presents the average measured operation latency, as reported by the benchmark.

Assise, Ceph, and NFS perform similarly for reads, where caching allows them to operate close to hardware speeds. For non-synchronous writes, NFS is up to 26% faster than Assise, as these go to its client kernel buffer cache in large batches (LevelDB has its own write buffer), while Assise is 69% faster than NFS for synchronous writes that cannot be buffered. Random IO and synchronous writes incur increasing LevelDB indexing overhead for all systems. Ceph performs worse than NFS for writes because it replicates (as does Assise) and

Figure 7: LevelDB random read latencies with warm replica.

Assise performs 22 \times better. Octopus bypasses the cache and thus performs worst for reads and better only than Ceph for writes, as it does not replicate.

Warm replica read latency. Warm replicas reduce read latency for warm data by allowing these reads to be served from remote NVM, rather than cold storage. For this benchmark, we configure Assise to limit the aggregate (LibFS and SharedFS) cache to 2GB and use the local SSD for cold storage. We then run the LevelDB random read experiment with a 3GB dataset. We repeat the experiment with two setups: (1) with 3 hot replicas and (2) with 2 hot and 1 warm replica. Figure 7 shows a CDF of read latencies. The benchmark accesses data uniformly at random, causing 33% of the reads to be warm. Consequently, at the 50th percentile, read latencies are similar for both configurations (served from cache). At the 66th percentile, reads in the first setup are served from SSD and have 2.2 \times higher latency than warm replica reads in the second setup. At the 90th percentile, the latency gap extends to 6 \times .

Filebench. Varmail and Fileserver operate on a working set of 10,000 files of 16KB and 128KB average size, respectively. Files grow via 16KB appends in both benchmarks (mail delivery in Varmail). Varmail reads entire files (mailbox reads) and Fileserver copies files. Varmail and Fileserver have write to read ratios of 1:1 and 2:1, respectively. Varmail leverages a write-ahead log with strict persistence semantics (`fsync` after log and mailbox writes), while Filebench consistency is relaxed (no `fsync`). Figure 8 shows average measured throughput of both benchmarks. Assise outperforms Octopus (the best alternative) by 6.7 \times for Fileserver and 5.1 \times for Varmail. Ceph performs worse than NFS for Varmail due to stricter persistence requiring it to replicate frequently and due to MDS contention, as Varmail is metadata intensive.

Optimistic crash consistency. We repeat this benchmark for Assise in optimistic mode (Assise-Opt) and change Varmail to use synchronous writes for the mailbox, but non-synchronous writes for the log. Prefix semantics allow Assise to buffer and

System	Processes	Partition [s]	Sort [s]	Total [s]	GB/s
Assise	160	20.3	43.0	63.3	5.1
	320	52.1	43.0	95.1	6.7
NFS	160	60.9	79.3	140.2	2.3
	320	104.1	84.2	188.3	3.4
DAX	320	–	44.1	–	–

Table 4: Average Tencent Sort duration breakdown.

coalesce the temporary log write without losing consistency. Assise-Opt achieves $2.1\times$ higher throughput than Assise. Fileserver has few redundant writes and Assise-Opt is only 7% faster.

MinuteSort. We implement and evaluate Tencent Sort [46], the current winner of the MinuteSort external sorting competition [7]. Tencent Sort sorts a partitioned input dataset, stored on a number of cluster nodes, to a partitioned output dataset on the same nodes. It conducts a distributed sort consisting of 1) a range partition and 2) a mergesort (cf. MapReduce [32]). Step 1 presorts unsorted input files into ranges, stored in partitioned temporary files on destination machines. Step 2 reads these files, sorts their contents, and writes the output partitions. Each step uses one process per partition; the parallelism equals the number of partitions. A distributed file system stores the input, output, and temporary files, implicitly taking care of all network operations.

We benchmark the MinuteSort Indy category, which requires sorting a synthetic dataset of 100B records with 10B keys, distributed uniformly at random. Creating a 2GB input partition per process, we run 160 or 320 processes in parallel, uniformly distributed over 4 machines. MinuteSort does not require replication, so we turn it off. It calls `fsync` only once for each output partition, after the partition is written. We compare a version running a single Assise file system with one leveraging per-machine NFS mounts. For Assise, we configure the temporary and output directories to be colocated with the mergesort processes. We do the same for NFS, by exporting corresponding directories from each mergesort node. We conduct three runs of each configuration and report the average. We use the official competition tools [7] to generate and verify the input and output datasets. We use equal dataset sizes to compare Assise and NFS, rather than equal time. Table 4 shows that Assise sorts up to $2.2\times$ faster than NFS. Running twice the number of processes only marginally improves performance, as Assise is bottlenecked by network bandwidth.

To show that Assise’s POSIX implementation does not reduce performance, we modify the sort step to map all files into memory using EXT4-DAX and use processor loads and non-temporal stores to sort directly in NVM, rather than using file IO. We can see that the sort phase is 3% slower with DAX. `libc` buffers IO in DRAM to write 4KB at a time to NVM, performing better than direct, interleaved appends of 100B records.

Figure 8: Avg. Varmail and Fileserver throughput. Log scale.

5.4 Availability

Ceph and Assise are fault tolerant. We evaluate how quickly these file systems return an application back to full performance after the fail-over and recovery situations of §3.4. To do so, we run LevelDB on the same dataset (§5.3) with a 1:1 read-write ratio and measure operation latency before, during, and after fail-over and recovery. We report average results over 5 benchmark runs.

Process fail-over. For this benchmark, we simply kill LevelDB. In this case, the failure is immediately detected by the local OS and LevelDB is restarted. Ceph can reuse the shared kernel buffer cache in DRAM, resulting in LevelDB restoring its database after 1.63s and returning to full performance after an additional 2.15s, for an aggregate 3.78s fail-over duration. With Assise, the DB is restored in 0.71s, including recovery of the log of the failed process and reacquisition of all leases. Full-performance operations occur after an additional 0.16s, for an aggregate 0.87s fail-over time. Assise recovers this case $4.34\times$ faster than Ceph, showing that process-local caches do not impede fast recovery.

OS fail-over. NVM’s performance allows for instant local recovery of an OS failure, rather than requiring a backup replica. To demonstrate, we run the primary in a virtual machine (VM). We kill the primary VM, then immediately start a new VM from a snapshot stored in NVM. The snapshot starts in 1.66s. We restart SharedFS within the new VM, which recovers the file system within 0.23s. Finally, as in the process fail-over experiment, LevelDB is restarted and resumes database operations after another 0.68s. The aggregate fail-over time is 2.57s, $40\times$ faster than Ceph’s fail-over to a backup replica (evaluated next).

Fail-over to hot backup. All following experiments use 2 machines (primary and backup). The LevelDB client processes poll the file system’s cluster manager for membership state, using a standard primary-backup ZooKeeper design pattern for node fail-over [47]. LevelDB initially runs on the primary, where we inject failures. Failures are detected by LevelDB clients using a 1s heartbeat timeout via the cluster manager. Once a node failure is detected, LevelDB immediately restarts on the backup.

A time series of measured LevelDB operation latencies during one experiment run is shown in Figure 9. Pre-failure, we see bursts of low latency in between stretches of higher latency. This is LevelDB’s steady-state. Bursts show LevelDB

Figure 9: LevelDB operation latency time series during fail-over and recovery. Log scale.

writes to its own DRAM log. These are periodically merged with files when the DRAM log is full, causing writes that are higher latency (and sometimes blocking with Ceph), as the writes wait on the log to become available.

We inject a primary failure by killing the primary’s file system daemon (SharedFS for Assise and OSD for Ceph) and LevelDB. During primary failure, no operations are executed. It takes 1s to detect the failure and restart LevelDB on the backup (light shaded box). Due to unclean shutdown, LevelDB first checks its dataset for integrity before executing further operations (dark shaded box). For failover, Assise need only evict the per-process log (up to 1GB) on the backup hot replica, making fail-over near-instantaneous. LevelDB returns to full performance in both latency and throughput 230ms after failure detection. Ceph takes 3.7s after failure detection to return to full performance. However, LevelDB stalls soon thereafter upon compaction (further dark shaded box), which involves access to further files, resulting in an additional 15.6s delay, before reaching steady-state. Ceph’s long aggregate fail-over time of 23.7s is due to Ceph losing its DRAM cache, which it rebuilds during LevelDB restart. Assise reaches full performance after failure detection $103\times$ faster than Ceph. LevelDB performs better on the backup, as neither file system has to replicate.

Primary recovery. After 30s, we restart the file system daemons on the primary, emulating the time for a machine reboot from NVM. During this time, many file system operations occur on the backup that need to be replayed on the primary. As soon as the primary is back online, we cleanly close the database on the backup and restart on the primary. Both Assise and Ceph allow applications to operate during primary recovery, but performance is affected. Assise detects outdated files via epochs and reads their contents from the remote hot replica upon access. Once read, the local copy is updated, causing future reads to be local. LevelDB returns to full performance 938ms after restarting it on the recovering primary.

Figure 10: Scalability of atomic 4KB file operations. Log scale.

Ceph also rebuilds the local OSD, but eagerly. Ceph takes 13.2s before LevelDB serves its first operation due to contention with OSD recovery and suffers another delay of 24.9s on first compaction, reaching full performance 43.4s after recovery start. Assise recovers to full performance $46\times$ faster than Ceph.

Fail-over to cold backup. We measure cascaded LevelDB fail-over time to an Assise replica with a cold cache. LevelDB serves its first request on the cold backup 303ms after failure detection, but with higher latency due to SSD reads. LevelDB returns to full performance after another 2.5s. At this point, the entire dataset has migrated back to cache.

5.5 Scalability

We evaluate Assise’s scalability via 1) sharded file operations under increasing load and increasingly localized lease management, and 2) parallel email delivery in Postfix [79].

5.5.1 Sharded File Operations

Processes in parallel create, write, and rename 4KB files with random data in private directories. This benchmark uses 3 machines (6 sockets) and can scale throughput linearly with the number of processes. To eliminate network bottlenecks to scalability, we turn replication off.¹ Figure 10 presents average throughput over 5 runs of an increasing number of processes, each operating on 480K files, balanced over processor sockets. Ceph uses 3 sharded MDSes (1 per machine). However, MDS sharding has negligible impact on Ceph’s performance.

Ceph’s remote MDSes have high overhead for atomic operations, as each client has to communicate with remote MDSes. This design prevents scalability beyond 8Kops/s. We emulate Orion by restricting CC-NVM to use a single SharedFS lease manager. In this case, data is stored on local NVM, but atomic operations still use a remote lease manager. Orion has RDMA mechanisms that simplify communicating with its MDS, but these mechanisms cannot be used for operations that affect multiple inodes (e.g., renames). Orion and Assise both use RDMA RPCs. While Orion operates in the kernel, our emulation uses user-level RDMA, which is light-weight, and Orion (emu) outperforms Ceph by $8\times$.

¹Due to the small size of our cluster, primary nodes would replicate to each other and scalability would be limited by per-node link bandwidth. A larger cluster would replicate to independent machines for each primary.

Figure 11: Postfix mail delivery throughput scalability.

To break down the benefit of local lease management in Assise, we progressively shard it, first by server (Assise-server), then by socket (Assise-numa), and finally by process (Assise). Assise-server outperforms Orion (emu) by $2.77\times$ and Assise-numa improves throughput by another $1.93\times$. Assise scales linearly with the number of processes until it hits NVM write bandwidth, improving throughput by another $12.86\times$. Assise outperforms Orion by $69\times$ and Ceph by $554\times$ at scale.

5.5.2 Postfix

We use the unmodified Postfix mail server to measure the performance of parallel mail delivery. A load balancer machine forwards incoming email from as many client machines as necessary to maximize throughput to Postfix queue daemons running on 3 testbed machines, configured as replicas. On each Postfix machine, a pool of delivery processes pull email from the machine-local incoming mail queue and deliver it to user Maildir directories on a cluster-shared distributed file system. To ensure atomic mail delivery, a Postfix delivery process writes each incoming email to a new file in a process-private directory and then renames this file to the recipient's Maildir.

We send 80K emails from the Enron dataset [51], with each email reaching an average of 4.5 recipients. This results in a total of 360K email deliveries. Each email has an average size of 200KB (including attachments) and the dataset occupies 70GB. We repeat each experiment 3 times and report average mail delivery throughput and standard deviation (error bars) in Figure 11 over an increasing number of delivery processes, balanced over machines. We compare various Assise configurations and Ceph with 2 MDSes (1 and 3 MDSes performed similarly).

Round-robin. In the first configuration (Assise-rr) the load balancer uses a round-robin policy to send emails to mail queues. Due to a lack of locality, mails delivered to the same Maildir often require synchronization across machines, causing CC-NVM to frequently delegate leases remotely, which increases delivery latencies. Despite this, Assise-rr is able to outperform Ceph by up to $5.6\times$ at scale. Ceph cannot improve throughput much further—even with 300 delivery processes, its throughput improves by 8% versus 48 processes.

Sharded. We shard Maildirs by Enron suborganization over machines [26]. The load balancer is configured to prefer the recipient's shard. For mail messages with multiple recipients,

it picks the shard with the most receivers. In case of mail queue overload, the load balancer sends mail to a random unloaded shard. Sharding users in this manner provides up to 20% better performance (Assise-sharded) due to the fact that repeated deliveries to users of the same clique are likely to occur on the same server, allowing CC-NVM to synchronize delivery locally. At 15 processes, we are network-bound due to replication. Sharding did not improve Ceph's performance.

Private directories. We shard Maildirs by delivery process, using process IDs for Maildir subdirectories, thereby eliminating the need for synchronization (Assise-private). This change is not backward compatible with existing mail readers, but it is the logical limit for sharding-based optimization. Assise-private scales linearly until it is bottlenecked by network bandwidth, but performance is similar to Assise-sharded. This shows that local synchronization in Assise has minimal overhead. Ceph performance continues to be gated by the MDS.

Summary. Our results show that, with careful sharding of the workload, Assise's hierarchical coherence allows LibFS processes to synchronize deliveries locally, providing almost the same performance and scalability as private directories.

6 Conclusion

Assise is a distributed file system that provides low tail latency, high throughput, scalability, and high availability with a strong consistency model. To take advantage of low-latency NVM, Assise demonstrates that filesystem metadata and data should be colocated with applications. Colocation not only enables high performance, but also fast recovery. Assise proposes a novel, crash-consistent cache coherence protocol that can leverage the performance of NVM, while providing linearizability. Assise uses hot replicas in NVM to minimize application recovery time and ensure data availability, while leveraging a crash-consistent file system cache-coherence layer (CC-NVM) to provide scalability. In comparing with several state-of-the-art file systems, our results show that Assise improves write latency up to $22\times$, throughput up to $56\times$, fail-over time up to $103\times$, and scalability up to $6\times$ versus Ceph, while providing stronger consistency semantics.

Assise is available at <https://github.com/ut-osa/assise>.

Abstract

Distributed in-memory storage systems are crucial for meeting the low latency requirements of modern datacenter services. However, they lose all state on failure, so recovery is expensive and data loss is always a risk. Persistent memory (PM) offers the possibility of building fast, persistent in-memory storage; however, existing PM systems are built from scratch or require heavy modification of existing systems. To rectify these problems, this paper presents Persimmon, a PM-based system that converts existing distributed in-memory storage systems into persistent, crash-consistent versions with low overhead and minimal code changes.

1 Introduction

In the past decade, distributed in-memory storage systems have become ubiquitous. Facebook and Twitter have petabytes of in-memory storage [2, 75], and in-memory replicated systems such as NOPaxos [58] and TAPIR [113] can process transactions within microseconds while providing consistency and fault-tolerance. As datacenter networks become faster and kernel bypass removes OS bottlenecks, only in-memory storage systems will be able to keep up with network speeds.

Unfortunately, in-memory storage systems have a crucial drawback: their lack of durability means that failed nodes must recover from a replica or another source (e.g., a persistent back-end database), which can be extremely slow. For example, a Facebook memcached cluster can take hours to regain full capacity if repopulated from another “warm” cluster, or days if repopulated from backend storage [75]. Even worse, state can be permanently lost if all replicas crash such as in a full datacenter failure. To reduce the impact of failures, many popular in-memory systems (e.g., Redis [85], RAM-Cloud [76]) support persistence, but it requires additional, complex code and/or incurs high performance overhead.

Persistent memory (PM) offers a promising solution for in-memory services. It is durable, offers performance close to DRAM, and is increasingly available in large sizes. However, PM systems require crash consistency [7, 57, 71, 79] (i.e., no system invariants are violated on a crash), which is compli-

cated and expensive to enforce. Maintaining crash consistency requires that operations are failure-atomic [45]; for example, on crashes, an operation’s deallocations and pointer updates must either atomically succeed or fail to avoid violating the invariant that pointers do not point to deallocated memory.

To ensure failure atomicity, PM systems must carefully flush volatile CPU state at specific times and possibly use write-ahead logging or other techniques to correctly recover from failures. These added flushes and writes impose significant overhead. As a result, most existing PM storage systems are carefully written from scratch for correctness and performance; even then, none can achieve the performance of today’s in-memory systems. Recent work, like RECIPE [57] and MOD [39], aim to reduce application complexity by converting existing data structures to persistence on PM; however, because they exploit certain data structure properties (e.g., non-blocking synchronization), they are not suited to all in-memory storage systems.

This paper aims to let existing in-memory storage systems more easily reap the benefits of persistent memory. We make the key observation that distributed systems are typically designed as RPC-processing state machines. State machines are an ideal abstraction for PM because: (1) they encapsulate application state for recovery; (2) their operations offer clear failure-atomic regions; and (3) their state can be recreated at any time by re-executing operations.

Based on this insight, we present Persimmon, a PM-based system that converts existing in-memory distributed storage systems into durable, crash-consistent versions with low overhead and minimal code changes. Persimmon offers a new abstraction for building PM applications: *persistent state machines* (PSM). PSMs offer a simple guarantee: once an operation on the PSM returns, its side-effects on the PSM will never be lost. PSM operations are also failure-atomic: if the operation did not return before a crash, either the entire operation will be applied after the crash or none of it. PSMs can run arbitrary application code; however, like other state machines (e.g., replicated state machines), PSM operations must not have external dependencies (e.g., they cannot open file

descriptors), must be deterministic, and are executed sequentially. As a result, Persimmon does not support multi-threaded applications that apply operations concurrently.

To minimize the performance overhead of accessing PM on the request processing path, Persimmon keeps two state machine copies, one in DRAM and one in PM. When the application invokes a PSM operation, Persimmon first executes the operation on the DRAM copy. If the operation is read-only, Persimmon returns. If the operation is read-write, Persimmon persistently logs the operation before returning. This design limits the critical path to DRAM for read-only operations and one sequential write to PM for read-write operations; however, it requires both a DRAM and a PM state machine copy, which can be large for in-memory storage systems.

On failure, Persimmon can recover the PSM by replaying the persistent log. However, to minimize recovery time, Persimmon asynchronously keeps the persistent state machine snapshot in PM up-to-date. The state machine abstraction lets Persimmon update the PM snapshot with a *crash-consistent shadow execution* of each PSM operation, which is then removed from the log. This design is crucial for large in-memory storage systems that might have terabytes of data. To recover, Persimmon simply copies the PM snapshot to DRAM, processes the remaining persistent log, and restarts the application. Our design uses a background process, which runs on another CPU, to perform the shadow execution, trading off the use of a CPU for faster recovery times.

From this description, it is clear that Persimmon minimizes the overhead of persistence on the request processing path. However, to achieve reasonable recovery times, the crash-consistent shadow execution of the log must also be efficient, so the log does not grow too large. Most of the difficult technical challenges lie in optimizing this shadow execution, and we are not aware of similar work that addresses this particular issue. Note that despite these technical challenges, using a persistent log is preferable to checkpointing for large in-memory storage systems that might have terabytes of data.

We use Persimmon to persist two in-memory distributed systems: Redis and TAPIR [113]. We implement both systems on Linux and with kernel-bypass networking. We evaluate Persimmon on three servers with 3 TB of Intel® Optane™ DC Persistent Memory and found:

- On a 90% read-heavy YCSB workload, Persimmon incurs no discernible overhead to the latency and throughput of standard Redis; and near-zero latency overhead and 5% throughput overhead over kernel-bypass Redis.
- On the Retwis benchmark, Persimmon incurs no discernible latency overhead and 5%–8% throughput overhead for both standard and kernel-bypass TAPIR.

Furthermore, on gigabyte datasets, both Redis and TAPIR can recover within 15 s after a crash. Porting each application to Persimmon required less than 150 lines of code changes.

Although this paper mainly focuses on porting *existing* in-memory applications to PM, Persimmon also simplifies the

development of *future* PM application. Even with high-level libraries, like Intel’s PMDK [80], it remains difficult to write PM code that is both fast and correct. In contrast, our PSM abstraction lets programmers write state machine code targeting regular memory, then Persimmon automatically provides persistence while correctly maintaining crash consistency with low overhead. Persimmon thus offers a solution for developing new, high-performance persistent applications as easily as developing in-memory applications.

2 Persimmon Overview

This section gives an overview of Persimmon, including its design goals and API, and defines the requirements and guarantees of the persistent state machine model. Persimmon is designed for the x86-64 processor with Intel® Optane™ DC Persistent Memory [46, 108]. We assume an underlying POSIX-based OS due to Persimmon’s use of fork; however, the design could be modified for other environments.

2.1 Design Goals

We identify three goals for Persimmon’s design.

Minimal Application Changes. Existing in-memory storage systems are highly optimized for low latency in everything from data structures to memory allocators. To maintain these optimizations and reduce programmer effort, Persimmon’s first goal is to minimize changes to existing application code.

Strong Guarantees. Reasoning about application state after a crash is difficult for PM applications [61, 62]. To simplify applications and ensure crash consistency, Persimmon’s second goal is to provide strong and clear persistence guarantees.

Good Performance. In-memory storage systems must respond to requests within microseconds, so they cannot afford the high cost of existing persistence mechanisms (e.g., logging to disk). To provide persistence with PM, Persimmon’s last goal is to impose less than a microsecond of latency overhead on in-memory systems with no persistence while also providing fast recovery times on the order of seconds.

2.2 Persimmon Persistent State Machine Model

Persimmon targets distributed systems deployed within a single datacenter that largely keep their state in memory and offer high-performance RPC processing. We assume the application state needed for recovery can be encapsulated in a *persistent state machine* (PSM) with the following properties:

- *Does not have external dependencies.* The state machine must contain no references to state outside the application process’s address space; e.g., it cannot have file descriptors or open sockets.
- *Executes deterministically.* Each operation executes identically every time with no dependence on external inputs (e.g., the current time, random numbers) other than the operation arguments.
- *Has no external side-effects.* State machine operations must perform only computation and memory allocation and de-

Persimmon Interface

- `psm_init()` \rightarrow `bool` - Initialization function; returns true if the application is in recovery.
- `psm_invoke_rw(op)` - Invoke read-write `op` with persistence on the state machine.
- `psm_invoke_ro(op)` - Invoke read-only `op` without persistence on the state machine.

Figure 1: Persistent state machine API implemented by Persimmon.

allocation (e.g., `mmap` and `munmap`). They must not invoke code with side-effects outside the application process (e.g., syscalls other than memory allocation).

These properties are common to state machine abstractions, and are required for correct shadow execution with Persimmon. Similar to replicated state machines (RSMs), persistent state machines require that operations execute sequentially for determinism. Due to the popularity of RSMs in the datacenter, we believe this requirement to be reasonable for many applications. For applications that require concurrency, it may be possible to apply existing techniques developed for RSMs [52, 72]; however, we defer the exploration of these techniques to future work.

2.3 Persimmon Persistent State Machine API

Persimmon provides a minimal application programming interface through its user-level library. The Persimmon library presents three functions to applications (Figure 1) that: (1) initialize the persistent state machine, (2) invoke a read-write PSM operation and (3) invoke a read-only operation. We offer the third function as an optimization for RPCs that only inspect state but do not update it, since many in-memory applications have a read-heavy workload. Programmers use the invocation functions to call existing application functions (e.g., execution of Redis commands on Redis data structures). Persimmon directly executes these functions on the PSM, so they must follow the properties laid out above.

An application starts by invoking the `psm_init` function, which returns a flag indicating whether the application has just recovered from a crash. If recovered, the persistent state machine will be returned to its state after the last completed operation. If not in recovery, the application should initialize the state machine by invoking an initialization operation (e.g., creating an empty Redis hash table) with `psm_invoke_rw`. The application can then begin RPC processing. On each RPC, we expect the application to invoke `psm_invoke_rw` if the RPC updates application state that is later needed for recovery. For correct recovery, the application must invoke the PSM operation *before* responding to the RPC. For RPCs that only access application state and do not make updates that must later be recovered (e.g., Redis `GET` operations), the application can use `psm_invoke_ro` for lower overhead.

Figure 2: Persimmon runtime.

2.4 Persimmon Persistent State Machine Guarantees

Persimmon ensures three guarantees for invoked PSM operations. The first applies to all invoked operations, while the remaining two only apply to `psm_invoke_rw` operations.

- **Linearizability.** Persimmon guarantees that all state machine operations are run in a serial order and that serial order reflects the order in which operations are submitted to Persimmon [40].
- **Durability.** Persimmon guarantees that persistent, read-write state machine operations are never lost once they return, regardless of machine failures. Operations will never roll back and their state modifications are never lost.
- **Failure Atomicity.** Persimmon guarantees that state machine operations are failure-atomic. If the operation has not returned before failure, then on recovery, the state machine will reflect a state entirely before the operation has run or entirely after.

While these guarantees are simple, they are sufficient to build a crash consistent application in the face of failures. Because each state machine operation is failure-atomic, applications can easily maintain crash consistency by grouping updates to related data structures into a single operation and ensuring that no invariants are violated at the end of each operation.

3 Persimmon Runtime

Persimmon runs in two processes to support executing unmodified state machine code in DRAM and, for shadow execution, instrumented state machine code on PM. The *application process* runs the application and the DRAM state machine copy, while the *shadow process* runs the crash-consistent, shadow execution of the PM state machine copy. Persimmon's runtime shares the application process' address space with the rest of the application and completely owns the shadow process. Figure 2 summarizes Persimmon's runtime organization.

3.1 Data Structures

To ensure fast recovery and failure atomicity for the persistent state machine, Persimmon maintains two in-memory state machine snapshots and the data structures listed in Table 1.

Table 1: Data structures maintained by Persimmon.

Name	Persistent?	Data structure	Purpose	Elements	Operations
Operation log	Yes	Fixed-size queue	Records invoked operations	Serialized operations	push, pop
DRAM snapshot	No	—	To execute state machine operations on critical path	—	—
PM snapshot	Yes	—	Persists effects of operations	—	—
Region table	Yes	Resizable array	Records memory used by PM snapshot	$\langle addr, size, path \rangle$	insert, remove
Undo log	Yes	Resizable stack	Provides crash consistency for PM snapshot	Data entry: $\langle addr, size, data \rangle$ Commit entry: $\langle new_tail \rangle$	append, clear

We detail the snapshots and data structures below:

- *Operation log*. Persimmon records each invoked read-write operation in the operation log. The application and shadow processes use the operation log as a shared single producer, single consumer queue.
- *DRAM state machine snapshot*. Persimmon uses this snapshot to execute state machine operations on the critical path. It is always up-to-date and is used to serve all read-only operations without persistence.
- *PM state machine snapshot*. Persimmon asynchronously updates this snapshot using shadow execution. The snapshot is up-to-date up to the end of the log.
- *Region table*. Persimmon records memory allocated by the PM state machine snapshot. The PM snapshot is managed at the granularity of *PM regions*, each of which is a contiguous chunk of PM backed by a file.
- *Undo log*. Persimmon uses write-ahead logging for crash-consistent shadow execution. Persimmon instruments state machine code and record every overwritten memory value in the undo log to ensure that a partially executed state machine operation can be rolled back on recovery.

As Persimmon processes state machine operations, it appends them to the operation log while the shadow process digests the log by re-executing each operation on the PM snapshot. Operations in the log represent how far the PM snapshot lags behind the DRAM snapshot. On recovery, operations in the log must be re-executed on the PM snapshot before the application can restart. We keep the log size below a fixed upper bound to ensure that the PM snapshot does not lag the DRAM snapshot by too much and require too much re-execution on recovery. Persimmon implements the operation log as a circular buffer with head and tail pointers, and assumes no operation’s arguments are larger than the log size.

3.2 Initialization and Normal Execution

When the application calls `psm_init`, Persimmon initializes its runtime in the following way:

1. Allocate the operation log.
 2. Start the shadow process.
 3. Initialize the DRAM and PM state machine snapshots.
 4. Initialize the region table with PM region metadata (§ 3.4).
 5. Allocate the undo log as a persistent array of entries (§ 4.2).
- As the application runs, it invokes state machine operations

through Persimmon, which are recorded to the log and eventually applied to the PSM. For each operation invoked through `psm_invoke_rw`, Persimmon performs the following:

1. Executes the operation on the DRAM snapshot.
2. Persists the operation as an entry in the operation log;
3. If the operation log is full, blocks until the shadow process digests more operations, freeing up space in the log.
4. Asynchronously, the shadow process re-executes each operation in the log on the PM snapshot using crash-consistent shadow execution (§ 4).

For operations invoked with `psm_invoke_ro`, Persimmon skips Steps 2–4. Persimmon blocks the application if the operation log is full. This design limits recovery time but requires that the shadow execution not lag behind too much as the application runs state machine operations. As a result, if the application invokes too many read-write state machine operations at a time, Persimmon will slow application performance significantly. We explore this phenomenon in our evaluation (§ 7.2.1).

3.3 Persimmon Shadow Process

Persimmon uses a separate process to perform shadow execution (the “shadow process”), where it switches to a dynamically instrumented version of the application for running the persistent state machine. Persimmon uses this instrumented version to manage persistent memory and ensure failure atomicity, which we discuss in §§ 3.4 and 4.3, respectively.

During initialization, Persimmon creates the shadow process by using `fork` to create a copy of the application process. Immediately after forking, the shadow process checkpoints itself using an existing Linux process checkpointing tool. This checkpoint conveniently stores essential process state that is orthogonal to Persimmon’s main functionality (e.g., the process ID), and serves as a “base image” on which Persimmon manages PM regions. This initialization must happen before the application sets up external dependencies (e.g., opens sockets) to avoid causing process checkpointing to fail.

After taking the checkpoint, Persimmon replaces the shadow process’s address space with persistent memory by creating a PM region for each existing application memory region. Specifically, Persimmon iterates through the existing memory regions using Linux’s `/proc/self/maps` interface. For each region, Persimmon writes its content to a new PM

file, `mmap`s the file into the address space *over* the existing region, and inserts an entry into the PM region table. We skip over read-only regions, which we assume will never become writable; the stack region, which we assume contains no persistent state (§ 4.3); and the operation log.

Finally, the shadow process begins shadow-executing state machine operations from the operation log. Although it executes the same state machine code as the application process does, the code is executed on the shadow process' persistent address space, and so any modifications to memory are reflected in the PM state machine snapshot. However, Persimmon cannot directly execute unmodified application code on PM because it is not failure atomic and allocates DRAM, not PM. Instead, the shadow process turns on dynamic instrumentation to capture memory allocation and writes in order to allocate PM and write to it in a failure-atomic manner.

3.4 Persistent Memory Management

To be able to recover the shadow process after a crash, Persimmon must manage its persistent memory and keep track of its metadata persistently. Persimmon manages the shadow process's persistent memory at the granularity of *PM regions*, each of which is contiguous range of persistent virtual memory. A PM region's content is stored in a file in a direct-access (DAX) file system [59] on persistent memory; the file is `mmap`'ed into the shadow process' address space, allowing access to PM. Persimmon uses a persistent *region table* to manage metadata for PM regions; each element in the table has the form $\langle addr, size, path \rangle$, denoting a PM region $[addr, addr + size)$ backed by a file located at *path*.

Persimmon keeps the region table in an immutable file in PM. Whenever the region table changes, Persimmon writes the entire updated table to a new file and removes the old. Any PM region files that are "orphaned" after a region table update are garbage-collected after the new region table is written. This mechanism provides failure atomicity for region table updates; although expensive, it is easy to implement and invoked only rarely. Because the table is small, Persimmon keeps a cached copy of it in DRAM.

Every time the shadow state machine allocates or frees memory, Persimmon must translate the operation to allocate or free PM regions instead. Persimmon uses dynamic instrumentation to intercept `mmap` and `munmap` system calls, which are typically made by the application's memory allocator.¹ Persimmon's PM management thus operates underneath the memory allocator and does not constrain the application to use one specific allocator.

Persimmon currently supports `mmap` calls that allocate anonymous memory with no address requirement / hint or backing file. For a `mmap` call of this type, Persimmon creates a PM region of the allocated length and transparently maps the PM region to the intended address. We currently don't

¹A third memory management system call is `brk`, which is not supported by our current implementation but can be similarly supported.

distinguish among page protection bits and assume that all allocated pages have all permissions. Persimmon supports `munmap` calls that free a single PM region or a part thereof, updating the region table before letting the calls through.

4 Crash-Consistent Shadow Execution

Persimmon's shadow execution uses dynamic instrumentation and undo logging to provide failure atomicity for state machine operations executing arbitrary application code. We chose dynamic binary instrumentation over static compiler instrumentation because application code often calls functions from dynamically linked external libraries (e.g., string functions in `libc`), which are only available in binary form at runtime. However, dynamic instrumentation comes with higher overhead than static, and a future direction is to improve instrumentation performance by combining static and dynamic instrumentation [96].

4.1 Overview

During shadow execution, Persimmon uses an *undo log* in PM to record the value at a persistent location before it is overwritten, similar to many prior systems [9, 16, 33, 81, 88, 99]. To support arbitrary application code in the PSM, Persimmon uses memory-level physical logging so that it can roll back an incomplete state machine operation at recovery time by copying back the previous memory values. The undo log is a sequence of entries, which come in two types:

- A *data entry* records the old value at a persistent location.
- A *commit entry* signifies that a state machine operation has finished; it contains a sole field `new_tail` recording what the operation log's tail pointer should advance to after the current operation is consumed.

The undo log supports append and clear operations. Each operation blocks until it persists.

In the shadow process, Persimmon instruments every write to a persistent location to append a data entry to the undo log before letting the write through. When a state machine operation completes, we *commit* the operation and remove it from the operation log following these steps:

1. Flush all previous writes and wait for them to persist.
2. Compute the updated tail pointer for the operation log and append a commit entry to the undo log.
3. Remove the operation from the log by advancing the tail pointer as computed.
4. Clear the undo log.

The recovery procedure either finishes committing the operation in progress according to the commit entry if one exists, or rolls it back (§ 5).

Undo logging dominates the shadow state machine's performance because (1) it could add additional work to every memory write, and (2) an undo log append must wait for persistence to PM, which is slow. Therefore, our design aims to reduce the number of undo log appends and the amount of extra code executed per application memory write.

Figure 3: The layout of an undo log element (§ 4.2).

To achieve these goals, Persimmon logs at the granularity of aligned 32 B data blocks. Writes that straddle blocks will generate multiple undo log entries, and writes smaller than 32 B will result in at least 32 B of data being logged. This strategy is motivated by the observation that if a location has been undo logged, then any subsequent writes to that location need not be logged. By logging in larger blocks, Persimmon takes advantage of spatial locality in memory writes to coalesce logging for adjacent locations. Insisting that all blocks be equal-sized and aligned ensures that blocks never overlap and simplifies the detection of duplicate blocks (§ 4.3).

4.2 Undo Log Layout and Operations

The undo log consists of a persistent array A of fixed-size 64 B elements (which is the cache line size), and the undo log size n , which is stored in DRAM only. Our implementation fixes the array’s total size to 2^{20} elements (32 MB), which is large enough for our applications. The array A is cache line-aligned, and so are its elements.

An array element either is *valid*, representing an undo log entry (§ 4.1), or is *invalid*. We maintain the invariant that $A[0..n-1]$ contains valid elements and $A[n..]$ contains invalid elements, so that n can be inferred from A upon recovery.

Figure 3 shows the layout of an array element. Each element is interpreted based on its `type` field:

- If `type` = 0, the element is invalid.
- If `type` = 1, the element is valid and represents a data entry that records the original value of $[addr, addr + 32 B)$. The `addr` field must be a 32 B-aligned address.
- If `type` = 2, the element is valid and represents a commit entry with `new_tail` (§ 4.1).

When appending an entry, we make sure that the `type` field, which also indicates validity, persists no earlier than the other fields. This does not require using an extra persist barrier—since writes to the same cache line reach PM in program order [19, 84], we simply need to write the `type` field last.

To clear the log, we set `type` to zero for elements $A[0..n-1]$ from left to right. If a crash occurs during the clearing, the recovered process will see that $A[0]$ is invalid and will then clear the entire array again.

With this undo log organization, an append requires only one persist barrier (at the end), and consecutive appends write to PM sequentially and avoid repeatedly flushing a single cache line (which is known to incur high latency on Optane persistent memory [12, 92]). Although clearing the log at commit time requires writing to all n entries, it is rare due to the batch commit optimization (§ 4.3) and can be optimized by, e.g., maintaining a persistent commit sequence number.

4.3 Dynamic Binary Instrumentation

Persimmon dynamically instruments memory writes for undo logging. The bulk of the logging logic is implemented in the function `log_write(addr, sz)`, which rounds up the range $[addr, addr + sz)$ to aligned 32 B blocks and appends an undo log entry for each block. Persimmon, in the shadow process, inserts a call to `log_write` before each application instruction that can write to memory. It translates repeat string operations into regular loops to instrument each iteration separately. For conditionally executed instructions, the instrumentation is executed only when the instruction is.

To minimize overhead from dynamic instrumentation and undo logging, Persimmon applies a number of optimizations:

Skipping the stack. Persimmon assumes that the application holds no persistent data on the stack. It does not save stack pages to PM, and as a result it does not need to instrument stack operations. Persimmon assumes that any memory operand that is an offset from the stack pointer `%rsp` points to the stack, and can thus efficiently skip instrumentation for a large number of instructions (notably, all pushes and pops). This assumption about `%rsp` usage can be validated at runtime by tracking all updates to the register [96], although we have not implemented this validation. The `log_write` function also skips writes to locations above `%rsp` minus 128 B (accounting for the red zone [63]), thereby filtering out any stack operations that do not use an offset from `%rsp`.

De-duplicating undo log entries. To avoid logging duplicate data, the `log_write` function maintains a hash set in DRAM for the `addr` field of existing undo log entries, and avoids appending entries whose `addr` already exists. This hash set must support lookup, insert, and clear operations, and fast lookup is key to making this optimization worthwhile.

Our hash set, closely modeled after the CPython dictionary [23], is implemented as a flat array of `addr`’s and resolves collisions with open addressing. The array size is fixed to 2^m (where $m = 14$ in our implementation); we use the simple hash function $h(addr) = addr/32$ (since `addr` is aligned to 32 B); and probing uses a linear recurrence with perturbation [23]. A zero element denotes an empty slot, and the hash set is cleared by zeroing out the entire array. Shadow execution commits once the hash set’s load factor reaches 50% (see the batch commit optimization below); in case the hash set becomes full, the de-duplication optimization is disabled.

With this hash set implementation, lookups that do not encounter collision are extremely fast. This allows us to insert a fast path de-duplication check, which we detail next.

Fast-path de-duplication check. Although de-duplication in `log_write` avoids redundant logging, the function call before every write is still costly as it requires saving and restoring application registers. We therefore insert a “fast path” check *before* the function call to filter out easy-to-identify duplicates. For a memory write to address *dest* of size *sz*, the call to `log_write` is skipped if both conditions hold:

Listing 1: Instrumentation inserted before a memory write of sz bytes. $\%dest$ and $\%tmp$ are placeholders for any two distinct general-purpose 64-bit registers. The `.hash_array` label refers to the base address for the hash set array.

```

1  (Reserve registers %dest and %tmp)
2  (Compute destination of the write, store in %dest)
3  (Reserve arithmetic flags)
4
5  # First check: the write is contained in
6  # a single block (not generated if sz=1).
7  leaq    (sz-1)(%dest), %tmp
8  xorq    %dest, %tmp
9  cmpq    $31, %tmp
10 ja     .slow_path
11
12 # Second check: look in the hash set.
13 movq    %dest, %tmp
14 shrq    $2, %tmp
15 andl    $131064, %tmp
16 movq    .hash_array(%tmp), %tmp
17 xorq    %dest, %tmp
18 cmpq    $32, %tmp
19 jnb     .skip
20
21 .slow_path
22 (Save application registers)
23 (Call log_write)
24 (Restore application registers)
25
26 .skip
27 (Restore arithmetic flags)
28 (Restore registers %dest and %tmp)

```

- The write is contained in a *single* aligned 32 B block, i.e., $\lfloor dest/32 \rfloor = \lfloor (dest + sz - 1)/32 \rfloor$.
- The block's address is found in the hash set on first try (without any probing), i.e., $H[i] = addr$ where H is the hash set array, $i = \lfloor dest/32 \rfloor \bmod 2^m$ according to the hash function, and $addr = \lfloor dest/32 \rfloor \times 32$ is the block address.²

Any memory write filtered out by the check is guaranteed to be a duplicate, and the check proves effective in our evaluation (§§ 7.2.1 and 7.2.3). Furthermore, as the computation required by the checks only require bit manipulations, the two checks can be implemented in 11 instructions using only two extra registers (one of which stores *dest* and is anyway required). Listing 1 shows the code inserted before a memory write.

Batch commit. Persimmon shadow-executes multiple state machine operations before committing, thus avoiding duplicate logging across multiple operations. After executing each operation, Persimmon checks to see if the de-duplication hash set is more than 50% full and if so, commits. We defer more intelligent batch sizing to future work.

Skipping newly allocated regions. Writes to a PM region that is newly allocated (i.e., after the most recent commit) do not need to be logged since, in case of a crash, the state machine will be reverted to before the region was allocated. The `log_write` function therefore maintains, in DRAM, a list of address ranges for newly allocated regions and searches

²Note that if no element exists in the hash set with hash value $h(addr)$, we have $H[i] = 0$ and the check fails as expected (assuming that the application never writes to the block starting at address zero).

through the list to skip logging such writes. This optimization is critical for supporting `calloc` implementations that manually zero out pages allocated with `mmap`.

5 Recovery

To minimize recovery times, recovery in Persimmon is relatively simple. After a crash, the first step is to restore the PM state machine snapshot to a consistent state:

- If the undo log contains a commit record, we set the operation log tail to *new_tail*. If an updated region table exists in PM, we switch to it and garbage collect the old region table. This completes the commit.
- If the undo log contains no commit record, we delete and garbage collect the updated region table (if one exists) and copy the old values from the undo log back to their respective locations. This rolls back the operation in progress at the time of the crash.

As a last step, we clear the undo log in both cases.

Starting from the consistent PM snapshot, Persimmon digests any remaining operations in the operation log so that all previously invoked operations are reflected in the snapshot. Replaying the log ensures that Persimmon maintains its guarantee that any invoked operation that returns will not be lost. This up-to-date snapshot is then copied into DRAM for the application process, and the application is restarted. Assuming that the PSM has captured all persistent application state, the application should be back in its pre-crashed state.

6 Implementation

We have implemented Persimmon in C++; it targets x86-64 Linux applications written in C or C++. We use CRIU [24] (v3.12) for process checkpointing during background process initialization (§ 3.3). For dynamic instrumentation (§ 4.3), we use DynamoRIO [8], a runtime code manipulation system. Persimmon's DynamoRIO client is linked into the application along with the DynamoRIO runtime. This setup allows Persimmon to start the application uninstrumented and only begin instrumentation in the background process once it is forked off. To avoid interfering with the application, our instrumentation code takes care not to call into shared libraries (e.g., `libc`), and instead uses DynamoRIO's memory allocator and our custom system call wrappers.³

7 Evaluation

Using our implementation, we demonstrate that Persimmon:

- Requires only a small amount of code modification for distributed in-memory storage systems.
- Achieves low overhead on workloads compared with no persistence for both Linux and kernel-bypass applications.
- Recovery quickly even for large memory sizes.

³Because our DynamoRIO client is linked into the application, it is not loaded by DynamoRIO's private loader, which would have created a separate copy of each library used by the client.

Table 2: Rough lines of code changed to port Redis and TAPIR.

	Lines added / changed	
	Redis	TAPIR
Initialize Persimmon	7	10
Factor out state machine init.	36	34
Serialize state machine operation	26	12
Deserialize & execute operation	45	25
Check for read-only operations	1	1
Refactor for better performance	—	57
Total	115	139

We ported Redis, a popular key-value store, and TAPIR [113], a distributed transactional data store, to use Persimmon. We first describe the code changes required to port these applications (§ 7.1), followed by performance comparisons (§§ 7.2.1 and 7.2.2). Finally, we use microbenchmarks to evaluate the effectiveness of Persimmon’s optimizations (§ 7.2.3).

7.1 Programming Experience

Although the Persimmon API is simple (Figure 1), porting real applications can require a few extra steps as real-world code bases are not always well-organized into a state machine abstraction, even if the application is processing RPCs. The programmer typically needs to:

1. Add a call to `psm_init()`, passing configuration arguments like the PM file system location.
2. Factor out the state machine initialization code into a single function, separating it from other initialization (e.g., network I/O), so that it can be skipped on recovery.
3. Write a function that serializes a state machine operation for operation logging. One can reuse the application’s existing RPC serialization, but, for better performance, we found it valuable to use a custom format that is cheaper to parse in the shadow process.
4. Write a function that deserializes and executes an operation, to be invoked under instrumentation in Persimmon’s shadow process. This function typically only needs to call the application’s RPC handler using the deserialized operation, but may need to suppress any I/O by the handler (e.g., sending a reply over the network).
5. Insert checks to distinguish read-write operations from read-only ones; such checks likely already exist for applications that support state machine replication. Invoke Persimmon for read-write operations.

We performed all of these steps for Redis because it was not well-organized into a state machine, especially because it is written in C, which is not an object-oriented language. TAPIR, on the other hand, was already designed as a state machine to work with its replication mechanism. Table 2 summarizes the code changes required to port Redis and TAPIR. We discuss each application in detail next.

7.1.1 Porting Redis

To port Redis, we treat each Redis command as a state machine operation and invoke it through Persimmon. To summarize, the changes made were:

1. Persimmon initialization took 6 lines of code (LoC).
2. To factor out the state machine initialization code, we separated out three blocks of code (7 + 7 + 22 lines) responsible for network and domain socket initialization, etc.
3. Redis operation serialization for the state machine took 26 lines of code. The serialization consists of the address of the Redis command’s handler function⁴ as well as the command’s arguments.
4. Redis operation deserialization, parsing, and dispatch took 24 lines of code. Since executing Redis commands requires a “client”, we reuse the fake client code from Redis AOF (21 lines), which also suppresses replies.
5. To determine whether an operation is read-only, we reused existing code from Redis’ state machine replication.

In all, Persimmon allowed us to achieve persistence for Redis with roughly 100 lines of code changes. In contrast, Redis’ own persistence implementation (AOF and RDB) consists of roughly 3000 lines of code, including complex logic such as request processing while log compaction is in progress. As another point of comparison, Pmem-Redis [82], a version of Redis that uses persistent memory, contains roughly 30000 new lines of C code over Redis 4.0.0, although we note that Pmem-Redis contains features that are orthogonal to Persimmon (e.g., defragmentation). Xu et al. report that manually porting Redis to persistent memory using PMDK [80] “is not straightforward and requires large engineering effort” [104, § 3.3]. They list five difficulties, which include supporting the many different Redis objects with different encodings, carefully ordering writes to maintain crash consistency, etc. None of the difficulties arose when we ported Redis using Persimmon.

Despite minimal changes, our port is the most feature-complete PM Redis port that we know of. For example, Persimmon-Redis supports complex Redis data structures like sets and hashes while the persistent Redis from WHISPER [73,98] only supports simple key-value pairs, and Pmem-Redis lacks support for optimized encodings like `intset` and `zipmap`. We also support hash table resizing, which is not supported by P-Redis due to its complexity [104]. Persimmon-Redis supports these features “out of the box”, without requiring additional code for each feature. In addition, Persimmon lets Redis retain `jemalloc` [47] as its memory allocator, which was carefully chosen by the Redis developers [86].

7.1.2 Porting TAPIR

The TAPIR transactional data store is built on top of the inconsistent replication (IR) protocol. We treat each IR RPC as a state machine operation. In the application, these RPCs

⁴As the shadow process is forked from the application process (§ 3.3), the application’s code segment is mapped at the same location in both processes.

are serialized using Protocol Buffers [83], and a naive Persimmon port uses the same serialization for operation logging. Although easy to implement, this strategy causes significant performance degradation as Persimmon has to execute Protocol Buffer parsing under shadow execution, which is slow.

To improve performance, we refactored TAPIR’s IR RPC handlers to take individual RPC fields as arguments, so that they can be called from the shadow process without first constructing protobuf objects. This refactoring involved roughly 50 LoC changes, which were mostly mechanical, and enabled operation logging using a simple custom format (like for Redis). In addition to this refactoring, we did the following:

1. Persimmon initialization took 11 lines of code.
 2. To factor out state machine initialization, we moved two code blocks (10 + 4 lines) and modified ~20 LoC to allow creating a RPC handler without a network connection.
 3. Operation serialization took 12 lines of code.
 4. Operation deserialization and invocation took 17 lines of code, plus an extra 8 lines to suppress replies.
 5. We reused application code to detect read-only operations.
- The overall code change amounts to roughly 140 lines in total.

To recover from replica failures, TAPIR uses a complex in-memory recovery protocol, inspired by VR, which has been proven to be incorrect [69]—under certain failure conditions, TAPIR can lose operations when recovering, causing it to miss updates. Persimmon-TAPIR fixes this problem transparently and lets replicas correctly recover their state on failures.

One of the benefits of TAPIR is that replicas can recover and immediately begin processing transactions. However, without the most up-to-date state, these recovered replicas will degrade performance by serving stale reads and unnecessarily aborting writes. TAPIR particularly suffers from this performance degradation because it needs $\frac{3}{2}f + 1$ to use the single-round trip fast path. For a 3-machine replica group, this number includes all of the participants. As a result, while the recovering replica is able to participate in transactions immediately, without the most up-to-date state, it is only hurting performance. However, Persimmon-TAPIR can significantly reduce this performance degradation by limiting the amount of state that the replica needs to recover.

7.2 Performance Evaluation

We evaluate Persimmon on three 52-core, dual-socket Intel Xeon Platinum 8272 2.6 GHz servers, each with 3 TB of Intel® Optane™ DC Persistent Memory in app direct mode and 768 GB of DRAM. We mount an ext4 file system in DAX mode [59] on the PM. Persimmon’s application and background processes run on two physical cores on a single NUMA socket and use only DRAM, PM, and the NIC on that socket. To supply the client workload, we use a server with a 20-core dual-socket Xeon Silver 4114 2.2 GHz CPU, connected with Mellanox CX-5 100 Gbps NICs and an Arista 7060CX 100 Gbps top-of-rack switch.

Table 3: Summary of Redis performance on YCSB (Zipfian constant = 0.75, 10% update, median of five runs). The persistence options are volatile (“Vol”), persistent through Persimmon (“PSM”), and persistent through append-only file (“AOF”), with our performance in bold. Shown are median latency at low load and peak throughput. Persimmon incurs, for Linux, negligible latency and throughput overhead and, for kernel bypass, negligible latency overhead and ~5% throughput overhead. Figure 4a shows the full latency vs throughput graph.

Redis Setup	Latency (μs)			Throughput (Kops)		
	Vol	PSM	AOF	Vol	PSM	AOF
Linux	17.8	17.5	18.6	227	227	107
Bypass	10.4	11.2	12.0	452	429	130

7.2.1 Redis Performance

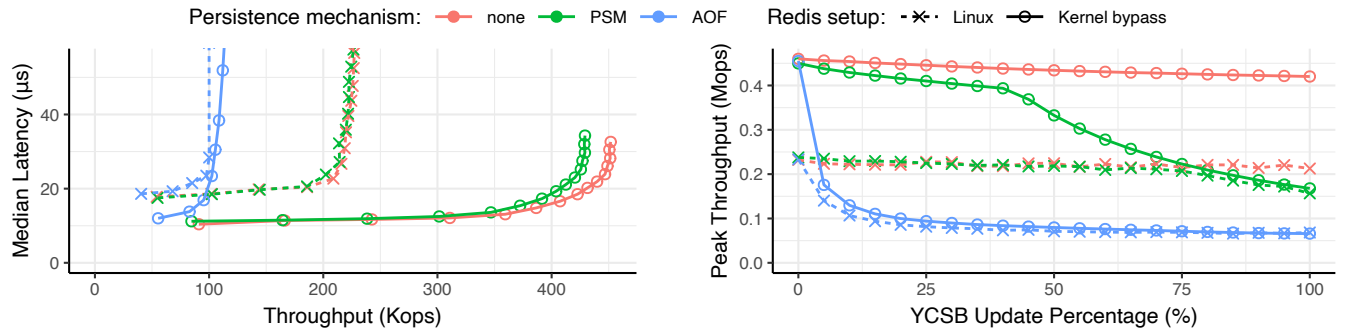

We use Persimmon to add persistence to two versions of Redis—regular Redis (v4.0.9), which processes requests over TCP using the POSIX API, and a high-performance, kernel-bypass version of Redis that uses the Demikernel’s DPDK library OS [26, 112]. We compare both Persimmon-Redis versions to Redis’s existing persistence mechanisms.

While Redis is an in-memory storage system, persisting Redis is popular enough for it to integrate two mechanisms for saving its state [85]: RDB, a snapshotting mechanism, and AOF, an append-only operation log. Using RDB requires pausing operation processing for a short period while Redis spawns a background process to checkpoint its database.

AOF logs every write operation received by the server to a file, similar to Persimmon’s operation logging. However, Redis typically recommends only `fsync`’ing those logged operations periodically to avoid performance overhead [85], so operations can be lost on a crash. AOF must also avoid the operation log growing unboundedly, so it periodically creates an RDB snapshot, letting it truncate the log. This process further degrades performance, so the Redis developers recommend only snapshotting once or twice an hour [85].

In some sense, these mechanisms are orthogonal to Persimmon. They have features that Persimmon does not provide (e.g., compact and platform-independent serialization), but do not provide cheap, general-purpose persistence to in-memory storage systems. Their implementation is specific to Redis, requires significant implementation effort, and, as shown below, can cause large performance degradation.

Experiment setup. We evaluate Redis performance using the YCSB benchmark [21]. We implemented a custom multi-threaded YCSB client, using Shenango [78], which supports both TCP and Demikernel’s UDP-based protocol. Following the official YCSB implementation [111], our client is closed-loop and does not use Redis pipelining, each YCSB record is represented with a Redis hash, and fields are accessed using Redis’ `HSET/HGET` commands. We load 13 million records; as is YCSB default, each record has 10 fields (i.e., 130 million items in total), and each field has a 100 B value. Our client is-

(a) Latency vs throughput for a 10%-update workload. Persimmon incurs negligible overhead over the Linux baseline, and a roughly 5% overhead to the peak throughput over the kernel-bypass baseline. (b) Peak throughput vs update percentage. Persimmon throughput stays within 9% of the kernel bypass baseline for up to 40%-update, and within 4% of the Linux baseline for up to 75%-update.

Figure 4: Redis performance on the YCSB benchmark (median of five runs, Zipfian constant = 0.75).

sues reads and updates according to a fixed ratio, and chooses which records to access according to a Zipfian distribution.

On the server side, the regular Redis server uses jemalloc (as is recommended for Linux) and our kernel-bypass Redis uses the Hoard memory allocator [3] (following the Demikernel implementation [26]). Where Redis AOF is enabled, we place the AOF log file on the PM file system, disable AOF rewriting, and configure it to always `fsync` before sending replies, providing the same level of durability as Persimmon.

End-to-end performance. We start with the end-to-end performance for a typical YCSB workload with 10% updates and a Zipfian constant of 0.75. We measure the latency and throughput for unmodified Redis, Persimmon Redis, and Redis AOF. Table 3 reports performance both on Linux and with kernel-bypass enabled through the Demikernel and shows:

- On Linux, Persimmon provides persistence while incurring negligible latency or throughput overhead.
- With kernel bypass, Persimmon incurs negligible latency overhead at low load, and a 5% degradation to peak throughput. Kernel bypass makes Redis significantly more efficient, so Persimmon has slightly more impact on performance.
- On Linux, AOF incurs $< 1 \mu\text{s}$ latency cost but a $2\times$ throughput penalty, a much higher overhead than Persimmon.
- With kernel bypass, AOF again incurs a small latency overhead but a $3.5\times$ throughput loss.

Some of the overhead of AOF is likely due to inefficiencies in accessing PM through ext4 and could be reduced using a specialized PM file system like NOVA [104, 105] or SplitFS [48]. Overall, Persimmon offers persistence at a much lower cost than Redis’s own custom persistence mechanism both on Linux and for future kernel-bypass deployments.

Figure 4a shows the full latency vs throughput plot for this workload with varied numbers of closed-loop clients. (Lower and to the right is better. The knee where latency goes up shows the peak throughput.)

Table 4: Redis recovery time and storage size for the three persistence mechanisms (median of three runs). Persimmon recovers $4.6\times$ – $6\times$ faster than AOF and RDB. The discrepancy between the Linux and kernel bypass implementations is likely due to memory allocators differences (jemalloc vs Hoard).

Redis Setup	Recovery Time (s)			Storage Size (GB)		
	PSM	AOF	RDB	PSM	AOF	RDB
Linux	14.6	87.4	87.8	23	16	2.8
Bypass	20.4	93.3	93.5	33	16	2.8

Peak throughput vs update ratio. Since Persimmon only logs and shadow-executes write operations, its overhead depends on the workload’s update-to-read ratio. Figure 4b shows peak Redis throughput as we vary the workload’s update percentage. Persimmon’s throughput remains within 4% of the baseline for up to 75%-update on Linux (represented by the red and green “x” lines in the middle of the graph), and within 9% of the baseline for up to 40%-update for kernel bypass (represented by the red and green “o” lines at the top). After these points, the shadow state machine becomes saturated and the throughput drops precipitously. Both versions can easily handle read-heavy workloads, which are common in practice.

Recovery speed and storage size. Table 4 shows Redis’ recovery speed and storage usage under different persistence mechanisms if we kill Redis after loading our YCSB dataset.⁵ Because Persimmon persists application data in its in-memory format, the bulk of its recovery is physically copying PM regions back into DRAM, while AOF and RDB require reloading the database. Consequently, Persimmon recovery is faster by $4.6\times$ (on Linux) to $6.0\times$ (for kernel bypass) and, we believe, can be further optimized by copying PM regions in parallel using multiple cores. However, Persimmon’s space

⁵The Persimmon recovery measurements do not include operation replay because it would take negligible time—since the operation log is only 32 MB, replaying even a full log would only take roughly one second for YCSB.

Figure 5: Disabling each optimization degrades Redis throughput on YCSB (Zipf = 0.75, kernel bypass, median of five runs). Note that disabling de-duplication also disables the fast-path check.

usage tracks the application’s RAM usage while AOF and RDB can use more compact serialization formats. The discrepancy between Linux and kernel-bypass Redis is most likely because they use different memory allocators (jemalloc vs Hoard), which lead to differing amounts of memory consumption and exhibit different allocation performance.

Effectiveness of optimizations. To evaluate Persimmon’s optimizations (§ 4.3), we measure Redis performance under Persimmon after disabling each optimization separately (note that disabling undo log de-duplication also disables the fast-path de-duplication check).⁶ Figure 5 shows that no optimization can be removed without degrading performance.

7.2.2 TAPIR Performance

As with Redis, we use Persimmon to add persistence to two versions of TAPIR—regular TAPIR, which processes requests over UDP using the POSIX API, and kernel-bypass TAPIR, which uses the Demikernel’s DPDK library OS. We compare each version to the original, non-persistent application.

We evaluate TAPIR performance using the Retwis benchmark [113], a Twitter-like transactional workload, with 10 million keys (where keys and values are 64 B) and a Zipf coefficient of 0.75. On the server side, we configure one shard with three replicas running on separate machines equipped with PM. For clients, we use a multi-process closed-loop load generator that processes RPCs over UDP using the POSIX API; it supports both the regular TAPIR and Demikernel protocols.

Table 5 reports the mean latency and peak throughput for Retwis transactions. Persimmon incurs negligible latency overhead for both the Linux and the kernel-bypass setups. For peak transaction throughput, Persimmon incurs a 5.4% degradation on Linux and a 7.3% degradation for kernel bypass. Note that the TAPIR transaction latency is much higher than the Redis latency from § 7.2.1 because each transaction in-

⁶We excluded the optimization that skips newly allocated regions because no new regions are allocated during these experiments (since our workload only overwrites existing keys). However, this optimization helps tremendously when loading the initial YCSB database.

Table 5: Summary of TAPIR performance on Retwis (Zipf = 0.75, three replicas). The persistence options are volatile and Persimmon (“PSM”), with our performance in bold. Shown are the mean transaction latency at low load (measured using five clients) and peak throughput (with at most 20 clients). Persimmon incurs negligible latency overhead and a 5%–8% throughput overhead. Figure 6 shows the full latency vs throughput graph.

TAPIR Server	Latency (μs)		Throughput (txn/s)	
	Volatile	PSM	Volatile	PSM
Linux	342	338	37 K	35 K
Bypass	310	309	41 K	38 K

Figure 6: Latency vs throughput for TAPIR on the Retwis benchmark (10 million keys, Zipf = 0.75, median of five runs). Throughput starts decreasing as more clients are added due to congestion collapse.

volves multiple RPCs sent to three replicas; and kernel bypass provides less benefit for TAPIR than for Redis because TAPIR performs more work per RPC and its code base is less heavily optimized. Figure 6 shows the full throughput vs latency plot for this workload (lower and to the right is better). After a crash, Persimmon can recover a replica within 7 s; we were not able to compare to a recovery baseline as TAPIR has not implemented recovery from another replica.

7.2.3 Optimization Microbenchmarks

We use microbenchmarks to demonstrate the effectiveness of Persimmon’s optimizations for crash-consistent shadow execution (§ 4.3). Each microbenchmark repeatedly invokes operations using `psm_invoke_rw`. Each operation performs 1024 memory accesses, where each access reads a 32 B *block* of memory into a `%ymm` register, performs an AVX-2 vector addition on it, and writes it back to the same memory location. We picked the access size of 32 B to match the undo logging granularity (§ 4.2). For clarity, we turn off batch commit unless otherwise specified. In each benchmark, we disable certain optimization(s) and use a memory access location pattern that demonstrates the effect of the optimization(s).

In Figure 7a, we disable undo log de-duplication and its fast-path check and vary the access frequency of each block—ranging from each operation accessing 1024 different

(a) *Undo log de-duplication* is most effective when few locations are accessed repeatedly. (b) *Skipping stack operations* is most effective with a large percentage of stack accesses. (c) *Batch commit* is most effective when operations access a lot of overlapping memory.

Figure 7: Effectiveness of Persimmon’s optimizations (median of five runs).

blocks sequentially to accessing a single block 1024 times. When memory accesses are concentrated on few locations, de-duplication can deliver up to $13\times$ throughput increase, and the fast-path check, an additional $5\times$. These optimizations incur no discernible overhead when there is no duplication.

In Figure 7b, we disable the optimization that skips stack accesses and direct a percentage of memory accesses to an array allocated on the stack. As expected, this optimization is most effective when state machine operations frequently access the stack, which we assume to be not persistent.

In Figure 7c, we enable the batch commit optimization with fixed batch sizes of 4 or 8 operations, and vary the percentage of overlap between blocks accessed by consecutive operations. Batch commit is most effective when it can group together many operations that access common memory locations.

8 Related Work

PM frameworks. Because PM’s low level interface (load, store, flush) can be hard to use, prior works have proposed PM frameworks that provide higher-level APIs [9, 16, 18, 22, 31–33, 41, 42, 45, 60, 65, 67, 81, 88, 95, 99, 102, 114]. Such a framework typically requires the programmer to (1) explicitly declare persistent data (e.g., by using a special `malloc`), (2) delineate failure-atomic regions using `begin/end` annotations, and (3) annotate operations that modify persistent data. The framework can then provide durability and failure atomicity by executing extra logic for each persistent operation, e.g., to log the operation and flush any modified persistent locations. Some of these frameworks reduce the programming burden by, e.g., inferring failure-atomic regions from existing synchronization points [9, 33, 41, 45, 60, 102], and by automatically interposing on persistent operations using language features [22, 95], static compiler instrumentation [9, 32, 33, 42, 102], or runtime methods [41, 88, 102].

Using these frameworks comes with two difficulties. First, despite their high-level APIs, porting an application using these frameworks can still be labor-intensive [66, 104] and bug-prone [61, 62]; we elaborate on the porting experience later in this section. Second, PM accesses and failure atom-

icity mechanisms on the critical path can impose significant performance overhead, especially for frameworks that implement automatic interposition. For example, microbenchmarks by Hsu et al. [41, § 5.6] show a $5\times$ – $25\times$ slowdown for NVthreads and a $70\times$ – $200\times$ slowdown for Mnemosyne and Atlas on memory accesses. While such overhead might be acceptable for I/O-bound applications, it can significantly slow down high-performance data stores with fast I/O.

Persimmon alleviates both difficulties. On the programming effort side, Persimmon does not require manually annotating of every persistent allocation; it simply persists all state encapsulated by the state machine. We are not aware of any other framework of its kind that provides this feature.⁷ Furthermore, by taking a full-process approach to persisting the shadow process machine, Persimmon rules out referential integrity bugs [16] (e.g., arising from PM-to-DRAM pointers) and relocation issues (where a persistent region is mapped to a different address after recovery).

For performance, Persimmon keeps the critical path execution as close to the original application as possible. As far as we know, Persimmon is the only system that can transparently retain the application’s memory allocator (rather than swap in a special PM allocator), thus preserving its memory layout.⁸ It also pushes all PM accesses (besides operation logging) and instrumentation into the background; this requires an extra CPU core, but minimizes overhead on the critical path.

Finally, Persimmon is the first system to use *dynamic binary instrumentation* to provide failure atomicity on PM. This allows application code to call into libraries that are dynamically linked or whose source is not available (§ 4).

Porting data structures to PM. Despite the high-level APIs provided by the PM frameworks, porting existing

⁷Except AutoPersist [88], a Java PM framework that only requires marking a “durable root” object from which all persistent state can be reached. However, it exploits properties of Java / the JVM and cannot be easily extended to support C/C++ applications.

⁸Romulus [22] can be used with any memory allocator but requires manual modification to the allocator code.

data structures to PM remains challenging.⁹ For example, Marathe et al. called their experience porting `memcached` “surprisingly non-trivial” [66], and Xu et al. reported five difficulties in porting Redis’ hash table using PMDK, e.g., supporting Redis’ many object encodings and having to order persistent writes carefully [104, §3.3]. With the high manual effort, bugs are likely to appear in PM code even when using high-level PM frameworks [61, 62]. In contrast, Persimmon requires minimal code changes to port an application (§ 7.1); in particular, we encountered none of the five difficulties identified by Xu et al. as we ported Redis using Persimmon.

Other works have noted that certain classes of data structures are easier to convert to PM and proposed techniques accordingly. For example, RECIPE [57] observes that concurrent indexes that implement helping and non-blocking reads are “inherently crash-consistent”; MOD [39] notes that purely functional data structures can be easily made failure-atomic through copy-on-write; and Friedman et al. [30] automatically transform a special class of lock-free data structures to be persistent by exploiting the *traversal* phase in these data structures’ operations. Persimmon makes no such assumptions on the application’s data structures.

Like Persimmon, Pronto [68] relies on state machine-like assumptions on the data structure—that it is encapsulated and has deterministic operations. This enables Pronto to implement persistence using semantic logging and periodic snapshotting. In contrast, Persimmon allows porting an entire application, rather than a single data structure, and maintains low latency even for large data sizes as it avoids the periodic stalls from the synchronous phase of snapshotting.

PM data structures / stores. Many prior works have redesigned in-memory data structures to be durable in PM. These include both tree-based [1, 10, 11, 14, 17, 44, 53, 56, 93, 97, 109] and hash-based structures [13, 25, 74, 87, 116–118]. There have also been hybrid designs that combine PM with DRAM [12, 43, 77, 100, 103, 110] and/or with SSD [49, 51, 110]. To achieve high performance, these data structures often use data layouts and operations specifically optimized for PM.

In contrast, Persimmon is not one data structure/store; rather, it allows porting an in-memory storage system to be persistent on PM. Although a Persimmon-transformed system might not achieve resource utilization on par with hand-crafted PM data stores, Persimmon is more general and can deliver good performance on real-life workloads.

Persimmon’s design is similar to that of Bullet [43], a persistent key-value store that serves requests from a “front-end cache” in DRAM, records operations in persistent logs, and uses background threads to apply logged operations to a persistent hash table. While Bullet only supports a limited set of operations, Persimmon generalizes the design to support general application-level operations. A future direction is to

⁹Here we focus on the *porting* experience and thus do not include works that *replace* an application’s data structure with a persistent one (e.g., swapping out the hash table of Redis with a persistent B-tree [93]).

incorporate Bullet’s cross-referencing logs into Persimmon to better support multi-core applications.

PM-aware file systems. A natural way of using PM is to view it as a fast storage device and incorporate it into the storage stack. Many file systems have been designed to effectively exploit the high performance of PM [15, 20, 27–29, 48, 50, 55, 64, 94, 101, 105–107, 115]. These PM-aware file systems can transparently speed up durable applications that perform I/O using the file system interface, but do not directly apply to in-memory applications that do not use the file system.

Logging for crash consistency. Logging has been used to implement crash consistency in many contexts outside of PM, e.g., in database management systems [4, 5, 34–37, 54, 70] and journaling file systems [6, 38, 89–91]. Persimmon’s logging mechanisms are conceptually similar, with a key difference being that we perform undo logging on application-supplied state machine operations (in x86-64) as opposed to SQL transactions or file system operations.

9 Conclusion

Persistent memory (PM) offers a promising solution to providing crash recovery to in-memory storage systems. However, manually porting applications to PM remains challenging. Persimmon leverages PM to provide persistence to existing in-memory storage systems while maintaining high performance and requiring minimal code changes. We use Persimmon to add persistence to Redis and TAPIR with ease while incurring minimal performance overhead on common workloads.

Acknowledgments

We thank our shepherd Vijay Chidambaram and the anonymous reviewers for their helpful comments on the paper. We’d also like to thank Aurojit Panda, David Culler, Vivian Fang, Amy Ousterhout, and other members of the UC Berkeley NetSys Lab, the RISELab, and the Microsoft Systems Research Group for their feedback. This work was funded in part by NSF Grants 1817115, 1817116, and 1704941, and by grants from Intel, VMware, Ericsson, Futurewei, and Cisco.

Abstract

Persistent Memory (PM) can be used by applications to directly and quickly persist any data structure, without the overhead of a file system. However, writing PM applications that are simultaneously correct and efficient is challenging. As a result, PM applications contain correctness and performance bugs. Prior work on testing PM systems has low bug coverage as it relies primarily on extensive test cases and developer annotations.

In this paper we aim to build a system for more thoroughly testing PM applications. We inform our design using a detailed study of 63 bugs from popular PM projects. We identify two application-independent patterns of PM misuse which account for the majority of bugs in our study and can be detected automatically. The remaining application-specific bugs can be detected using compact custom oracles provided by developers.

We then present AGAMOTTO, a generic and extensible system for discovering misuse of persistent memory in PM applications. Unlike existing tools that rely on extensive test cases or annotations, AGAMOTTO symbolically executes PM systems to discover bugs. AGAMOTTO introduces a new symbolic memory model that is able to represent whether or not PM state has been made persistent. AGAMOTTO uses a state space exploration algorithm, which drives symbolic execution towards program locations that are susceptible to persistency bugs. AGAMOTTO has so far identified 84 new bugs in 5 different PM applications and frameworks while incurring no false positives.

1 Introduction

Persistent Memory (PM) is a promising new technology that offers an appealing performance-cost tradeoff for application developers. PM technologies, such as Intel Optane DC [36], can offer persistent memory accesses with latencies that are only $2\text{--}3\times$ higher than the latencies of DRAM [70]. Moreover, such PM technologies are cheaper than DRAM per GB

of capacity [3]. As byte-addressable memory, PM can also be accessed via processor load and store instructions. Application developers have already started building systems that use PM directly, without relying on heavyweight system calls to ensure durability, including ports of popular systems such as memcached [24] and Redis [21].

While using PM directly via persistent data structures can offer performance, it is challenging to write PM-based applications that are simultaneously correct and efficient [12, 18, 33, 52, 54, 60, 71, 76]. Persistent memory writes in the CPU cache must be explicitly flushed to PM using specific instructions or APIs. In certain cases, PM flush operations need to be ordered using memory fences to enforce crash consistency. Incorrect usage of these mechanisms can result in *persistency bugs* which break crash-consistency guarantees or degrade application performance. Persistency bugs are challenging to diagnose because their symptoms are easily masked. For example, crash-consistency bugs may be masked because PM writes are implicitly flushed when dirty (or updated) cache lines are evicted from the CPU—furthermore, flushes which are required for proper crash consistency under one execution path may be redundant and unnecessary under a different program execution path, leading to performance degradations.

Several systems have been built to aid with testing PM applications; however, these existing approaches are either specific to a target application or require significant manual developer effort. Intel designed Yat [44] and pmemcheck [65] specifically to test the crash consistency and durability of PMFS (Persistent Memory File System) [27] and PMDK (Persistent Memory Development Kit) [20], respectively. To find bugs, Yat exhaustively tests all possible update orderings, and pmemcheck tracks annotated updates. Both of these tools are specific to a single system (PMFS and PMDK, respectively) and are hard to generalize. Other tools like Persistency Inspector [62], PMTest [50], and XFDetector [49] are applicable to general PM systems, but require developer annotations and extensive test suites to thoroughly test PM applications.

In order to determine the extent to which persistency bug finding can be automated (i.e., not require program annota-

tions) to test general systems, we perform a study of 63 bugs in PM applications and frameworks. We identify two application-independent patterns of PM misuse (*missing flush/fence* and *extra flush/fence*) which cover the majority (89%, or 56 out of 63) of bugs in our study and can be detected automatically. The remaining bugs are application-specific; for example, many of the remaining bugs involve misusing transactions when updating data-structures. Existing PM testing approaches do not identify application-independent patterns of misuse, and therefore require annotations to detect any PM bug. In addition to classifying bugs based on their pattern of PM misuse, we also classify bugs based on whether they affect performance or correctness.

Based on the insights gained through our study, we present AGAMOTTO, a framework for detecting bugs in PM applications that does not rely on extensive test cases. Instead, AGAMOTTO uses symbolic execution [8] to thoroughly explore the state space of a program. In addition to expanding path coverage, symbolic execution also allows AGAMOTTO to detect persistency bugs in an application without access to underlying physical PM resources. AGAMOTTO introduces a memory model to track updates made to PM by the explored program paths, and supports *bug oracles* which use the PM state to identify bugs in the program. AGAMOTTO automatically detects persistency bugs using two *universal persistency bug oracles* based on the common patterns of PM misuse identified by our study. The first is an *unflushed/unfenced* oracle that identifies modifications to PM cache lines that are not flushed or fenced (both a correctness and performance issue) and the second an *extra-flushed/fenced* oracle that identifies duplicate flushes of the same cache line or unnecessary fences (a performance issue [18, 52, 60, 71, 76]).

To identify application-specific persistency bugs, AGAMOTTO allows developers to provide *custom persistency bug oracles*. To demonstrate the versatility of custom oracles, we implemented two such oracles in AGAMOTTO to detect bugs related to misuse of the PMDK transactional API [20, 49, 50].

Analyzing large PM applications using traditional symbolic execution [8] leads to scalability issues since the state space of possible executions grows exponentially with the size of the analyzed program. AGAMOTTO uses a novel search algorithm that prunes the execution states it analyzes, allowing AGAMOTTO to discover more bugs. Prior to symbolic execution, AGAMOTTO uses a whole-program static analysis to determine instructions that modify PM (stores, flushes, etc.) and assigns a unit priority to them. AGAMOTTO then assigns an aggregate priority to each instruction by back-propagating the unit priorities from each PM-modifying instruction—this makes the aggregate priority a measure of the number of PM-modifying instructions reachable from a particular instruction. AGAMOTTO uses priorities to steer symbolic execution into program states that frequently modify PM.

We used AGAMOTTO to find 84 new persistency bugs in real-world systems including PMDK (a mature PM li-

brary) [20], memcached-pm [24], Redis-pmem [21], NVM-Direct [7], and RECIPE [45]. In particular, we found 13 new correctness and 70 new performance bugs using the universal persistency bug oracles, and 1 new correctness bug using a custom persistency bug oracle. We report all bugs to their authors, and so far 40 of them have been confirmed and none denied.

In this paper we make the following contributions:

- We perform a detailed study of persistency bugs in PMDK as well as bugs found by prior work, and present a new taxonomy of persistency bugs.
- We build AGAMOTTO¹, a persistency bug detection tool that can test real-world PM programs using a novel state exploration algorithm. AGAMOTTO automatically detects bugs using two universal persistency bug oracles, without relying on user annotations or an extensive test suite. AGAMOTTO is extensible with custom bug oracles that can detect application-specific bugs.
- We use AGAMOTTO to find 84 new bugs in 5 applications and persistent memory libraries, compared to the 6 persistency bugs found in persistent applications by the state of the art (PMTest [50], which finds 3 bugs, and XFDetector [49], which finds 3 bugs). AGAMOTTO does not incur any false positives in our evaluation.

In the rest of this paper, we first provide background on PM programming and describe the challenges of PM bug finding (§2). We then present the results of our PM bug study and provide common patterns of PM misuse that identify PM bugs (§3). Then, we discuss the persistency bug detection algorithms and search techniques underlying AGAMOTTO (§4). Next, we describe the high-level design of AGAMOTTO and evaluate the system with respect to both the number of bugs found and the impact of these bugs (§6). Finally, we describe related PM bug detection work (§7).

2 Background and Challenges

We now provide a background on persistent memory (PM) programming and difficulties associated with writing correct and efficient PM programs.

2.1 Persistent Memory Programming

```
1 int *x = pm_alloc(), *y = pm_alloc();
2 *x = 1;
3 clwb(x)
4 sfence()
5 *y = 1;
6 clwb(y)
7 sfence()
```

Listing 1: A PM programming example.

PM implementations support a programming interface that diverges from that of conventional storage devices. Rather than

¹Released at <https://github.com/efeslab/agamotto>

using comparatively slow system calls to access persistent memory, applications can accelerate PM accesses by directly mapping pages of PM into their address space and performing byte-addressable load/store operations. Like volatile memory accesses, PM IO may be cached and buffered in volatile memory (i.e., the CPU cache) in order to increase performance.

The added performance comes at the cost of increased complexity for the application developer. Volatile memory can retain updates to PM for an indefinite period of time (e.g., until a cache line gets evicted). Ensuring that stores to PM are durable requires two steps. First, a developer must issue a *flush* for the cache-line that contains the updated data. Then, the developer orders flushes using existing fence operations (e.g., *SFENCE*). Note that an unordered flush may not be written to persistent memory before a crash, so fences are required for durability. Consider Listing 1, which allocates two integers in persistent memory and issues ordered writes to the integers. In order to guarantee that the write to x (line 2) is ordered before the write to y (line 5), a flush and fence must occur between the updates (lines 3 and 4). To ensure that the write to y (line 5) is durable, a flush and fence must occur after the write (lines 6 and 7).

The x86 instruction set architecture (ISA) provides two flush instructions: *CLFLUSHOPT* and *CLWB*. *CLWB* differs from *CLFLUSHOPT* in that *CLWB* hints the CPU to keep the cache line in the cache whereas *CLFLUSHOPT* does not. x86 provides two fence instructions: *MFENCE*, which orders all loads, stores, and flushes; and *SFENCE*, which orders all stores and all flushes. Additionally, x86 provides *CLFLUSH*, which acts as both a flush and fence for a specific cache line (i.e., only orders the flush that the *CLFLUSH* itself issues, other *CLWB* and *CLFLUSHOPT* instructions must be ordered by a separate fence). Finally, x86 allows non-temporal stores, which bypass the cache and thus do not require a flush but do require a fence for durability. Note that the classification of PM instructions into flush and fence operations is not x86-specific. For example, ARM provides flush (e.g., *DC CVAP*) and fence (e.g., *DSB*) operations [5, 67] with similar semantics to x86 flushes and fences.

2.2 Challenges of Detecting PM Bugs

PM interfaces for durability and performance are easy to misuse [49, 50] and the resulting persistency bugs can be challenging to detect. Persistency bugs exhibit many characteristics that make them difficult to detect. First, finding a persistency bug requires identifying whether PM cache-lines are dirty, but the x86 ISA does not provide a mechanism to determine the state of a cache-line. Thus, detecting a persistency bug requires modeling PM state and instrumenting the program for tracking state updates, which is challenging to accomplish using traditional debugging tools. Second, in the case of correctness bugs, the root cause and symptoms of a persistency bug are often loosely tied together: while the

Project	Missing Flush/Fence	Extra Flush/Fence	Other	Total
PMDK	49	6	2	57
PMTest	1	1	1	3
XFDetector	-	-	3	3
Total	50	6	7	63

Table 1: The results of our bug survey.

symptoms of a correctness persistency bug is only revealed after a crash, the PM misuse (i.e., the root cause) may be hundreds of thousands of instructions before the crash even occurred. Finally, persistency bugs are easily masked by other system behavior. For example, flushes which are redundant in one execution path of the program may be necessary under a slightly different execution path, while correctness persistency bugs may be masked by the CPU when evicting a dirty cache-line from its cache.

Unfortunately, developers cannot solely rely on PM frameworks (e.g., PMDK [20]) to prevent these bugs. As we show in §3, many applications use PM libraries incorrectly and even these established libraries themselves may misuse PM.

3 PM Bug Study and Classification

In this section, we present a study of persistency bugs. We construct a corpus of 63 persistency bugs from a mature PM library, PMDK [20], and persistency bugs from PM projects (PMFS [27] and Redis-pmem [21]) that were found by state-of-the-art PM bug detection tools (PMTest [50] and XFDetector [49]). We chose PMDK, because it is a mature project with a thorough issue tracker [23] representing a large collection of existing bugs. We use this corpus to identify common patterns of PM bugs.

Table 1 shows a summary of our results². Overall, we find that two application-independent PM patterns explain the vast majority (56/63 bugs) of the reported persistency bugs. We find that PM bugs can result in either correctness problems, which may lead to data corruption, or performance problems. In particular, the *missing flush/fence* pattern, in which an update to persistent memory is missing subsequent flush and/or fence operations, accounts for 50/63 bugs and can lead to either correctness or performance issues. The *extra flush/fence* pattern, in which a cache-line is redundantly flushed or a fence instruction is issued that is not needed for PM durability, accounts for 6/63 bugs and leads to performance degradation. The remaining 7 are caused by application-specific violations, most of which involve a misuse of the PMDK transaction API. Note, our study may be biased towards bugs that are detectable by existing PM bug detection tools, because PMDK

²We provide a link to our bug study results in the AGAMOTTO GitHub repository: <https://github.com/efeslab/agamotto/blob/artifact-eval-osdi20/artifact/README.md>

developers extensively use `pmcheck` [65] to detect bugs. In the rest of this section, we present examples of these bugs together with more detailed descriptions.

3.1 Missing Flush/Fence Pattern

```
1 //oid is a pointer to PM
2 if (if_free != 0)
3     *oid = NULL;
4 // BUG: missing flush and fence
```

Listing 2: A missing flush/fence correctness bug adapted from PMDK Issue #1103, Pull Request (PR) #3907.

The most common bug pattern in the bugs in our study is the missing flush/fence pattern, in part because PMDK developers extensively use `pmemcheck` [65] which identifies this pattern of PM misuse. In this bug pattern, an update to PM is not made durable because it is missing a subsequent flush and/or fence operation. An example of the pattern is shown in Listing 2. Here, a pointer to persistent memory, `oid`, is not flushed when `if_free != 0`. If the program crashed and restarted, the pointer might point to its old value, which could lead to rogue writes or malformed data reads. This bug is fixed by adding proper flush and fence operations after the modification.

In contrast, the missing flush/fence pattern is detectable without any application-specific information. In our study, instances of the missing flush/fence pattern are correctness issues, where the program is unable to recover from a crash similar to the one in Listing 2. In our evaluation (see §6), we also found instances of the missing flush/fence pattern which are performance bugs. In these instances, an application uses persistent memory to store volatile data, which hinders performance due to the higher latency of PM accesses relative to DRAM accesses. Existing studies suggest that placing volatile data in PM can decrease application performance by as much as 5% [26]. There are PM data structures that intentionally include this pattern [53] as a programming simplification. However, in the applications included in our study and evaluation, all instances of the missing flush/fence pattern are persistency bugs.

3.2 Extra Flush/Fence Pattern

The other common pattern of persistent memory misuse which we identify in our study is the extra flush/fence pattern. In this pattern, a cache-line is redundantly flushed, or a fence instruction which is not needed for PM durability is executed. An example of this is shown in Listing 3. In this example, an array located in persistent memory is resized in-place using the call to `resize_array`, new elements are initialized to 0, and new elements are flushed to persistent memory. However, when the size of the array is reduced (i.e., `new_size`

```
1 //array is an array of integers in PM
2 //with length = size
3
4 //resizes array in-place
5 resize_array(array, new_size);
6
7 // if size >= new_size, no copying occurs
8 for (size_t i = size; i < new_size; i++)
9     array[i] = 0;
10
11 // BUG: when new_size < size, underflow!
12 for (size_t i = 0; i < new_size - size; ++i)
13     clwb(array[i + size])
14 sfence();
```

Listing 3: An extra flush/fence performance bug adapted from PMDK issue #1117, PR #3860.

< `size`), an underflow in line 12 causes unnecessary flushes and leads to a performance degradation [18, 60, 71, 76] (e.g., an additional flush and fence can add an average of 250ns of latency [51, 73], where the base latency of uncached PM accesses can be as low as 96ns [37]).

Similar to the missing flush/fence pattern, the extra flush/fence pattern is detectable without any application-specific information. The extra flush/fence pattern results in performance degradation. As flush and fence instructions are used in non-PM contexts (e.g., fences provide semantics for memory consistency), there may be instances of this pattern that are not persistency bugs. However, in the applications in our study and evaluation, all instances of the extra flush/fence pattern are persistency bugs.

3.3 Other Bugs

```
1 // store pool's header
2 /* BUG: header made valid before
3    pool data made valid */
4 header = ...
5 clwb(header);
6 sfence();
7 pool = ...
8 clwb(pool);
9 sfence();
```

Listing 4: An example correctness bug adapted from PMDK Issue #14.

The remaining 7 bugs in the study are application-specific; i.e., in these cases, data is correctly flushed to PM and there are no redundant flush operations, but the application misuses PM, leading to performance or correctness issues. For example, Listing 4 depicts a bug adapted from the memory pool allocator in PMDK which results in a correctness issue. In order to recover from a crash, the values in `header` and `pool` must be consistent; however a crash at Line 7 will result in an updated value of `header` without an updated value of `pool`.

Figure 1: Components of AGAMOTTO. Green-shaded boxes are AGAMOTTO-specific.

3.4 Summary and Insights

We summarize several key results we obtained and the insights we gathered from this bug study which inform AGAMOTTO’s design decisions.

- The missing flush/fence and extra flush patterns are prevalent (56/63 of the bugs we found) and application-independent. Hence, an automated approach (i.e., requiring little to no developer effort or source modification) could and should be used to detect them across a variety of platforms.
- In our study, all instances of the missing flush/fence and extra flush/fence patterns are persistency bugs; we hypothesize that this trend will hold for general PM applications. In §6, we find that all instances of these patterns are persistency bugs across a variety of PM libraries and applications.
- The remaining bugs, while less prevalent in our survey, are still potential sources of inconsistency and/or performance loss. An ideal tool should allow developers to specify application-specific patterns without requiring extensive test cases and significant developer annotations.

4 Design

In this section, we describe the design of AGAMOTTO. AGAMOTTO aims to achieve four high-level design principles:

Automation. Bug-finding can take a substantial amount of developer effort [56,68]; AGAMOTTO aims to automate as much as possible to reduce this burden. For example, AGAMOTTO is non-intrusive (i.e., requires no source-code modifications) and leverages basic test cases (e.g., existing unit tests or example code) to explore execution paths in an application.

Generality. AGAMOTTO can test any PM application.

High Accuracy. AGAMOTTO aims to report no false positives (i.e., reporting a bug where there is none) while also reducing false negatives (i.e., failure to find a bug).

Extensibility. AGAMOTTO can be easily extended to find application-specific bugs.

The major components of AGAMOTTO are shown in Fig. 1 (green-shaded boxes represent the key components unique to

AGAMOTTO). AGAMOTTO relies on an existing symbolic execution engine (KLEE [8] in our prototype) to explore the state space of a PM program. During this exploration, AGAMOTTO uses a custom PM model to express and track updates to persistent memory regions (i.e., writes, flushes and fences). Since AGAMOTTO tracks PM symbolically, it does not need access to PM resources in order to detect persistency bugs in a PM application. As AGAMOTTO explores the state space of the program, it checks for PM bugs using universal bug oracles, as well as any custom bug oracles that users may provide. Universal oracles check for the missing flush/fence pattern and the extra flush/fence patterns of PM misuse identified in our study. Custom oracles can check for application-specific bugs, which may be correctness bugs (e.g., ordering bugs) and/or performance bugs (e.g., redundant transaction operations) akin to prior work [49,50].

At the heart of AGAMOTTO lies its PM-aware state space exploration algorithm, which is effective in steering symbolic execution towards program locations that exercise PM. In symbolic execution, inputs are symbolic (unconstrained) values in a program’s initial state. When the program reaches a branch depending on symbolic input, the current state is forked and the constraints on input are updated depending on the branch condition. As states increase by forking, symbolic execution needs to employ a state-space exploration strategy. Existing state space exploration strategies, such as maximizing code coverage, are not optimized for finding PM bugs, and thus waste resources exploring uninteresting paths.

Instead, before symbolically executing the program, AGAMOTTO uses a custom static analysis to determine instructions that can modify persistent memory. AGAMOTTO then uses a back-propagation algorithm to assign a weight to each instruction equal to the number of PM-modifying instructions that are reachable from that instruction. AGAMOTTO prioritizes exploring the program state whose currently-executed instruction has the highest such weight. We find that the number of PM-modifying paths is much smaller than the total number of execution paths in practice, allowing AGAMOTTO to thoroughly explore the set of executions that lead to persistency bugs (see §6).

When AGAMOTTO’s oracles detect a bug during state space exploration, AGAMOTTO relies on its underlying symbolic execution engine to invoke a constraint solver and determine the inputs that led to the bug, thereby creating a test case that a developer can use for debugging.

In the rest of this section we provide details regarding the key components of AGAMOTTO.

4.1 PM Model and PM State Tracking

AGAMOTTO facilitates persistency bug detection by tracking the state of persistent memory objects in the program. For each PM allocation, AGAMOTTO tracks constraints on the *persistency state* of the allocated cache lines. The persistency

state of a cache-line indicates whether the cache line is *dirty* (i.e., modified), *pending* (i.e., updates to the cache-line are flushed but not ordered) or *clean* (i.e., updates to the cache-line are both flushed and ordered). As AGAMOTTO symbolically executes, it updates constraints on the persistency state of PM cache-lines to reflect the behavior of the program. AGAMOTTO uses these constraints to identify execution paths which contain persistency bugs, (i.e., when redundant flushes are issued, or updates are not properly ordered).

Identifying PM allocations In order to be application-agnostic and automated, AGAMOTTO tracks persistent memory allocations from the system level, rather than tracking high-level calls to persistent memory allocators (e.g., `pmem_alloc`) [50]. Tracking PM allocations at a system level trades off performance in favor of automation, since this approach over-approximates PM allocations. AGAMOTTO marks all opened files that match a user-specified persistent memory device regular expression (e.g., `pmem/*`) as PM files and treats memory-mappings of PM files as persistent memory objects.

Tracking Persistent Memory State. When AGAMOTTO symbolically executes an instruction that operates on a PM object, it generates constraints on the persistency state of the cache-lines that comprise the memory objects. A store instruction (e.g., `x86 MOV`) adds a constraint that the destination of the store is in the dirty state. Flush instructions (e.g., `CLWB` and `CLFLUSHOPT`) generate a constraint that denotes that the destination is in the pending state. Non-temporal stores (e.g., `x86 MOVNT`) are similar to regular stores, except their destination is immediately put into the pending state (i.e., non-temporal stores are treated as a store+flush), as non-temporal stores bypass the CPU cache but are weakly ordered (like flush instructions) and still require some form of memory fence. Global fences (e.g., `SFENCE`, `MFENCE`) add constraints to indicate that all PM cache lines are clean, whereas cache-line fences (e.g., `CLFLUSH`) add a constraint denoting that their destination is clean.

4.2 Persistency Bug Oracles

AGAMOTTO uses the persistent memory state in order to support two types of persistency bug oracles. First, AGAMOTTO provides two built-in *Universal Persistency Bug Oracles*, which check for bugs based on the patterns we identify in §3. Second, AGAMOTTO allows developers to specify custom, application-specific persistency bug oracles, which we have used to provide two oracles for the PMDK Transaction interface [20].

```

1 // Unflushed Bug Oracle
2 def check_unflushed(state):
3     for pm_obj in state:
4         forall cachelines in pm_obj:
5             if not cacheline.is_clean:
6                 raise error(correctness)
7
8 // Extra flush/fence Bug Oracle
9 def check_extra_flush(state, cacheline):
10    if cacheline in state is clean:
11        raise error(performance)
12 def check_extra_fence(state):
13    if state has no pending updates:
14        raise error(performance)
15
16 // Call Oracles on instructions:
17 def executeInstruction(state, inst):
18    if (state.terminated or state.unmapped):
19        check_unflushed(state)
20    if inst is flush:
21        check_extra_flush(state,
22                           inst.cacheline)
23
24    // do flush
25    if inst is fence:
26        check_extra_fence(state)
27        state.commit_pending()

```

Listing 5: Pseudo-code for Universal Persistency Bug Oracles and how they are used as AGAMOTTO explores the state space.

4.2.1 Universal Persistency Bug Oracles

AGAMOTTO provides two universal persistency bug oracles, one that detects an instance of the missing flush/fence bug pattern (indicating a correctness or performance bug), and one that detects an instance of the extraneous flush/fence bug pattern (indicating a performance bug). We sketch the algorithms in Listing 5. AGAMOTTO reports a missing flush/fence bug for each cache-line in a persistent memory object that is not clean (i.e., the constraints on the persistent state indicate that the cache-line may be dirty or pending) at the time when the persistent memory is no longer addressable (due to either `munmap` or program exit). AGAMOTTO identifies an extraneous flush/fence operation bug on any flush (e.g., `CLFLUSH`) to a cache-line which must already be pending or clean based on the constraints on the persistent state. AGAMOTTO also identifies an extraneous flush/fence bug on any fence (e.g., `SFENCE` or `MFENCE`) which has no pending flushes to mark clean. For both of these oracles, AGAMOTTO reports program location information (e.g., stack frame and source code location) for the most recent update to each cache line which violates the conditions checked by the oracle. In our evaluation (see §6), we show that these oracles do not incur any false positives across a variety of PM frameworks and applications.

4.2.2 Custom Bug Oracles

In addition to the generic bug oracles, AGAMOTTO facilitates the use of custom bug oracles. Custom bug oracles are defined separately from the application, which allows them to be versatile tools for detecting application-specific bugs. For example, a developer might use a custom oracle to validate the correct usage of PM frameworks (e.g., identifying duplicate log entries in the PMDK `libpmemlog`) or assert that certain

```

1 class PmemObjTxAddChecker
2 : public CustomChecker {
3     bool in_tx;
4     // [address, address+size)
5     typedef pair<ref<Expr>, ref<Expr>> TxRange;
6     list<TxRange> added_ranges;
7
8     void checkTxBegin(Function *f,
9                       ExecutionState &state) {
10         if (!in_tx && f->getName() == "
11             pmemobj_tx_begin")
12             in_tx = true;
13     }
14
15     void checkTxAdd(Function *f,
16                    ExecutionState &state) {
17         if (f->getName() !=
18             "pmemobj_tx_add_common") return;
19         // 1. Get the address from the stack.
20         ref<Expr> address = f.getArgument(0);
21         ref<Expr> size = f.getArgument(1)
22         // 2. Get end bound
23         auto r_end = address + size;
24         auto new_range = TxRange(address, r_end);
25         // 3. Check for overlaps.
26         // If overlap, there's a bug!
27         if (overlaps(state, new_range))
28             reportError(state, RedundantTxAdd);
29         // 4. Add the new range.
30         added_ranges.push_back(new_range);
31     }
32
33     void checkTxEnd(Function *f,
34                    ExecutionState &state) {
35         if (f->getName() == "pmemobj_tx_end")
36             in_tx = false;
37     }
38 public:
39     PmemObjTxAddChecker(...) {...}
40     // This is the entry point
41     virtual void operator()(
42         ExecutionState &state) override {
43         checkTxBegin(getFunction(state), state);
44         checkTxAdd(getFunction(state), state);
45         checkTxEnd(getFunction(state), state);
46     }
47     if (!in_tx) added_ranges.clear();
48 }
49 };

```

Listing 6: An psuedo-code example of a custom oracle, designed to check for redundant PMDK transaction “adds” (i.e., redundant log updates).

structures are operated on in the correct way (e.g., checking that PM referenced as `struct foo` is only ever modified in a PMDK transaction). Custom bug oracles define a function that takes as input an explored program state (i.e., the current state of symbolic memory and variables in the program) and an instruction; after each instruction is executed within this state, AGAMOTTO calls all configured custom bug oracles. We provide two case studies on designing and implementing custom oracles, which we use to find 4 application-specific bugs that were reported by prior work and 1 new application-specific bug. Both of the custom oracles which we present are precise, i.e., they do not introduce false positives. We describe them at a high-level below, then discuss their implementation in §5.

Redundant Undo Log Oracle. This oracle checks to ensure that data does not get logged in PMDK’s undo log mechanism multiple times. We show a pseudo-code example of an oracle in Listing 6. PMDK’s transactional API implements an undo log which is used to back up data before it is modified—if a transaction is interrupted by a program error or a crash, the data can be recovered from the log. A misuse of this API, however, can lead to redundant entries being created in the undo log, which degrades performance. To track these errors, this oracle keeps track of transaction boundaries (TX_BEGIN, TX_END) and the memory ranges backed up in the undo log. If overlapping memory ranges are added during a single transaction, the oracle signals a performance bug. We use this oracle to reproduce the application-specific performance bug found by PMTest in PMDK’s example B-tree data structure.

Atomic Operation Oracle. This oracle ensures that a developer-specified structure is crash-recoverable through correct use of a PMDK transaction. In particular, the oracle verifies that the structure is only updated within a PMDK transaction and is properly added to the PMDK undo log. We used this oracle to find 3 existing bugs; 2 in the PMDK Atomic Hashmap and 1 in Redis-pmem.

4.3 PM-Aware Search Algorithm

AGAMOTTO uses symbolic execution to explore the state space of the program. In order to analyze large persistent memory applications, AGAMOTTO prioritizes exploring program states that are most likely to modify persistent memory using a PM-aware search algorithm. We now first explain the static analysis that AGAMOTTO uses to compute exploration priorities. We then explain the operation of AGAMOTTO’s state space exploration and why AGAMOTTO’s approach is more effective at finding persistency bugs than traditional coverage-guided exploration heuristics.

4.3.1 Whole-Program Static Priority Computation

The goal of AGAMOTTO’s static analysis is to determine the number of reachable PM-modifying instructions from each instruction in the program. That way, AGAMOTTO can guide symbolic execution towards program locations that are expected to access PM heavily, and uncover more bugs. This technique can be effective as the number of overall instructions expected to modify PM is much smaller than the number of instructions which modify volatile memory [59].

To achieve this, AGAMOTTO first identifies all PM-modifying instructions in the program by leveraging a sound, whole-program (i.e., interprocedural) pointer analysis [4, 14, 31, 32]. The analysis maps each pointer in the program to a set of memory locations; soundness guarantees that any two pointers which may alias will have a non-empty intersection of these sets of memory locations.

```

1 char *pbuf = mmap(<PM file>);
2 ...          // (# of PM-modifying insts)
3 do_read = ...          // (2)
4 if (do_read)          // (0)
5     a = pbuf[x]        // (0)
6     foo()              // (0)
7 else                  // (2)
8     a = ...            // (2)
9     pbuf[x] = a        // (2)
10    clwb(pbuf[x])      // (1)
11    // BUG: Missing sfence!
12 exit(0)              // (0)

```

Listing 7: An example of AGAMOTTO’s static analysis. All PM-modifying instructions are highlighted. Each instruction is annotated with a comment which denotes the result of the priority calculation.

AGAMOTTO then determines whether a given memory location may have been allocated as persistent memory. To do this, AGAMOTTO conservatively assumes that all `mmap` calls which accept a non-negative or variable file descriptor may return a pointer to persistent memory. While this approach over-approximates the persistent memory allocated by the program, as we show in §6, it accelerates persistency bug finding compared to default exploration strategies. Note that this conservative approach only affects the PM-aware search strategy, it does not introduce false positives in AGAMOTTO’s PM state tracking.

Then, AGAMOTTO classifies each instruction in the program as a persistent memory-modifying instruction if the instruction is a global fence (e.g., `SFENCE`), or a store (e.g., x86 `MOV`), flush (e.g., `CLWB`), or cache-line fence (e.g., `CLFLUSH`) that may point to a persistent memory location.

AGAMOTTO only computes points-to information for pointers which may alias PM. For shared libraries, AGAMOTTO first statically links the binary, then computes the alias information. If the shared library is used to modify PM (i.e., has some shared memory modification function which is used to modify PM), then that part of the shared library code will be analyzed.

Finally, AGAMOTTO uses a back-propagation algorithm to calculate the number of reachable PM modifying instructions for each program location. AGAMOTTO iterates through the interprocedural control flow graph from the exit points in the program (e.g., calls to `exit` or `return` from `main`) to the first instruction in the program. For each instruction, AGAMOTTO assigns the *priority* of the instruction to be the sum of the *weight* of the current instruction (1 if the current instruction is a PM-modifying instruction, 0 otherwise) and the maximum number of reachable PM-modifying instructions from the current instruction.

We show a small example of this priority computation in Listing 7, where each instruction is annotated with the result of the priority calculation. Each PM-modifying instruction (`pbuf[x]=a` and `clwb(pbuf[x])`) adds 1 to the priority and the priorities are backpropagated to the entry point (Line 3).

Figure 2: State space exploration with two strategies: (1) KLEE-Default (based on code coverage), (2) AGAMOTTO’s priority-driven exploration. This example corresponds with the bug described in Listing 7.

4.3.2 State Exploration Strategy

AGAMOTTO relies on an existing symbolic execution engine (KLEE [8]) to explore the possible states of the program. Symbolic execution starts with an initial program state which contains a current statement (similar to a program counter), a symbolic memory (where memory values are unknown), and symbolic inputs (e.g., an unknown integer value). As the program statements are symbolically executed, the symbolic execution engine simulates the effects of the program statements on symbolic inputs and memory, and updates explored program state accordingly. Moreover, the symbolic execution engine forks the explored state into two every time a branch that depends on symbolic values is encountered.

After executing a program statement in an explored state, the symbolic execution engine selects a new state to advance next. When selecting a state to explore, AGAMOTTO chooses the state whose current statement has the highest statically-computed aggregate priority (i.e., number of reachable PM modifying statements from the current instruction).

Fig. 2 shows an example of state space exploration for the the example code snippet in Listing 7, where `Init` represents the initial state of the program and the buggy state where the program omitted an `sfence` instruction is in the `else` path. For brevity, `foo` is depicted as a single statement that is explored at once.

The KLEE-Default strategy, which is a breadth-first exploration strategy augmented by randomized, coverage-guided prioritization, may explore states that are not useful to detecting the bug. When applied to the code in Listing 7, the KLEE-Default exploration strategy will explore the state in the `if` branch for a single statement (`a=pbuf[x]`) and switch to the state in the `else` branch for another statement (`a=...`). This cycle will repeat once more in the `if` branch (`foo()`) and in the `else` branch (`pbuf[x]=a`, `clwb(pbuf[x])`); exploration will reach the bug in a total of 4 state transitions.

AGAMOTTO, on the other hand, directly explores the `else` branch because its static analysis assigns the `else` branch a high aggregate priority. Consequently, AGAMOTTO can

discover the bug with a single state transition.

Although the number of explored states in our example is small, in practice, the number of states in a program is exponential in the number of branches that depend on symbolic input. Consequently, AGAMOTTO’s exploration strategy allows it to discover many more bugs compared to KLEE’s default strategy, as we demonstrate in §6.

5 Implementation

AGAMOTTO comprises a persistent memory model (~400 LOC of C++), a static analysis component (~2600 LOC of C++), and a state space exploration component (~100 LOC of C++) built atop Klee [8]. AGAMOTTO also provides 2 custom bug oracles for validating the use of the PMDK transaction API (~180 LOC of C++ for both oracles and ~200 LOC of C++ for shared custom oracle API functions).

Running real-world complex PM applications also required expanding KLEE by ~4000 LOC of C++. These additional changes were primarily to the *environment model*, which symbolically simulates syscalls and operating system facilities, such as a file system. AGAMOTTO targets the Intel x86 ISA since it is the most broadly-used platform for PM programming. Hence, AGAMOTTO adds support to KLEE for interpreting PM-specific x86 instructions (e.g., CLWB). Supporting a different ISA or persistency model [34, 42, 63] simply requires identifying the flush and fence operations in the ISA. In addition, AGAMOTTO adds to KLEE support for common inline assembly functions such as atomic instructions, as well as porting an extensive environment model for multithreading (i.e., POSIX threads) from Cloud9 [16], which was built on an older version of KLEE. AGAMOTTO adds support for symbolic files to model and track the state of mapped persistent memory and anonymous symbolic `mmap`. Finally, AGAMOTTO adds symbolic socket traffic to the environment model, which allows an application to receive symbolic input over a socket. Symbolic socket traffic allows AGAMOTTO to model client applications that send commands to a server process.

Developing an automated bug finding tool for persistent memory presents key challenges. To identify persistent memory allocations in a PM framework agnostic way without relying on developer annotations, AGAMOTTO tracks allocations at the system level (e.g., calls to map a persistent memory file). This represents a significant divergence from KLEE, which tracks allocations at the libc interface (e.g., `malloc` and `free`), and introduces performance challenges. Applications often allocate MBs or GBs of persistent memory, but KLEE is optimized for tracking memory objects that are KBs in size; treating each persistent memory mapping as a single memory object leads to poor performance when KLEE solves constraints. Instead, AGAMOTTO carefully partitions persistent memory into separate, yet logically adjacent, objects (empirically, we find 16KB chunks to balance the tradeoff between solver time and management overhead). AGAMOTTO also

tracks the set of live persistent memory objects to reduce time resolving symbolic addresses for global fence operations.

AGAMOTTO supports custom persistency bug checkers with a simple yet powerful interface. Specifically, a developer implements a method that takes as input the state being explored symbolically and asserts pre- and post- conditions on the state of persistent memory based on an understanding of how their application should behave. AGAMOTTO provides a library of basic utilities (e.g., error reporting, calls to the symbolic solver) that comprise ~200 LOC and allows bug oracles to use type information provided by LLVM. AGAMOTTO provides 2 custom oracles to detect application-specific persistency bugs in PMDK and Redis (§4.2.2). We implement the *Redundant Undo Log Oracle* in 96 LOC and less than a day of developer effort. The *Atomic Operation Oracle* extends the Redundant Undo Log Oracle—it comprises an additional 86 LOC on top of the inherited functionality and also took less than a day to implement.

6 Evaluation

In this section, we evaluate the effectiveness and usefulness of AGAMOTTO. We start by giving an overview of the new bugs AGAMOTTO has found (84)³ and the insights we gather from them (§6.1). We also discuss the positive responses that we have received after reporting bugs to PM application developers (§6.2). We then evaluate the performance of AGAMOTTO and how our novel search tactic compares to the default symbolic execution search strategy in KLEE (§6.3).

Evaluation Targets. We evaluate AGAMOTTO by testing representative state-of-the-art PM-application and libraries consistent with the libraries and applications tested by prior work [49, 50]. We evaluate AGAMOTTO on two PM libraries. First, we test the PMDK [20] library from Intel, the most active and well-maintained open-source PM project, which has been maintained for over 6 years. Consistent with existing tools [50], we use example data structures provided with PMDK (e.g., B-tree, RB-tree and hashmap implementations) and an application provided by Intel [22] as drivers for our testing. In addition to PMDK, we test NVM-Direct, a PM library from Oracle that is under active development. To drive our testing of NVM-Direct, we use their example test application they provide for demonstrating the API.

We additionally evaluate AGAMOTTO by testing three real-world PM applications. We test Redis-pmem, a port of Redis, a popular in-memory database and memory caching service, to PMDK that is maintained by Intel. We likewise select memcached-pm, a port of memcached, a popular high-performance memory caching server, to PMDK that is main-

³We provide a link to our evaluations results in the AGAMOTTO GitHub repository: <https://github.com/efeslab/agamotto/blob/artifact-eval-osdi20/artifact/README.md>

System	Source (GitHub)	Version
PMDK	pmem/pmdk	v1.8
RECIPE	utsaslab/RECIPE/tree/pmdk	53923cf
memcached-pm	lenovo/memcached-pmem	8f121f6
NVM Direct	oracle/nvm-direct	51f347c
Redis-pmem	pmem/pmem-redis pmem/redis	cc54b55 v3.2

Table 2: Software configuration; we tested two versions of Redis-pmem

tained by Lenovo. Finally we test RECIPE’s P-CLHT index, a state-of-the-art persistent index representing a research prototype. Note, we only test the P-CLHT index from RECIPE because the other four indices all use a volatile allocator which prevents crash-consistency. Since KLEE symbolically emulates system calls without running real kernel code, we are unable to test PMFS [27], an evaluation target that has been considered by prior work [50].

We test each application by providing a symbolic environment model (e.g., providing symbolic arguments and files with symbolic contents) rather than instrumenting the source code to create symbolic variables. We test RECIPE’s P-CLHT index using their example application, which manipulates the basic structure of the index through standard insertion, deletion, and lookup operations. We use symbolic socket traffic (See §5) to test the Redis-pmem and memcached-pm server daemons using partially symbolic packets (i.e., packets with some concrete values, like the Redis command string, with symbolic values for the keys and values).

When testing applications that use PMDK (PMDK, Redis-pmem, and RECIPE), we enable both universal bug oracles and our two custom bug oracles designed for PMDK (see §4.2.2). When testing NVM-Direct, we only use the universal bug oracles.

When using AGAMOTTO to test an application, AGAMOTTO also tracks all persistent memory use from the libraries used by the application. In the case that AGAMOTTO finds a bug in PMDK while testing an application which uses PMDK (e.g., memcached-pm, Redis-pmem, or RECIPE), we report the bug as a bug in PMDK.

Evaluation Setup. We ran our experiments across two servers, one with a Intel(R) Xeon(R) Silver 4114 CPU @ 2.20GHz and one with a Intel(R) Xeon(R) Gold 6230 CPU @ 2.10GHz. Each individual experiment (a single run of AGAMOTTO) was limited to a max of 10 GB of DRAM and 1 hour of runtime. We show our software configuration in Table 2. Note that none of our experiments use persistent memory hardware since AGAMOTTO symbolically models all interactions with persistent memory.

System	MC		MP		EP		AS		Total	
	N	K	N	K	N	K	N	K	N	K
memcached-pm	1	-	19	-	1	-	-	-	21	-
NVM-Direct	7	-	7	-	9	-	-	-	23	-
PMDK	1	1	14	-	6	-	1	3	22	4
RECIPE	1	-	7	-	6	-	-	-	14	-
Redis-pmem	3	-	1	-	-	-	-	1	4	1
Total	13	1	48	-	22	-	1	4	84	5

Table 3: The Bugs found using AGAMOTTO. For each bug class (MC: Missing flush/fence Correctness, MP: Missing flush/fence Performance, EP: Extra flush/fence Performance, and AS: Application-Specific), we report the number of new bugs AGAMOTTO found, **N**, and the number of bugs detected that were previously known, **K**.

6.1 Overview

We show a summary of our bug-finding results in Table 3⁴. Overall, AGAMOTTO found 84 new bugs across our 5 main test targets: 62 missing flush/fence bugs (13 correctness bugs and 48 performance bugs), 22 extra flush/fence performance bugs and 1 new application-specific correctness bug. We also detect all 5 persistency bugs found by prior work in user-space applications and confirm that we find no false positives with our universal or custom oracles. Here, we describe the bugs that we find in greater detail.

Missing flush/fence bugs. Using our built-in unflushed bug oracle, we found 62 new bugs; we manually identified that 13 are correctness bugs and 48 are performance bugs. Of the 13 correctness bugs, 10 are caused by missing flushes and 3 are caused by missing fences—all of the missing fence bugs are found in Redis-pmem. AGAMOTTO found the missing flush/fence bug in PMDK that was reported by PMTest. Of the correctness bugs, AGAMOTTO finds 1 in memcached-pm, 1 in PMDK, 1 in RECIPE’s P-CLHT index, 7 in NVM-Direct, and 3 in Redis-pmem. Of the performance bugs, AGAMOTTO finds 19 in memcached-pm, 14 in PMDK, 7 in RECIPE’s P-CLHT index, 7 in NVM-Direct, and 1 in Redis-pmem.

Extra flush/fence bugs. We found 22 new bugs using the extra flush/fence bug oracle. Of these bugs, AGAMOTTO found 9 in NVM-Direct, 6 in PMDK library functions and 6 in RECIPE’s P-CLHT index.

Application-specific bugs. AGAMOTTO identified 1 new application-specific correctness bug in the PMDK atomic hashmap example using the extra flush/fence universal bug oracle. Using the atomic operation oracle, AGAMOTTO found all

⁴We provide the full detailed table in an online table available here: <https://github.com/efeslab/agamotto/tree/artifact-eval-osdi20/artifact#resources>.

3 application-specific correctness bugs which were reported by XFDetector⁵. Using the redundant undo log oracle, AGAMOTTO detected the application-specific performance bug in the PMDK example B-tree structure that was discovered by PMTest. AGAMOTTO is unable to find the application-specific performance bug that PMTest found in PMFS because AGAMOTTO is unable to execute kernel code.

6.2 AGAMOTTO Reporting

We presented our initial results to Intel’s PMDK team, Oracle’s NVM-Direct team, and to the authors of RECIPE and received overall positive feedback. At the time of writing, we have not yet heard back from Lenovo developers regarding bugs in memcached-pm. PMDK developers confirmed our findings about performance issues. Oracle’s developers confirmed they were aware of some of the issues we reported and noted that “Resources for software development are always in short supply, so the open source version of NVM_Direct has suffered. I wish it was not so, but it is. Your email may be the push that gets us to do something about it. Thank you.” RECIPE’s authors confirmed and started patching all the bugs we reported to them and asked us to open-source AGAMOTTO for continued testing. Despite existing tools for testing PM (one of which was even built for RECIPE [45]), one of RECIPE’s authors stated that “These are some really good finds, since it was difficult to debug our own code without having a proper tool.”

We conclude that AGAMOTTO has been successful in finding bugs that developers care about.

6.3 Performance Analysis

Benefit of AGAMOTTO’s State Exploration Strategy. We evaluate AGAMOTTO’s state exploration strategy compared to the default search strategy in KLEE. We compare these two strategies for all of our 5 test targets: memcached-pm (Fig. 3a), NVM-Direct (Fig. 3b), RECIPE’s P-CLHT index (Fig. 3d), on PMDK’s libpmemobj examples (Fig. 3c), and on Redis-pmem (Fig. 3e). We run each exploration strategy for one hour, since one hour is short enough to integrate into a development cycle but long enough to cover a substantial number of execution paths. In all cases, AGAMOTTO’s search strategy finds all reported bugs in less than 40 minutes. For Redis-pmem, the bugs we detect were exposed quickly, allowing both strategies to find all 4 in under 3 minutes. For all of our tests, AGAMOTTO is able to find at least one bug in under 5 minutes, which suggests that AGAMOTTO might even be usable during interactive debugging sessions.

We conclude that AGAMOTTO’s static-analysis guided search strategy is more effective in finding bugs than the default state exploration strategy in KLEE.

⁵XFDetector reports 4 new bugs, but one of these bugs is unrelated to persistent memory but detectable with their fault injection framework.

System	Source Size (KLOC)	Dependencies (KLOC)	Static Analysis Run time (min)
memcached-pm	18	36	2.20
NVM-Direct	1	14	0.02
PMDK	2	35	0.60
RECIPE	13	35	0.55
Redis-pmem	54	149	19.6

Table 4: The offline overhead of AGAMOTTO’s static analysis. Thousand lines of code (KLOC) is provided for program sources (the driver applications for NVM-Direct and PMDK) and for shared libraries.

Static Analysis Run time. We show the run time of AGAMOTTO’s static analysis in Table 4. For most applications we test, the overhead of static analysis is low (less than 4 minutes) relative to the length of time spent finding bugs. Redis-pmem has a larger static analysis run time, particularly due to the number of external libraries it links with—however, the results of the static analysis can be cached across many runs for external libraries.

6.4 Case Study: PM Performance Bugs

Prior works on PM argues for the importance of the performance bugs that are identified by AGAMOTTO. For example, Pelley et al. show that extra flush and fence operations are detrimental to application performance [63], and a study of memcached-pm found that storing volatile data in PM reduces application performance by roughly 5% [26].

To further validate the importance of the performance bugs identified by AGAMOTTO, we perform a performance case study on the P-CLHT data structure from RECIPE. We manually fix the performance bugs and then measure the performance of the data structure on concurrent insert operations, i.e., load operations (each thread inserts new keys into the hash table). We chose insert operations, since they stress the update path on which these bugs were found. We report the performance in Fig. 4. The overall throughput increases dramatically, ranging between 24% to 47%. The main contributor to this throughput increase is moving commonly used locks from PM to DRAM.

7 Related Work

Persistent Memory Frameworks. Crash consistency mechanisms for persistent memory have been considered for years [6, 11, 15, 18, 64]. The difficulty of designing crash-consistent programs for persistent memory has inspired many persistent memory specific crash-consistent frameworks which ease the burden on PM application developers. These frameworks either provide a library interface that can be used in standard programming languages (PMDK [20], NV-Heaps [17], LSNVMM [35]), provide lan-

Figure 3: Comparison of the KLEE default search strategy to AGAMOTTO.

guage extensions to augment C/C++ with persistent data types (e.g., Mnemosyne [73], NVL-C [25]), or both (e.g., NVM-Direct [7]). Some systems also use transactional hardware mechanisms to provide more efficient updates to persistent memory (NV-HTM [10], Crafty [30]). However, while these mechanisms may make programming easier, they may still contain persistency bugs. Furthermore, this plethora of PM libraries and extensions motivate the need for generalizable, automated debugging tools.

PM-optimized file systems offer some degree of crash consistency as well [19, 27, 43, 72, 74, 75], as many PM-optimized file systems offer full-data consistency, rather than just maintaining metadata consistency [9]. However, these mechanisms require the application to use the POSIX interface, as data journaling cannot be efficiently performed for direct-access files. Additionally, applications can suffer from significant performance degradations by accessing PM through the file system rather than through direct memory mappings [37].

Tools for Detecting Persistency Bugs. The state-of-the-art tools for detecting persistency bugs are PMTest [50] and XFDetector [49]. PMTest is a tracing system which transforms updates to persistent memory into a trace of operations, which is asynchronously validated against programmer-defined rules for persistent memory updates. PMTest is flexible and fast, but requires developer effort to generate persistent memory rules and incurs a high rate of false negatives, as it must be driven by concrete test cases. The authors of PMTest [50] manually instrument applications to find two similar patterns to AGAMOTTO application-independent patterns: the extra flush/fence bug pattern and a delayed flush/fence pattern, in which a delay in the durability of an PM update prevents crash consistency. Delayed flush/fences are inherently application-specific (and thus require developer effort), and there were no delayed flush/fence bugs in our study. XFDetector is a fault injection framework designed to detect cross-failure bugs, which manifest when recovery code accesses

	Agamotto	PMTest	XFDetector	pmemcheck	Persistence Inspector
Core Mechanism	Symbolic Execution	Trace Validation	Fault Injection	Binary Instrumentation	Binary Instrumentation
Accuracy	High	Low	Medium	Low	Low
Automation	High	Low	Medium	Low	Low
Generality	Medium	High	Medium	Very Low	Low
Extensibility	High	High	Low	Low	Low

Table 5: A qualitative comparison between AGAMOTTO and related work, as measured by our design goals (§4).

Figure 4: The write throughput (in kilo-operations per second) of the P-CLHT data structure before and after patching performance bugs. “Original” denotes the unmodified P-CLHT structure and “Patched” denotes P-CLHT after we patch the performance bugs.

data which was not guaranteed to be safely persisted before a failure. While XFDetector is effective at detecting semantic bugs with low developer effort, XFDetector still relies on developer-provided concrete test cases. RECIPE [45] uses a PIN-based tool for testing their converted PM indices, which also incurs a high false positive rate due to requiring extensive test cases. pmemcheck [65] and Persistence Inspector [62], which are binary instrumentation tools built by Intel, require a large amount of developer effort to use as they are heavily annotation based. We summarize the high-level feature differences between AGAMOTTO and other persistency bug detection frameworks in Table 5.

Tools for Testing Crash Consistency. Crash consistency testing has been the study of many works on both legacy file systems and PM-optimized file systems [13, 28, 29, 41, 44, 55, 58]. Many of these tools either test for semantic bugs specific to file systems or are only targeted for block-based storage devices. Yat [44] specifically targets crash consistency testing for Intel’s persistent memory file system (PMFS [27]). However, Yat tests crash consistency by computing all possible instruction orderings to find crash consistency bugs—a task which can take over 5 years to fully test [44].

Bug Taxonomies. Many papers taxonomize software bugs in other contexts. In the storage context, JUXTA [57] draws a distinction between shallow (roughly equivalent to application-independent) and semantic (application-specific)

bugs while CrashMonkey [55] studies the effects and number of operations required to induce crash consistency bugs in file systems. More generally, Li et al. [47] and Liu et al. [48] classify software bugs into universal bug classes (e.g., memory-related, concurrency and incorrect failure handling) and semantic (application-specific) bugs. The key distinction between our study and these prior studies is our focus on persistent memory systems.

The Thread Between Concurrency and Consistency. Several works have identified a similarity in data races [1, 39, 61] in concurrent programs and semantic crash consistency bugs [45, 49]. Traditional data races result in inconsistent data being read across threads of execution, which many systems have been designed to detect and fix [2, 38, 40, 46, 66, 69]. Principles from data race detection have been adapted to build PM crash consistency mechanisms (i.e., in RECIPE [45]) and PM semantic crash consistency detection tools (i.e., XFDetector [49]). When applied to AGAMOTTO, these principles inform the design of custom bug oracles.

8 Conclusion

Persistent Memory (PM) can be used by applications to directly and quickly persist data without the overhead of a file system. However, writing PM applications that are simultaneously efficient and correct is challenging. In this paper, we presented a system for more thoroughly testing PM applications. We informed our design using a detailed study of 63 bugs from popular PM projects. We then identify two application-independent (i.e., universal) patterns of PM misuse which are widespread in PM applications and can be detected automatically.

We then presented AGAMOTTO, a generic and extensible system that leverages symbolic execution for discovering misuse of persistent memory in PM applications. We introduced a new symbolic memory model that is able to represent whether or not PM state has been made persistent, as well as a state space exploration algorithm which can drive AGAMOTTO towards program locations that are susceptible to persistency bugs. We used AGAMOTTO to identify 84 new bugs in 5 different applications and frameworks, all without incurring any false positives and not requiring any source code modifications or extensive test suites.

A Artifact Appendix

A.1 Abstract

We provide the public repository for AGAMOTTO, which is a fork of KLEE available on GitHub. AGAMOTTO's artifact includes instructions for building and running AGAMOTTO, as well as a pre-installed VM and scripts used to reproduce the core results from our paper.

A.2 Artifact check-list

- **Public repository link:** <https://github.com/efeslab/agamotto/tree/artifact-eval-osdi20/artifact>
- **Data:** Links to our bug study findings and to a table describing new bugs found with AGAMOTTO: <https://github.com/efeslab/agamotto/tree/artifact-eval-osdi20/artifact#resources>
- **Code licenses:** AGAMOTTO inherits KLEE's open source license, which can be read in the repository here: <https://github.com/efeslab/agamotto/blob/artifact-eval-osdi20/LICENSE.TXT>.

A.3 Description

All information is available at our public GitHub repository. We have written a README specifically for the Artifact Evaluation process, which can be found here: <https://github.com/efeslab/agamotto/tree/artifact-eval-osdi20/artifact>

A.3.1 How to access

We provide information on how to access our repository and all relevant resources here: <https://github.com/efeslab/agamotto/tree/artifact-eval-osdi20/artifact#agamotto-osdi-20-artifact>

A.4 Installation

The instructions for compiling AGAMOTTO and installing the prerequisites can be found here: <https://github.com/efeslab/agamotto/tree/artifact-eval-osdi20/artifact#artifacts-functional-criteria>

A.5 Evaluation and expected result

We provide instructions for reproducing the main results from our paper along with the expected results here: <https://github.com/efeslab/agamotto/tree/artifact-eval-osdi20/artifact#results-reproduced>.

A.6 Notes

We are endeavoring to maintain AGAMOTTO as an open-source tool for debugging PM applications and hope to encourage its use for a wide variety of applications. Any issues that are found with the available artifact or any needed clarifications can be submitted as GitHub issues on our repository (<https://github.com/efeslab/agamotto/issues>).

Orchard: Differentially Private Analytics at Scale

Edo Roth, Hengchu Zhang, Andreas Haeberlen, Benjamin C. Pierce

University of Pennsylvania

Abstract

This paper presents Orchard, a system that can answer queries about sensitive data that is held by millions of user devices, with strong differential privacy guarantees. Orchard combines high accuracy with good scalability, and it uses only a single untrusted party to facilitate the query. Moreover, whereas previous solutions that shared these properties were custom-built for specific queries, Orchard is general and can accept a wide range of queries. Orchard accomplishes this by rewriting queries into a distributed protocol that can be executed efficiently at scale, using cryptographic primitives.

Our prototype of Orchard can execute 14 out of 17 queries chosen from the literature; to our knowledge, no other system can handle more than one of them in this setting. And the costs are moderate: each user device typically needs only a few megabytes of traffic and a few minutes of computation time. Orchard also includes a novel defense against malicious users who attempt to distort the results of a query.

1 Introduction

When operating a large distributed system, it is often useful to collect some data from the users' devices—e.g., to train models that will help to improve the system. Since this data is often sensitive, differential privacy [28] is an attractive choice, and several deployed systems are using it today to protect the privacy of their users. For instance, Google is using differential privacy to monitor the Chrome web browser [31], and Apple is using it in iOS and macOS, e.g., to train its models for predictive typing and to identify apps with high energy or memory usage [7, 8]. Other deployments exist, e.g., at Microsoft [27] and at Snap [68].

Today, this data is typically collected using *local* differential privacy [31]: each user device *individually* adds some random noise to its own data and then uploads it to a central entity, which aggregates the uploads and delivers the final result. This can be done efficiently at scale, but the final result contains an enormous amount of noise: as Google notes [14], even in a deployment with a billion users, it is easy to miss signals from a million users. Utility can be improved by reducing the amount of noise, but this weakens the privacy guarantee considerably, to the point where it becomes almost meaningless [80].

One way to avoid this problem is to collect the data using *global* differential privacy instead. In this approach, each device provides its raw, un-noised data to the central aggregator, which then adds random noise only once. This clearly produces results that are more precise, but it also requires a lot of trust in the aggregator, who now receives the individual users' raw data and must be trusted not to look at it. Cryptographic techniques like multiparty computation [84] and fully homomorphic encryption [38] could theoretically avoid this problem, but, at least with current technology, scaling either approach to millions of participants seems implausible.

The recently proposed Honeycrisp system [76] can provide global differential privacy at scale, with a single, untrusted aggregator. Instead of fully homomorphic encryption, Honeycrisp uses additively homomorphic encryption, which is much more efficient. However, the price to pay is that Honeycrisp can answer only one specific query, namely count-mean sketches [8] with additional use of the sparse-vector operator. This query does have important applications (for instance, it is used in Apple's iOS), but it is by no means the *only* query one might wish to ask: the literature is full of other interesting queries that can be performed with global differential privacy (e.g., [15, 31, 40, 41, 55, 64, 70, 83]). Right now, we are not aware of any systems that can answer even one of these queries at scale, using only a single, untrusted aggregator.

In this paper, we show how to substantially expand the variety of queries that can be answered efficiently in this highly distributed setting. Our key insight is that many differentially private queries have a lot more in common than at first meets the eye: while most of them transform, group, or otherwise process the input data in some complicated way, the heart of the algorithm is (almost) always a sequence of sums, each computed over some values that are derived from the users' input data. This happens to be exactly the kind of computation that Honeycrisp's collect-and-test (CaT) primitive can perform efficiently, using additively homomorphic encryption. Thus, CaT turns out to be far more general than it may seem: it can perform the distributed parts of many queries, leaving only a few smaller computations that can safely be done by the aggregator, or locally on each user device.

The key challenge is that, for many queries, the connection to sums over per-user data is far from obvious. Many differentially private queries were designed for a centralized setting where the aggregator has an unencrypted data set and

can perform arbitrary computations on it. Such queries often need to be transformed substantially, and existing operators need to be broken down into their constituents, in order to expose the internal sums. Moreover, a naïve transformation can result in a very large number of sums—often far more than are strictly necessary. Thus, optimizations are needed to maintain efficiency.

We present a system called Orchard that can automatically perform these steps for a large variety of queries. Orchard accepts centralized queries written in an existing query language, transforms them into distributed queries that can be answered at scale, and then executes these queries using a generalization of the CaT mechanism from Honeycrisp. Among 17 queries we collected from the literature, Orchard was able to execute 14; the others are not a good fit for our highly distributed setting and would require a different approach.

Our experimental evaluation of Orchard shows that most queries can be answered efficiently: with 1.3 billion users (roughly the size of Apple’s macOS/iOS deployment [6]), most user devices would need only a few megabytes of traffic and a few minutes of computation time, while the aggregator would need about 900 cores to get the answer within one hour. For queries that make use of the sparse-vector operator, this is competitive with Honeycrisp; for the other queries we consider, we are not aware of any other approach that is practical in this setting. In summary, our contributions are:

- the observation that many differentially private queries can be transformed into a sequence of noised sums (Section 2);
- a simple language for writing queries (Section 3);
- a transformation of queries in this language to protocols that can answer them in a distributed setting, using only a single, untrusted aggregator (Section 4);
- the design of Orchard, a platform that can efficiently execute the transformed queries (Section 5);
- a prototype implementation of Orchard (Section 6); and
- an experimental evaluation (Section 7).

We discuss related work in Section 8 and conclude the paper in Section 9.

2 Overview

Scenario: We consider a scenario—illustrated in Figure 1—with a very large number of users (millions), who each hold some sensitive data, and a central entity, the *aggregator*, that wishes to answer queries about this data. We assume that each user has a device (say, a cell phone or a laptop) that can perform some limited computations, while the aggregator has access to substantial bandwidth and computation power (say, a data center).

Threat model: We make the OB+MC assumption from [76]—that is, we assume that the aggregator is honest-but-curious

Figure 1: Scenario.

(HbC) when the system is first deployed and usually remains HbC thereafter, but may occasionally be Byzantine (OB) for limited time periods; for instance, the aggregator could be a large company that is under public scrutiny and would not violate privacy systematically, but may have a rogue employee who might tamper with the system and not be discovered immediately. For the users, we assume that most of them are correct (MC) but that a small percentage—say, 2–3%—can be Byzantine at any given time. This is different from the typical assumption in the BFT literature, where one often assumes that up to a third, or even half, of the nodes can be Byzantine. However, BFT systems are typically a lot smaller than the systems we consider: with 4–7 replicas, compromising a third of the systems means just one or two nodes, whereas, in Apple’s deployment with 1.3 billion users, a 3% bound would mean 39 million malicious users, which is much larger than, e.g., a typical botnet.

Assumptions: Our key assumptions are (1) that the approximate number of users is known and (2) that the adversary cannot create and collude with a nontrivial number of Sybils. For instance, the devices could have hardware support for secure identities, such as Apple’s T2 chip or Intel’s SGX.

Goals: We have four key goals for Orchard:

- **Privacy:** The amount of information that either the aggregator or other users can learn about the private data of an honest user should be bounded, according to the formulation of differential privacy.
- **Correctness:** If all users are honest, the answers to queries should be drawn from a distribution that is centered on the correct answer and has a known shape;
- **Robustness:** Malicious users should not be able to significantly distort the answers; and
- **Efficiency:** Most users should not need to contribute more than a few MB of bandwidth and a few seconds of computation time per query.

2.1 Differential privacy

Differential privacy [28] is a property of randomized queries that take a database as input and return an aggregate output. Informally, a query is differentially private if changing any single row in the input database results in “almost no change” in the output. If each row represents the data of a single individual, this means that any single individual has a statistically

Query		Support
Decision-tree learning (ID3)	[34]	Yes
k-means	[15]	Yes
Perceptron	[15]	Yes
Principal Component Analysis (PCA)	[15]	Yes
Logistic regression	[2]	Yes

Histograms	[83]	Yes
k-Medians	[40]	Yes
Cumulative Density Functions	[55]	Yes
Range queries	[45]	Yes
Bloom filters (RAPPOR)	[31]	Yes
Count Mean Sketch	[8]	Yes
Sparse vector (Honeycrisp)	[76]	Yes
Iterative Database Construction	[41]	No
Teacher Ensembles (PATE)	[64]	No
Vertex programs (DStress)	[63]	No

Table 1: Selection of differentially private queries from the literature, and support by Orchard.

negligible effect on the output. This guarantee is quantified in the form of a parameter, ϵ , which controls how much the output can vary based on changes to a single row. Formally, we say that q is ϵ -differentially private if, for any two databases d_1 and d_2 that differ in a single row, and any set of outputs R ,

$$\Pr[q(d_1) \in R] \leq e^\epsilon \cdot \Pr[q(d_2) \in R]$$

In other words, a change in a single row results in at most a multiplicative change of e^ϵ in the probability of any output, or set of outputs.

A standard method for achieving differential privacy for numeric queries is the *Laplace mechanism* [28], which involves two steps: first calculating the *sensitivity*, s , of the query—which is how much the un-noised output can change based on a change to a single row—and second, adding noise drawn from a Laplace distribution with scale parameter s/ϵ ; this results in ϵ -differential privacy. For queries with discrete values, the standard method is the *exponential mechanism* [56], which defines a “quality score” $q(d, x)$ that measures how well a value x represents a database d , and then selects value x with probability proportional to $e^{\frac{eq(d, x)}{2s}}$, where s is the sensitivity of q . This again results in ϵ -differential privacy.

Differential privacy is compositional, that is, if we evaluate two queries q_1 and q_2 that are ϵ_1 - and ϵ_2 -differentially private, respectively, then publishing the results from both queries is at most $(\epsilon_1 + \epsilon_2)$ -differentially private. This property is often used to keep track of the amount of private information that has already been released: we can define a *privacy budget* ϵ_{\max} that corresponds to the maximum loss of privacy that the subjects are willing to accept, and then deduct the “cost” of each subsequent query from this budget until it is exhausted. For a detailed discussion of ϵ_{\max} , see, e.g., [46].

By now, there is a rich literature on differential privacy proposing many different forms of queries for many different use cases. We have done a careful survey to collect examples that would make sense in our highly distributed setting; Table 1 contains the queries we found, which will also be used in our evaluation (Section 7.1).

2.2 Alternative approaches

Local differential privacy (LDP): As discussed earlier, another way to avoid trusting the aggregator is to use LDP [31]—that is, for each user to add noise to his or her data individually, *before* uploading it to the aggregator, instead of noising just the final result. However, there are two important challenges. The first is that the noise in the final result now grows with the number of users: for instance, a sum of values from N users now contains N draws from a Laplace distribution $L(\frac{s}{\epsilon})$, instead of just one! The effective error grows a bit more slowly, with $\Theta(\sqrt{N})$ [29, §12.1], but still, with $N = 10^9$ and $\epsilon = 0.1$, the median error will be approximately 300,000 with LDP and only 10 with GDP—a difference of several orders of magnitude, which can be severely limiting in practice [14]. The second challenge is that the noise is added by the *users* and not by the aggregator; thus, even a very small number of malicious users can, by using large, correlated values as their “noise” terms, severely distort the final result [22]. We will revisit this problem in Sections 5.3 and 7.3.

Multiparty computation (MPC): In principle, the data could also be aggregated using MPC [84], a cryptographic technique that enables a group of participants to jointly evaluate a function f such that each participant only learns the final output of f , but not the inputs of each participant. It may seem that all we need to do is set $f := q \circ L(\frac{s}{\epsilon})$, where q is the query and L is a draw from an appropriate Laplace distribution. The problem, however, is efficiency: generic MPC scales poorly with the number of participants. While there are very efficient solutions for two parties (e.g., [49]) and reasonably efficient ones for a few dozen parties (e.g., [82]), we are not aware of a technique that would be practical with millions or billions of participants.

Fully homomorphic encryption (FHE): With FHE [38], users could encrypt their data with a public key and upload them to the aggregator, who could run the query on the ciphertexts, add noise, and then decrypt only the final result using a private key. As with MPC, this approach works for arbitrary queries, and it has the advantage that most of the work is done by the aggregator. However, if the aggregator has the private key, it can also decrypt the users’ individual uploads—and even if this problem were solved somehow, computation on FHE ciphertexts is still many orders of magnitude slower than computation on plaintexts, so, with a billion participants, this approach does not seem realistic.

Figure 2: CaT workflow.

2.3 Honeycrisp

Honeycrisp [76] can efficiently answer one specific query (namely count-mean sketches) in our setting. As in the hypothetical FHE approach, users encrypt their private data and upload only the ciphertexts to the aggregator; however, there are two critical differences. The first is that Honeycrisp uses *additively* homomorphic encryption, which is orders of magnitude faster than FHE and can be done efficiently at scale. The second is that, to prevent the aggregator from decrypting individual ciphertexts, Honeycrisp delegates key generation and decryption to a small *committee* of 20–40 randomly selected user devices, which uses MPC to perform these (small) tasks. As before, this enables the aggregator to do all of the “heavy lifting” (collecting and aggregating ciphertexts) without ever seeing unencrypted data from individual users; thus, the aggregator does not need to be trusted.

The main drawback of Honeycrisp is that it only supports a single query. Internally, it uses a primitive called Collect-and-Test (CaT), which works roughly as follows (see also Figure 2): each user device computes a vector of numbers, encrypts it with a public key that was generated by the committee, and uploads it to the aggregator, which sums up the ciphertexts using the additive homomorphism. The aggregator then proves to the users that it has computed the sum correctly (which the aggregator, in its Byzantine phases, may not necessarily do); if so, the committee noises and decrypts the final result. This is the primitive that we leverage for Orchard.

Notice that CaT aggregates *vectors*, not just individual numbers. For additively homomorphic encryption, Honeycrisp uses Ring-LWE, which has large ciphertexts that can be subdivided into many smaller fields; these can then be aggregated in parallel. The choices from [76] yield 4,096 counters with about 50 bits each; thus, a single invocation of CaT can efficiently sum up vectors with thousands of elements. We will leverage this fact for our query optimizations (Section 4.5).

2.4 Approach and roadmap

Our key insight is that CaT is far more general than it might appear: indeed, the sums it can compute are at the heart of a wide range of differentially private queries. (This is not a coincidence: in fact, a common way to certify differential privacy—e.g., in [10, 25, 36, 42, 72, 85]—is to use a linear type

system to track how much a change in a single user’s data can affect a given sum or count.) Thus, by rewriting queries to take advantage of CaT, we can considerably expand the range of queries that can be answered at scale. At a high level, Orchard works as follows:

1. The analyst submits her query as a *centralized* program that computes the desired answer based on a (hypothetical) giant database that contains data from all users. Orchard verifies that the query is differentially private (Section 3).
2. Orchard transforms this program into a distributed computation that relies on CaT, using several optimizations—such as vectorization—to ensure efficiency (Section 4).
3. Orchard executes the distributed program, using protocols from Honeycrisp with some additional steps, and returns the answer to the analyst (Section 5).

3 Query language

There are several existing programming languages (e.g., [10, 26, 36, 42, 57, 59, 85, 86]) that can certify differential privacy. Rather than proposing yet another, we adopt an existing language, Fuzz [42]. Fuzz is a functional language, which simplifies our transformations, and its privacy analysis is driven by lightweight type annotations, which is convenient for the analyst. However, the choice is not critical; other languages could be used as well.

3.1 Running example: k -means

To conserve space, we introduce the Fuzz language through an example: the widely used k -means clustering algorithm, shown in Figure 3, which will also be our running example for the rest of this paper. For a more complete description of Fuzz, please see [77, §A].

The k -means algorithm divides a given set of points (the input data) into k clusters and returns a centroid for each cluster. It proceeds in several iterations; for clarity, the figure shows only the iteration step, with k hard-coded to 3. The `step` function is given the current estimates of the centroid positions, `c1`, `c2`, and `c3`, and the set of points `pts`; it first assigns each point to the closest centroid, based on the l_2 distance (`assign`), and then partitions the set of points into three subsets, one for each centroid. Finally, it produces three new centroid positions `c1'–c3'` for the next iteration by averaging the coordinates of the points in each subset. This is done by first summing up the coordinates in each partition, and by counting the points; then the `lap` primitive adds Laplace noise to the sums and counts, and then performs the division.

3.2 Language features

In most ways, Fuzz is a conventional functional language; just two special features are relevant here. One is that it has

a *linear type system*, described in [72], that certifies an upper bound on the sensitivity of all operations on private data; when a noising primitive such as `lap` (for the Laplace distribution) or `em` (for the exponential mechanism) is invoked, the parameter s (Section 2.1) is known, and the noise can be drawn from the correct distribution. The other feature is a *probability monad* that ensures that no private data can “escape” from the program without having passed through `lap` or `em` first. Together, these features ensure that, as long as the top-level program has a type of a certain form, it is guaranteed to be differentially private.

Fuzz encapsulates private data in variables of a special type, `bag`, which represents a set with one element for each individual who contributed data. There are several primitives that operate on bags: `bmap` applies a given function to each element of a bag, `bfilter` removes elements for which a given predicate returns false, and `bpartition` splits a bag into several sub-bags, based on the value a given function returns for each element. All of these primitives take bags as arguments and produce new bags, so the private data remains confined in bags. The final bag primitive is `bsum`, which adds up the elements of a bag.

3.3 Alternative languages

Using a language other than Fuzz should not be difficult because the key to Orchard, the basic structure of summing followed by a release mechanism, is present in many other languages for differential privacy. Notice that, in Fuzz, summing via `bsum` is the only way to turn bags into data values that can potentially be released. A similar structure is present, e.g., in PINQ [57], which has three aggregation primitives, of which one (`NoisySum`) is equivalent to `bsum` followed by `lap`; the other two (`NoisyAvg` and `NoisyMed`) are equivalent to `bsum` followed by `em`. Another imperative example, Fuzzi [86], supports the addition of new aggregation primitives through an extension mechanism, but the information we need could be specified as part of the extension. The critical features Orchard needs are 1) a sensitivity analysis and 2) a way to recognize the aggregation primitives in the code.

Another possible approach would be to embed Fuzz as a library into a more traditional data analytics language, such as Python3. This embedded-language approach has already seen success in Deep Learning frameworks, such as TensorFlow [1] and PyTorch [66].

4 Query transformation

Next, we describe how Orchard transforms centralized Fuzz queries so that they can be executed in a distributed setting.

4.1 Program zones

We begin by observing that, if a Fuzz program is differentially private, it necessarily has a very specific structure and can be

```
assign c1 c2 c3 pt =
  let d1 = sqdist c1 pt
      d2 = sqdist c2 pt
      d3 = sqdist c3 pt
  in if d1<d2 and d1<d3 then 0 else
      if d2<d1 and d2<d3 then 1 else 2

noise totalXY size = do
  let (x, y) = totalXY
  in do x' ← lap 1.0 x
        y' ← lap 1.0 y
        size' ← lap 1.0 size
  return (x'/size', y'/size')

totalCoords pts =
  let ptxs = bmap fst pts
      ptys = bmap snd pts
  in (bsum 1.0 ptxs, bsum 1.0 ptys)

countPoints pts =
  bsum 1.0 (bmap (\pt → 1) pts)

step c1 c2 c3 pts =
  let [p1, p2, p3] =
      bpartition 3 (assign c1 c2 c3) pts
      p1TotalXY = totalCoords p1
      p1Size = countPoints p1
      p2TotalXY = totalCoords p2
      p2Size = countPoints p2
      p3TotalXY = totalCoords p3
      p3Size = countPoints p3
  in do
    c1' ← noise p1TotalXY p1Size
    c2' ← noise p2TotalXY p2Size
    c3' ← noise p3TotalXY p3Size
  return (c1', c2', c3')
```

Figure 3: One step of the k -means algorithm, written in Fuzz. The colors represent the “zones” of computation.

broken into three different “zones” (which we color-code in our example in Figure 3):

- **Red zone** computations run directly on the data of an individual user—here, the `assign` function, which finds the closest centroid for each user’s data point.
- **Orange zone** computations are performed on user data that has been aggregated but not yet noised—here, the `lap` operators, which add Laplace noise to the sums.
- **Green zone** computations involve only noised data and constants—here, the final divisions in `noise` and the parts of `iter` that set up the rest of the computation.

The Fuzz type system enforces clear boundaries between these zones: data can only pass from red to orange by aggregation (via `bsum`), and aggregate data can only pass from orange to green by noising (via `lap` or `em`). Moreover, red-zone code always operates on an *individual* element of a bag—that is, on data from a single user. And lastly, none of the operations producing bags offer any way to combine multiple elements of one bag when computing an element of another bag; in other words, every element of every bag that can ever exist is derived (by filtering, partitioning, or mapping) from some single element of some bag that was initially provided as input to the top-level program.

This stratification allows us to map Fuzz programs to Honeycrisp-like computations by mapping the zones to the different parties in Figure 2. Red-zone code is executed directly by user devices; computations in this zone only need the data of one user at a time, so each user device can run it without sending any secrets anywhere. The summation at the red-to-orange boundary can be done as in Honeycrisp, by users encrypting their red-zone outputs and sending them to the aggregator, who adds them up using homomorphic addition and then passes the encrypted sum to the committee. Orange-zone code can be executed by the committee, using MPC, and the members of the committee will be able to decrypt the encrypted sums only after appropriate noise is added. Data that passes from orange to green zones must first pass through a release mechanism (`lap` or `em`) and be thus noised appropriately, so green-zone code can be safely executed “in the clear” by the aggregator itself.

The Orchard compiler uses a special operator to coordinate the mapping, summing, and releasing steps among red, orange and green zones. We call this operator `bmcs` (broadcast, map, clip and sum), and introduce it in the following subsection.

4.2 The `bmcs` operator

The operator `bmcs` (`b`, `m`, `c`, `r`) takes four parameters and behaves as follows:

- first, it *broadcasts* some public state `b` from the aggregator to the user devices;
- on each user device i , it *maps* the local private data d_i to a private vector $v_i := m(b, d_i)$ using the provided map function `m` (which can use the public state in its computation);
- on each user device, it *clips* the elements of v_i such that $|v_{i,k}| \leq c_k$; and finally
- it *sums* all these private vectors from all client devices through homomorphic addition to compute $v := \sum_i v_i$ and returns $r(v)$ using the provided *release function* `r`.

The `bmcs` operator captures the workflow of a single “round” of the distributed protocol; `m` is the red-zone computation for that round; `r` is the orange-zone computation. The clipping vector `c` is needed to guarantee privacy (see Section 5.3).

By rewriting a given Fuzz program to use only `bmcs` rather than the individual bag operations `bmap`, `bfilter`, `bsum`, and `bpartition`, we make its “phase-structure” explicit so that we can directly evaluate it on a Honeycrisp-like distributed platform. We next describe how Orchard does this.

4.3 Extracting dependencies

When the analyst submits a Fuzz program to Orchard, Orchard begins by reducing complex bag operations (`bpartition` and `bfilter`) into combinations of the two fundamental bag operations—`bmap` and `bsum`. A `bpartition` that splits a bag

into k partitions is reduced into a `bmap` that first maps each value in the bag to a partition index, followed by k `bfilter` operations that filters out each of the individual partitions. A `bfilter` operation is reduced into a `bmap` operation that maps each value v in the bag to an optional value v' —when the filter predicate evaluates to true on v , the optional value $v' := \text{Some } v$, otherwise $v' := \text{None}$.

Orchard then normalizes the program to ensure that all variable names are unique, and that each variable is either the result of a bag operation or the result of a release mechanism (`lap` or `em`). To achieve this, Orchard freshens all variable names, and performs aggressive inlining to eliminate all other variables. Conversely, if a bag operation was originally part of an expression and did not have a name, it is given one. In the resulting normal form, programs make explicit relations between the input database, the intermediate bags and released values, and the output of the program.

Next, Orchard infers dependencies between variables by building a graph with a vertex for each unique program variable. Two vertices (u, v) are connected with a directed and labeled edge f if v is the result of running the bag operation f over u . Since the normalized program only contains two simple bag operations, the label f is either the map function supplied to some `bmap`, or the clip bound supplied to some `bsum`. Since Fuzz forbids unbounded loops over private data, this graph is acyclic. Furthermore, since both `bmap` and `bsum` take one bag variable as input and produce another bag variable as output, there is at most one edge between any two vertices in this graph. This implies the graph is in fact a directed tree, and at the root of this tree is the input bag.

This tree is a complete snapshot of the red zone computations encoded in the normalized Fuzz program. Since the dependency tree tells us how to compute any bag value given the bag variable name, we only need to keep bag variable names at their use sites. So we remove all bag operations from the normalized Fuzz program, and use the dependency tree as a reference for emitting code when a bag variable is used. We call the remaining normalized program the “core”.

The core contains a mixture of orange zone and green zone computations. Since Orchard eliminates all other program variables in an earlier pass, the variables in the core must either be the result of a bag computation, or the result of a release mechanism. In particular, we call the variables that are results of bag computations “exit vertices” in the tree. (These vertices are scalar numbers, and thus cannot contain any outgoing edges, because no bag operations take scalar numbers as inputs.) By analyzing the core and inspecting the path from the input database to exit vertices, we can emit code in the `bmcs` form.

4.4 Transformation to `bmcs` form

The next step traverses the core in a forward pass, while maintaining a intermediate set S of variables. The set S is the

set of variables that are results of release mechanisms at the current program position during the forward pass.

When the traversal encounters a release mechanism (`lap` or `em`), it first compares the set of variables used in this release mechanism against S . If the set of used variables is a subset of S , then this release mechanism only adds further noise to already released data, and there is no need to invoke `bmcs`.

On the other hand, if a variable v is used in the release mechanism but is not a member of S , then v must be the result of some bag operation. In this case, we must invoke `bmcs` to compute v and release.

Let p be the path from the input database to the variable v . Orchard now computes a map function m_p and a clip value c_p as follows. It initializes $m_p := id$ and $c_p := \infty$, then it traverses p starting from the input database. When it encounters a `bmap` f , it updates $m_p := m_p \circ f$; and when it encounters a `bsum` c , it updates $c_p := c$.

In general, a release mechanism may refer to multiple variables v_1, \dots, v_i that are results of bag operations. For each v_i , Orchard walks its corresponding path p_i to compute m_{p_i} and c_{p_i} . It then fuses these map functions and clip bounds into a new map function $mdb = (m_{p_1} db, \dots, m_{p_i} db)$ and a new clip bound $c = c_{p_1} ++ \dots ++ c_{p_i}$, where $++$ represents vector concatenation.

Finally, if $f(v_1, \dots, v_i)$ is the release mechanism that uses program variables v_1, \dots, v_i , we build the release function $rsum = f(prj_1 sum, \dots, prj_i sum)$. Here, sum is the aggregated vector, and each prj_i projects the corresponding value for v_i out of the aggregated vector sum.

4.5 Optimizations

The transformation process that has been described so far will calculate the correct result, but in general it will produce many redundant `bmcs` operations because it walks the core in a forward pass and emits one `bmcs` call for each release mechanism that uses private data. We can do better by observing that release mechanism calls often do not depend on each other (such as the three calls to `noise` in the `k-means` example) and can in fact be fused into one `bmcs` call.

Orchard exposes these optimization opportunities to the code transformation process through a simple source code rewriting step. After Orchard has inlined and normalized the input Fuzz program, but before code transformation into `bmcs`, Orchard performs local dependency analysis on release mechanism calls, using a marker combinator `par` to combine release mechanisms that have no dependency relations.

For example, the three `lap` calls in the `noise` function for the `kmeans` example will be rewritten into:

```
((x', y'), size') ←
  par (par (lap 1.0 x) (lap 1.0 y))
      (lap 1.0 size)
```

Since Orchard inlines the `noise` function, in fact all nine `lap` calls in the `step` function for the `k-means` example will be

combined through the marker `par` combinator (there are three `lap` calls in each `noise` call, and there are three `noise` calls).

The purpose of the `par` combinator is to allow code transformation to fuse release mechanisms together just by looking at the syntax of the program under analysis. In the last phase of code transformation, when Orchard encounters a `par` combinator, it first recursively emits the map and release functions for the two arguments to `par`. Let us call these map functions m_1 and m_2 , and the release functions r_1 and r_2 . Next, Orchard fuses them together by creating a new map function $mdb = (m_1 db, m_2 db)$, and a new release function $rsum = (r_1 sum, r_2 sum)$. The clip bounds are concatenated to produce a fused clip bound. The code transformation recursively fuses the release mechanisms combined with nested `par` combinators, until finally only a single `bmcs` call is emitted for all of the combined release mechanisms.

4.6 Limitations

Our implementation currently insists that all loops in the red and orange zones terminate after a finite number of rounds, and it disallows unbounded recursion in these zones. Finite loop bounds are common in the differential privacy literature because they simplify the reasoning about the privacy cost; queries with unbounded loops, such as the PrivTree algorithm [87], tend to require more sophisticated reasoning, and thus cannot be verified by most automatic checkers. If necessary, the limit in the red zone could be replaced with timeouts and default values [42]. Notice that we *do* allow unbounded loops in the green zone, so we can still use dynamic predicates to check for convergence, e.g., in `k-means` clustering.

Orchard's front end relies on an existing programming language and type system, and it inherits their limitations. In particular, if a query is differentially private but the Fuzz type system cannot prove it, Orchard will reject it, and if a query's real sensitivity is s_1 but Fuzz only derives a sensitivity value $s_2 > s_1$, Orchard will use s_2 . These limitations could be removed by using a different source language – e.g., one with a more advanced type system, such as DFuzz [36], or one that allows the analyst to help with the privacy proofs, such as `apRHL` [4].

Orchard's optimization for fusing independent release mechanisms only recognizes fusion opportunities for release mechanisms that are syntactically next to each other. Due to this simplistic nature, Orchard may miss opportunities for fusion of release mechanisms that are only revealed through a more global dependency analysis. However, in our experiments, we find that this limitation does not prevent us from emitting code with the optimal number of `bmcs` calls. We plan on improving the fusion analysis in future work.

5 Query execution

Next, we describe the platform Orchard uses to execute distributed queries once they have been transformed using the method from the previous section.

5.1 Overall workflow

Orchard implements *b_{mcs}* using the CaT primitive from Honeycrisp [76], with three important additions: Orchard supports more than one round, it adds the broadcast step (which was not needed for Honeycrisp’s one hard-coded query), and it supports more general computations on the user devices and within the committee’s MPC (which Orchard needs for the red and orange zones). Protocols for sortition and verifiable aggregation (discussed below) are used verbatim, so the correctness proofs from [76] still apply. The platform consists of two components: a *server*, which runs in the aggregator’s data center, and a *client*, which runs on each user’s device (e.g., phone or laptop). These components operate as follows.

Setup: When an analyst wants to ask a query, she formulates it in the language from Section 3 and submits it to the server. The server typechecks the query, to verify that it is differentially private; if not, it aborts. The server then transforms the query as described in Section 4, but keeps only the code for the green zone. The server then triggers a *sortition* protocol that causes a very small, random *committee* of user devices to be elected. (As in Honeycrisp, a typical committee size is about 30–40, out of perhaps 10^9 devices.) The server sends the query to the committee, whose members perform the same transformation as the server but keep only the code for the orange zone of each *b_{mcs}* operation, as well as the associated privacy costs ϵ_i . The committee runs an MPC to generate a keypair for an additively homomorphic cryptosystem, and each committee member keeps a share of the private key. The server then executes the prefix (if any) of the green-zone computation that does not involve private data.

Broadcast: When the server encounters the i th *b_{mcs}* operation, it sends the sequence number i to the committee. The committee deducts ϵ_i from the privacy budget ϵ_{\max} and, if this succeeds, signs an *execution certificate* that contains the query, the public key, and the sequence number i of the *b_{mcs}*, and returns the certificate to the server. This certificate is needed to convince the clients that the server has “paid” the privacy cost ϵ_i for the specific step they are about to execute; the sequence number prevents query reexecution without charging the privacy budget again.

Map and clip: The server now distributes the certificate, along with any broadcast state in the *b_{mcs}*, to the clients. Each client (1) verifies that the committee was elected properly, that the execution certificate is signed by the committee, and that the certificate is not a duplicate; (2) transforms the query to obtain the red-zone computation for the i th *b_{mcs}* operation; (3) executes the red-zone code on its local data; (4)

encrypts the result with the public key from the certificate; and (5) uploads the result to the server, along with a zero-knowledge proof that (a) the local input was in the correct range; (b) the red zone was executed correctly; and, if $i > 1$, that (c) the client has not changed its local input since the first *b_{mcs}* in the current query.

Sum: The server aggregates all the uploads using homomorphic addition and then publishes a Honeycrisp-style summation tree, so the clients can verify that it has included each user’s data exactly once; if not, they can report the aggregator. Next, the committee performs another MPC to execute the orange-zone code (which noises and decrypts the computed aggregate) and then sends the plain-text result to the server, which uses it as the result of the *b_{mcs}* operation and continues executing the green-zone code. If the server encounters further *b_{mcs}* operations, it repeats the broadcast, map, clip, and sum steps for each of them.

5.2 Security: Aggregator

One key difference from Honeycrisp is that Orchard’s red- and orange-zone computations are not hard-coded and must be compiled from the query instead. A naïve approach could have been to have only the server perform the transformation and to have it provide the red- and orange-zone code to the committee and to the clients, respectively. However, in this case it would have been easy for the server to, say, replace the orange zone with the identity function (to disable noising) and/or to replace the red zone with “if the user is Alice, return data $\times 10^9$, else 0” (without proper clipping).

Orchard avoids this issue by (1) having the committee and the clients compile the red and orange zones directly from the original query and by (2) including the query in the execution certificate, so that all correct participants can be sure they are part of the *same* query. Since a correct client or committee member would perform the compilation as specified, it would (correctly) reject any proposed query that was not differentially private, and it would include all the necessary elements, such as clipping and noising. A dishonest server still has control over the green zone and can run any arbitrary code there. However, it can only hurt itself by doing this: the users’ privacy is guaranteed by the red and orange zones, and any data that reaches the green zone is already properly declassified.

Of course, the aggregator can misbehave in several other ways, but the compilation attack is the only one that is specific to Orchard; the others were already possible in Honeycrisp, and the defenses from Honeycrisp continue to apply. For completeness, we briefly review some key defenses below; for a complete description, please see [76, §3].

Privacy budget: A malicious aggregator could try to run more queries than the privacy budget allows. To prevent this, the budget balance is maintained by the committee. In each round, the committee checks whether the remaining privacy budget is sufficient to execute the query; if so, it signs a query

authorization certificate that includes, among other things, the remaining budget and the current round number. This certificate is sent to all user devices, which check it before uploading their responses. If the committee changes, the new members rely on the budget from the previous round's certificate.

Targeting individuals: A malicious aggregator could try to learn the private data of specific users by performing the aggregation incorrectly – perhaps by leaving out data from certain users, or by multiplying the encrypted data from other users with a large constant (which is possible in an additively homomorphic cryptosystem), or even by pretending that a single user's data is the result of the entire aggregation. To prevent this, Orchard requires the aggregator to construct a *summation tree* to prove that it has computed the aggregation correctly. Each user device checks a small portion of this tree.

Reporting channel: We assume that there is an external channel that devices can use to report the aggregator, if they should discover that the aggregator has misbehaved. Like Honeycrisp, Orchard produces evidence that the devices can use to substantiate such a report; for instance, this evidence could be posted in an online forum (Twitter, Wikipedia, ...) or it could be given to the press. In a large-scale deployment, the aggregator would typically be a large entity with a reputation to lose, so this mechanism should provide an incentive for the aggregator to follow the protocol correctly.

Collusion: If the aggregator is also the manufacturer of the user devices (which would be the case, e.g., in a deployment by Apple or Google), a malicious aggregator could try to roll out a backdoored OS version or manufacture a large number of additional devices, with which it could then collude. Here, our assumption that the aggregator is Byzantine only *occasionally* (the OB in our OB+MC assumption) is critical, because it limits the potential impact of such misbehavior.

Committee tampering: For a committee of size C , Orchard requires that $\frac{2C}{5}$ committee members are honest. With 2–3% Byzantine users, as we have assumed in Section 2, the chances of randomly sampling a committee with too many Byzantine users are miniscule; with $C = 40$, the chances of ever encountering it during a period of ten years, with one round every day, would be about 0.001%. However, a malicious aggregator could try to increase this probability by preventing honest users from participating in the sortition. To defend against this, the aggregator must maintain a Merkle tree of all the users, so that the results of the election are verifiable by all devices.

5.3 Security: Malicious clients

Another key difference from Honeycrisp is that there can be more than one *bmcS* invocation and that clients can potentially learn some information about the result of previous invocations from the broadcast step. This is not a privacy issue because the type system ensures that any broadcast state

has been properly noised, but a group of malicious clients could potentially use this information in a targeted attack.

As a concrete example, suppose a large online retailer uses the k -means algorithm from Figure 3 to calculate the positions for k new shipping centers, based on the locations of their current customers; suppose, further, that a small group of users wishes to ensure that one of the centers is built in their home town. Notice that each *bmcS* broadcasts the set of centroids from the previous round. In the last round, the attackers can use this information to calculate exactly (modulo noise) what their locations would need to be to move the nearest centroid to their town and then change their inputs accordingly.

To prevent adaptive attacks like this, Orchard can optionally use verifiable computation (VC) [65] on the client side. When this is enabled, clients must upload a cryptographic commitment to their local data along with their first *bmcS* response, and they must include, with each response, a zero-knowledge proof that (a) they have executed the red-zone code correctly and (b) their initial commitment opens to the input they used in the current round. With this defense, the attackers can only choose their initial inputs. As we will show in Section 7.3, this makes a successful attack much harder.

5.4 Handling churn

A third difference is that Orchard computations with multiple *bmcS* rounds can take much longer than Honeycrisp's single-round computation. This raises two concerns: (1) the workload of the committee is somewhat higher, and (2) devices are more likely to go offline during the computation.

To address the first concern, Orchard can optionally choose a fresh committee after a few *bmcS* rounds. This requires a few more devices to serve on committees, and it adds a bit more work for the overall system because each new committee has to generate a fresh keypair, but it is safe, and it limits the work that any given committee member has to perform. To address churn in the committee, Orchard uses Shamir secret sharing to ensure that the committee can reconstruct the private key even if it has lost a few of the shares because the corresponding committee members have gone offline.

This leaves the concern that some *user* devices will leave (and others join) between rounds. This does not affect correctness, since the red zone retains no state between rounds, but it does mean that the *bmcS* sums could be computed over data from slightly different sets of users. Almost by definition, differential privacy cannot release anything that is specific to particular users, so the overall impact of individual user arrivals or departures should be small [29, §2.3.2]. The effect of higher levels of churn depends on the algorithm and on the kinds of users that are joining or leaving. For instance, consider the effect that a major power outage in a large geographic region – say, the 2003 blackout in the Northeastern U.S. [33] – would have on a query that was already in progress. If the query was choosing facility locations within the United

States, the results would be severely distorted, since it would suddenly appear as if there were no users in the Northeast at all. If, however, the query was measuring the age distribution of the users, the impact would be small, since the age distribution in the Northeast would be roughly comparable to the age distribution elsewhere.

6 Implementation

For our experiments, we built a prototype of Orchard. We used Haskell to implement the Fuzz frontend and the transformations, and Python for the backend. Our prototype generates and runs the actual red-zone and orange-zone code; for the aggregation (which would be done with millions of users in a real deployment), we benchmark the individual steps and then extrapolate the cost. Overall, our prototype consists of about 10,000 lines of code, and is publicly available [62].

Encryption: For additively homomorphic encryption, we use the Ring-LWE scheme [54]. This works over a polynomial ring $R_p := \mathbb{Z}_p[x]/(x^n + 1)$, where p is a prime and n is a power of 2. The secret key is a random polynomial $s(x) \in R_p$, and the public key is a pair generated by sampling a random $a \in R_p$ and setting the public key to be $(a, b) \in R_p^2$, where $b := a \cdot s + e \in R_p$, for some “error” $e \in R_p$ chosen from an appropriate error distribution. The plaintext space is \mathbb{Z}_q^l , where $q, l \in \mathbb{Z}$, $l \leq n$, $q \ll p$ and $|p \bmod q| \ll q$. To encrypt a vector $z \in \mathbb{Z}_q^l$, the encryptor generates a random $r \in R_p$, and computes the ciphertext $(u, v) := (a \cdot r + e_1, b \cdot r + \lfloor p/q \rfloor \cdot z) \in R_p^2$. Decryption is then simply $z = \text{round}(v - u \cdot s, \lfloor p/q \rfloor) / \lfloor p/q \rfloor$, where $\text{round}(x, y)$ rounds each coefficient of x to the nearest multiple of y . (We assume the errors e, e_1, e_2 are sufficiently small relative to p/q .)

This encryption scheme allows us to represent our key generation and decryption protocols with a small constant number of additions and one multiplication in the polynomial ring. Moreover, it allows us to pack many ‘slots’ of ciphertexts into one large ciphertext, with almost no additional cost. Given our security parameter choices, this scheme yields up to 4,096 counters, each with a capacity of roughly 50 bits.

MPC: We use the SCALE-MAMBA framework [50] to implement the MPC operations for key generation and for the orange zones (Section 5.1). For key generation and decryption we used code we obtained from the authors of [76]. SCALE-MAMBA supports an arbitrary number of parties and is secure in the fully-malicious model. Operations are performed in a finite field modulo a configurable prime p , which allows for the support of both integers and floating points. This is a natural fit for our Ring-LWE encryption scheme, which also requires an integer modulus, and thus no additional modular arithmetic needs to be implemented within the MPC. In Ring-LWE, the additive homomorphism of plaintexts is modulo some integer q , where $|p \bmod q| \ll q$; ideally, $p = 1 \bmod q$.

Secret sharing: SCALE-MAMBA also supports Shamir secret sharing [78]. We use this to shard the private key among the k committee members in such a way that any subset of $t + 1$ members can reconstruct the entire key. At the same time, t dishonest nodes cannot learn anything about the key, and $t + 1$ honest nodes can detect any errors introduced by dishonest nodes. This enables Orchard to tolerate the loss of a few committee members. We modified the open-source SCALE-MAMBA source code to reconstruct the secret key automatically, if needed, using the remaining shares.

Verifiable computation: We use the zk-SNARK protocol [11] to enable clients to prove, in zero knowledge, that they have done the red-zone computation correctly, with consistent inputs (Section 5.3). For benchmarking, we used the implementation from the Pequin toolchain [67].

Security parameters: We use the LWE-estimator tool [53] of Albrecht et al. [5] to obtain concrete parameters that provide sufficient security based on the best known attacks on LWE. We chose dimensionality $n = 4096$, a 128-bit prime p , and a Gaussian error distribution with $\sigma = \frac{\sqrt{2}}{2}$ (which we approximate as the centered binomial distribution with $N = 2$ trials) in each dimension, which gives over 128 bits of security. For the verifiable aggregation, we use the same choices as Honeycrisp, namely SHA-256 hashes and RSA-2048 signatures.

7 Evaluation

Our experimental evaluation is designed to answer four high-level questions: (1) How many private queries can Orchard support? (2) How well do Orchard’s optimizations work? (3) How effective are Orchard’s defenses against malicious clients? And (4) what are the costs of Orchard?

7.1 Coverage

To get a sense of how many (private) queries Orchard can support, we did a careful survey of the differential privacy literature to find queries that are plausible candidates for our highly distributed setting. We collected as many different kinds of queries we could find; we excluded only a) queries that were substantially similar to ones we already had (e.g., different variants of computing CDFs), and b) queries where we simply could not imagine the data being distributed across lots of individual devices.

Table 1 (in the Overview section) shows the queries we found, as well as the papers we found them in. We then implemented each query in Fuzz, taking care to write the queries as they were presented in the papers, and not in a way that would be convenient for Orchard (e.g., with computations already grouped the way `bmcS` would require them).

We found that, out of the 17 queries we found, 14 (82%) were accepted by Orchard. The three queries that did not work were PATE [64], IDC [41], and DStress [63]. These

Query	Naïve	Optimized
ID3	$2md$	$m + 1$
k-means	$3m$	$m + 1$
Perceptron	$2md$	$m + 1$
PCA	$d^2 + d$	1
Logistic regression	$d + 1$	2
Naïve Bayes	$2d$	2
Neural Network	$2m(d + 1)$	$m + 1$
Histograms	b	1
k-Medians	$3m$	m
CDF	b	1
Range queries	b	1
Bloom filters	d	1
Count Mean Sketch	d	1
Sparse vector	1	1

Table 2: `bmcS` rounds needed for each query, with and without optimizations. d is the input vector length, m the number of iterations, and b the number of buckets (see Section 7.4).

queries are not a good fit for our model. DStress operates on graphs, whereas we assume a set of per-user records. IDC is a “template algorithm” with an oracle function U , and good choices for U require functions beyond simple bag operations. PATE requires training private (un-noised) “teacher” models and then training a “student” model with noisy labels provided by the teachers. In our model, only the aggregator could play the role of PATE’s teachers, but we do not trust it to see sensitive data in the clear, so we cannot express this algorithm.

Overall, our data suggests that Orchard is able to execute a wide variety of differentially private queries—even though these queries were designed for the centralized model.

7.2 Optimizations

A naïve translation of a centralized query typically results in a lot more `bmcS` invocations than necessary. To estimate how much our optimizations can help with this, we compiled each query twice, once with the full transformation and once with optimizations disabled; we then counted the `bmcS` operations in the resulting programs.

Table 2 shows our results. In most cases, our optimizations substantially reduced the number of `bmcS` rounds that were needed. (The exact reduction depends on the parameters.) Since the rounds are done sequentially (the `bmcS` calls in the green-zone code are “blocking”), and since `bmcS` accounts for almost all of a typical query’s runtime, this means a much lower processing time.

We manually inspected the optimized code, looking for opportunities to further reduce the number of rounds, but could not find any. In principle, Orchard’s optimizations could miss opportunities for fusing release mechanisms (Section 4.6), but this did not occur for any of the queries we tried.

Figure 4: Impact of malicious users.

7.3 Robustness to malicious users

To examine how much Orchard’s defenses help against malicious users, we implemented the attack scenario from Section 5.3. Recall that this involves an online retailer using k -means to find locations for $k = 3$ new shipping centers and a group of attackers trying to cause one of the centers to be built in their home town. We randomly sampled latitudes and longitudes for $N = 10^4$ honest users from a rectangle that includes the lower 48 U.S. states, and we used Seattle, Houston, and New York as reasonable guesses to initialize the centroid positions. We then simulated the behavior of Orchard, as well as four hypothetical alternatives: (1) local differential privacy (LDP); (2) global differential privacy (GDP) with a trusted aggregator; (3) GDP with input clipping (IC), which rejects coordinates outside the valid range and was implemented in [76]; and (4) LDP with output clipping (OC), which requires users to clip their *noised* values to $10\times$ the valid range. The attackers try to move the East Coast centroid (which is near Richmond, VA without the attack) to Pittsburgh, PA, using the strategy from Section 5.3; we assume that the attackers do not have knowledge of any data from previous Orchard queries (because, if this information was still relevant, the aggregator would likely have no need to issue a new query). We vary the number of attackers A , and we assume that the attackers are able to estimate N but do not know the locations of the other users. We say that the attack succeeds if the final East Coast centroid is within 20 miles of Pittsburgh.

Figure 4 shows the distance from Pittsburgh of the resulting East Coast centroid for each scenario and with various values for the parameters; the figure shows medians across 500 independent runs. Without a defense, GDP and LDP succumb to even a single attacker, who can observe the centroid’s location in the penultimate round and then calculate an input (far outside the valid range) that will move the centroid to Pittsburgh in the final round. The residual error is due to noising; it decreases as A increases. Notice that GDP’s error is even lower than LDP’s; this is because GDP adds less noise.

With OC, the attackers can no longer report arbitrary values and must instead choose the largest value in the right direction that will be accepted, but the attack still succeeds with about $A = 31$ (0.3% of the users). IC further restricts the range; success now requires $A = 500$ attackers. With Orchard, the

Figure 5: Bandwidth (a) and computation (b) required of each participant in a run of each algorithm.

attackers cannot adapt, and since they do not know up front what values to report—reporting, say, Portland, ME, would risk “overshooting” and moving the centroid away from Pittsburgh again—their best strategy is to simply report Pittsburgh as their location. With this strategy, the attack takes about $A = 20,000$ —far more than the number of honest users.

7.4 Experimental setup

Next, we used our prototype to measure Orchard’s costs to users, committee members, and the aggregator. We benchmarked the client-side software on a laptop with a 2.3 GHz dual-core processor and 8 GB of RAM running macOS Catalina. To simulate committee members operating in a global setting, we used `t2.large` EC2 instances with 8 GB of RAM, located in all available geographic regions (including the U.S., Europe, Asia, and Brazil), to get realistic latencies. For our aggregator experiments we used eight PowerEdge R430 servers with 64 GB of RAM, two Xeon E5-2620 CPUs, and 10 Gbps Ethernet; the operating system was Fedora Core 26 with a Linux 4.3.15 kernel. This equipment seems reasonably close to what a real-world aggregator might have available in its data center.

Many of our algorithms have parameters that affect the cost. For k -means and k -medians, we chose $m = 5$ and $k = 3$, because [9] notes that, given proper cluster initialization, the solution after five rounds is consistently as good or better than that found by any other method. For Perceptron, we chose $m = 10$, because the algorithm is guaranteed to converge after at most $O(1/\alpha^2)$ iterations, where α is the margin in a linearly separable dataset [75]. With vectors of size 10, we assume 1-separability to get this guarantee. For ID3, we set vector dimension $d = 100$ because we can support estimating entropy for counters of up to vectors of size 1 million (e.g., all possible 6-digit zip codes) with far fewer counters on the aggregator’s side. For the neural network, we chose $m = 20$ epochs, for which [44] shows accuracy competitive with SGD.

Since Orchard is a generalization of Honeycrisp, we report Honeycrisp’s numbers for comparison. We got these numbers by executing Honeycrisp’s fixed query, which compiles to a single `bmcS`, with Orchard’s additions disabled.

7.5 Cost for normal participants

The key costs to a normal Orchard participant are: (1) the red-zone computation itself; (2) encrypting the value to be uploaded; (3) generating the zero-knowledge proofs; and (4) verifying the aggregator’s summation. (The transformations

themselves are cheap; this step never took more than 410 ms for any of our 14 queries.) To quantify these costs, we benchmarked the Orchard client while it was executing each of our 14 queries; to get realistic numbers for sum verification, we emulated a system with $N = 1.3 \cdot 10^9$ users for the client to interact with. We measured the number of bytes sent, as well as the computation time spent on Orchard operations.

Figure 5 shows our results. Both the bandwidth and the computation time vary significantly between queries, but they are largely proportional to the number of `bmcS` rounds, whose cryptographic operations dominate the cost. The red-zone computations themselves are typically trivial (many simply return a value), so their cost is very small in comparison; we simply include it with the other protocol overheads in Figure 5(b). Overall, the bandwidth costs are modest, ranging from 1 MB to about 25 MB per query. The computation typically takes at most a few minutes.

The neural-network query is an outlier; it takes about 25 minutes of computation time, which raises some concerns, e.g., about battery life on mobile devices. This high cost is mostly due to the high number of rounds we used ($m = 20$), to show what would happen when training on a “hard” problem. For “easy” lower-dimensional problems, even a single pass can be statistically optimal [69].

To measure the cost of the defense from Section 5.3, we selectively disabled the part of the zero-knowledge proof that concerns input consistency; this typically reduced the proving time by about 3%. This is because the client already has to prove that the encrypted value is in the correct range; the marginal cost of this extra proof obligation is very small.

7.6 Cost for the committee

For each query, Orchard selects a small committee of C user devices that are expected to participate in the key-generation MPC, as well as in the per-`bmcS` MPC that performs decryption and orange-zone computations. To quantify the cost to committee members, we set up committees with EC2 instances as described in Section 7.4, triggered each of our 14 queries, and measured the bandwidth and computation that the two MPCs consume. We report the cost of a single iteration of each MPC.

Figure 6 shows our results; where queries use two `bmcS` rounds per iteration, we report the cost of the more expensive one (indicated with an asterisk). The cost of the key-generation MPC depends only on the key length, and is thus identical for all queries; the cost of the orange-zone MPC

Figure 6: Bandwidth (a) and computation (b) required of each committee member during one round of orange-zone computation.

Figure 7: Bandwidth (a) and computation (b) required of the aggregator.

varies with the query, but not by much. Overall, decryption dominates the costs, and, since every bmcs call fits into one large packed ciphertext, we see the same behavior for all queries. In absolute terms, these costs are significant; a typical query with one round of bmcs consumes about 3 GB of traffic and five minutes of computation time; the total is higher if additional rounds are required.

Notice that the chances of actually being selected for the committee are tiny: for $N = 1.3 \cdot 10^9$ users, a typical committee size is about $C = 40$, so each user is only about $9 \times$ more likely to be chosen than to win the jackpot in Powerball. Nevertheless, it may be useful to excuse resource-limited devices, such as mobile phones, from committee service and to rely mostly on devices like desktops and laptops, when possible.

7.7 Cost for the aggregator

Next, we quantify the costs of the aggregator, who must collect the input from each device, verify the zero-knowledge proofs, sum up the inputs, generate the summation proof, and distribute this proof to each device. We do not currently have a large enough deployment of Orchard to run this experiment end-to-end, so we estimate the costs based on benchmarks of the individual steps. We set the number of rounds as discussed in Section 7.4, and we report results for $N = 1.3 \cdot 10^9$.

Figure 7 shows the number of bytes the aggregator would need to send for each query, as well as the number of Xeon E5-2620 cores it would need to ensure that the computations do not last for more than one hour. As before, the costs depend mostly on the number of rounds; the cost of the green-zone computation is insignificant. The most expensive query (Neural Network) would require 892 cores, or 74 machines with two E5-2620 CPUs each. It would also involve sending 13,180 TB, which is a lot but actually corresponds to about 10 MB per user. For comparison: the average transfer size of a web page is about 2 MB [47]; typically, much of this is offloaded to CDNs, and the same would be possible for Orchard’s summation proofs.

Scalability: We also ask how well Orchard scales with the number of participating users N . This is mostly a concern for

Figure 8: Bandwidth (a) and computation (b) required of the aggregator, for different system sizes.

the aggregator: the size of the MPCs (and, thus, the cost for committee members) does not depend on N at all, and the cost for individual users grows only very slowly, with $O(\log N)$, because of the summation trees. We estimate the costs of the aggregator as above, but this time we vary N .

Figure 8 shows our results (all scales are logarithmic). Although the scaling is technically $O(N \log N)$ because the height of the summation trees grows with N and each user must be sent some paths in the tree for verification, the non-linear component is small in both figures, which means that Orchard scales very well with N . This is expected, since Orchard is based on Honeycrisp, which scales similarly, and nothing in Orchard destroys this scalability.

8 Related work

To our knowledge, Orchard is the first *general* system that can process a wide variety of queries with (1) a single untrusted aggregator, (2) global differential privacy, and (3) scalability to millions of users.

Different trust assumptions: Several other systems require at least some trust in additional parties. Prochlo [14] anonymizes the user data using a shuffler, who must not collude with the aggregator; this reduces the privacy cost of LDP algorithms considerably [30]. Similarly, the crypto service provider in [37, 60] must not collude with the evaluator, and the proxy in PDDP [21] and the aggregator in Leontiadis et al. [51] must not collude with the analyst. UnLynx [35] and Prio [23] use the anytrust model, that is, a group of servers

of which at least one must be honest; SecureML [58] uses a pair of non-colluding servers; and other solutions, such as [20, 24, 48, 74], use a trusted third party for at least some steps. These additional trust assumptions yield substantial benefits, but recruiting parties that will help the aggregator but are sufficiently trustworthy to users may not be easy.

Some solutions, such as [52] use trusted hardware like Intel’s SGX. We avoid this approach in Orchard because current TEE implementations are not yet sufficiently trustworthy, as shown, e.g., by the many successful attacks on SGX [61].

Local differential privacy: Google’s RAPPOR [31, 32] uses LDP to aggregate data; similar systems have been deployed, e.g., by Apple [8], Microsoft [27], and Snap [68]. As discussed in Section 2.2, LDP requires significantly more noise than GDP, which can be limiting in practice [14], and it is vulnerable to attacks from small groups of colluding users [19, 22].

Smaller scale: A variety of solutions are available for systems with at most a few thousand users. For instance, Shi et al. [79] use a distributed key generation scheme to remove trust in the aggregator, and [3] use pairwise blinding instead of encryption, but these approaches do not work well under churn. Some systems have scaled MPC to impressive sizes – for instance, SEPIA [18] handles hundreds of users, and Reyzin et al. [73] perform secure aggregation for thousands, by adding homomorphic threshold encryption – but supporting millions of users with MPC seems unrealistic. Bonawitz et al. [17] use secret sharing, but, with n users, several costs grow with $O(n^2)$; Bindschaedler et al. [13] and Goryczka and Xiong [39] require $O(n^2)$ communication; Rastogi and Nath [71] use (t, n) -threshold encryption; and Halevi et al. [43] have $O(n)$ latency, since users must interact with the aggregator sequentially.

Federated learning: FL [12, 16] is another approach to working with highly distributed data. Most existing systems do not guarantee differential privacy, and the ones that do typically rely on LDP, such as [2]. Zhu et al. [88] recently proposed an interactive protocol with better privacy, specifically for discovering heavy hitters, but it does trust the aggregator with one simple task (thresholding). Truex et al. [81] relies on threshold Paillier, but it is limited to small deployments.

9 Conclusion

Prior to Orchard, it may have seemed that running differentially private queries at scale required either making compromises (on privacy, accuracy, or trust) or custom-building a cryptographic protocol. Orchard shows that, because of structural similarities among many queries, general solutions do exist, even when there is only a single, untrusted aggregator. There are still types of queries that Orchard does not support—one interesting example are queries on graphs—but we speculate that, by finding and exploiting similar structural patterns, solutions could be built for some of them as well.

Achieving 100Gbps Intrusion Prevention on a Single Server

Zhipeng Zhao, Hugo Sadok, Nirav Atre, James C. Hoe, Vyas Sekar, Justine Sherry
Carnegie Mellon University

Abstract

Intrusion Detection and Prevention Systems (IDS/IPS) are among the most demanding stateful network functions. Today's network operators are faced with securing 100Gbps networks with 100K+ concurrent connections by deploying IDS/IPSeS to search for 10K+ rules concurrently. In this paper we set an ambitious goal: Can we do all of the above in a single server? Through the Pigasus IDS/IPS, we show that this goal is achievable, perhaps for the first time, by building on recent advances in FPGA-capable SmartNICs. Pigasus' design takes an FPGA-first approach, where the majority of processing, and all state and control flow are managed on the FPGA. However, doing so requires careful design of algorithms and data structures to ensure fast common-case performance while densely utilizing system memory resources. Our experiments with a variety of traces show that Pigasus can support 100Gbps using an average of 5 cores and 1 FPGA, using 38 \times less power than a CPU-only approach.

1 Introduction

Intrusion Detection and Prevention Systems (IDS/IPS) are a critical part of any operational security deployment [39, 40]. Such systems scan packet headers and payloads to check if they match a given set of *signatures* containing a series of strings and regular expressions. Signature rulesets are obtained through offline techniques (e.g., crafted by experts or obtained from proprietary vendor algorithms) [6].

A recurring theme in IDS/IPS literature is the gap between the workloads they need to handle and the capabilities of existing hardware/software implementations. Today, we are faced with the need to build IDS/IPSeS that can support line rates on the order of 100Gbps [14] with *hundreds of thousands* [11] of concurrent flows and capable of matching packets against *tens of thousands of rules* [6]. This paper answers this challenge with the Pigasus FPGA-based IDS/IPS which meets the above goal *within the footprint of a single server*.

An important technology push that enables our effort is the emergence of server SmartNICs [29, 31]. Here, FPGA capabilities have become embedded in commodity server NICs. Of the various classes of high-performance accelerators (e.g., GPUs), SmartNIC FPGAs are an especially promising alternative in terms of cost-performance-power tradeoffs, if they can be harnessed appropriately. Indeed, recent efforts have demonstrated the promise of FPGAs for low power, low costs and high performance for some simpler network functions such as software switching in Microsoft's AccelNet [21].

While many before us have integrated FPGAs with ID-

S/IPS processing [10, 16, 18, 19, 22, 34, 41–43, 46, 48, 49], for the most part these have focused on offloading only a specific functionality (e.g., regular expression matching) to the FPGA. Unfortunately, traditional offloading cannot close the order-of-magnitude performance gap to offer 100Gbps IDS/IPS processing within the footprint of a single server. Even if regular expression search were *infinitely fast*, Snort 3.0 would still on average operate at 400 Mbps/core, requiring 250 cores to keep up with line rates! For orders of magnitude improvements, an accelerator has to improve performance for a *majority* of processing tasks, not just a small subset.

Hence in designing *Pigasus*, we argue for an *FPGA-first architecture in IDS/IPS processing*. Here, the majority of packet processing for IDS/IPS is performed via a highly-parallel datapath on-board the 100Gbps SmartNIC FPGA. Pigasus FPGA performs TCP reassembly directly on the FPGA so that it can immediately apply exact string matching algorithms over payload data to determine which “suspicious” packets need to enter a “full match” mode requiring additional string matches and regular expression matching. Inverted from the classic FPGA offload paradigm, Pigasus FPGA leaves to the CPU only the final match stage to check a small number of signatures on excerpts of the bytestream (on average, 1.1 signatures/packet and 5% of packets are sent to the CPU). By processing most benign traffic on the FPGA, the Pigasus FPGA-first architecture can reach 100Gbps and 3 μ s latency in the common case.

A natural consequence of Pigasus' FPGA-first approach is that we are now faced with supporting stateful packet processing on FPGA. The challenge includes not only multi-string pattern matching for *payload matching* but also *TCP bytestream reassembly* to be both performed at 100Gbps line rate. (Out-of-order TCP packets must be reassembled so detection is made even when a rule's pattern match across TCP packet boundaries.) Existing NF-specific programming frameworks for FPGAs [30, 36] do not provide the necessary abstractions for searching bytestreams, nor do they scale to the necessary scale and efficiency to meet our goals. A practical system needs to be able to track at least 100K flows and check at least 10K patterns at 100Gbps line rates, all the while staying within the available processing and memory resources of modern SmartNIC FPGAs. To meet these objectives, our design makes two key contributions:

Hierarchical Pattern Matching: Traditional streaming string search algorithms use NFA-based (state machine) algorithms. While these algorithms are very fast with small rulesets, we measured that supporting the Snort Registered Ruleset [6]

would require 23MB of Block RAM (BRAM), more than the entire capacity of our FPGA (16 MB). We instead take inspiration from Hyperscan [47], designed for x86 processors, which uses hash table lookups instead of a traditional state machine approach for exact-match string search. The (software) pattern matcher in Snort 3.0, which uses Hyperscan, offers a better starting point for our hardware design: it can support all 10K rules using 785KB of memory at a rate of 3.2Gbps on our FPGA. Scaling this to 100Gbps, however, requires replicating the state 32 times over (once again overflowing memory); Pigasus uses a set of *hierarchical filters* to reduce the overall amount of memory required per pipeline replica, enabling search over 32 indices in parallel while consuming only about 2MB of BRAM. Because Pigasus' pattern matcher is so memory-efficient, Pigasus additionally checks for extra strings in the pattern matcher that Snort would push to the 'full match' stage (implemented in Pigasus on the CPU). At the additional cost of 1.3MB of memory, scanning for extra strings results in 2× fewer packets (and 4× fewer rules/packet) reaching the full matcher than Snort.

Fast Common-Case Reassembly: Conventional approaches to TCP reassembly use fixed-length, statically allocated buffers. This prevents highly out-of-order flows from hindering performance (since insertion is constant time) and from consuming too much memory (since buffer sizes are fixed). However, fixed buffers are very memory inefficient; the strategy proposed in [49] would require 6.4GB of memory to support 100K flows. A linked list would be more memory dense, but more vulnerable to out-of-order flows stalling pipeline parallelism or exhausting buffer space. Pigasus adopts the memory-dense linked list approach, but only on an out-of-order *slow path* which runs in parallel to the primary fast path; if the memory buffer approaches capacity, large flows are preferentially reset to prevent overload. On the fast path, packets access a simple table storing the next byte expected and increment it accordingly, thus, in-order flows are performance-wise isolated from out-of-order flows. This allows Pigasus to be memory-efficient (requiring on average 5KB per out-of-order flow) while isolating well-behaved traffic from performance degradation when the IDS is inundated with misbehaving, out-of-order packet data.

Together, the above design choices allow us to do *the majority of processing on a highly-parallelized FPGA fast-path* while fitting *memory within the available resources*. As a result, for the empirical traces, Pigasus can process 100Gbps using an average of 5 cores and 1 FPGA, requiring an average of 85 Watts. In contrast, Snort 3.0 [5] – which uses Hyperscan [47] for string matching – would require 364 cores and 3,278 Watts. Pigasus is publicly available at <https://github.com/cmu-snap/pigasus>.

2 Background & Motivation

We now introduce software IDS/IPS systems (§2.1) and FPGAs (§2.2). We then analyze IDS/IPS performance and bound the throughput gains achievable via offloading using measurements of Snort 3.0 (§2.3).

2.1 IDS/IPS Functionality

The key goal of a signature-based¹ IDS/IPS system is to identify when a network flow triggers any of up to tens of thousands of signatures, also known as *rules*.

A given signature may specify one or several *patterns* and the entire signature is typically triggered when all patterns are found. Patterns come in the following three categories:

- *Header match*: a filter over the flow 5-tuple (e.g., 'all traffic on port 80', 'traffic from 145.24.78.0/24');
- *String match*: an exact match string to detect within the TCP bytestream or within a single UDP packet;
- *Regular expression*: a regular expression to detect within the TCP bytestream or within a single UDP packet.

Signatures are detected at the granularity of a 'Protocol Data Unit' (PDU) – that is, a signature is only triggered if all matches are found within the same PDU (not over the course of the entire flow). By default, a PDU consists of one packet, but it is possible to define other protocol-specific PDUs spanning multiple packets (e.g., one HTTP GET request).

When an IDS/IPS operates in *detection* mode, a triggered signature results in an alert or an event recorded to a log. When an IDS/IPS operates in *prevention* mode, a triggered signature may raise alerts, record events, or *block* traffic from the offending flow or source. IPSes hence must operate inline over traffic and are latency sensitive – a packet may not be released to the network until after the IPS has completed scanning it. IDSes, on the other hand, may operate asynchronously and are often deployed over a secondary traffic 'tap' which provides copies of the active traffic.

Software IDS/IPS Performance: One of the most widely-known IDS/IPSes is Snort [38] and our work aims to be compatible with Snort rulesets. In our experiments, we primarily work with the Snort Registered Ruleset, which contains roughly 10,000 signatures [6]. This ruleset, combined with conversations with system administrators, sets our goal of supporting 10K rules. In addition, we target 100Gbps as the state-of-the-art line rate [14] and we aim to support 100K flows. To the best of our knowledge there exists no measurement study detailing how many flows to expect at 100Gbps so we derive our 100K flow goal by extrapolating a two-orders-of-magnitude growth factor from a 2010 study [11].

In 2019, Intel published Hyperscan [47], an x86-optimized library for performing both exact-match and regular-expression string matching. Hyperscan is the key new element

¹There exist other models of IDS/IPS which are 'script based' – executing arbitrary user code over scanned traffic – such as Zeek [7, 35]. These IDS/IPSes are out of scope for this work.

Figure 1: Single-core, zero loss throughput for Snort 3.0 over empirical traces.

in *Snort 3.0*, which is $8\times$ faster than its predecessor. Nonetheless, we find that Snort 3.0 cannot meet our goal of supporting 100Gbps, 100K flows, and 10K rules on a single server.

We ran Snort 3.0 on a 3.6GHz server and measured the *single-core throughput* over 7 publicly available network traces (described more thoroughly in §6.1). We plot the results in Figure 1. Generously assuming that Snort 3.0 is capable of *perfect* multicore scalability, this would require 125-667 cores to support 100Gbps of throughput, or 4-21 servers.

2.2 FPGA Basics

Why look to FPGAs to improve IDS/IPSeS? While there are many platforms (‘accelerators’) that offer highly parallel processing, we choose FPGAs because they are (a) energy-efficient (using $4\text{--}5\times$ fewer Watts than GPUs [12]) and (b) because they are conveniently deployed on SmartNICs where they are poised to operate on traffic without PCIe latency or bandwidth overheads.

FPGA Compute: FPGAs allow programmers to specify custom circuits using code. However, implemented naively, FPGA-based designs can be much slower than their CPU counterparts because FPGA clock rates operate $5\text{--}20\times$ slower than traditional processor clock rates. To achieve performance speedups relative to CPUs, circuits must be designed with a high degree of parallelism. FPGAs achieve parallelism either through *pipeline parallelism*, in which *different* modules operate simultaneously over different data, or through *data parallelism* in which copies of the *same* module are cloned to operate simultaneously over different data.

FPGA Memory: Today’s FPGAs offer programmers a collection of memory options. Block RAM (BRAM) is the ‘king’ of FPGA memory because read requests receive a response within one cycle. Furthermore, BRAM is very friendly to parallelism. Divided into 20Kb *blocks* with two ports each, it is possible to read from all BRAM blocks in parallel (and each BRAM block twice) per cycle. When a developer wishes to issue more than two parallel reads to a BRAM block per cycle, they may choose to *replicate* the block to allow more simultaneous read-only accesses to stored data. Our FPGA offers 16MB of BRAM.

Our FPGA also offers 8GB of on-board DRAM (which

Figure 2: Fraction of CPU time spent performing each task in Snort 3.0.

Figure 3: Projected speedup in software given various single-task offloads.

takes about 20 cycles between read request and response) and 10MB of eSRAM (which takes fixed 12 cycles between read request and response). Because of the multi-cycle latency for these two classes of memory, they are not suitable for storing data that must be read/written every cycle. Furthermore, both are more bandwidth-limited than BRAM and offer fewer lookups in parallel. However, as we will discuss in §4.2, pushing what data is feasible into these classes of memory is necessary to free up as much BRAM as possible to support fast-path memory-intensive processing.

2.3 FPGAs and IDS/IPS Performance

We are not the first to integrate FPGAs into IDS/IPS processing. However, prior work follows an ‘offload’ approach to utilizing the FPGA, where the CPU is ‘primary’ and performs the majority of processing, and the FPGA accelerates a single task [10, 16, 18, 19, 22, 34, 41–43, 46, 48, 49]. Most research in this space targets offloading regular expression matching alone [22, 41, 48], although some target TCP reassembly [42, 49] or header matching [27] instead. Unfortunately, a basic analysis based on Amdahl’s law reveals why this approach fundamentally cannot bring IDS/IPS performance onto a single server at 100Gbps.

In Figure 2 we illustrate the *fraction of CPU time* spent on each task in Snort 3.0: *MSPM* (which, in Snort 3.0, implements header and partial string matching), *Full Matching* (which, in Snort, implements regular expressions and additional string matching), *TCP Reassembly*, and *other tasks*. As we can see, no single task dominates CPU time – at most, the MSPM consumes 46% of CPU time for one trace.

Using Amdahl’s Law, we can see that even if MSPM were offloaded to an imaginary, *infinitely-fast* accelerator, throughput would increase by only 85% to 600Mbps/core, still requiring 166 cores to reach 100Gbps. In Figure 3, we show the idealized ‘speedup factor’ from offloading any individual module (assuming an infinite accelerator) for each of our traces; no module even reaches as much of a speedup as $2\times$.

The key lesson is simple: a much more drastic approach is needed to achieve line-rate throughput on a single server.

Figure 4: Pigasus architecture.

3 System Overview

We now present an overview of Pigasus. Recall that our target is to achieve 100Gbps, for 100K concurrent flows, and 10K rules within the footprint of a single server. We first describe our rationale behind Pigasus’ *FPGA-first* approach (§3.1) before presenting Pigasus’ packet processing datapath module by module (§3.2) and discussing how Pigasus makes best use of memory resources (§3.3). Finally, we lay out the threat model that we consider (§3.4).

3.1 An FPGA-First Design

Following our analysis in §2.3, we argue for an *FPGA-first* design for IDS/IPS processing. By *FPGA-first*, we mean that the FPGA is the *primary* compute platform – performing the majority of work – and that the CPU is *secondary*, operating only as needed. Following our analysis in §2.3, any approach to speed up IDS/IPs by orders of magnitude must take on parallelizing *as much of the system as possible*.

We can even consider an extreme design, running the *entire system* on the FPGA, disposing the need for CPUs. However, we avoid this approach and choose instead to leave regular expressions and the ‘full match’ stage on traditional processors. The reason is simple – compared to the other packet processing modules, implementing the Full Match stage entirely on the FPGA provides lower performance benefits at a higher cost in terms of memory. As we will see in §5, the Full Match stage only interacts with $\approx 5\%$ of packets in the Pigasus design. Hence, it is *not* a performance bottleneck for the majority of packets. Furthermore, regular expression parsing is a very mature research and yet state-of-the-art hardware algorithms do not reach our performance and memory demands for Pigasus. We estimate that GRAPEFRUIT [37], a state-of-the-art regular expression engine for FPGAs, would require 8MB of BRAM to statically map all the regular expressions from our ruleset on the FPGA, and yet would still only keep up with a few Gbps of traffic. Hence, we would likely need multiple replicas of the GRAPEFRUIT design – at least 24MB of BRAM – to keep up with the average of 5Gbps of traffic that reach the full matcher. Therefore, offloading regular expressions would exhaust our memory budget for little gain, in that *the majority of packets will never execute the full matcher anyway*.

3.2 Pigasus Datapath

Figure 4 depicts the major components of Pigasus’ architecture. Notice that the Parser, Reassembler, and Multi-String Pattern Matcher (MSPM) are implemented in the FPGA while the Full Matcher is offloaded to the CPU.

Initial packet processing: Each packet first goes through a 100Gbps *Ethernet Core* that translates electric signals into raw Ethernet frames. These frames are temporarily stored in the *Packet Buffer*; each frame’s header is separately sent to the *Parser* – which extracts TCP/IP header fields as metadata (e.g., sequence numbers, ports) for use by the Reassembler and MSPM – and then forwards the header to the Reassembler.

Reassembler: The Reassembler sorts TCP packets in order so that they can be searched contiguously (*i.e.*, to identify matches that span across multiple packets). The Reassembler is able to record the last few bytes of the packet’s predecessor in that flow in order to enable cross-packet search in the MSPM. UDP packets are forwarded through the Reassembler without processing. The key challenge in designing the Reassembler is doing so *at line rate* with state for *100K flows*; we discuss the design of the Reassembler in §4.

Data Mover: While the Parser and Reassembler operate on headers and metadata alone, the MSPM operates on full packet payloads. The Data Mover receives the (sorted) packet metadata from Reassembler and issues requests to fetch raw packets from the *Packet Buffer* so that they can be forwarded to the MSPM.

Multi-String Pattern Matcher: The MSPM is responsible for (a) checking every packet against the header match for all 10,000 rules, and (b) *every index of every packet* against all of the string-match filters for all 10,000 rules. Pigasus’ MSPM does more work than Snort 3.0’s equivalent module: Snort 3.0 searches for only *one* exact match string (called the fast pattern) in the MSPM, and pushes detection of the remainder of the strings to the ‘full match’ module. By searching for all of the exact match strings in the MSPM, Pigasus reduces the number of packets sent to the Full Match stage by more than $2\times$ relative to Snort 3.0, and also reduces the number of suspected rules for the full matcher to check per packet by $4\times$. We describe the Pigasus MSPM design in §5.

DMA Engine: For each packet, the MSPM outputs the set of *rule IDs* that the packet partially matched. If the MSPM outputs the empty set, the packet is released to the network; otherwise it is forwarded to the DMA Engine which transfers the packet to the CPU for Full Matching. To save CPU cycles, the DMA Engine keeps a copy of the packets sent to the Full Matcher; this allows the Full Matcher to reply with a (packet ID, decision) tuple as a response rather than copying the entire packet back over PCIe after processing. The DMA Engine distributes tasks across cores in a round-robin fashion.

Full Matcher: On the software side, the Full Matcher polls a ring buffer which is populated by the DMA Engine. Each packet carries metadata including the *rule IDs* that the MSPM determined to be a partial match. For each rule ID, the Full Matcher retrieves the complete rule (including regular expressions) and checks for a *full match*. It then writes its decision (forward or drop) to a transmission ring buffer which is polled by the DMA Engine on the FPGA side. If the decision is to forward, the DMA Engine forwards the packet to the network; otherwise the packet is simply erased from the DMA Engine's Check Packet Buffer.

3.3 Memory Resource Management

The core obstacle to realizing an FPGA-first design is fitting all of the above functionality (except the full matcher) within the limited memory on the FPGA. As discussed in §2.2, BRAM is the 'best' of the available memory: it is the only class of memory that can perform read operations in one cycle, and it is also the most parallel. However, it is limited to only 16MB even on our high-end Intel Stratix 10 MX FPGA.

Therefore, we reserve BRAM only for modules which read or write to memory the most frequently, with multiple accesses per packet; namely the Reassembler and the Multi-String Pattern Matcher. Specifically, the Reassembler performs multiple accesses per packet as it needs to check for out-of-orderness, manage the out-of-order packet buffer, and check and release packet headers when an out-of-order 'hole' is filled. The MSPM too entails multiple memory accesses per packet, as every index of every packet must be checked against 10K exact-match string rules, and every packet header must be checked against the header matches for 10K rules.

To save BRAM, we allocate the other stateful modules such as the Packet Buffer and DMA Engine to less powerful eSRAM and DRAM respectively.² eSRAM and DRAM turn out to be sufficient for these tasks because the Packet Buffer and DMA Engine have much less stringent demands in terms of bandwidth and latency. In the case of the packet buffer, packet data is written and read only once and hence bandwidth demand is low but still exceeds DRAM's peak throughput; the

data mover prefetches each packets 12 cycles before pushing it to the MSPM, keeping throughput high with a negligible latency overhead. The DMA Engine uses DRAM – which has the highest and variable latency and the lowest bandwidth – for the Check Packet Buffer. Since on average only 5% of packets require Full Matching functionality, this places little stress on DRAM bandwidth; the latency overhead of DRAM, while high when compared to BRAM, is still 10× faster than the PCIe latency suffered by packets sent to the CPU for full match.

Even though this leaves us with almost³ the full capacity of BRAM for the Reassembler and Multi-String Pattern Matcher, realizing these modules is challenging. For instance, using traditional NFA-based search algorithms for the MSPM, given our public ruleset, would require 23MB – more than our 16MB BRAM capacity. Similarly, statically allocating 10KB of out-of-order buffer (*i.e.*, 10 packets) per flow for even 10K flows easily exceeds 100MB. Thus, in §4 and §5, we describe our design optimizations to ensure that the Reassembler and MSPM both 'fit' on-board without compromising performance.

3.4 Threat Model

Pigatus sits between an attacker and its intended target; an attacker may attempt to target Pigatus itself in order to indirectly damage the services Pigatus protects. We assume the attacker does not have physical access to the server running Pigatus, that the operating system and configuration tools for Pigatus are secure, and that the attacker cannot modify Pigatus' configuration. The attacker *may* inject arbitrary traffic into the input stream which Pigatus processes. In this context, we consider two classes of attacks. First, an attacker may attempt to *bypass* Pigatus – that is, send traffic which matches an IDS/IPS rule, but somehow 'trick' Pigatus into allowing it through – *e.g.*, by reordering packets, sending duplicate packets, etc. Snort 3.0 employs numerous approaches to address these types of attacks (*e.g.*, timeouts and memory limits) which are straightforward for Pigatus to replicate. Second, an attacker may attempt to *slow down* Pigatus – sending out-of-order or very small packets to reduce Pigatus' effective throughput and hopefully stall or drop innocent traffic. These classes of attacks can always be overcome by 'scaling on demand' – *i.e.*, running more instances – but we set an additional goal of Pigatus being *at least as robust* as Snort 3.0.

4 Reassembly

Reassembly refers to the process of reconstructing a TCP bytestream in the presence of packet fragmentation, loss, and out-of-order delivery. Reassembly is necessary in Pigatus because the MSPM and Full Matcher must detect patterns (strings or regular expressions) that may span across more than one packet (*e.g.*, searching for the word 'attack' should

²FPGA manufacturers have been experimenting with varied classes of memory on-board the FPGA over the past few years. From the manufacturers' perspective, Pigatus can be seen as a success story for how varied memory enables more diverse applications which tailor their memory usage to per-task and data structure demands.

³We do use BRAM in some other places for internal buffers/queues.

not fail just because ‘att’ appears at the end of packet n and ‘ack’ appears at the beginning of packet $n + 1$). Note that our goal is not a full TCP endpoint and hence we are not responsible, *e.g.*, for producing ACKs; the IDS/IPS is a passive observer of traffic between two existing endpoints, merely re-ordering the packets it observes for analysis. The key objective of our Reassembler is to perform this re-ordering for 100K’s of flows, while operating at 100Gbps, *within the memory limitations* of our FPGA.

4.1 Design Space for TCP Reassembly

Hardware design often favors data structures that are *fixed-length*, *constant-time* and generally *deterministic*, and most TCP reassembly designs follow suit. For instance, [49] allocates a fixed 64KB packet buffer in DRAM and uses 7 pairs of pointers to track OOO state for each flow; similarly, [42] maps a fixed-sized ‘segment array’ in DRAM to track per-flow state. By using static buffers, these designs are guaranteed constant-time insertion of out-of-order packets into memory; furthermore, the memory consumed by any individual flow is fixed so freeing space is also deterministic. In addition, each flow is bounded in its resource consumption and so a highly out-of-order flow cannot take over the available address space, starving other flows.

The problem with these designs is that, by allocating a fixed buffer, they both *waste memory* and *limit out-of-order flows*. For example, allocating 64KB for *each and every flow* [42] would require 6.4GB to support 100K flows – orders of magnitude bigger than our BRAM capacity. Even worse, the vast majority of flows *don’t need the space* most of the time because *most packets arrive in order*. On the other hand, flows which do suffer a burst of out-of-order packets (perhaps due to network loss) that exceeds the 64KB capacity cannot be served, even if there is memory available.

For software developers, the obvious response to these challenges is to use a more memory-dense data-structure such as a linked-list, where each arriving segment is allocated on-demand and inserted into the list in order. Because memory is allocated on demand, no memory is wasted, and those flows which need more capacity are able to consume more as available. In our empirical traces, 0.3% of packets arrive out of order, with ‘holes’ in the TCP bytestream typically filled in after 3 packet arrivals from the same flow. In a linked-list based design, this means that on average an out-of-order flow consumes 5K bytes at most.

From a hardware perspective, however, a linked list is an unorthodox choice: pipeline parallelism depends on each stage of the pipeline taking a fixed amount of time. Since linked lists have variable insertion times, depending upon how far into the list a segment must be inserted, linked lists can lead to pipeline stalls which result in non-work-conserving behavior upstream from the slow pipeline stage, and hence overall poor throughput. We find that by carefully designing the reassembly pipeline as a combination of a *fast path* (only

Figure 5: Reassembly Pipeline.

handling in-order flows) and a *slow path* (that handles the remaining out-of-order flows), one can achieve the best of both worlds.

4.2 Pigasus TCP Reassembler

Pigasus takes the linked list approach, targeting a more memory efficient design. However, to avoid pipeline stalls due to variable-time packet insertions, Pigasus uses *three execution engines* to manage reassembly state, each of which handles a different class of incoming packet headers. The *Fast Path* processes in-order packets for established flows; the *Insertion Engine* handles SYN packets for new flows; and the *OOO Engine* handles out-of-order packets for existing flows. Because Pigasus is implemented in hardware, these engines can all run simultaneously (on different packet headers) without stalling each other, but must be careful not to conflict in accessing shared state in the Reassembly Flow Table. The flowchart in Figure 5 describes the sequence of steps that occur when a packet header arrives at the Reassembler.

The Flow Table, in representation, is a hash table mapping the classic flow 5-tuple identifier to a table containing (a) the *next expected sequence number* for an in-order packet, and (b) the *head* node for a linked list containing the headers of *out-of-order* packets waiting for a ‘hole’ in the TCP sequence number space to be filled. We discuss how the Flow Table is implemented in §4.3.

Fast Path: Upon arrival from the parser, each packet header is picked up by the Fast Path which looks up the flow’s entry in the Flow Table. If no entry exists for that flow, the Fast Path pushes the packet header on to a queue for the Insertion Engine and moves on to the next packet. If there exists an entry for that flow, but (a) the packet header does not match the next expected sequence number in the Flow Table, or (b) the *head* node in the flow table is not null, the Fast Path pushes the packet header on to a queue for the OOO Engine. Finally, if the packet header *does* match the next expected sequence number in the flow, the Fast Path updates the expected sequence number in the Flow Table to the sequence number for the subsequent packet in the flow and pushes the current packet out towards the MSPM. Every task on the Fast Path runs in constant time, and so throughput is guaranteed through this engine to be 25 Million packets-per-second, which amounts to at least 100Gbps so long the average packet size is greater than 500B (Internet traces typically have an average packet

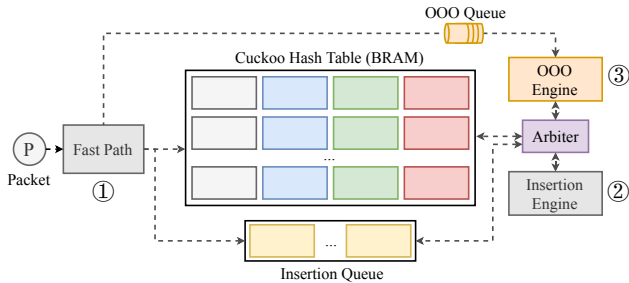

Figure 6: Flow Table and OOO Engine.

size of more than 800B [15]).

OOO Engine: The OOO Engine does not run in constant time, instead dequeuing packets provided for it from the Fast Path as it finishes operating over the previous packet.⁴ For each dequeued packet, the OOO engine allocates a new node representing the packet’s starting and ending sequence numbers, traverses the linked list for that flow, and inserts the newly-allocated node at the appropriate location. If the packet fills the first sequence number ‘hole’ in the linked list, then the OOO Engine removes the now-in-order packet headers from the list, releases them to the MSPM, and also updates the Flow Table entry with the new linked list head and next expected sequence number. If the OOO Engine detects that BRAM capacity for OOO flows exceeds 90% of its maximum capacity, it drops the flow with the longest linked list.

Insertion Engine: The Insertion Engine inserts new flow entries into the Flow Table; like the OOO Engine this path too can take variable time. We discuss the insertion engine in more detail in the next subsection.

Overall, allocating memory on-demand avoids memory wastage, and enables Pigasus to better serve OOO flows that do have a higher memory requirement. Additionally, bifurcating the reassembly pipeline into *fast* and *slow* paths prevents out-of-order flows – which require non-deterministic amounts of time to be served in our design – from impacting the performance of in-order flows, which represent the common case.

4.3 Implementing the Flow Table

While the Fast Path, Insertion Engine, and OOO Engine all operate simultaneously, they must synchronize over shared flow state (for instance, to keep the next expected sequence number for each flow consistent). We briefly discuss the implementation of our Flow Table that provides fast and safe concurrent access to these three engines.

The flow table design borrows a key data-structure from FlowBlaze [36]: an FPGA-based hash table that employs deamortized cuckoo hashing [8, 28]. We illustrate this data structure in Figure 6. The design provides high memory

⁴Experimentally, we actually observe that this slow path is mostly idle when running over our traces, as most packets arrive in order or mostly in-order. We artificially stress this path to overload in our evaluation, but doing so requires an extreme rate of packet loss.

density (up to 97% occupancy using 4 or more sub-tables [8, 28, 36]), and worst-case constant-time reads, writes, and deletions for existing entries. It also guarantees that, for an Insertion Queue whose size is logarithmic in the number of flow table entries (in practice, a small value), the queue will not overflow [8]. We implement the hash table using dual-port BRAM, and the Insertion Queue using a parallel shift-register (capable of storing 8 elements).

The key to maintaining the hash table’s deamortization property is the Insertion Engine, which is responsible for inserting: (a) new flows, and (b) flows that were previously evicted from the hash table during a ‘cuckoo’ step. Effectively, the Insertion Engine dequeues an element from the front of the Insertion Queue, and attempts to insert it into the hash table. If at least one of the 4 corresponding hash table entries is unoccupied, it simply updates the flow table and proceeds to the next queued element; otherwise, it *evicts* one of the 4 flow table entries at random, pushes the evicted entry onto the queue, and inserts the dequeued element in its place.

To guarantee conflict-free flow table access, we have the following prioritization of operations to the table. First, note that the Fast Path and OOO Engine never conflict over the same entry – the flow is either in order or not. The Insertion Engine *can* conflict with both the Fast Path and OOO Engine, as it may try to ‘cuckoo’ entries. Hence, we enforce the following priorities: (1) Fast Path > Insertion Engine (to ensure deterministic performance on the Fast Path), and (2) Insertion Engine > OOO Engine (to ensure that the queue drains and since, empirically, the OOO path is underutilized). Since our BRAM is dual-ported, we allow the Fast Path direct access to the Flow Table, while accesses originating from the OOO Engine or Insertion Engine are managed by an arbiter that enforces the aforementioned priority scheme.

4.4 Worst-Case Performance

Since Pigasus serves on the front-lines of network defenses, it is a prime target for Denial-of-Service (DoS) attacks. Most of Pigasus’ underlying components are, by design, fully pipelined, enabling packet data to ‘stream through’ without ever stalling the system. However, this is not the case for the OOO path in the TCP reassembler. While all *in-order* packets are guaranteed full throughput, an attacker could potentially slow down the OOO path by injecting out-of-order flows into the system.

The key question is how this out of order traffic will impact ‘normal’ or ‘innocent’ TCP connections. We observe in our traces that 0.3% of packet arrivals from innocent connections arrive out of order, hence 99.7% of innocent traffic will ‘stream through’ the fast path, unimpacted by slowdowns on the OOO path. But, worst-case slowdowns on the OOO path *can* stall innocent traffic behind lengthy linked-list traversals due to a malicious sender.

Using mathematical models (elided for space), we quantify the performance of our system in terms of the *goodput*, or the

packet rate (in Gbps) corresponding to ‘innocent’ traffic that the system can sustain in steady state. Then, the attacker’s objective is to inject adversarial traffic on the ingress link so as to minimize the achieved goodput.

Starting with a 100Gbps ingress link, we characterize the adversarial scenario using two parameters: the fraction of input traffic that is adversarial, a , and the fraction of non-adversarial input traffic that is in-order, t . Table 1 depicts the expected goodput for different values of a and t (using an average packet size of 500B for innocent traffic) according to the model. Ideally, all innocent traffic would traverse the system unhindered, but we see that slowdowns on the OOO path *can* make Pigasus fall short of this goal – especially at high rates of attack traffic injection – but that the OOO path is not entirely stalled and out of order packets do, eventually, make it through the system.

		In-order Traffic% (t)			Ideal
		99.7%	99.0%	90%	
Attack Traffic Rate (a)	10Mbps	99.7	99.1	91.5	99.99
	100Mbps	99.6	98.9	90.1	99.9
	1Gbps	98.7	98.0	89.1	99
	10Gbps	89.7	89.1	81.0	90

Table 1: Total Goodput (in Gbps) for various combinations of the attack traffic rate and fraction of in-order traffic. In-order traffic is isolated from slowdown, even when an adversary introduces substantial out-of-order flows.

5 Multi-String Pattern Matching

Checking tens of thousands of string patterns against a 100 Gbps bytestream makes the multi-string pattern matcher (MSPM) module by far the most operation-intensive and performance critical component in Pigasus.

Role of MSPM in IDS/IPS: As explained in Section 2, a Snort signature/rule comprises three classes of patterns: a *header match*, a set of *exact match strings*, and a set of *regular expressions*. A packet triggers the rule iff *all* patterns are identified.

To avoid checking every single pattern for every index and every packet, rulesets are designed for a two-step matching process. In Snort, the MSPM is responsible for checking *header matches* and *one, highly-selective exact match string*, called the *fast pattern*. Only packets which both match the header match and the fast pattern are forwarded to the *full matcher* which checks regular expressions and any secondary exact match strings (referred to as non-fast pattern strings). Pigasus’ MSPM checks for fast patterns, headers, and non-fast patterns, reducing the load on the CPU-side full matcher.

MSPM Design Landscape: To the best of our knowledge, there are other no hardware or software projects reporting multi-string matching of tens thousands of strings at 100 Gbps. Classically implemented with parallel NFAs, the best

Figure 7: MSPM in Snort 3.0. Every String Matcher selected by the Port Group Module is evaluated sequentially.

hardware-based string matcher that we know of [16] would require 23MB of BRAM to represent the exact match search strings alone (ignoring the additional header matches).

To attain a more efficient design, we instead look to *software* and Intel’s Hyperscan algorithm for string matching, which is AVX parallelizable and provided an $8\times$ speedup compared to state-machine based string matchers in software [47]. Although naïvely re-implementing Hyperscan on the FPGA is in fact more memory intensive than the NFA approach (requiring 25MB to sustain 100Gbps), we find that by re-architecting Hyperscan’s hash table-based design, we can reduce this memory footprint to only 2MB, leaving memory to spare and *expand* on the Hyperscan approach to search for *all* strings (rather than a fast-pattern only) for a total memory budget of 3.3MB. The key idea is to arrange hash table filters hierarchically, with *low memory* filters placed early in the pipeline with a *high replication factor*; this filters out a majority of traffic early. Subsequent stages of the MSPM may be more memory-intensive, per-module, but each stage handles less and less traffic and hence requires less replication.

In what follows, we first describe Hyperscan’s two-stage MSPM, which checks for header matches and fast patterns. We then describe Pigasus’ three-stage MSPM, which checks for fast patterns, header matches, and non-fast pattern strings using highly parallel, hierarchical filters to improve memory density.

5.1 MSPM in Software

Snort 3.0 + Hyperscan: In Snort 3.0, the MSPM is implemented using Intel’s Hyperscan, illustrated in Figure 7.

Packets are first checked for their *header match*. Across all 10K rules, there are only ≈ 400 *unique* header match values. Rules which share the same header match fields are said to belong to the same *port group*. The port group module outputs a set of *port group IDs* which the packet matches; this output set is never empty because some rules wildcard their header match and hence match all packets. An average packet matches 2 port groups.

Packets are then checked for their *fast pattern string match*. For each port group, there exists a *string matcher* which checks fast patterns for all rules within that port group. Snort must check every string matcher for each port group the packet matches.

Within the string matcher, Snort must iterate over every index of the payload checking whether it matches any of the fast patterns in the port group. Rather than using a state machine

to do this, Hyperscan uses a collection of hash tables. For each possible fast pattern length⁵ a hash table is instantiated containing the fast patterns of that length. Hyperscan then performs an exact-match lookup for all substrings at each index, looking up whether or not the substring is in the hash table – potentially $(8 \times l)$ lookups for a packet of length l .

To reduce the number of expensive sequential lookups, each string matcher contains a SIMD-optimized *shift-or filter* [9] prior to the hash table; this filter outputs either a ‘0’ or ‘1’ for every byte index of the packet, indicating whether or not that index matches *any* fast pattern in the hash tables; indices which result in a ‘0’ output from the shift-or stage need not be checked.

The string matcher – combining shift-or and hash tables – then outputs a set of *rules* which the packet matched both in terms of *header* and *fast pattern*; together, the packet and the potential rule matches are passed to the full matcher. However, for 89% of packets, this stage outputs the empty set and the packet bypasses the full match stage entirely.

5.2 MSPM in Pigasus

A straightforward port of the Snort 3.0 MSPM engines and data structures onto the FPGA consumes 785KB of memory and forwards at a rate of 3.2Gbps. Taking advantage of the high degree of parallelism offered by the FPGA, one could, in theory, scale to 100Gbps via *data parallelism*, i.e., replicating this 32 times. Unfortunately, doing so would require 25MB of BRAM. We now describe how Pigasus re-architects the Hyperscan algorithm to achieve this high degree of parallelism within available resources. Since this results in leftover memory, we can then *extend* Pigasus’ MSPM to scan for non-fast pattern strings as well.

As shown in Figure 8, Pigasus flips the order of Hyperscan’s MSPM, starting with string matching before moving on to header matching and port grouping.

Fast Pattern String Matching (FPSM): To perform string matching, Pigasus (like Hyperscan) also has a *filtering* stage in which packets traverse two parallel filters: a shift-or (borrowed from Hyperscan) and a set of per-fast-pattern-length hash tables. We check the shift-or and (32×8) hash tables in parallel. Hash tables only store 1-bit values indicating whether a given (index, length) tuple results in a match – but it does not store the 16-bit rule ID. The output from the filters is ANDed together, reducing *false positives* from either filter alone by $5 \times$.

The shift-or and 1-bit hash table⁶ consume only 65KB and 25KB respectively, thus they are relatively *cheap* to replicate $32 \times$ over in order to scale to 100Gbps. In theory, these filters can generate (32×8) matches per cycle (i.e., 8 matches per filter); however, in the common case, most packets and

most indices *do not match any rules*, and therefore require *no further processing*.⁷ This gives us the opportunity to make subsequent pipeline stages narrower. We design a ‘Rule Reduction’ module that selects non-zero rule matches from the filter’s 256-bit wide vector output and narrows it down to 8 values.

Applying this filter first allows us to use fewer replicas of subsequent data structures (which are larger and more expensive), since most bytestream indices have already been filtered out by the string matcher. This enables high (effective) parallelism with a lower memory overhead.

Header Matching: In this stage, we use the packet header data to determine whether the matches produced by the previous (FPSM) stage are consistent with the corresponding rule’s Port Group. At this point, we only need to create 8 replicas of the 17KB Rule Table and 68KB Port Grouping modules to check 8 rules simultaneously.

Using the (index, length) tuple that resulted in a match in the FPSM stage, we look up the corresponding rule ID in the Rule Table. Next, using this rule ID, we look up the Port Group that this rule maps to; this could be a *single* port, a *list* or *range* of ports, or a *wildcard* (indicating a match on any port). If this packet’s port number is a subset of this rule’s Port Group, the rule is considered a match; otherwise, the rule is ignored.

Our initial design of the MSPM stopped here (at the Traffic Manager 1 stage in Figure 8), aiming merely to reproduce Snort’s functionality, which only scans for fast patterns and headers. Packets which matched the fast pattern and header on at least one rule were sent to the CPU for processing. While packets which did not produce any matches at either the FPSM or Header Matching stage were simply streamed to the output interface.

This resulted in a design that sent 11% of packets to the CPU for processing, with an average of 4.4 rules searched per packet – and required only 2MB of memory! Given that this amounted to a fraction of our resource budget for the MSPM, we asked ourselves: can we do more?

Non-Fast Pattern String Matching (NFPSM): Pigasus further filters down the packets and rules destined for the CPU to only 5% of packets, with just 1.1 rules/packet (on average), by additionally searching for *all* string matches within a rule on the board. Note that, on average, only 11% of packets reach the Non-Fast Pattern Matcher, and, by this point, we know which rules (on average 4.4 of them) the packet might match on. Naïvely, one might iteratively search for each string in the ≈ 4.4 rules, but because each packet has a variable number of rules and each rule has a variable number of strings (between 1 and 32), this approach would likely lead to low throughput and/or pipeline stalls.

Instead, Pigasus once again uses a set of hash tables (like in the FPSM) to search for all strings simultaneously. It then

⁵Up to 8 bytes – longer fast patterns are truncated.

⁶Subtly, this is not a true Bloom filter [13] because we only perform one hash per input; implementing multiple hashes increases resource utilization and complexity, we find, with little gain.

⁷Note that our filters never produce false negatives.

Figure 8: Pigasus' MSPM, which requires a total of 3.3MB of BRAM.

creates a compact, bloom-filter-like representation ('fingerprint') of the matched strings. To compute the fingerprint, we first represent the set of (index, length) tuples generated by the 8 NFPSM hash tables as a 16-bit vector by setting $bit[index \bmod 16]$ to '1' for each length bucket. Next, for each bucket, all of the 16-bit vectors generated for a given packet are ORed together to create a 16-bit 'sub-fingerprint' for that bucket. Finally, these sub-fingerprints are concatenated into a 128-bit fingerprint representing the entire packet. The fingerprinting process is illustrated below:

Figure 9: Rule matching fingerprints in the NFPSM.

The NFPSM can now look up a corresponding fingerprint – generated in the same way – for each of the ≈ 4.4 rules, and now can do a parallel set comparison between the two fingerprints. If, for every bit in the *rule's fingerprint*, the corresponding bit in the *packet's fingerprint* is also set, there is high probability that all of the exact match strings for the rule were matched. But, if any of the corresponding bits are *not* set, we can be certain that at least one of the non-fast pattern strings were not matched, thus eliminating the rule as a potential match. The 5% of packets which match at least one rule fingerprint are forwarded to the CPU; the remainder are released as non-matching and therefore innocent packets.

It is worth noting that, as the last stage of our hierarchical filtering, the non-fast pattern matcher has the lowest throughput capacity. This saves on resources, but can make the NFPSM vulnerable to overload. Where the fast pattern matcher is designed to process up to 100Gbps of incoming data, the non-

fast pattern matcher tops out at a peak throughput of 50Gbps. 50Gbps is more than enough to handle the average rate of 11Gbps, but a spike of rule-matching malicious traffic can at times overload the non-fast pattern matcher. In this case, when the first traffic manager (between the header matcher and the non-fast pattern matcher) detects *backpressure* from the NFSM, it steers some packets directly to the CPU for checking. Temporarily increasing the load on software, where it is easier to 'scale out' and provision additional resources.

End-to-End: By hierarchically filtering out packets, the MSPM reduces the amount of traffic traversing each subsequent stage of the MSPM. This means that the earliest stages require high levels of replication, but the latter stages can, on average expect lower throughput and hence require less replication. Consequently, latter stages require lower memory consumption. End-to-end, the MSPM requires 3.3MB of memory, fitting well within our BRAM bounds while doing *more* filtering than what a naïve port of the Hyperscan algorithm would be capable of. Nonetheless, the reduced capacity of the MSPM in the latter phases of the MSPM does make these components vulnerable to overload; in these cases Pigasus temporarily shunts additional traffic to CPUs, where it is easier to provision on demand and as needed.

6 Evaluation

In this section, we evaluate Pigasus and show that:

- Pigasus is at least an order of magnitude more efficient than state-of-art Snort running in software: using 23 – 200× fewer cores, and 18 – 62× less power;
- Pigasus' performance gains are resilient to a variety of factors such as small packets, out-of-order arrivals, and the rule-match profile of the traffic;
- The Pigasus architecture actually has resource headroom, suggesting a roadmap for handling even more complicated workloads.

We start by describing the evaluation setup we use for the rest of the section before the detailed results.

Table 2: Resource breakdown. Percentages are relative to the total amount of resources in a Stratix 10 MX FPGA.

6.1 Setup

Implementation and Resource Breakdown: We implement Pigasus using an Intel Stratix 10 MX FPGA Development card [2] as the SmartNIC in a 16-core (Intel i9-9960X @ 3.1 GHz) host machine. The Stratix 10 MX FPGA has 16MB of on-chip BRAM, 10MB of eSRAM, and 8GB of off-chip DRAM. Table 2 shows the FPGA resources used by each component of Pigasus when configuring it to support 100K flows and 10K rules. To implement Pigasus’ CPU/software components, we adapt Snort 3 to allow it to receive reconstructed PDUs and rule IDs, coming from the FPGA directly into its Full Matcher. We run Snort 3 software experiments in an Intel i7-4790 CPU @ 3.60 GHz.

Traffic Generator: We installed both DPDK Pktgen [1] and Moongen [20] on a separate 4-core (Intel i7-4790 @ 3.6 GHz) machine with a 100Gbps Mellanox ConnectX-5 EN network adapter. DPDK Pktgen achieves higher throughput when replaying PCAP traces – up to 90Gbps – and hence we use the DPDK Packet Generator when running experiments with recorded traces. Moongen is better at generating synthetic traffic at runtime and can do so at up to the full 100Gbps offered by the underlying network. We specify in each experiment which traffic generator was used.

Traces and Ruleset: We test Snort and Pigasus both using the publicly available Snort Registered Ruleset (snapshot-29141) [6] and different traces from Stratosphere [44]: *CTU-Mixed-Capture-1–5*, *CTU-Normal-12*, and *CTU-Normal-7*. We refer to them as *mix-1–5*, *norm-1*, and *norm-2*, respectively. For the *mixed* traces, we use the **before.infection* pcaps. We use Stratosphere traces because their packet captures contain the original payloads, which is essential when evaluating IDSes.

Measuring Throughput and Latency: We measure throughput in two ways: 1. The *Zero Loss* throughput is measured by gradually increasing the packet generator’s transmission rate until the system (Snort or Pigasus) first starts dropping packets; 2. The *Average* throughput is computed as the ratio of the cumulative size of packets in the trace (in bits) to the total time required to process the trace. We measure latency (at low load) using DPDK Pktgen’s built-in latency measurement routine. Unfortunately, DPDK embeds timestamps in the packet body, which never triggers the CPU-

Figure 10: Number of cores required to process each trace at 100Gbps using Pigasus (FPGA + CPUs) and Snort (traditional CPUs alone). Pigasus numbers are based on implementation; Snort numbers are extrapolated from its single-core throughput and assume perfect linear scaling.

side Full Matching functionality. Instead, we measure the end-to-end latency for Pigasus on an empirical trace using FPGA-side counters, and then adding the baseline FPGA loopback latency to it.

6.2 End-to-end performance and costs

In this section, we compare the performance, power, and cost of Pigasus vs. legacy Snort.

Provisioning for 100Gbps throughput: Figure 10 reports the number of server cores required to achieve 100Gbps for the evaluated Stratosphere traces for different settings. The top half is under the assumption of loss-free processing without buffering, while the bottom reports the steady-state core requirements based on the assumption that we could buffer packets during the peak periods and defer the full matching to allow the cores to catch up after the peak has passed.

The Pigasus results are based on experiments where the system is tested at increasing number of cores at maximum throughput, until we observe no packet loss. For the Snort experiments we run Snort in both IDS and IPS mode (with DPDK) on a single core and increase the throughput until it begins to drop packets. Note that while we report the actual number of cores required to run Pigasus, for Snort we extrapolate the single-core experiment to determine the number of cores that we would need to keep up with 100Gbps. This considers that Snort’s throughput scales linearly with the number of cores and, therefore, represents an ideal *lower bound* to the actual number of cores needed to run Snort. Overall, we see that Snort in IDS mode requires 23 – 185× more cores than Pigasus (65× on average), and in IPS mode requires 23 – 200× more cores (72× on average).

Latency: Of course, in a practical IPS we care not only about throughput/provisioning but also per-packet latency. We plot the distribution of per-packet latency in Figure 11. We find

Figure 11: CDF of latency of Pigasus vs. Snort.

that Pigasus yields almost an order of magnitude improvement in the median latency, and up to $3\times$ improvement in the tail latency. As a point of comparison, we also show the baseline performance of a simple FPGA loopback measurement (*i.e.*, without any processing) and the Pigasus fast-path for packets that do not need further CPU processing. We find that the Pigasus fast path is very efficient and almost comparable to the baseline. We also find that Pigasus end-to-end latency only deviates substantially from the fast path for the tail. While we hypothesized some improvements in latency, we were puzzled by the magnitude of the improvement. Investigating why Snort was much slower revealed that on average, while Pigasus reduced the latency for the Reassembly (by $6\mu s$), Parser (by $4\mu s$), and the MSPM (by $3\mu s$) as expected relative to software, the additional reduction came from avoiding Packet I/O overhead in software (around $5\mu s$).

Power footprint: Figure 12 depicts the estimated power consumption required to achieve 100Gbps throughput for three configurations: Snort in IDS mode, Snort in IPS mode, and Pigasus in IPS mode. On the CPU side, we use Intel’s Running Average Power Limit (RAPL) interface [23] to measure per-core power consumption in steady-state. To verify its accuracy we also measured the power utilization using an electricity usage monitor [4] and found consistent results. On the FPGA side, we use the Board Test System [2] (part of Intel’s FPGA Development Kit) to measure power dissipation in the FPGA core and I/O shell. We observe that, across all traces, Snort (in *either* mode) has a $13 - 59\times$ higher power consumption than Pigasus ($34\times$ on average). We further note that the reported wattages for Pigasus represent a conservative estimate; while the total power consumption on the FPGA side is 40W, the core fabric accounts for just 13W, and the remainder is used for I/O (including Ethernet). Conversely, we only charge Snort for power consumed during compute tasks, ignoring other overages (such as Network I/O).

Cost: To estimate the Total Cost of Ownership (TCO), we consider both the capital investment and the power cost for each configuration. To estimate the capital investment, we use the per-core pricing data for the AMD EPYC 7452 CPU (\$68.75 per core). For Pigasus, we also incorporate the market price of an Stratix 10 MX FPGA [2] (\$10K). Assuming

Figure 12: Estimated wattage to achieve 100Gbps.

that the number of cores needed in practice is between the *Zero Loss* and *Average* in Figure 10, we estimate that the capital cost of the CPU-only solution is between \$7,922 and \$25,045, while the capital cost of Pigasus is between \$10,189 and \$10,344. To estimate the power costs we assume a lifetime of 3 years and electricity cost at \$0.1334/kWh (average electricity rate in the US [3]). The power cost of the CPU-only solution at 9W/core is between \$3,636 and \$11,494, while the cost for Pigasus is between \$227 and \$298. Then, combining the capital investment and the power cost, the TCO of the CPU-only solution is between \$11,558 and \$36,539, while the TCO of Pigasus is between \$10,416 and \$10,642, saving between \$1,142 and \$25,897. We note that these estimates consider retail prices and do not account for other operational costs, such as cooling and rack space, which we expect to favor Pigasus. Moreover, for 100K flows and 10K rules we only use about half of a Stratix 10 MX; one may consider adapting the design to a smaller FPGA, further reducing the cost of Pigasus.

Recall that our original goal was to achieve 100Gbps supporting hundreds of thousands of flows matching tens of thousands of rules on a single server with a reasonable cost/resource footprint. The above results suggest that Pigasus indeed achieves this goal (with ample headroom).

6.3 Microbenchmarks and sensitivity analysis

In this section, we present Pigasus’ performance sensitivity to traffic characteristics. We probe deeper into Pigasus’ performance under differing levels of malicious traffic. We further characterize the performance impact of *packet size*, and *out-of-order degree* of flows.

Dependence on CPU Offload: We construct semi-synthetic traffic traces by mixing malicious flows extracted from *mix-1* trace with innocent trace *norm-2* in different proportions.⁸ Figure 13 (a) depicts the dependence of zero-loss throughput on the fraction of malicious flows (in terms of relative packet count). We report results for Pigasus (using both 1 and

⁸Note that not every packet in a malicious flow triggers a match.

(a) Zero-loss throughput.

(b) Number of cores required to achieve 100Gbps.

Figure 13: Impact of the fraction of malicious traffic on system throughput.

16 cores) and Snort IPS (with 1 core). We observe that, as long as the fraction of malicious traffic is smaller than 15%, Pigasus is able to process packets at line-rate using a single CPU core. With 16 cores Pigasus can process packets at line rate for up to 50% of malicious traffic. After the 50% mark, performance begins to degrade gradually. We repeated the same experiments disabling the software component of Pigasus and observed that the throughput matches the 16-core experiment, suggesting that the hardware is the bottleneck. More specifically, the MSPM’s rule reduction logic is stressed by the large number of potential rule matches.

Figure 13 (b) depicts the number of cores required to achieve 100Gbps as a function of the fraction of packets from malicious flows for up to 50%. Results for Snort are extrapolated from the single-core throughput. Despite the performance degradation observed in (a), Pigasus scales considerably better than Snort, requiring two orders of magnitude fewer cores. We also note that, while the hardware only becomes the bottleneck at an extreme fraction of malicious traffic, the design can be made even more robust using two hardware pipelines (discussed further in §6.4).

Dependence on Packet Size: We first consider the impact of packet size on Pigasus’ performance stemming from the linked-list based TCP reassembler design. We configure the Moongen packet-generator to generate fixed-sized synthetic packets, and measure end-to-end, zero-loss throughput as we vary the packet size. Figure 14 illustrates this dependence. We observe that, for packets exceeding 500B (comparable to average packet sizes on the Internet [15]), Pigasus is capable of processing at line rate. (More generally, Pigasus by design

Figure 14: Zero-loss throughput achieved by Pigasus for a range of packet sizes.

Figure 15: Zero-loss throughput achieved by Pigasus for a range of Loss Probabilities (lp) and Recovery Distances (rd).

can sustain 100Gbps as long as the average packet size is greater than 500B over a window of $87\mu s$ estimated base on buffer size.)

Dependence on Out of Order Degree: We characterize the OOO degree using randomly generated synthetic packet traces controlled by two independent variables: the packet loss probability (lp) [32] and the recovery distance (rd).⁹ Figure 15 depicts the impact of these parameters on Pigasus’ end-to-end, zero-loss throughput. We sweep the loss probability from 0.3% to 30%, and the recovery distance from 3 to 100. At typical values ($lp = 0.3\%$, $rd = 3$), Pigasus achieves a single-core throughput of 100Gbps, which degrades gradually with increasing packet loss and recovery distance. It is worthwhile to note that, at typical packet loss rates, the Re-assembler can handle around 50 OOO packet arrivals without any degradation in end-to-end throughput.

6.4 Future outlook

Supporting 100Gbps with 100K flows and 10K rules requires only about half of the resources in our FPGA. We now explore what we can do with the additional capacity.

One option is to duplicate the existing processing pipeline (which runs at 100Gbps/25Mpps) each to serve a different subset of flows, increasing the throughput to 200Gbps, at the cost of creating additional copies of all the MSPM engines. Another option is to increase the number of supported flows

⁹Recovery distance is defined as the number of same-flow packets that arrive before a hole created by a lost packet is filled. In Pigasus, this value determines the amount of work (in cycles) that the OOO Engine must perform for each packet that arrives out of order.

Figure 16: Tradeoff between the number of supported rules and concurrent flows when using one or two 100Gbps hardware pipelines.

or rules. Figure 16 depicts the three-way tradeoff between the scalability of the number of rules, concurrent flows, and replicated hardware pipelines. The design with two pipelines benefit from better throughput but have fewer room for storing rules or flows. There is plenty of scaling headroom in the Pigasus FPGA frontend design for more rules and flows.

7 Related Work

We now review some of the most related work, some of which served as inspiration for Pigasus.

Pattern matching: The design of the hash table filter in our Multi-String Pattern Matcher is similar to the filters used by DFC [17] and Hyperscan [47]. An important difference, however, is that instead of using a second hash table to associate potential string patterns with their identifiers, we directly use the matched index as a pattern identifier. This helps to reduce the amount of resources required by the hardware implementation. We also employ fewer, but much larger filters, since cache-friendliness is not a concern for FPGA design.

Using FPGAs to accelerate IDS/IPS: Many previous work have also made a case for using FPGAs to implement network functionality [21, 30, 33, 36, 45]. ClickNP [30] and Flow-Blaze [36] present abstractions for making it easier to implement network functionality in FPGAs. However, they do not provide the necessary abstractions for searching bytestream nor they would be able to scale to meet our goals for throughput and number of rules. Some propose using FPGAs to accelerate IDS/IPS [10, 16, 18, 19, 34, 43, 46, 49]. However, all of these works do not implement a complete IDS/IPS and fail to meet our target for throughput or number of rules. Even though, Snort Offloader [43] proposes using an FPGA to implement an entire IDS/IPS, it only supports very simple operations, not including components that are essential for correct IPS operation, *e.g.*, TCP reassembly.

Other accelerators: Other works have looked at using hardware accelerators to improve some IDS/IPS components. Kargus [25] uses GPUs to accelerate exact-pattern and regular-expression matching. However, their use of GPUs contributes

to increasing both power and latency. PPS [26] uses PISA switches to implement DFAs and accelerate arbitrary regular expressions. But are limited to only UDP and can only support a small number of string patterns. More important, however, we note that by only accelerating the latest IDS/IPS stages, these solutions are fundamentally limited in the throughput improvements they can achieve.

8 Conclusions

In many ways, IDS/IPS are one of the most stressful network workloads for both traditional software and hardware. As such, the gap between the workload demands and what was achievable on a single server always seemed elusive. The design of Pigasus is a singular proof point that a seemingly unattainable goal (100Gbps line rates for 100K+ flows matching 10K+ of complex rules) on a single server is well within our grasp. Looking forward, we believe that we can further unleash the potential benefits of FPGAs for this unique workload by further eliminating CPU bottlenecks and potentially moving additional functionality onto the FPGA. Given the future hardware roadmaps of FPGAs and SmartNICs, we believe that our insights and successes can more broadly inform in-network acceleration beyond IDS/IPS as well.

A Artifact Appendix

A.1 Abstract

Pigasus has a hardware component, that runs on an FPGA, and a software component which is adapted from Snort 3. The current version requires a host with a multi-core CPU and an Intel Stratix 10 MX FPGA (with 100 Gb Ethernet) [2]. Pigasus' artifacts are open source and publicly available.

We provide detailed instructions to reproduce Figure 10. This figure supports our main claim that Pigasus requires two-order of magnitude fewer cores than state-of-the-art Snort 3. In addition to the steps in this appendix and on the repository README, we also provide video archives that reproduce Figure 10 for both the Snort 3 Baseline¹⁰ and the Pigasus¹¹ experiments.

A.2 Artifact check-list

- **Algorithm:** Pigasus Multi-String Pattern Matcher.
- **Program:** Snort 3 [5] for baseline experiments; DPDK pkt-gen [1] and Moongen [20] to generate packets.
- **Compilation:** Intel Quartus Prime [24].
- **Data set:** Stratosphere Laboratory Datasets [44].
- **Run-time environment:** System running Linux with Snort 3 [5] software dependencies installed. Quartus 19.3 with Stratix 10 device support is required to load the bitstream to the FPGA.
- **Hardware:** Two servers, one with an Intel Stratix 10 MX FPGA [2] and another with a DPDK-compatible 100 Gb NIC. Power-measurement experiments require either a CPU with a power measurement interface (*e.g.*, RAPL [23]) or an external electricity usage monitor.
- **Execution:** Disable power optimizations in the BIOS, isolate cores from the Linux scheduler, and pin processes to cores.
- **Experiments:** Experiments are run manually with Pigasus on one machine and a packet generator on another.
- **Public link:** <https://github.com/cmu-snap/pigasus>
- **Code licenses:** 'BSD 3-Clause Clear License' for the hardware component and 'GNU General Public License v2.0' for the software component. Check the repository for details.

A.3 Description

How to access

To access the artifact, clone the repository from GitHub:

```
$ git clone https://github.com/cmu-snap/pigasus.git
```

This repository also includes a README with the most up-to-date instructions on how to install and extend Pigasus.

¹⁰https://figshare.com/articles/media/snort_baseline_mp4/12922160

¹¹<https://figshare.com/articles/media/pigasus/12922178>

Hardware dependencies

Pigasus requires a host with an Intel Stratix 10 MX FPGA [2]. This host should have PCIe Gen3 or greater and a slot with 16 lanes for the FPGA. Experiments require an extra host equipped with a DPDK-compatible 100 Gb NIC to be used as a packet generator. For the experiments, the two hosts are connected back to back. The power-measurement experiments require either a CPU with a power measurement interface (*e.g.*, RAPL [23]) or the use of an external electricity usage monitor.

Software dependencies

Pigasus' software component is adapted from Snort 3 [5] and inherits the same software dependencies. §A.4 provides instructions on how to install those. The provided implementation works on Linux only and was tested on Ubuntu 16.04 and 18.04. Experiments require the installation of vanilla Snort 3, for comparison, as well as DPDK pktgen and Moongen in the packet generator host. To be able to load the bitstream on the FPGA, an installation of Quartus 19.3 as well as the Stratix 10 device support are required.¹²

Data sets

To obtain the Stratosphere traces go to <https://www.stratosphereips.org/datasets-overview>.

A.4 Installation

These instructions assume that you already have the bitstream to be loaded on the FPGA. For instructions on how to synthesize the design, refer to the repository README.

Software Configuration

In a system running a fresh install of Ubuntu 18.04, with the Pigasus repository cloned to the home directory, start by setting the required environment variables and useful aliases by adding the following to your `.bashrc` or equivalent:

```
export pigasus_rep_dir=$HOME/pigasus
export pigasus_inst=$HOME/pigasus_install
export LD_LIBRARY_PATH=/usr/local/lib:${LD_LIBRARY_PATH}
export LUA_PATH="$pigasus_inst/include/snort/lua/?.lua;"

alias pigasus="taskset --cpu-list 0 $pigasus_inst/bin/snort"
alias sudo='sudo '
```

Make sure you apply these changes:

```
$ source ~/.bashrc
```

Then install the dependencies using the provided script:

```
$ cd $pigasus_rep_dir
$ ./install_deps.sh
```

Once the dependencies are installed, build Pigasus as follows:

```
$ cd $pigasus_rep_dir/software
$ ./configure_cmake.sh --prefix=$pigasus_inst
  --enable-pigasus --enable-tsc-clock
  --builddir=build_pigasus
```

¹²Both can be obtained at: <https://fpgasoftware.intel.com/19.3/>.

```
$ cd build_pigasus
$ make -j $(nproc) install
```

Hardware Configuration

To load the bitstream make sure the Quartus tools are in your path by setting the following environment variables in your `.bashrc` or equivalent:

```
# quartus_dir should point to the Quartus installation dir.
export quartus_dir=
export INTELFGAOCCLSDKROOT="$quartus_dir/19.3/hld"
export QUARTUS_ROOTDIR="$quartus_dir/19.3/quartus"
export QSYS_ROOTDIR="$quartus_dir/19.3/qsys/bin"
export IP_ROOTDIR="$quartus_dir/19.3/ip/"
export PATH=$quartus_dir/19.3/quartus/bin:$PATH
export PATH=$quartus_dir/19.3/modelsim_ase/linuxaloem:$PATH
export PATH=$quartus_dir/19.3/quartus/sopc_builder/bin:$PATH
```

Make sure you apply these changes:

```
$ source ~/.bashrc
```

A.5 Evaluation and expected result

In what follows, we describe how to run the experiments to reproduce Pigasus results from Figure 10. Before every experiment we reload the bitstream on the FPGA and reboot the server. This ensures that we always start from the same FPGA state:

```
$ cd $pigasus_rep_dir/pigasus/hardware/hw_test/
$ ./load_bitstream.sh
$ sudo reboot
```

Once the machine is back, to run the software component, first insert the kernel module:

```
$ cd $pigasus_rep_dir/software/src/pigasus/pcie/kernel/linux
$ sudo ./install
```

Then, run Pigasus, using the following command:

```
$ cd $pigasus_rep_dir/software/luar
$ sudo pigasus -c snort.lua --patterns ~/rule_list
```

The `snort.lua` uses the same syntax as in Snort 3, you should modify it to include the Snort Registered Rule Set [6]. In our experiments, we modified the rules to remove some features currently not supported by Pigasus, including `services`, `file_data` and `nocase`. We also use the same modified rules in the baseline experiment.

When Pigasus finishes the startup process it will stop printing logs to the screen. Once this happens, you can invoke the FPGA JTAG console to configure the FPGA internal state. To do so, open another terminal and enter:

```
$ cd $pigasus_rep_dir/hardware/hw_test/
$ ./run_console
% source path.tcl
```

If the last command produces an error, exit the JTAG console with `Ctrl+C` and rerun the last two commands. Once the last command runs successfully type the following commands to configure the buffer size, set the number of cores, and check the FPGA internal state:

```
% set_buf_size 262143
% set_core_num 1
% get_results
```

This last command should return all zeros as no packets have been sent yet.

Now that Pigasus is running and properly configured, we can start the packet generator on another machine. Here we assume that DPDK pktgen is properly configured on the other machine and has been started.

You can specify the rate to send packets, where 100 means 100% line rate. To ensure that DPDK pktgen will only send the trace once, specify the number of packets to match the trace size. The example pcap we are using is the `norm-2.pcap`, which has 456,709 packets. After setting these parameters, you can start sending packets.

```
Pktgen:/> set 0 count 456709
Pktgen:/> set 0 rate 100
Pktgen:/> str
```

Once the packet generator finishes sending packets, go back to the JTAG console on the other host and type the following:

```
% get_results
```

This should return 456,709 received packets and 456,709 processing packets. This means that Pigasus processed all the packets sent at max rate, without loss.

Now stop Pigasus by going back to the first terminal and typing `Ctrl+C`. It will print `rx_pkt`, which should match the `dma_pkt` reported by the FPGA in second terminal. This means that all packets sent from the FPGA to the CPU for full evaluation were processed.

A.6 Experiment customization

Experiments may be customized to use different rule sets and different packet traces. Pigasus design can also be changed to support a different number of concurrent flows or rules.

A.7 Artifact Evaluation Methodology

Submission, reviewing and badging methodology:

DORY: An Encrypted Search System with Distributed Trust

Emma Dauterman, Eric Feng, Ellen Luo, Raluca Ada Popa, and Ion Stoica

University of California, Berkeley

Abstract. Efficient, leakage-free search on encrypted data has remained an unsolved problem for the last two decades; efficient schemes are vulnerable to leakage-abuse attacks, and schemes that eliminate leakage are impractical to deploy. To overcome this tradeoff, we reexamine the system model. We surveyed five companies providing end-to-end encrypted filesharing to better understand what they require from an encrypted search system. Based on our findings, we design and build DORY, an encrypted search system that addresses real-world requirements and protects search access patterns; namely, when a user searches for a keyword over the files within a folder, the server learns only that a search happens in that folder, but does not learn which documents match the search, the number of documents that match, or other information about the keyword. DORY splits trust between multiple servers to protect against a malicious attacker who controls all but one of the servers. We develop new cryptographic and systems techniques to meet the efficiency and trust model requirements outlined by the companies we surveyed. We implement DORY and show that it performs orders of magnitude better than a baseline built on ORAM. Parallelized across 8 servers, each with 16 CPUs, DORY takes 116ms to search roughly 50K documents and 862ms to search over 1M documents.

1 Introduction

Users have grown increasingly reliant on filesharing systems such as Box, Dropbox, and iCloud. However, attacks on storage servers [88, 95, 98, 109] have exfiltrated large amounts of sensitive data belonging to many users, jeopardizing user privacy as well as the reputation and business of the victim organizations. End-to-end encrypted storage systems [73, 107, 115, 121, 124] provide a strong defense against this type of attack: the client stores all cryptographic keys and the server receives only encrypted data, and so an attacker that compromises the server can only exfiltrate encrypted data.

At the same time, end-to-end encrypted filesharing services struggle to provide the same functionality as plaintext storage providers like Dropbox because the server cannot decrypt the data to process it. Server-side search is a critical tool that users expect for convenience and companies require for compliance.

Despite a large body of work on searchable encryption [23, 25, 35, 37–40, 50, 52, 67, 68, 94, 97, 111, 114, 116], *practical and leakage-free* search on encrypted data has remained an unsolved problem for two decades. Existing work can largely be divided in two categories: (1) practical but leaking search

access patterns, or (2) not leaking search access patterns but expensive.

In the first category, an attacker can learn sensitive data by observing search access patterns. We now explain what search access patterns are intuitively by contrasting them to the leakage already existing in deployed end-to-end encrypted filesystems [73, 107, 115, 121, 124]. In these filesystems, when a user accesses a file, the server learns that this specific user accessed that specific file, but it does not see the content due to end-to-end encryption. The concern with leaking search access patterns on top of this filesystem leakage is that search access patterns can leak information at the word level, allowing an attacker to potentially reconstruct search queries and document plaintext [22, 65, 72, 84, 102, 106, 129].

Consider a simple example of how an attacker can exploit search access patterns [129]. The server stores an inverted search index for Alice’s emails mapping an encrypted keyword to an encrypted list of files. The attacker sends a one-word email to Alice containing “flu”. If Alice’s client updates entry 924 of index on the server, the attacker learns that index[924] is for “flu”. By repeating this process for every word in the dictionary, the attacker can discover the word corresponding to every index entry. Later when Alice receives a confidential email, the attacker can derive all the words in that email based on which index entries are updated. More sophisticated attacks can reconstruct both entire documents and search queries from even more advanced search schemes [22, 65, 72, 84, 102, 106, 129]. In this paper, we informally define search access pattern leakage as the set of documents matching a search keyword, the size of that set, and any information about the search query. In contrast, if a scheme does not leak search access patterns, then during a search on a folder, the search server learns only that a search is now happening in that folder.

The second category of existing work typically relies on Oblivious RAM (ORAM) [54, 99, 119], a cryptographic tool that allows a client to read and write data from a server without revealing access patterns. Many academic works point to an inverted index inside ORAM as a straightforward way to eliminate leakage [61, 96, 116]. Unfortunately, even though the asymptotic complexity of ORAM is polylogarithmic in the index size, the cost of even the most practical ORAM schemes remains prohibitively expensive for our setting. For example, inserting a file requires an expensive ORAM operation for *every* keyword in that file (and there can be hundreds).

Given that practical, leakage-free search remains a difficult

problem, we revisit the system model: What do real end-to-end encrypted filesharing systems actually require from a search system? Would the problem become more tractable in their system model?

Choosing a system model. We surveyed five companies that provide end-to-end encrypted filesharing, email, and/or chat services: Keybase [73], PreVeil [107], SpiderOak [115], Sync [121], and Tresorit [124]. To the best of our knowledge, this is the first study of requirements for encrypted search in real filesharing systems. We discuss our findings in §2 and summarize the ones most relevant to DORY here:

Efficiency requirements. These companies care about two primary metrics: latency and monetary cost. They are not concerned about the asymptotic complexity of the search algorithm and would accept an algorithm with runtime linear in the number of documents as long as their concrete performance and cost requirements are met (see Table 2).

Trust model requirements. Some of these companies were already splitting trust to back up secret keys or distribute public keys, and we wanted to know if we could leverage a similar distributed trust assumption to make the problem of encrypted search more tractable. While these companies were willing to split trust across multiple domains, some had two requirements aimed at strengthening the distributed trust assumptions. First, if at least one trust domain is honest, then an attacker that controls all the remaining trust domains and observes user queries should not learn search access patterns. In particular, we need to protect against a *malicious* attacker rather than an honest-but-curious one and should not assume that the attacker follows the protocol. The second requirement, stated intuitively, is that only search access patterns should be protected by distributed trust, and an attacker that compromises *all* trust domains should not immediately learn the contents of the search index.

While prior work explores some forms of distributing trust for encrypted search [15, 19, 45, 62, 64, 108], we are not aware of any work that meets both the efficiency and distributed trust requirements outlined above without leaking any search access patterns, as explained in §8.

Our system: DORY. We design and implement DORY (Decentralized Oblivious Retrieval sYstem), an encrypted-search system that splits trust to meet the real-world efficiency and trust requirements summarized above (and detailed in §2). DORY ensures that an attacker who cannot compromise every trust domain does not learn search access patterns.

We implemented and evaluated DORY to show that it performs better (for some metrics, orders of magnitude better) than an ORAM baseline (§7). DORY also meets the companies' efficiency requirements; parallelized across 8 servers, searching over 1M documents takes 862ms, and, using workload estimates from the companies, we estimate that DORY costs roughly \$0.0509 per user per month.

DORY combines cryptographic and systems techniques to overcome the security and efficiency challenges of previous so-

lutions. Several of the companies we surveyed have expressed interest in deploying DORY, and one of them already has plans to integrate DORY into their system in the near future.

1.1 Summary of techniques

Choosing an oblivious primitive. Given the inefficiencies of ORAM, a key challenge was choosing a cryptographic primitive for hiding search access patterns. We identified a relatively recent cryptographic tool, distributed point functions (DPFs) [51] (a specific type of function secret sharing [20, 21]), as particularly promising for our setting. DPFs allow us to leverage ℓ servers (for practical constructions, $\ell = 2$) to retrieve part of the search index without any group of $< \ell$ servers learning which part of the index we're retrieving (the problem of private information retrieval, or PIR [27, 28]). A DPF-based solution requires a linear scan over the index, but the overhead per index entry is small because it relies on AES evaluations, which are implemented efficiently in hardware.

Designing the search index. An important challenge is how to structure the search index to support efficient search and update operations. To minimize the overhead of updating the search index when a file is uploaded, the client should only need to upload a small, constant-sized amount of data per file, and ideally avoid performing an expensive cryptographic operation for every keyword in that file. To minimize search overhead, we need to limit the number of DPF queries. To achieve both of these goals, we keep a table where each row corresponds to a bitmap of words for a document. An update simply requires the client to insert a *row* by uploading a new bitmap, and, a search only requires a single DPF request to retrieve the *column* corresponding to a keyword (§4.1). However, this bitmap can become quite large to accommodate every word in the dictionary. To reduce the size of this bitmap (and thus the time for the linear scan), we use a Bloom filter, which provides compression while preserving column alignment. Bandwidth from the servers to the client is linear in the number of files searched over, but we require less than 1 byte per file (§7) and, more importantly, this fixed bandwidth enables DORY to hide the number of search results, which can be exploited in volume-based attacks [22, 72, 102].

Encrypting the search index. To prevent an attacker that compromises all the servers from immediately reconstructing the plaintext search index, we need to encrypt each bit in the Bloom filter before inserting it into the search index. Unfortunately, the expansion of encryption would increase the size of the search index (and thus the time for the linear scan) by the security parameter λ (typically $\lambda = 128$). To ensure that the encrypted index is the same size as the plaintext index, we instead mask the bits using a random one-time pad that we ensure is unique for each version of the file (§4.1).

Defending against a malicious attacker. DPFs do not protect against malicious attackers. To protect against a malicious attacker that compromises all but one of the trust domains, we leverage MACs to allow the client to check the integrity

of search results in a way that makes blackbox use of DPFs. Applied naively, adding MACs would increase the search bandwidth and storage at the server by a factor of λ . To address this problem, we employ aggregate MACs [71] to turn λ from a multiplicative factor to an additive one (§4.3).

Providing fault tolerance. Splitting trust across different trust domains naturally requires additional servers. With secret-sharing, one tool for distributing trust, servers store different data that they may not share. Then, to provide fault tolerance, each of these servers would need to be replicated. We observe that in DORY, servers can use each other for fault-tolerance even though they are in *different* trust domains due to two properties (§5): (1) each server has an identical copy of the state, and (2) the client can perform integrity checks.

Reducing the cost of replication. To execute a search query correctly, all the servers must operate on the same version of the state. This is challenging because clients can issue update and search requests concurrently. One possibility is to use standard Byzantine fault-tolerant (BFT) consensus techniques to solve this problem, but this would require $3f + 1$ trust domains to handle f failures. Instead, we observe (1) the ways in which our system setting is less demanding than that of BFT, and (2) that our cryptographic protocol enables clients to check integrity even if all servers are compromised; using these, DORY only needs $f + 1$ trust domains (§5).

2 Finding DORY: identifying a system model

To understand real-world use cases, we surveyed five companies providing end-to-end encrypted file storage, email, and/or chat solutions: Keybase [73], PreVeil [107], SpiderOak [115], Sync [121], and Tresorit [124]. For each company, we asked a set of questions (see full version [36]) over the course of discussion(s) and email exchanges. This study was conducted as we were in the process of designing our system. We summarize our findings in Tables 1 and 2 and in the following sections. We report statistics in aggregate to preserve the confidentiality of individual companies, as they requested. These statistics and requirements motivate DORY’s system model.

About the companies. Before we report the results of our survey, we give a brief background about each company. Keybase [73], founded in 2014 in the US and recently acquired by the video-conferencing company Zoom [128], keeps a publicly auditable key directory and offers open-source, end-to-end encrypted chat and storage systems. PreVeil [107], founded in 2015 in the US, focuses on both encrypted chat and storage solutions and open-sources some of its tools. SpiderOak [115], founded in 2007 in the US, offers encrypted storage, backup, and messaging solutions leveraging a private blockchain and open-sources many of its tools. Sync [121], founded in 2011 in Canada, and Tresorit [124], founded in 2011 in Switzerland, both provide encrypted storage. With the exception of Keybase, these companies generally target enterprise customers and support compliance with regulations

	Keybase	PreVeil	SpiderOak	Sync	Tresorit
Need server search?	✓	✓	✓	✓	✓
Have server search?	✗	✗	✗	✗	✗
File sharing?	✓	✓	✓	✓	✓
Email?	✗	✗	✗	✗	✗
Chat?	✓	✓	✓	✗	✗
Mobile client?	✓	✓	✓	✗	✓

Table 1: The search use-cases for each of the five companies we surveyed.

Table 2: Survey statistics. In accordance with the companies’ confidentiality wishes, we report most fields in aggregate although we report individual responses for max permissible search latency (only 4 of the companies responded).

System cost & scale	
Avg. #docs/user	100 - 45K
Max #docs/user	100K - 1.3M
Price/month/user	\$0-20
Search requirements	
Max added \$/month/user	\$0.70-5.54
Max search latencies (s)	[0.5, 1, 1, 4]
Est. update/search ratio	50/50

such as GDPR or CMMC. Some of these companies report over 750K users in over 180 countries.

The need for server-side search. Every company expressed a need for server-side search on encrypted data either for their desktop client in cases where users do not have all the files downloaded, or for the mobile or web clients. However, none currently support server-side search; they all told us that they tried at some point to develop a solution (most had researched the academic literature), but their efforts were eventually thwarted by concerns about performance or search access patterns. Several of the companies we surveyed had built or used a client index as a temporary solution, but they did not see this as a long-term solution because of its inability to index many files locally (e.g. enterprise data) or its resource consumption (especially on mobile). In §7.5, we discuss how synchronization between clients makes this solution infeasible in cases where documents are constantly updated.

They all stated interest in deploying a server-side solution that met their functionality, security, and performance requirements, if such a solution were to exist.

2.1 System requirements

Search must be responsive. The companies reported maximum search latencies between 500ms and 4s (Table 2). The company that reported a maximum search latency of 500ms reported tens of thousands to hundreds of thousands documents per user, while some of the companies that reported larger maximum search latencies had users with approximately a million documents.

Monetary cost for search must be small. These companies prioritize keeping the cost of search below \$0.70 per user per month in order to make it feasible to deploy search to all users without increasing prices (Table 2). While some companies were willing to consider charging more for the ability to search, other companies believed that users would be unwilling to pay

extra because they are used to free search on other platforms. **Multiple users must be able to update and search the same documents.** Each company allows multiple users to access the same file. Therefore, a search solution should be designed with multiple clients in mind and minimize the amount of state clients need to synchronize between operations.

Revoking a user's access must be cheap. All these companies implement revocation lazily [9, 48, 53, 56, 66, 110], meaning that when a user's access to a folder is revoked, the remaining users generate a new key and, rather than re-encrypting every document in the folder under the new key, simply use the new key for subsequent updates. In this way, the revoked user can still access documents that haven't been updated since the time of revocation. These companies want to adopt a similar approach for search. When a user is revoked, rather than re-computing the entire search index (as in ORAM-based solutions), subsequent updates should not allow the revoked user to search over the updated documents.

Relaxations. In addition to learning requirements, we also learned several system relaxations these companies accepted. The companies did not require search results to be fresh (they could be stale for up to a few minutes), and they were also willing to accept a small number of false positives (several other search schemes have also leveraged this allowance [15, 52]).

2.2 Distributed trust requirements

The majority of prior encrypted search work considers a single-server model where the attacker can take control of the entire system. As some of these companies were already leveraging distributed trust (e.g. Keybase to distribute public keys via social media servers, PreVeil to backup secret keys secret-shared among multiple clients), we wanted to know if they were willing to accept a distributed trust model for encrypted search as well, as this could be an opportunity for providing a more efficient search. We found that all the companies were open to a distributed trust model, although several companies had more specific requirements for how to distribute trust:

Hide search access patterns even with only one honest trust domain. These companies wanted the guarantee that if at least one trust domain is honest, then an attacker cannot learn search access patterns. They did not want to assume that other trust domains behaved correctly, so they wanted a malicious threat model rather than an honest-but-curious one.

Distributed trust only for search access patterns. These companies wanted to limit the damage caused by an attacker who compromises *all* the ℓ trust domains by ensuring that putting the ℓ search indices together does not readily provide the attacker with the plaintext search index. For example, if a company is subpoenaed and every trust domain must hand over its search index and search access patterns from then on, the company can choose to suspend search services to protect users' privacy by reducing search access pattern leakage, similar to the case where Lavabit chose to suspend operation rather than reveal Snowden's emails [4]. In such a case,

reconstructing the index from the ℓ servers' index shares should result in end-to-end encrypted data. This requirement rules out solutions based on secret-sharing a plaintext search index across multiple servers because an attacker compromising all trust domains can recover the plaintext index.

2.3 Opportunities

From the survey results reported above, we summarize what we considered opportunities to make the problem of encrypted search easier:

- Performing a linear scan to search is feasible if the response time and the cost on expected workloads are acceptable.
- Distributing trust across multiple trust domains is acceptable if certain security requirements are met.

These opportunities serve as the basis for our system design.

2.4 Building a distributed trust system

We now discuss how to build a system where an attacker who compromises part of the infrastructure cannot easily gain access to the entire infrastructure. Such a model has already been deployed in several real systems, including cryptocurrencies relying on consensus such as Ripple [90] or Stellar [86], Certificate Transparency [81], and academic work [31].

Split across clouds. By treating different clouds as distinct trust domains, a malicious cloud provider (or an attacker that can exploit a vulnerability in one cloud infrastructure), cannot gain access to both trust domains.

Split across institutions. By using trust domains in competing organizations or nonprofits generally trusted by the public (e.g., the Electronic Frontier Foundation), users can have a stronger assurance that the organizations are unlikely to collude.

Split across jurisdictions. By separating trust domains by jurisdiction (i.e. different countries), a single legal authority cannot gain access to the entire system.

If the trust domains are deployed in the cloud, we can take advantage of the fact that cloud providers are monetarily incentivized to provide availability. Fail stops can still occur naturally, but cloud providers make it easy to detect failures and launch new servers. Clients can report statistics on the lack of availability of a trust domain, and the organization deploying the system can take its business elsewhere.

2.5 Future directions

As we conducted our survey, some companies mentioned additional features that, while not necessary for initial deployment, are desirable. Although we do not support these in DORY, we note them here as potential directions for future work.

Concentrate resources in a single trust domain. The trust domain already used for the filesystem should do most of the work for search as well. Each additional trust domain should do little work, so that adding a new trust domain should be cheap. DORY concentrates resources to some extent, (§5), but, as discussed in §4, still requires a server in each trust domain to perform a linear scan.

Richer search functionality. Several companies mentioned that they would appreciate richer search functionality beyond

simple keyword search (e.g. ranked search based on term frequency.) DORY only returns the set of documents containing a keyword, leaving ranked search for future work.

3 System design overview

In DORY, we focus only on the search system for end-to-end encrypted filesharing systems and not on the design of these filesharing systems. These systems [73, 107, 115, 121, 124] already exist and are in use. We design DORY to build on top of and interface with these systems as described in §3.2. For this purpose, we abstract out the underlying filesystem.

3.1 The underlying filesystem

End-to-end encrypted filesystems (including the five companies we surveyed in §2) tend to follow a common design pattern, which we now describe. To hide the contents (including the name) of documents, these filesystems assign a document ID to each document and associate the ID with an encryption of the document contents. Documents accessible by the same users are grouped into *folders*, each of which has a corresponding ID. Users who have access to the same folder share a (logical) secret key used to encrypt the documents in that folder. In this way, while the server learns the IDs of documents being accessed, the number of documents in each folder, and which users have access to which folders, it does not see the contents of the documents.

When a user is added to a folder, the other users share the existing folder key with the new user, and when a user's access to a folder is revoked, the remaining clients choose a new folder key. To prevent the remaining clients from having to re-encrypt every document in the folder after a user is revoked, these systems employ lazy revocation (as described in §2.1).

Users may choose to keep some documents synchronized with the server (i.e., store the most recent version of the document locally) and others not synchronized (i.e., do not store locally and retrieve them from the server only as needed). In either case, the user has already downloaded the most recent version of the document before she sends an update. In the case where two clients try to update the same file simultaneously, these systems often create two versions of a file.

DORY integrates with the filesystem (FS) using the following FS API (depicted in Figure 3):

- `getCurrKey(folderID) → k`: Get the current key associated with the group of files in `folderID`.
- `getDocKey(docID) → k`: Get the key used in the most recent update for `docID`.
- `getDocIDs(folderID) → docIDs`: Get all the document IDs used for the documents in `folderID`.
- `getVersion(folderID, docID) → version`: Get the current version number associated with a file.

3.2 The DORY API

When a user searches or updates a file, the filesystem client calls the DORY client via DORY's API so that DORY performs

Figure 3: System software architecture. The figure shows the structure of the software rather than the physical system itself, where the server is instantiated across multiple machines.

the search or incorporates new updates into the search index. We now describe DORY's client API, depicted in Figure 3.

When the user updates a document in the underlying filesystem, the user's client also sends an update to the DORY client to maintain the search index, allowing DORY servers to respond to subsequent search queries correctly.

The underlying filesystem already handles key management by giving permitted users access to the folder key(s). DORY leverages this key management mechanism so the permissions of the filesystem naturally extend to DORY: when a user is added to or removed from a folder in the underlying filesystem, she also gains or loses the ability to search in DORY.

We also utilize the fact that to update a document in the underlying filesystem, the user has already downloaded that document (if it is not being added for the first time). We employ the conflict-resolution mechanisms in the underlying filesystem to resolve conflicts in search index updates.

DORY exposes the following API to filesystem clients:

- `Update(folderID, docID, prevWords, currWords)`: Given the folder ID, the document ID of a document in that folder, the previous set of keywords in that document `prevWords`, and the current set of keywords in that document `currWords`, update the state at the DORY servers.
- `Search(folderID, keyword) → docIDs`: Given the folder ID to search over and a keyword, find all the documents containing that keyword. DORY has a small (configurable) false positive rate, but DORY has no false negatives.

Updates require the client to upload a small, constant-sized amount of data per file, and searches require the server to perform a linear scan over the search index for a given folder (the cost of search for a user only depends on the number of files that user has access to).

3.3 System architecture

Folders in DORY are divided into *partitions*, each of which is managed by a different group of servers. A deployed system may contain many such partitions, and execution across partitions occurs in parallel. The following entities comprise DORY's system architecture for a single partition (Figure 4):

- **Filesystem server**: The underlying filesystem provides the functionality described in §3.1.
- **Replicas**: The ℓ DORY replicas maintain identical copies of the search index and execute search queries. Each replica is deployed in a separate trust domain. In our implementation, we use $\ell = 2$.

Figure 4: DORY’s physical system architecture for a single partition (filesystem server not pictured). Replicas should be deployed in different trust domains, and each holds a copy of the search index.

- **Master:** The DORY master ensures that the ℓ replicas have the same view of the state and that the clients know the version of this state and which servers to contact. The master can be deployed in any existing trust domain.
- **Clients:** Multiple clients send requests to the filesystem server and the DORY master and replicas. Each client only needs to store three 128-bit keys (and can optionally cache version numbers received from the master).

To search, the client must interact with ℓ replicas for each partition. The master can be co-located with the filesystem server to ensure that updates to the search system and underlying filesystem occur atomically, although this is not necessary.

3.4 Threat model and security properties

We now describe DORY’s security properties at a high level, and include DORY’s formalism (detailing the guarantees) and proof in the full version [36]. In short, we achieve the security goals in §2.2. We discuss security at the level of trust domains, each of which may deploy one or more servers.

Below, we assume that the underlying filesystem is maliciously secure. In particular, we assume that DORY’s client can always retrieve the correct version number from the underlying filesystem. Providing such a guarantee (e.g., by detecting rollback and fork attacks in filesystems) is a well-studied line of work [11, 63, 70, 75, 82]. If the underlying filesystem only defends against an honest-but-curious attacker, though, DORY also only protects against such an attacker.

Security with one honest trust domain. A malicious attacker that compromises $\ell - 1$ of the ℓ trust domains does not learn any search access patterns. More precisely, such an attacker learns nothing except what is leaked by the underlying filesystem, as well as the timing of individual search requests and the folders they take place over. This security property implies both forward privacy, the privacy of newly added files in the presence of previous queries, and backward privacy, the privacy of deleted files after deletion, as defined by Stefanov et al. [116]. Notably, we do not leak the number of search results; if leaked, this information could open the door to volume-based attacks [102] (parameters that determine result sizes are public).

Security with no honest trust domains. DORY’s goal is to hide search access patterns when at least one trust domain is honest. When all trust domains are compromised, we have

the modest goal of defaulting to the security of prior schemes leaking search access patterns, instead of readily losing all security by immediately exposing the search index. In this case, the only additional leakage (on top of what the attacker learns if at least one trust domain is honest) is a deterministic identifier for the keyword queried. In the security definition for our cryptographic protocol, we model the attacker as seeing queries only after the point of compromise; in reality, systems retain leakage (e.g. cache state) that increases the amount of information the attacker can access [57].

We formally model the end-to-end security guarantees of DORY for the case where at least one trust domain is honest and the case where no trust domains are honest by defining an ideal functionality \mathcal{F} that specifies the behavior of an ideal system, capturing the properties discussed above. \mathcal{F} further captures the fact that the client can verify the integrity of the result. In the full version [36], we present a formal definition using \mathcal{F} and prove the following theorem, which captures DORY’s security:

Theorem 1: *Using the definitions in the full version [36], DORY securely evaluates (with abort) the ideal functionality \mathcal{F} when instantiated with a secure PRF, a secure aggregate MAC, a secure distributed point function, and a secure filesystem that implements the ideal filesystem functionality.*

DORY does not provide availability if any one trust domain refuses to provide service (see §2.4 for how cloud providers are monetarily incentivized to provide availability).

Relationship with underlying filesystem. DORY interfaces with deployed end-to-end encrypted filesystems (§3.1). These, as mentioned, allow the server to learn the ID of the file being accessed (but not its contents). While search itself is protected in DORY, some side effects of the search results are not: If, after seeing the search results, a user decides to open (and retrieve from the filesystem) a file in the results, an attacker could infer that the file matched the search. DORY does not address these side effects, but simply aims to not add any leakage to the overall system during search. These side effects (and leakage due to the filesystem) can be prevented by running DORY on top of an oblivious filesystem.

Extension to oblivious filesystems. Some file storage proposals [10, 26, 58, 91, 92] hide which files are being accessed. These are usually based on oblivious algorithms [119], which have significant overhead and have not yet been deployed. Nevertheless, in §4.5, we discuss how DORY can be used to provide search for an example of such a filesystem design, demonstrating that DORY’s techniques do not require the server to know the file ID being updated.

4 Search design

We start by describing a basic encrypted search scheme that leaks search access patterns and is only secure against an honest-but-curious attacker in §4.1. We will show how to modify our basic scheme to eliminate search access patterns

Figure 5: Search index layout for n documents with Bloom filters of length m . Updates write *rows* and searches retrieve *columns*.

in §4.2, move from an honest-but-curious to malicious threat model in §4.3, and support dynamic membership in §4.4. We show the pseudocode for the complete search protocol in the full version [36]. For simplicity, we only discuss search servers, which we assume are deployed in different trust domains, and ignore the master and filesystem servers in this section.

4.1 A strawman search index

In our initial version, clients have access to a single server. For every document, the server stores an encrypted Bloom filter corresponding to the set of keywords in the document. To update the search index for a particular document, the client computes the Bloom filter for the contents of the document and encrypts it using a one time pad unique to that update. We generate the mask for a document using a pseudorandom function (PRF) keyed with a per-folder key and the current document version number as input. The key management functionality built into the underlying filesystem ensures that every client has a copy of this PRF key.

If there are n documents in the search index and Bloom filters are m bits, then we can think of the server as storing an $n \times m$ table where each element is a single bit (Figure 5). Each row in the table is a Bloom filter for a document, and the i th row corresponds to the document with ID i . For an update, the client sends a new *row* that the server inserts into its table. This allows the client to easily modify existing documents and add new ones: the server either replaces an existing row with the new row or appends the new row to the table.

To search for a keyword, the client must find all the documents where the Bloom filter indexes corresponding to that keyword are set to “1”. The client can check this by retrieving from the server the *columns* corresponding to the Bloom filter indexes for that keyword. The client can decrypt bit b_i in a column by computing the mask for row i , extracting the mask bit corresponding to that column r_i , and then evaluating $b_i \oplus r_i$. If the i th entry in each of the decrypted columns is set to “1”, then the client marks document i as containing the keyword. In order to prevent the attacker from learning the queried keyword from the requested indexes, we compute the Bloom filter indexes using a PRF keyed with a per-folder key and the keyword as input. This key is managed by the underlying filesystem in the same way that the other PRF key is.

We note that in order for the contents of the client’s update to remain hidden from the server, the client must be able to retrieve the correct version number from the underlying filesystem.

tem. Without this guarantee, the client could use the same mask twice, leaking information about the update contents. For this reason, we only provide security against a malicious attacker if the underlying filesystem also provides the correct version numbers (discussed in §3.4). This strawman proposal is similar to the one described in [76].

4.2 Eliminating search access patterns

To eliminate search access patterns, we need to hide from the server which columns the client is retrieving during a search. To do this, we use a private information retrieval (PIR) protocol [27, 28], which allows a client to retrieve an entry in a database from a server (1) without the server learning which entry is being retrieved, and (2) using total communication sublinear in the database size.

Tool: Distributed Point Functions (DPFs). One efficient way to implement PIR is using a distributed point function (DPF) [51] (later generalized as function secret sharing [20, 21]), which we identify as particularly well-suited for our setting. DPFs allow a client to split a point function f into *function shares* such that any strict subset of the shares reveal nothing about f , but when the evaluations at a given point x are combined, the result is $f(x)$.

A DPF is defined by the following algorithms:

- $\text{DPF.Gen}(a, b) \rightarrow (K_1, \dots, K_\ell)$: Generates keys K_1, \dots, K_ℓ that allow the ℓ servers to jointly evaluate the point function that evaluates to b at input a .
- $\text{DPF.Eval}(K_i, x) \rightarrow y$: Evaluates the function share corresponding to key K_i at server i on input x to produce output y .

To evaluate the point function f where $f(a) = b$ on some input x , the client generates keys for all ℓ servers by running $\text{DPF.Gen}(a, b)$ and sending K_i and x to server i for all ℓ servers. Server i then runs $\text{DPF.Eval}(K_i, x)$ and returns the result y_i to the client. The client can then compute $y_1 \oplus y_2 \cdots \oplus y_\ell$ to reconstruct $f(x) = y$. We make black-box use of the construction from Boyle et al. where $\ell = 2$ [21].

Leveraging DPFs to search. To hide search access patterns, we switch from having the client interact with a single server to having the client interact with ℓ servers in different trust domains that hold identical copies of the search index. To retrieve column j , the client generates shares of the point function that evaluate to all 1’s at column j and all 0’s for all other columns. The client then sends a function share to each server. Each server evaluates its function share for each column, ANDing the DPF evaluation with the contents of the column, and sends the XOR of the results back to the client. The client then assembles the responses to recover column j .

Using DPFs to retrieve columns requires a linear scan over the search index for a folder. While this is expensive asymptotically, we only aim to show efficiency for realistic workloads, motivating our decision to compress the search index using Bloom filters.

4.3 Protecting against malicious attackers

So far, we have assumed that all servers are honest-but-curious. We now show how to defend against a malicious attacker (namely, an attacker that can deviate from the protocol) that can compromise up to $\ell - 1$ of the ℓ servers. To achieve this, we need to ensure that for a search, the server evaluates the DPF on columns corresponding to the most recent updates sent by the client (not corrupted or old updates).

Strawman: MAC for every bit. We start by showing a strawman that employs MACs, but increases the bandwidth and search latency by roughly a factor of the MAC tag size (typically 256). For each update, the client additionally sends a MAC tag for every bit in the encrypted Bloom filter. The client cannot send a single tag for the row because to search, the client must retrieve individual columns rather than entire rows. We can think of the server as now storing a second table of MAC tags where each entry of this table is the tag for the corresponding entry in the original table (as in Figure 5).

We need to ensure that (1) a tag is only valid for a particular document update (to prevent replay attacks) and that (2) it cannot correspond to a different Bloom filter index. To do this, we compute the MAC over not only the single Bloom filter bit, but also the document ID, Bloom filter index, and document version number. As with the PRF key, we use the key management functionality in the underlying filesystem to ensure that every client has a copy of the MAC key.

The client now runs the DPF over the columns in both the original table and the MAC tag table. After assembling the responses from all ℓ servers, the client can check that the tag for every bit is correct. However, this increases both the bandwidth and the time to perform the linear scan over the index (i.e., the search latency) by a factor of the tag size. We identify aggregate MACs as a tool to transform this factor from a multiplicative to an additive one.

Tool: Aggregate MACs. We leverage aggregate MACs [71] to allow the servers to combine individual MAC tags into a single aggregate MAC tag. Aggregate MACs, analogous to aggregate signatures [17], allow multiple MAC tags computed with possibly different keys on multiple, possibly different messages to be aggregated into a shorter tag that can still be verified using all the keys. Notably, aggregating MAC tags does not require access to the keys.

The Katz-Lindell aggregate MAC construction [71] works as follows. To generate a MAC tag for some message m using a key k , we simply use a pseudorandom function MAC and compute $t \leftarrow \text{MAC}(k, m)$. To aggregate MAC tags t_1, \dots, t_n , the aggregator computes $T \leftarrow \oplus_{i=1}^n t_i$. To verify an aggregate MAC tag T using messages m_1, \dots, m_n and keys k_1, \dots, k_n , the verifier checks $T \stackrel{?}{=} \oplus_{i=1}^n \text{MAC}(k_i, m_i)$.

Aggregating MAC tags to improve performance. To improve performance by a factor of the tag size, we allow the servers to combine individual tags into a single aggregate tag. To search, the server evaluates the DPF on the contents of the

column and a single aggregate tag for the entire column.

Aggregating MAC tags also allows us to reduce storage space at the servers. Rather than storing an entire separate MAC table, the servers instead keep an array of aggregate tags, one for each column. On each update, the client XORs the old tag with the new tag (which is why Update takes both `prevWords` and `currWords`). By then XORing this value with the aggregate tag, the server can remove the old tag and add the new tag. To ensure that this aggregate MAC tag is maintained correctly, the server must check that the client has the latest version of the document; otherwise it rejects the update.

4.4 Supporting dynamic membership

Users might be added to or removed from a folder, requiring the new group to generate a new key. This new key might be in use at the same time that some parts of the search index were generated using an old key in order to support lazy revocation. We let the underlying filesystem handle key management, but we need to ensure that our search protocol supports multiple keys that may be active at the same time.

Decrypting search results is straightforward; to decrypt the results for an individual document, the client uses the same key from the last update to that document. Aggregating MAC tags is also simple because we can aggregate tags computed with different keys. We can remove old tags and add new tags with different keys using XOR in the same way as before.

4.5 Generalizing to oblivious filesystems

We briefly discuss how DORY is compatible with a filesystem that hides which document is being accessed within a folder, showing that DORY does not inherently require knowledge of which document is being accessed.

We can build a filesystem that hides document access patterns using PathORAM [119], which acts as an oblivious key-value store for each folder. To support multiple users, we keep an encrypted copy of the ORAM client state at the server (discussed in §7.1). Each ORAM block contains the encrypted contents of a document.

One straightforward way to search over this filesystem would be to store an inverted index in ORAM. This would hide which document is being updated, but updates would require an ORAM access for every word in the document.

Instead, we apply DORY to this filesystem. Rather than storing encrypted Bloom filters in a table as in §4.1, we store them in a second PathORAM to hide which document is being updated. We use the same techniques for supporting multiple users as in the underlying filesystem.

To perform an update, the client generates an encrypted Bloom filter as before and needs to insert it into the ORAM index. This creates a new challenge, because ORAM accesses require the client to re-encrypt other ORAM blocks, and standard symmetric key encryption breaks DORY's column alignment. To address this, we keep track of a new value shared among users for each document: the ORAM access number, which is incremented after each ORAM access. Instead of

generating PRF masks using the document’s version number, we now generate them using the document’s ORAM access number, allowing clients to safely re-encrypt Bloom filters.

To execute a search, the client still generates a DPF query for the Bloom filter indexes in question and the server still needs to perform a linear scan over the search index (we must scan over every bit in every Bloom filter). Another challenge arises, because while the order of the scan was obvious when the search index was a table, the order is less obvious for the tree structure of PathORAM. We solve this problem by traversing the tree in a fixed order to generate a table layout. The client can interpret the results by reconstructing the traversal order using the position map stored as part of the ORAM client.

5 Replication across trust domains

DORY requires that the servers processing search requests operate on the same version of the index in order for the client to receive a valid response; otherwise, the cryptographic shares from the DPF cannot be combined correctly. Because our system processes a mix of update and search requests, the servers need to agree on the index state. The client also needs to know the document version numbers corresponding to the index that the servers used to execute the search; otherwise, the client will be unable to decrypt and verify the result.

Because we are in an adversarial environment, a natural solution is to use a Byzantine fault-tolerant (BFT) consensus algorithm [1, 16, 24, 33, 77, 79] to agree on the ordering of update and search requests. Standard BFT provides the properties we need, but requires $3f + 1$ servers, each in its own trust domain, to handle f failures. A large number of trust domains is expensive to maintain and difficult to deploy, increasing the overall system cost. We make several observations about our setting that allow us to use only $f + 1$ trust domains.

Observations we leverage. We make three observations that allow us to tailor the problem of consensus to DORY:

DORY deterministically detects server misbehavior. Our cryptographic protocol already defends against malicious servers; if a server executes the client’s query incorrectly or over an incorrect version of the index, the client will detect this (triggering a manual investigation). This is a significant departure from the Byzantine fault model where failure information is imperfect. By handling server misbehavior at the cryptographic protocol layer, we can use a fail-stop rather than Byzantine failure model at the consensus layer. This and the next observations allow us to use just $f + 1$ trust domains to tolerate f failures.

Trust domains provide availability. To support search, DORY needs all $f + 1$ replicas to be available. We need to ensure that servers across multiple trust domains remain online to allow clients to search. Here we leverage the observation that for trust domains deployed in the cloud, the cloud provider is monetarily incentivized to provide availability (§2.4). This means that if a server in a trust domain fails, either it will eventually come back online or another server will take its

Figure 6: System architecture and protocol flow for updates (left) and searches (right). ❶ Client sends update to master. ❷ Master propagates updates to replicas. ❸ Client requests version number(s) from master. ❹ Client splits search request across replicas.

place; even if failures occur, $f + 1$ servers will be available again at some point in the future.

DPFs give us replication for free. The challenge now is to reinitialize the state of these failed servers. The use of DPFs in our cryptographic protocol requires all replicas to have identical copies of the search index. Normally it is unsafe to transfer state between trust domains, as the recipient has no way to verify correctness. However, because the client can check the integrity of the state used to execute a search query, we can safely copy state across trust domains. Because we have $f + 1$ servers, at least one server will always remain online to preserve the state of the index.

5.1 Algorithm

A DORY cluster contains the following entities (Figure 6):

Master: The master receives updates and manages replica state. The master stores the most recent updates and version numbers (both the overall system version number and individual document version numbers), but not the entire search index. The master can be deployed in any trust domain, as clients can detect misbehavior when verifying search results. **Replicas:** The replicas receive updates from the master and perform searches from the user. The replicas store the most recent versions of the index as well as the version numbers (both the overall system version number and individual document version numbers). We must deploy ℓ replicas in ℓ different trust domains to ensure that the client can split its search request across different trust domains. However, the total number of replicas n may be greater than ℓ in order to improve fault-tolerance.

We additionally use a watchdog service (commonly available in the cloud) that periodically checks that all servers are still online and triggers recovery when it detects a crash.

Properties. Our replication algorithm should provide the following properties:

- **Correctness:** If *all* of the replicas and the master fail, a client with the correct set of document version numbers can detect this.
- **Fault-tolerance:** If at most $n - 1$ of the n replicas fail, then the search index is preserved. If the master fails, then the

most recent set of updates can be recovered with help from the client.

We do not guarantee availability if individual trust domains do not provide availability.

Algorithm. We now explain how we handle updates and searches and recover from failure (see Figure 6).

Updating a document. To update a document, the client sends the update along with the new document version number to the master. The master needs to send the update to the replicas and increment the version number. Because the master might fail while sending the update to the replicas, the master runs two-phase commit [80] with the replicas to ensure that all the replicas receive the update and associated version number. We do not need to worry about replica failures during two-phase commit (and so do not need multiple replicas in each trust domain); if a replica fails, the watchdog service will detect this and coordinate recovery as described below.

Searching for a keyword. To search for a keyword, the client first needs to learn the current version numbers from the master (both the overall system version number and the corresponding individual document version numbers). If the client has a relatively recent set of document version numbers, the master can simply send updates for a few of the document version numbers, making the overall bandwidth much smaller than the number of documents. The client then generates a search query for ℓ of the replicas. The replicas execute the search on the version of the index corresponding to the system version number sent by the client.

Coordinating recovery. We rely on the watchdog service to detect failures. If at least ℓ of the replicas across ℓ different trust domains remain online, clients can continue searching. Otherwise, we can start new replicas and transfer the state from a remaining replica to the new replica, even if the replicas are in different trust domains. This will cause a slight delay for clients waiting to search, but is safe due to the underlying cryptographic protocol (as discussed above). We do not need to worry if the master fails, because the master does not respond to the client until it has propagated the update to the replicas. If a replica fails during two-phase commit, the master can roll back the two-phase commit and then start another replica in the same trust domain and copy the state across trust domains.

5.2 Batching

Rather than running two-phase commit between the master and replicas for every update, we can apply batching to amortize the cost. Instead of immediately sending an update to the replicas, the master aggregates a batch of updates and, when this batch reaches a certain size or a certain amount of time has elapsed, it runs two-phase commit with the replicas to transfer the current batch of data.

However, now that the master is responding to clients before sending the updates to the replicas, we need to ensure that the master does not lose state when it fails. In particular, the master needs to be able to recover the updates that were waiting to be

committed to the replicas. The master does this by comparing the individual document version numbers at the replicas with those at the filesystem server. For each document where the version numbers differ, the master can request an update from the next client to come online with access to that document.

6 Implementation

We implemented DORY in ~5,000 lines of C (for the distributed point function and other low-level cryptographic operations) and Go (for the networking and consensus). We used the OpenSSL library, and our DPF implementation closely follows the one in Express [43]. We instantiate the PRF using AES. We also implemented the DORY client on an Android Google Pixel 4. In addition to the C code, which we ported to the mobile platform, we wrote ~1,200 lines of Java. We used the tiny AES library [123] to minimize memory usage in our mobile implementation. Our implementation supports a single folder and does not include the watchdog service and coordinated recovery described as part of §5 or the generalization to oblivious filesystems described in §4.5. The source code is available at <https://github.com/ucbrise/dory> (see Appendix A for details).

6.1 Parallelism

The linear scan over the search index can be easily parallelized across both cores and servers because it carries no state from document to document.

Thread-level parallelism. Since we evaluate the DPF on each column of the search index, we parallelize the scan operation by simply assigning each thread a number of columns and then combining the results computed by each thread.

Server-level parallelism. We can partition the search index by having different pairs of replicas maintain different parts of the search index. The client then sends a search query to all pairs of replicas and simply computes the union of the results. Replica partitioning improves latency since each replica now only needs to search over a part of the index instead of the full index. Each pair of replicas can store part of the search index for many folders, making it possible to keep search latency low, but the overall throughput high.

6.2 Fast PRF evaluation

In order to decrypt the search result received from the server, the client must compute a mask for each individual document. To reduce the number of PRF evaluations to decrypt, we group Bloom filter indexes for the same keyword in the same 128-bit block. This grouping allows the client to decrypt the search results for one document using a single PRF evaluation. This does not significantly impact the false positive rate of the Bloom filter because we can now model a m -bit Bloom filter storing w words as $m/128$ independent Bloom filters each storing $128w/m$ words.

7 Evaluation

We evaluated DORY to determine (1) how it performs in comparison to existing techniques and (2) whether it meets

Table 7: On the left, Bloom filter sizes (in bytes) necessary for > 1 expected false positive assuming an average of 73.18 keywords per document where each keyword hashes to 7 Bloom filter indexes (Table 7a). On the right, breakdown of search latency without parallelism and end-to-end search latency with parallelism where p is the degree of server parallelism (Table 7b).

Docs	BF size	Docs	Time breakdown, $p=1$ (ms)				End-to-end latency (ms)		
			Consensus	Client	Network	Server	$p=1$	$p=2$	$p=4$
$\leq 2^{10}$	140 B	2^{10}	0.73	0.54	58.67	2.68	62.62	61.81	61.51

(a)

(b)

the requirements outlined by the companies we surveyed. We consider the following metrics: latency (§7.2), throughput (§7.3), storage (§7.4), bandwidth (§7.5), and cost (§7.6). We compare DORY’s performance to two different variations of DORY as well as plaintext search and a baseline built on ORAM (§7.1) that provides similar guarantees to those of DORY. We show that DORY meets the requirements outlined by the companies we surveyed and outperforms (in some cases, by orders of magnitude) our ORAM baseline (§7.1).

Experimental setup. We evaluate DORY on AWS using r5n.4xlarge instances with 128GB of memory and 16 CPUs for the replicas and the master. We use a c5.large client with 4GB of memory and 2 CPUs to model a user’s desktop machine. We use an Android Pixel 4 to measure the time to search on a mobile client. We place the two trust domains in different regions (east-1 and east-2) to ensure that machines are in different clusters to model different organizations, although in practice these clusters would likely be geographically close to maximize performance. All communication occurs over TLS. We run experiments for a single folder; a real system would maintain many such folders in parallel.

System parameters from Enron email dataset. We use the Enron email dataset, which is commonly used to evaluate searchable encryption schemes [22, 65, 84, 94, 96, 97, 129] to set Bloom filter sizes for DORY. We leverage the same standard keyword extraction techniques used in Obliv [94]: we stemmed the words and removed stopwords and words that were > 20 or < 4 characters long or contained non-alphabetic characters. In the over 500K emails, each email has an average of 73.18 keywords with a standard deviation of 114.89.

Regarding the configuration of the Bloom filters, each keyword hashes to 7 locations in the Bloom filter, as we found that it provided a reasonable tradeoff between the time to perform the linear scan at the server and bandwidth. We choose the Bloom filter size based on the number of documents in a folder so that, for every search in that folder, the search results have less than one false positive document in expectation. The sizes of the Bloom filters are specified in Table 7a.

7.1 Baselines

We evaluate DORY in comparison to four baselines:

- **ORAM baseline:** Eliminates search access patterns using ORAM (expected to incur a significant overhead). With this baseline, we show how DORY compares to a solution that provides comparable security guarantees.
- **Plaintext search:** Searches over a plaintext inverted index and does not provide any security guarantees (expected to have much lower overhead than DORY).
- **Semihonest DORY:** Modifies the DORY protocol to only provide security against semihonest adversaries (expected to have lower overhead than DORY).
- **Leaky DORY:** Modifies the DORY protocol to allow search access pattern leakage by using only one trust domain and querying the replica directly for the indexes corresponding to a keyword rather than using a DPF (expected to have lower overhead than DORY).

Semihonest DORY illustrates the overhead of the MAC checks necessary to defend against malicious adversaries, and leaky DORY illustrates the overhead of the DPF queries. In all of the baselines except the ORAM baseline, we use the same consensus system as in DORY, although for the baselines where there is only one trust domain (leaky DORY and plaintext search), the master only needs to send update batches to a single trust domain (we model this by placing all servers in the same AWS region). Only the ORAM baseline has security guarantees comparable to those of DORY.

ORAM baseline. Many academic works [61, 65, 96, 116] point to an inverted index in ORAM [54, 99] as a way to achieve searchable encryption without search access pattern leakage, making it a natural baseline for searching within a folder. Traditional ORAM is designed for a single client and requires the client to maintain ORAM client state hidden from the server [119]. A separate line of work explores extending single-user constructions to multi-user settings [10, 26, 58, 91–93]. Mayberry et al.’s system [93] is particularly fit for our setting as it protects mutually trusting clients (clients with access to a given folder) from a malicious server. For a semi-honest server or for a malicious server for which we have a mechanism to

verify the data returned (discussed in §3.4), their protocol uses a single-user ORAM and requires clients to store the encrypted ORAM client at the server. To perform an operation, the client acquires a lock at the server, downloads and decrypts the ORAM client state, performs the operation, encrypts and sends back the state, releasing the lock.

Client failures. We observed that the above proposal did not consider client failures. If a client fails after issuing operations at the server but before uploading the updated client ORAM state, the next client’s access may leak search access patterns (e.g. if it searched for the same word as the previous client). To handle client failures, we require each client to record a client “prepare” operation at the server, and if it fails before completing, the next client can finish the operation.

Eliminating frequency leakage. Popular keywords require multiple ORAM blocks to store all the document identifiers containing that keyword. We need to ensure that the number of blocks accessed doesn’t leak the frequency of a keyword due to known attacks [102], as DORY does not leak this frequency. For each search, we fetch the maximum number of blocks a keyword maps to. Similarly for each keyword we update in a document, we fetch the maximum number of blocks a keyword maps to and write back a single block.

Implementation. We implemented our baseline on top of an existing open-source PathORAM implementation in Go [101].

Evaluation on Enron email dataset. While DORY’s performance relies only on the system parameters and not the contents of the documents themselves, the performance of both our ORAM and plaintext search baselines depends on document contents. We evaluate these baselines using subsets of the Enron email dataset with the same keyword extraction techniques described above. To evaluate different numbers of documents, we take different-sized subsets of the Enron email dataset. We treat updates as adding an entire email to the index. Because the Enron email dataset only has ~ 528K emails, we do not measure the ORAM and plaintext search baseline beyond that number of documents.

7.2 Latency

Update latency. Figure 8 shows that the update latency of DORY is orders of magnitude faster than that of the ORAM baseline. This holds for both the desktop and mobile clients (Figure 9). The baseline requires a number of ORAM accesses (each of which necessitates a round trip) linear in the number of document keywords. In contrast, DORY simply uploads a single encrypted Bloom filter. Update latency determines (1) how long it takes for updates to be reflected in search results and (2) how long the client must remain online. Neither is a concern in DORY where updates are processed in less than 1ms, but the ORAM baseline requires clients to remain online for hours. Note that semihonest DORY has a faster update time than DORY because the client does not have to generate a MAC for every bit in the Bloom filter.

Search latency. Table 7b shows the breakdown in search

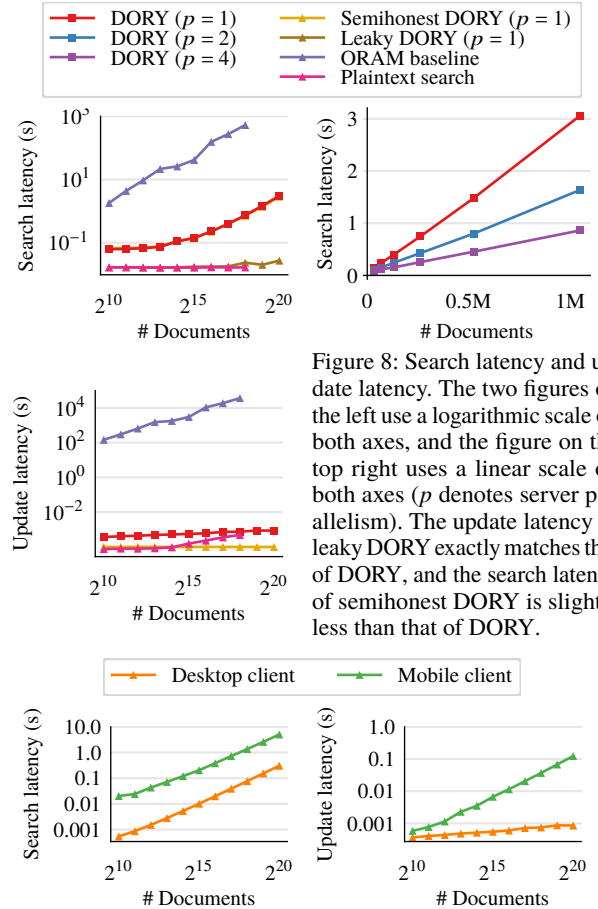

Figure 8: Search latency and update latency. The two figures on the left use a logarithmic scale on both axes, and the figure on the top right uses a linear scale on both axes (p denotes server parallelism). The update latency of leaky DORY exactly matches that of DORY, and the search latency of semihonest DORY is slightly less than that of DORY.

Figure 9: Latency for mobile client and desktop client. Both plots use a logarithmic scale on both axes.

latency. As the number of documents increases, the majority of time is spent performing the linear scan at the server. This is apparent in Figure 8, where leaky DORY’s search latency is significantly lower than that of DORY and stays relatively constant as the number of documents increases due to the fact that leaky DORY does not need to perform a linear scan.

Despite overheads incurred due to the linear scan, DORY is orders of magnitude faster than the ORAM baseline. The MAC overhead to protect against malicious adversaries is barely noticeable, as semihonest DORY and DORY have almost identical search latencies. Mobile clients incur additional overhead in comparison to desktop clients (the mobile client spends 5 seconds on client-side processing for 1M documents). This overhead is below 1 second for 2^{17} documents (Figure 9).

By increasing the degree of parallelism p and partitioning the search index across replica groups, we can reduce the server time by roughly a factor of p , as this time is linear in the number of documents (Figure 8). Parallelism allows us to reach the target latency set by the companies (Table 2).

7.3 Throughput

DORY achieves significantly higher throughput than the ORAM baseline (Figure 10). Parallelism improves DORY’s

Figure 10: Throughput under a variety of workloads (U indicates updates, S indicates searches). The performance of semihonest DORY closely matches that of DORY. All plots use a logarithmic scale on both axes.

Figure 11: Effect of parallelism (p denotes the degree of parallelism) on throughput for different workloads (U indicates updates, S indicates searches).

throughput by roughly a factor of p for larger numbers of documents (Figure 11). Relative to other workloads, DORY performs best under update-heavy workloads (updates require an insertion while searches require a linear scan), and the ORAM baseline performs best under search-heavy workloads (searches require fewer ORAM accesses than updates).

7.4 Storage

Server state. Figure 12 shows how DORY uses substantially less storage space at the server than the ORAM baseline and storage space comparable to that of a plaintext inverted index. DORY’s index continues to grow at a constant rate for large numbers of documents while the index for plaintext search grows more slowly, making the plaintext search index smaller than the DORY search index for larger numbers of documents.

Client state. DORY only requires that the client store three 128-bit keys. To generate an update or decrypt a search result, the client also needs to know the version number for each document. To minimize bandwidth, the client can optionally cache the latest version numbers so that it only needs to retrieve the version numbers that changed. For 45K documents (the highest average number of documents per user among the companies we surveyed), storing these version numbers would require 175.8KB. For 1M documents, storing these would require 3.84MB. Our ORAM baseline only requires the client to store a single 128-bit AES key to encrypt and decrypt the ORAM client, and plaintext search requires no client storage.

Figure 12: Storage space and bandwidth for DORY in comparison to other baselines. The update bandwidth of leaky DORY exactly matches that of DORY, and the search bandwidth of semihonest DORY is slightly less than that of DORY.

7.5 Bandwidth

Search and update bandwidth is also much smaller in DORY than in the ORAM baseline (Figure 12). The ORAM baseline incurs a significant overhead by sending the encrypted client state, but ORAM accesses are responsible for the majority of the communication. In contrast, the search bandwidth in DORY is linear in the number of documents, and the update bandwidth depends on the size of the Bloom filter. MACs are responsible for a significant part of the update bandwidth in DORY, which is why semihonest DORY has much lower update bandwidth. The difference in search bandwidth between leaky DORY and DORY is due to the size of the DPF keys; however, unlike plaintext search, the search bandwidth for both is still linear in the number of documents. We do not include the bandwidth to retrieve version numbers for individual document numbers in DORY, as these version numbers can for the most part be cached at the client as described above.

Comparison to client index. To evaluate the practicality of a client-side index instead of DORY, we built an inverted index over the Enron email dataset using a B+ tree. We found that the index is 159.9MB and while it is feasible to store this amount of data, even on a mobile device, synchronization requires significant bandwidth. One way to keep this data structure updated would be to require each client to download the contents of every update. However, this solution requires the same amount of bandwidth as syncing all the files locally, which we were trying to avoid in the first place. Instead, we could keep an encrypted copy of the client index at the server. Which part of the index is updated leaks information about the document contents, and so whenever a client performs an update, it must encrypt the entire index and send it to the server. Before a client updates or searches, it must download the most recent copy of the search index. This results in roughly a 365× increase in search bandwidth and a 3,334× increase in update bandwidth in comparison to DORY.

7.6 Cost

The companies we surveyed estimated a workload with 50% updates and 50% searches, and the highest average number of documents per user reported was 45K. The throughput of two replicas and a master operating on a folder of 45K documents under this workload is 19.5 operations/second. One of the companies reported that active users make roughly 50 updates per day, and so based on 100 operations per day and the cost to run a single r5n.4xlarge instance (\$1.192/hour), each user costs roughly \$0.0509 per month, well under the maximum permissible cost per user per month of \$0.70-\$5.54 reported by the companies. Depending on the way in which trust is distributed (see §2.4), trust domains may incur additional setup and maintenance costs not captured by our calculation.

8 Related Work

Symmetric Searchable Encryption (SSE). A long line of work has examined the problem of Symmetric Searchable Encryption (SSE) [23, 25, 35, 37–40, 50, 52, 67, 68, 97, 111, 114, 116], summarized in the following surveys [18, 59, 103]. Many of these schemes assume a single user and do not support efficient revocation, but more importantly, they permit some search access pattern leakage, opening the door to attacks [22, 65, 72, 84, 102, 106, 129]. SEAL [39] explicitly allows developers to tradeoff between leakage and performance.

Multi-server SSE and ORAM. Some SSE schemes use multiple servers to improve efficiency but still permit leakage, with some providing richer functionality than simple keyword search [15, 45, 64, 78, 100, 108]. Bösch et al. [19] and Hoang et al. [62] use multiple servers to hide search access patterns and improve efficiency. Hoang et al. [62] use a similar table layout where updates and searches correspond to different dimensions in the table. However, both schemes do not support multiple users, assume honest-but-curious servers, and require expensive updates to hide the document being updated. Our scheme also has similarities to distributed ORAM schemes that leverage multiple servers to hide access patterns with improved efficiency [3, 42, 55, 89, 117]. Implementing search with one of these schemes would still require clients to perform an ORAM access for every document keyword during an update.

Multi-user SSE and ORAM. Many existing multi-user searchable encryption schemes that support fast revocation use a different key for each user and leverage proxy encryption [8, 13] or pairings [13, 74, 104, 122]. This class of schemes use deterministic query encryption algorithms that leak search access patterns. The most efficient ORAM constructions assume a single user, with multi-user ORAMs incurring a much larger overhead by leveraging expensive tools such as multi-party computation (MPC) [10, 26, 58, 91, 92].

SSE and ORAM with trusted hardware. One way to improve performance and, in the case of search, potentially reduce leakage is by leveraging trusted hardware. ZeroTrace [113], Obliviate [5], OblIDB [44], GhostRider [83], Tiny ORAM [46],

and Shroud [87] combine oblivious techniques with trusted hardware. HardIDX [49], Oblix [94], POSUP [60], and Amjad et al. [6] use trusted hardware specifically for the problem of searching on encrypted data. Unlike DORY, such solutions only require a single server, but they necessitate both additional trust assumptions (due to known side-channel attacks) and additional deployment costs.

Prior use of DPFs in systems. Splinter [125] uses function secret sharing (both DPFs and range queries) to allow users to efficiently make private queries on a public, immutable database. DURASIFT [45] uses DPFs with MPC across multiple servers to support boolean expressions of keyword searches for multiple users without leaking search access patterns. However, its techniques incur significant overhead in comparison to ours, and the authors consider thousands rather than millions of documents. Floram [42] uses DPFs to implement a distributed-trust ORAM that has linear costs but fast concrete performance. Metadata-hiding communication also benefits from DPFs (e.g. Riposte [32] and Express [43]).

BFT consensus and fault-tolerance. BFT consensus [1, 16, 24, 33, 77] is a classical problem. Prior work has explored reducing the number of participants in BFT consensus by separating agreement from execution [127], only activating some nodes when failures are detected [41, 69, 126], relaxing synchrony assumptions [2, 85, 105], adopting a hybrid fault model [105], and using an attested, append-only log [29]. A separate line of theoretical work considers Byzantine fault-tolerance specifically for the case of private information retrieval [12, 14, 47, 120] using information-theoretic tools.

Oblivious systems. ObliviStore [118], Obladi [34], Opaque [130], Cipherbase [7], and Taostore [112] are practical systems for obliviously storing and querying data (not necessarily for the problem of searchable encryption).

9 Conclusion

DORY is an encrypted search system that distributes trust to meet real-world efficiency and security requirements. By reexamining the system model, we are able to build a system that is performant without leaking search access patterns.

Acknowledgments. We would like to thank Zoë Bohn, Henry Corrigan-Gibbs, Ioannis Demertzis, Saba Eskandarian, Vivian Fang, David Mazières, Rishabh Poddar, and Wenting Zheng for providing feedback on early drafts. We also thank the leadership of Keybase, PreVeil, SpiderOak, Sync, and Tresorit for generously taking the time to meet with us and discuss their use cases. We thank the OSDI anonymous reviewers for their detailed feedback, and our shepherd Andreas Haeberlen for his working reviewing our camera-ready. A Artifact Appendix

A.1 Abstract

Our DORY prototype is an encrypted search system that splits trust between multiple servers in order to efficiently hide search access patterns from a malicious attacker that controls all but one of the servers. We support parallelism across multiple servers in order to reduce search latency and increase throughput. DORY is written in a combination of C (for the distributed point function and other low-level cryptographic primitives) and Go (for the networking and consensus) for approximately 5,000 lines of code. Our experiment scripts use AWS EC2 instances. Our artifact is available here:

<https://github.com/ucbrise/dory>

A.2 Artifact check-list

- **Data set:** Enron email dataset used to choose system parameters and set sample documents.
- **Metrics:** Latency, throughput
- **Experiments:** Search latency breakdown, search latency with parallelism, search throughput with parallelism
- **Required disk space:** 18MB
- **Expected experiment run time:** Approximately 4 hours
- **Public link:** <https://github.com/ucbrise/dory>
- **Code licenses:** Apache v2

A.3 Description

A.3.1 How to access

Our Amazon AWS AMI is public (the AMI IDs for different regions are set in our scripts). See Appendix A.4 for instructions on running scripts for configuring security groups and the key pair as well as starting a cluster.

A.3.2 Software dependencies

We use the hashicorp msgpack library (<https://github.com/hashicorp/go-msgpack>) for parsing messages and libstemmer (<http://snowball.tartarus.org/download.html>) for stemming keywords. We build on the DPF implementation in Express [43] (<https://github.com/SabaEskandarian/Express>). We also use the OpenSSL library for low-level cryptographic primitives.

A.3.3 Data sets

The Bloom filter size in our experiments is based on statistics from the Enron email dataset [30] (see Table 7a). The sample documents to interactively search over in `sample_docs/` are also from the Enron email dataset.

A.4 Installation

The instructions for setting up the Amazon AWS security groups and key pair are available here: <https://github.com/ucbrise/dory#setting-up-aws-security-groups-and-keypairs>. The instructions for starting a cluster of EC2 instances using our public AMIs are available here: <https://github.com/ucbrise/dory#setup>. We use `r5n.4xlarge` instances in different regions that are geographically close (`east-1` and `east-2`). We also provide instructions for building from source here: <https://github.com/ucbrise/dory#building-from-source>.

A.5 Experiment workflow

To start running experiments, the reviewer should first create a cluster (Appendix A.4). Each figure (or group of figures) reproduced has a corresponding script to run the experiment. Each figure reproduced has another script to plot the data collected. Details are available here: <https://github.com/ucbrise/dory#running-experiments>. After running experiments, the reviewer should teardown the cluster following instructions here: <https://github.com/ucbrise/dory#setup>.

Because the ORAM baseline experiments in our paper take approximately a week to run, we only reproduce two data points (1,024 and 2,048 documents), making the experiment take a little over an hour.

A.6 Evaluation and expected result

The above instructions reproduce Table 7b, Figure 8, Section 7.2, Figure 10, and Figure 11. There may be some variation from the figures in the paper based on how long the experiments are allowed to run.

Our scripts plot the figures using the ORAM baseline data we collected ourselves, as the experiments we provide for reviewers only reproduce two data points. Reviewers can

compare the two data points we reproduce to the data we collected to verify that the data matches up.

More detailed instructions on running experiments and interpreting results are available here: <https://github.com/ucbrise/dory#running-experiments>.

A.7 Experiment customization

Reviewers can configure experiments to run for more trials, run for different numbers of documents, or use different Bloom filter sizes.

A.8 Notes

We implement the DORY search protocol as described in the body of the paper, and our implementation does not include a

complementary end-to-end encrypted filesystem that could use or interface with DORY. We support keyword search with a small, configurable number of false positives (we do not support regular expressions or other advanced search features).

A.9 AE Methodology

Submission, reviewing and badging methodology:

SafetyPin: Encrypted Backups with Human-Memorable Secrets

Emma Dauterman
UC Berkeley

Henry Corrigan-Gibbs
EPFL and MIT CSAIL

David Mazières
Stanford

Abstract. We present the design and implementation of SafetyPin, a system for encrypted mobile-device backups. Like existing cloud-based mobile-backup systems, including those of Apple and Google, SafetyPin requires users to remember only a short PIN and defends against brute-force PIN-guessing attacks using hardware security protections. Unlike today's systems, SafetyPin splits trust over a cluster of hardware security modules (HSMs) in order to provide security guarantees that scale with the number of HSMs. In this way, SafetyPin protects backed-up user data even against an attacker that can adaptively compromise many of the system's constituent HSMs. SafetyPin provides this protection without sacrificing scalability or fault tolerance. Decentralizing trust while respecting the resource limits of today's HSMs requires a synthesis of systems-design principles and cryptographic tools. We evaluate SafetyPin on a cluster of 100 low-cost HSMs and show that a SafetyPin-protected recovery takes 1.01 seconds. To process 1B recoveries a year, we estimate that a SafetyPin deployment would need 3,100 low-cost HSMs.

1 Introduction

Modern mobile phones and tablets back up sensitive data to the cloud. To protect users' privacy, this data must be encrypted under keys that are not available to the cloud provider. Unfortunately, with 3.8 billion smartphone users, it is impractical to expect them all to store, say, a 128-bit AES backup key. Not everyone has a computer, or trustworthy friends who can keep shares of a backup key, or even a safe place to store a backup key on paper. As a result, mobile OSes have fallen back to protecting backups with the least common denominator: device screen-lock PINs. Using PINs is good for security because a user's screen-lock PIN never leaves her device (so the cloud provider never learns it). Using PINs is good for usability because users generally remember them.

Unfortunately, PINs have such low entropy (e.g., six decimal digits) that no feasible amount of key stretching can protect against brute-force PIN-guessing attacks. Instead, modern backup systems—such as those from Apple [47], Google [82], and Signal [55]—rely on hardware-security modules (HSMs) in their data centers to thwart brute-force attacks. Specifically, devices encrypt their backup keys under the public keys of HSMs, but each device includes a hash of its screen-lock PIN as part of the plaintext. HSMs return decrypted plaintext only to clients that can supply this PIN hash. Furthermore, HSMs limit the number of decryption attempts for any given user

Figure 1: Our cluster of 100 low-cost hardware security modules (SoloKeys [72]) on which we evaluate SafetyPin.

account. For fault tolerance, a device typically encrypts its backup key to the public keys of five HSMs, allowing any one of the five to recover the backup key.

This status quo still falls short of acceptable privacy for two reasons. First, HSMs are not perfect, yet each HSM in these systems is a single point of security failure for millions of users' backup keys. Second, these systems make it difficult for clients to detect security breaches. For instance, if a malicious insider working in a data center physically steals an HSM, then to anyone outside the company it looks like an unremarkable single hardware failure. Alternatively, if an insider successfully guesses someone's PIN, the victim may have no idea her backup was ever compromised.

This paper presents SafetyPin, a PIN-based encrypted-backup system with stronger security properties. The key idea behind SafetyPin is that recovering any user's backed-up data either requires (a) guessing the user's PIN or (b) compromising a very large number of HSMs—e.g., 6% of all HSMs operated by a provider. (The 6% figure here is a tunable system parameter.) Such large-scale attacks would typically need to span multiple data centers, be harder for insiders to pull off undetected against physical devices, cost more, and also likely cause service disruptions visible to end users.

One way to achieve SafetyPin's security goal would be to threshold-encrypt the client's hashed PIN and backup key in such a way that decrypting the client's backup key would require the participation of 6% of all HSMs in the system. Unfortunately, this approach lacks scalability. If each client recovering a backup must interact with 6% of the system's HSMs, adding more HSMs improves security without improving throughput. As the number of HSMs in the system increases, we would like the system's overall throughput to increase in tandem with its security (i.e., the attacker's cost).

To achieve scalability, SafetyPin takes a different approach:

devices threshold-encrypt their backup keys to a small cluster of n HSMs such that decryption requires the participation of most HSMs in the cluster. The cluster size n is independent of the total number of HSMs in the system, and depends on both the fraction of compromised HSMs the system can tolerate and the fraction of HSMs that can fail-stop. (For example, to tolerate the compromise of 6% of HSMs where half of a cluster is allowed to fail-stop, we can set the cluster size $n = 40$.) This design achieves our scalability goal, since each device need only communicate with a small fixed number of HSMs during recovery. This design also achieves our security goal because the cluster of n HSMs that can decrypt a client's backup depends on the client's secret PIN, via a primitive we introduce called *location-hiding encryption*. Hence, even if an attacker compromises 6% of the HSMs in the system as a whole, the chances that the attacker compromises a "useful" set of HSMs—i.e., at least half of the HSMs in the device's chosen cluster—is very small. More precisely, we show that if the total number of HSMs in the system is large enough (a few hundred or more), the probability that an attacker can decrypt a backup via HSM compromise is not much higher than the probability of simply guessing the client's PIN.

In modern backup systems, each HSM only needs to monitor the number of PIN attempts for a small subset of users, but because of our location-hiding encryption primitive, every HSM needs to be able to verify the number of PIN attempts for every user. To maintain this information scalably, the HSMs use a new type of distributed log. Third parties can monitor this log to alert users whenever a backup-recovery attempt is underway. Since a compromised service provider may see which HSMs a mobile device interacts with during recovery (and could compromise those HSMs to recover the users' backed-up data), HSMs revoke their ability to decrypt backups after completing the recovery process. Implementing this revocation requires adapting "puncturable encryption" [38] to storage-limited HSMs. While our prototype is focused on PIN-protected backups, these primitives have potentially broader applicability to problems such as private storage in peer-to-peer systems and cryptocurrency "brain wallets."

We implemented SafetyPin on low-cost SoloKey HSMs [72]. We evaluate the system using a cluster of 100 SoloKeys (Figure 1) and an Android phone (representing the client device). Generating a recovery ciphertext on the client, excluding the time to encrypt the disk image, takes 0.37 seconds. To process 1B recoveries a year, or 123K recoveries per hour, we estimate that we would need 3,100 SoloKeys. In a SafetyPin deployment of 3,100 HSMs, tolerating the compromise of 6% of the HSMs (i.e., 194 HSMs), the client must interact with a cluster of 40 HSMs during recovery. Running our backup-recovery protocol across a cluster of this size takes 1.01 seconds.

Limitations. A limitation of SafetyPin is that the set of HSMs a device uses for recovery can leak information about the user's PIN. In particular, an attacker who controls the data center can learn a salted hash of the user's PIN during recovery.

This is unfortunate in the common case that people re-use the same PIN after recovery [23, 42, 32, 70]. We discuss one mitigation in Section 8. Also, while it is possible to detect when PINs can safely be re-used, we have not yet implemented this functionality.

In addition, SafetyPin is more expensive than today's PIN-based backup systems. SafetyPin requires the data center operator to operate a much larger fleet of HSMs (roughly 50 – 100× larger) than the standard HSM-based backup systems require. SafetyPin clients must also download roughly 2MB of keying material per day in a SafetyPin deployment supporting one billion recoveries per year, due to the periodic rotation of large HSM keys. Even so, we expect that the cost of storing and transferring disk images (GBs/user) will dwarf these costs.

2 The setting

Entities. Our encrypted-backup system involves three entities, whose roles we describe here.

Client. Initially, the client holds (1) a username with the service provider, (2) a human-memorable passphrase or PIN, (3) a disk image to be backed up, and (4) the public keys of the service provider's HSMs. Later on, the client should be able to recover her backed-up data using only her username, her PIN, and access to the other components of the backup system.

In SafetyPin, as in today's PIN-based backup systems, security depends on the client having access to the HSMs' true public keys: If a malicious service provider can swap out the HSMs' true public keys for its own public keys without detection, the service provider can immediately break security. Using a distributed log (Section 6) can ensure that all clients see a common set of HSM public keys, to prevent targeted attacks. Hardware-attestation techniques, as used in the FIDO [67] and SGX [44] specs, can provide another defense.

We also assume the provider has traditional account authentication (e.g., Gmail passwords) to prevent random third parties from consuming PIN guesses, but we omit this from the discussion for simplicity.

Service provider. The service provider offers the encrypted-backup service to a pool of clients and it maintains the data centers in which the backup system runs. For example, the service provider could be a mobile-phone vendor, such as Apple or Google. The service provider's data centers contain the network infrastructure that connects the HSMs. They also contain large amounts of (potentially untrustworthy) storage and computing resources. Our security properties will hold against a service provider that becomes compromised at any point after the system is set up.

Hardware security modules (HSMs). The service provider's data centers contain thousands of hardware security modules. An HSM is a tamper-resistant computing device meant for storing cryptographic secrets. HSMs have fully programmable processors but are typically resource-poor (see Table 2). It is possible to lock an HSM's firmware before deployment,

Device	Price	$g^x/\text{sec.}$	Storage	FIPS
SoloKey [72]	\$20	8	256 KB*	
YubiHSM 2 [84]	\$650	14	126 KB	
SafeNet A700 [68]	\$18,468	2,000	2,048 KB	✓
Intel i7-8569U (CPU)	\$431	22,338	n/a	

Table 2: Hardware security modules offer physical security protections but are computationally weak compared to a standard CPU.

The g^x/sec is NIST P256 elliptic-curve point-multiplications per second. “FIPS?” refers to whether the device meets the FIPS 140-2 standard for HSMs. (* The 256 KB storage on the SoloKey is shared between code and data.)

which makes remote compromise and key-extraction attacks more difficult. Each HSM has a public key and stores the corresponding secret key in its secure memory.

The attack scenario. The service provider (Apple, Google, etc.) spends vast amounts of money acquiring a large user base for products that store user data in the cloud. The provider risks reputational damage and journalistic scrutiny if it cannot ensure the durability and confidentiality of user data.

A service provider can deploy SafetyPin as a way to build trust among its user base and to protect its own infrastructure against future compromise. By enlisting third-party organizations to monitor the SafetyPin deployment’s public distributed log, the provider can build further public trust in the system.

At some point after the provider deploys SafetyPin, a powerful attacker wishes to steal user data. The attacker may have malicious insiders working for the provider. It may physically compromise data centers to steal HSMs. It may intercept shipments to tamper with some of the HSMs on their way to the data center. The attacker could also be a state actor employing legal pressure to gain access to data centers. Nonetheless, the attacker is sensitive to both the cost of attacks and the risk of public exposure.

Both the attack cost and risk of exposure increase with the number of HSMs the attacker must compromise. For instance, while a malicious insider working at a data center may be able to abscond with a single HSM—passing the missing device off as a hardware failure—removing 100 HSMs is a much riskier proposition. A state actor who can order the provider to hand over HSMs may be dissuaded if doing so will attract press coverage either by making non-targeted clients’ data unrecoverable or creating a damning public audit trail.

The attacker may compromise clients as well as the provider. For instance, the attacker may have a good guess at a target user’s PIN, perhaps because of CCTV footage showing the user unlocking a mobile device. While SafetyPin cannot prevent the attacker from gaining access to the data with the correct PIN, the risk will be higher to the attacker if stolen PINs cannot be used without exposing the attack in SafetyPin’s public distributed log.

Notation. The set $\mathbb{Z}^{>0}$ refers to the set of natural numbers $\{1, 2, 3, \dots\}$. For a positive integer n , we let $[n] = \{1, \dots, n\}$

and we use \perp to denote a failure symbol. For strings a and b , we write their concatenation as $a||b$. Throughout, we use λ to denote the security parameter, and we typically take $\lambda = 128$ (i.e., for 128-bit security).

3 System goals

SafetyPin implements an encrypted-backup functionality, which consists of two routines:

- the *backup* algorithm, which the client uses to produce its encrypted backup, and
- the *recovery* protocol, in which the client uses HSMs to recover the backup plaintext from ciphertext.

We define these protocols with respect to a number of HSMs $N \in \mathbb{Z}^{>0}$ and a finite PIN space $\mathcal{P} \subseteq \{0, 1\}^*$. For convenience, we define the *master public key* mpk for a data center to be all N HSMs’ public keys: $\text{mpk} = (\text{pk}_1, \dots, \text{pk}_N)$. The syntax of an encrypted-backup system is then as follows:

$\text{Backup}(\text{mpk}, \text{user}, \text{pin}, \text{msg}) \rightarrow \text{ct}$. Given the master public key mpk , a client username user , the client’s PIN $\text{pin} \in \mathcal{P}$, and a message $\text{msg} \in \{0, 1\}^*$ to be backed up, output a recovery ciphertext ct . This routine runs on the client and requires no interaction with HSMs. The client uploads the resulting ciphertext ct to the service provider.

$\text{Recover}^{\mathcal{S}, \mathcal{H}_1, \dots, \mathcal{H}_N}(\text{mpk}, \text{user}, \text{pin}, \text{ct}) \rightarrow \text{msg or } \perp$. The client initiates the recovery routine, which takes as input the master public key mpk , a client username user , a PIN $\text{pin} \in \mathcal{P}$, and a recovery ciphertext ct .

During the execution of *Recover*, the client interacts with the service provider \mathcal{S} and a subset of the HSMs $\mathcal{H}_1, \dots, \mathcal{H}_N$. Each HSM \mathcal{H}_i holds the master public key mpk , and its secret decryption key sk_i . During recovery, the data center provides the client’s username user to each HSM.

The recovery routine outputs a backed-up message $\text{msg} \in \{0, 1\}^*$ or a failure symbol \perp .

We now describe the security properties that such a system should satisfy. We work in an asynchronous network model; we use standard cryptographic primitives to set up authenticated and encrypted channels between the client, service provider, and HSMs.

Property 1: Security. If the client obtains the HSMs’ true public keys, then even an attacker that:

- controls the service provider (in particular, is an active network attacker inside the data centers and has control of the service provider’s servers and storage),
- compromises an f_{secret} (e.g., $f_{\text{secret}} = \frac{1}{16}$) fraction of HSMs in the data center *before* the client begins the recovery process, and
- compromises all of the HSMs in the data center *after* the recovery protocol completes,

still should learn nothing about any honest client’s encrypted message (in a semantic-security sense [35]) beyond what it

can learn by guessing that client's PIN.

Discussion: The adversary can inspect all clients' recovery ciphertexts and then choose to compromise a large set of HSMs that depends on these ciphertexts. Such attacks are relevant when, for example, a state actor with the power to compromise many HSMs targets the backed-up data of a specific set of users.

Two important caveats are: (1) SafetyPin does not protect against an attacker compromising HSMs while recovery is in progress (see Figure 4) and (2) as implemented, SafetyPin does not protect the PIN: an adversary that observes which HSMs the client contacts during recovery may learn a salted hash of the PIN after recovery completes. Section 6.3 discusses how to detect and mitigate this leakage by protecting the salt.

Property 2: Scalability. The recovery protocol should require the client to interact with a constant number of HSMs, independent of the number of HSMs in the data center. (This constant may depend on the security parameter and on the fraction of HSMs whose compromise the system can tolerate.) Hence, providers can deploy additional HSMs to scale capacity. Concretely, when we configure the system to tolerate the compromise of $f_{\text{secret}} = \frac{1}{16}$ of the data center's HSMs, our protocol requires the client to communicate with 40 HSMs during recovery.

Property 3: Fault tolerance. Every client should be able to recover her encrypted message even if a constant fraction f_{live} (e.g. $f_{\text{live}} = \frac{1}{64}$) of the HSMs in the data center fail-stop.

Setting parameters. For the remainder of this paper, we set the fraction of compromised HSMs that the system can tolerate to $f_{\text{secret}} = \frac{1}{16}$ and the fraction of HSMs that can fail while still allowing the client to recover her backup to $f_{\text{live}} = \frac{1}{64}$. This choice is reasonable because large companies have more than 16 data centers, while smaller companies can collaborate on a shared deployment with 16 physical security perimeters. By adjusting the other parameters, it is possible to achieve any $0 < f_{\text{secret}} < 1$ or $0 < f_{\text{live}} < 1$. (In Section 9.2, we discuss how the choice of these values affects other system parameters.)

4 Architecture overview

We now describe our encrypted-backup protocol (Figure 3) and explain how it satisfies the design goals of Section 3. We will discuss possible extensions and deployment considerations in Section 8.

4.1 The back-up process

The client begins the back-up process holding

- the public keys of all HSMs in the data center,
- its secret PIN, and
- a disk image to be backed up (the “message”).

To back up its disk image, the client samples a subset of n HSMs out of the N total HSMs in the data center where $n \ll N$. The client chooses this subset by hashing (a) public

information: the service name, its username, and a public salt the client chooses at random, and (b) its secret PIN. The client then encrypts its message with a random AES encryption key, and then splits this AES key into n threshold shares using Shamir secret sharing [69], such that any threshold t of the shares suffice to recover the AES key. The client prepends each share with the client's username to ensure that the ciphertexts are bound to the client's username. The client then encrypts one share to the public key of each HSM in its chosen subset.

The client's recovery ciphertext then consists of: its public salt, the AES-encrypted message, the n encrypted shares of the AES key, and a configuration-epoch number that the service provider can use to identify the set of HSMs that were in service at the time the client created its backup. The client computes the ciphertext locally and uploads it to the backup service provider, with no HSM interactions required.

To explain why this construction is scalable: since only a constant number of HSMs $n \ll N$ participate in the decryption process, the system scales well as the number of HSMs in the data center increases.

To explain why this construction should be secure: if the attacker cannot guess the client's PIN, the attacker does not know which set of n HSMs (out of the N total) it needs to compromise to recover the client's AES key. So, the best attacks are either to: guess the client's PIN or compromise a large fraction of the data center.

This argument requires that each individual key-share ciphertext leak no information about which HSM can decrypt it—a cryptographic property known as “key privacy” [8]. However, even key-private encryption schemes do not always remain secure against an adversary that adaptively compromises secret keys, which leads to our first technical challenge:

Challenge 1. *How can we ensure that the client's recovery ciphertext “leaks nothing” about which HSMs are required to decrypt the client's message, even against an attacker who can adaptively compromise HSMs?*

In Section 5, we explain how to solve this problem using *location-hiding encryption*, a new cryptographic primitive.

4.2 The recovery process

The client begins the recovery process holding:

- the public keys of all HSMs in the data center,
- its secret PIN, and
- its recovery ciphertext (which the client can fetch from the service provider).

First, the client asks the service provider to record its recovery attempt in the *append-only log*, implemented collectively by the service provider and HSMs. The log holds a mapping of identifiers to values. The service provider can insert new identifier-value pairs into the log but the service provider cannot modify or delete the values of defined identifiers, ensuring that there is at most one immutable value for each identifier.

Figure 3: An overview of the recovery-protocol flow. Each HSM i holds a secret key sk_i . The client holds a vector mpk of all HSMs’ public keys. ① During backup, the client uses its PIN and the master public key to encrypt its data msg into a recovery ciphertext ct . The client then uploads this recovery ciphertext ct to the service provider. ② During recovery, the client downloads its recovery ciphertext. ③ The client asks the data center to log its recovery attempt. ④ The service provider collects a batch of client log-insertion requests, updates the log, and aggregates the new log into a Merkle tree. The service provider and HSMs run a log-update protocol. At the end of this protocol, each HSM holds the root of the Merkle tree computed over the latest log. ⑤ The service provider sends the client a Merkle proof π that the client’s recovery attempt is included in the latest log (i.e., in the latest Merkle root). ⑥ The client sends the recovery ciphertext ct and log-inclusion proof π to the subset of HSMs needed to decrypt the recovery ciphertext. ⑦ The HSMs check the proof and return shares of the decrypted ciphertext to the client. The client uses these to recover the backed-up data msg .

The recovery attempt is logged as follows. The client begins by using public information (service name, username, and salt in the recovery ciphertext) along with its secret PIN to recover the subset of n HSMs it picked during backup. The client then hashes these values together with some randomness to produce a cryptographic commitment h to the identities of these HSMs and to its recovery ciphertext. The client then asks the service provider to insert the identifier-value pair $(user, h)$ into the log, where $user$ is the client’s username. (In this discussion, we use the client’s username as the key for simplicity. In practice, to preserve privacy, we might use an opaque device-install UUID.)

The service provider collects a batch of these log-insertion requests, produces a Merkle-tree [59] digest over the updated log, and runs a log-update protocol with the HSMs. At the end of this protocol, the HSMs hold the updated log digest. The service provider then returns to the client a Merkle proof π proving that the pair $(user, h)$ appears in the latest log digest.

Since the service provider and HSMs run the log-update protocol periodically (e.g., every 10 minutes), the client will have to wait a few minutes on average to decrypt its backup. The client already has to download its large encrypted disk image, which will likely take minutes, so these steps can proceed in parallel.

The client then contacts its chosen set of n HSMs over an encrypted channel, such as TLS. The client sends to each HSM: its username, the opening of its commitment h (i.e., the values and randomness used to construct the commitment h), and the Merkle inclusion proof π . Each HSM

- recomputes the commitment h and checks the inclusion proof π (to confirm that the recovery attempt is logged), and
- decrypts its share of the client’s AES key, confirms that the username in the decrypted plaintext matches the one provided by the client (which prevents user A from attempting to decrypt user B ’s ciphertext, in collusion

with a malicious service provider).

If both of these checks pass, the HSM returns the AES-key share to the client.

Given any t of these decryption-key shares, the client can recover the AES key used to encrypt its backup. The client can then use this AES key to decrypt its backed-up message.

Since at most one log entry can exist per username, the use of the log ensures that each user can make at most one recovery attempt. In this way, the system defeats brute-force PIN-guessing attacks. With a slight modification, it is possible to allow each user to make a fixed number (e.g., 5) guesses, or a fixed number of guesses per time period (e.g., 5 per month).

A counter-intuitive property of this scheme is that the client never explicitly provides its PIN to the HSMs. The fact that the client knows which subset of the HSMs to contact implicitly proves the client’s knowledge of the PIN because the set of n HSMs is much smaller than the total number of HSMs N .

This overview leaves some technical details unexplained. In particular:

Challenge 2. *How do the HSMs implement the append-only log without sacrificing scalability or security?*

A straightforward way to implement the log would be to have each HSM store the entire state of the log. But then every HSM would have to participate in every recovery attempt, which would not meet our scalability goals. Another implementation would be to have the data-center operators maintain the log, but then malicious data centers could violate the append-only property, and thus mount brute-force PIN-guessing attacks, without HSMs noticing.

In Section 6, we explain how the HSMs can collectively maintain such an append-only log in a scalable and secure manner. At a high level, the (potentially adversarial) data center maintains the state of the log, which we represent as a list of identifier-value pairs. Every time the data center wants to insert an identifier-value pair into the log, the data center must

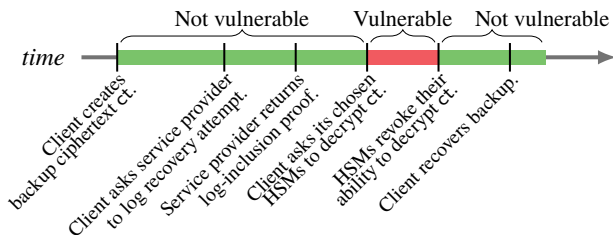

Figure 4: Since HSMs in SafetyPin revoke their ability to decrypt a client’s recovery ciphertext, SafetyPin protects against HSM compromise attacks that take place before recovery begins and after it completes. An attacker who can compromise HSMs while recovery is in progress can break security.

prove to a random subset of the HSMs that the identifier to be inserted is undefined in the current log. Provided that at least one honest HSM audits each log-insertion, we can guarantee that the values associated with log identifiers are immutable (i.e., that we maintain the log’s append-only property). In this way, (a) each HSM needs to participate in only a vanishing fraction of the recovery attempts and (b) even an attacker who can compromise many of the HSMs cannot break the append-only nature of the log.

One remaining issue is that an attacker who observes the data center network may see which HSMs a client interacts with during recovery and decide to compromise that exact set of HSMs after recovery completes.

Challenge 3. *For scalability, the client should only communicate with a small number of HSMs during recovery. But then how can we protect against an attacker who compromises these HSMs after recovery completes?*

Our idea is as follows: after a client runs the recovery protocol, each participating HSM *revokes* its ability to decrypt that client’s recovery ciphertext. So, even if an after-the-fact attacker compromises the HSMs that participated in recovery, the attacker learns no useful information. The only window of vulnerability is at the moment after the client contacts its HSMs and before the HSMs complete revocation (Figure 4). Making this work on resource-limited HSMs requires new technical tools, which we describe in Section 7.

5 Protecting the mapping of users to HSMs with location-hiding encryption

In this section, we define and construct *location-hiding encryption*, which the client uses to encrypt its backup data.

The location-hiding encryption routine takes as input (1) a set of N public keys, (2) a short PIN, and (3) a message, and outputs a ciphertext. In our application, the N public keys are the public keys of the N HSMs in the data center.

The cryptosystem has three main properties, which we formalize in the full version [24]:

1. *Security.* To successfully decrypt the ciphertext, an attacker must either (a) guess the PIN or (b) control more than a constant

fraction f_{secret} of the N total secret keys. This security property must hold even if the attacker can adaptively compromise an f_{secret} fraction of the N secret keys. In our application, this implies that unless an adversary can guess the PIN or compromise a constant f_{secret} fraction of the HSMs in the data center, it learns nothing about the client’s backed-up data.

2. *Scalability.* Given the PIN used to encrypt the message, it is possible to decrypt the message using a small subset of the N secret keys corresponding to the N public keys used during encryption. In our application, a client who knows the correct PIN can recover its backup by interacting with only a small cluster of n HSMs (for some parameter $n \ll N$) out of the N total HSMs. So as N grows, each HSM needs to participate in a vanishing fraction of the total recovery attempts.

3. *Fault tolerance.* Given the PIN, it is possible to decrypt a ciphertext even if a random fraction f_{live} of all secret keys are unavailable. In our application, this implies clients can recover their backups even if an f_{live} fraction of all HSMs fail.

We call this primitive “location-hiding encryption” because there is a small set of n HSMs that the attacker could compromise to decrypt the ciphertext, but the cryptosystem *hides the location* of these HSMs within the larger pool of N HSMs.

Our construction

Our construction of location-hiding encryption is just a careful composition of existing primitives. However, it takes some analysis to prove that the composition provides the desired security properties. We describe our construction here in prose and we include the security definitions and proofs in the full version [24]. The construction makes use of a public-key encryption scheme (hashed ElGamal encryption [27, 15]) and an authenticated encryption scheme (e.g., AES-GCM).

Setup. In our construction, each HSM i , for $i \in [N]$, holds a keypair (pk_i, sk_i) for the public-key encryption scheme. Let $t \in \mathbb{Z}^{>0}$ be a threshold such that if each HSM fails with probability f_{live} , then in a random sample of n HSMs, there are at least t non-failed HSMs with extremely high probability. Our instantiation takes $t = n/2$ for $f_{\text{live}} = \frac{1}{64}$.

Encryption. The encryption routine takes as input a list of N public keys (pk_1, \dots, pk_N) , a PIN, and a message msg . To encrypt the message using our location-hiding encryption scheme:

1. Sample a random AES key k and a random salt.
2. Split k into t -out-of- n -Shamir secret shares k_1, \dots, k_n [69].
3. Hash the PIN and salt and use the result as a seed to generate a list of n random indices $i_1, \dots, i_n \in [N]$.
4. Encrypt each key-share k_j with public key pk_{i_j} .
5. Finally, return (a) the salt, (b) the n public-key ciphertexts, and (c) the AES encryption of msg under key k .

Decryption. To decrypt given the ciphertext and PIN:

1. Hash the salt and PIN to reconstruct the set of indices $i_1, \dots, i_n \in [N]$ used during encryption.
2. Use secret keys $sk_{i_1}, \dots, sk_{i_n}$ to decrypt the n shares of the AES key k . (In fact, only t of the shares are necessary.)
3. Using the recovery routine for Shamir secret sharing, recompute the AES key k from its shares.
4. Decrypt and return msg using the AES key k .

Notice that the decryption routine only uses the PIN to sample the set of secret keys used for decryption. In our application, this implies that the client never needs to explicitly provide its PIN (or even a hash of its PIN) to the HSMs; contacting the right subset of HSMs is enough to ensure that the client provided the correct PIN.

The intuition behind the security analysis is straightforward: with hashed ElGamal encryption, the ciphertext reveals no information about which n public keys (out of the N total where $n \ll N$) were used during encryption. Thus, the ciphertext reveals no information about which secret keys the attacker must compromise unless the attacker can guess the PIN. Without these secret keys, the attacker cannot learn anything about k , and therefore cannot decrypt the message.

In the full version [24], we formalize our location-hiding encryption scheme and prove that it is secure in the random oracle model when instantiated with the hashed ElGamal encryption (with certain constraints on n and N).

There are two reasons why the security analysis is non-trivial: First, we must ensure that the ciphertext leaks nothing about the n keys to which it was encrypted (i.e., that it is *key-private* [8]). Second, we must ensure that the encryption scheme remains secure even if an attacker can adaptively compromise secret keys. This is known as security under *selective-opening attack* [9, 29, 43]. Showing that both properties hold at once is the source of the technical complexity.

6 The distributed log

In SafetyPin, the HSMs collectively maintain a *distributed log*, which any external party can read and replay. The service provider maintains the log state and the HSMs monitor log insertions to ensure that the service provider does not violate the log’s append-only property.

We use this log for two primary purposes:

1. **Limiting PIN guesses.** To prevent an attacker from brute-force guessing a client’s PIN, we use the log (as described in Section 4) to enforce a global limit on the number of recovery attempts that the HSMs allow per username.
2. **Monitoring recovery attempts.** The service provider logs each recovery attempt, so any SafetyPin client can inspect the log to learn whether someone (e.g., a foreign attacker or snooping acquaintance) has tried to recover their backed-up data. A client could then take mitigating action—such as contacting their service provider, a law-enforcement agency, or the press.

A third use for the log—which comes directly from related

work [30] and which we have not yet implemented—is to **manage HSM group membership**. Whenever the service provider wants to add or remove an HSM from the data center, the service provider operator could record this information in the log before the other HSMs will accept the change. All SafetyPin clients can thus verify that they are communicating with the same set of HSMs. In addition, clients can also detect suspicious changes in the set of HSMs in the data center. (For example, if the service provider replaces all HSMs in the data center over the course of a day.)

The log is simply a list of identifier-value pairs maintained by the service provider. Clients can insert identifier-value pairs in order to record recovery attempts, and HSMs maintain a digest of the log state. Our distributed log must satisfy the following key property:

If any honest HSM ever accepts that an identifier-value pair (id, val) is included in the log, the HSM should never accept that (id, val') is included in the log, for any value val' \neq val.

6.1 Underlying data structure

Terminology. The log L is a list of key-value pairs. Since we use the word “key” in this paper to refer to cryptographic keys, we call log keys “identifiers.” We say that a log L' “extends” a log L if (a) L is a prefix of L' and (b) every identifier in L' appears at most once.

Our distributed log uses an authenticated data structure [75, 64, 77] that implements the following five routines:

- $\text{Digest}(L) \rightarrow d$. Return a constant-size digest d representing the current state of the log.
- $\text{ProveIncludes}(L, \text{id}, \text{val}) \rightarrow \{\pi_{\text{Inc}}, \perp\}$. Output a proof π_{Inc} that attests to the fact that the identifier-value pair (id, val) is in the log represented by digest $d = \text{Digest}(L)$.
- $\text{DoesInclude}(d, \text{id}, \text{val}, \pi_{\text{Inc}}) \rightarrow \{0, 1\}$. Return “1” iff π_{Inc} proves that the log that digest d represents contains (id, val).
- $\text{ProveExtends}(L, L') \rightarrow \{\pi_{\text{Ext}}, \perp\}$. Output a proof π_{Ext} that $d' = \text{Digest}(L')$ represents a log that extends the log that digest $d = \text{Digest}(L)$ represents.
- $\text{DoesExtend}(d, d', \pi_{\text{Ext}}) \rightarrow \{0, 1\}$. Return “1” iff π_{Ext} proves that the log that digest d' represents extends the log that digest d represents.

The inclusion and extension proofs must be complete (honest verifiers accept valid proofs) and sound (honest verifiers reject invalid proofs), as we define in the full version [24].

Implementing the data structure. Nissim and Naor [64] show that it is possible to implement these log primitives using only Merkle trees [59]. We summarize their construction in the full version [24]. At a very high level: the digest of the log is just the root of a Merkle tree computed over all of the entries of the log, represented as a binary search tree indexed by id. A log-inclusion proof π_{Inc} is a Merkle proof of inclusion relative to this root. A log-extension proof π_{Ext} is a proof that: (1) every identifier inserted to the new log did not exist in the

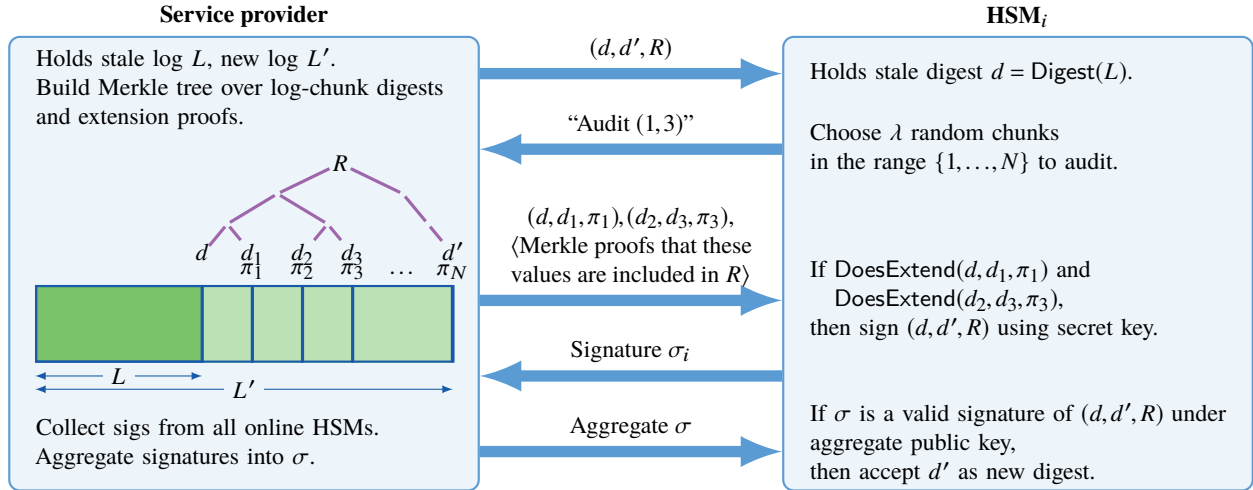

Figure 5: The protocol that the service provider and HSMs use to update the HSM's log digest.

old log and (2) the new digest represents the old log tree with the new values inserted. It is possible to prove both assertions using a number of Merkle proofs proportional to the number of log insertions.

6.2 Building a distributed log

We now explain how to use the primitives of Section 6.1 to build our distributed append-only log.

Initializing the log. The service provider maintains the entire state of the log L . Each HSM stores a log digest d which, in steady state, is the digest of the log L that the service provider holds. Initially, the log L is empty and each HSM holds the digest of the empty log.

Inserting into the log. A client can insert an entry (id, val) into the log by simply sending the pair to the service provider. The service provider adds this entry to its log state L .

Proving log membership to HSMs. Before the HSMs allow a client to begin the recovery process, the HSMs require proof that the client's recovery attempt is logged. Assume for the moment that the service provider holds a log L and all HSMs hold the up-to-date digest $d = \text{Digest}(L)$. (We will explain how the HSMs get the latest log digest in a moment.) Then, a client can prove inclusion of any pair (id, val) in the log by asking the service provider for an inclusion proof. The service provider computes $\pi_{inc} = \text{ProveIncludes}(L, id, val)$ and returns the inclusion proof to the client. The client then sends (id, val, π_{inc}) to the HSM, which can check $\text{DoesInclude}(d, id, val, \pi_{inc})$ to be convinced that (id, val) is in the log represented by its digest d . This inclusion check is fast—logarithmic in the log length.

Updating the log digest at the HSMs. After a sequence of log-insertions, the service provider holds a log state L' . The HSMs will be holding a digest $d = \text{Digest}(L)$ of a stale log L . If the service provider is honest, the new log L' extends the old log L .

To update the log digest at the HSMs, the service provider will first send the new digest $d' = \text{Digest}(L')$ to every HSM. Next, the data center must convince each HSM that this new digest d' represents a log that extends the log L that the old digest d represents.

One non-scalable way to achieve this would be for the service provider to send an extension proof $\pi_{ext} = \text{ProveExtends}(L, L')$ to every HSM. The problem is that the time required to check this extension proof grows linearly with the number of new log entries. So if every HSMs checked the entire extension proof, the throughput of the system would not increase as the number of HSMs increases.

Instead, we use a randomized-checking approach, as in Figure 5. If there have been I insertions to the log since the last update, the service provider divides the updates into N chunks, each containing I/N insertions. The service provider then applies these chunks of updates to the old log L one at a time, producing a digest d_i and extension proof π_i for each of the N intermediate logs $(i \in \{1, \dots, N\})$. The service provider then sends the root R of a Merkle-tree commitment to these digests to each HSM.

Each HSM then asks the service provider for a random λ -size subset of the intermediate digests and extension proofs, where λ is a security parameter. The service provider returns the requested digests and extension proofs and proves that these values are included in the Merkle root R . Each HSM checks its requested intermediate extension proofs using $\text{DoesExtend}(\cdot)$ and checks the Merkle proof relative to the root R . The HSMs auditing the first and last chunks also ensure that the intermediate digests match the old digest d and the new digest d' , respectively.

If these extension and Merkle proofs are valid, each HSM signs the tuple (d, d', R) using an aggregate signature scheme [14], and returns the signature to the service provider. Once all online HSMs have signed, the service provider aggre-

gates these signatures and broadcasts the aggregated signature to all HSMs. If any HSM fails during this process, the service provider notifies the HSMs and they restart this log-update process. (In the full version [24], we describe how the log can make progress even if HSMs fail during the log-update protocol.)

The HSMs check the aggregate signature on (d, d', R) relative to the HSMs' aggregate public key. If the signature is valid, the HSMs accept the new digest d' .

Security. If there are at most f_{secret} compromised HSMs, then even if f_{secret} honest HSMs are slow, $(1 - 2f_{\text{secret}})N$ honest HSMs will participate in any successful protocol execution. If each of these HSM audits C chunks, then the probability that no honest HSM audits a particular log chunk is

$$\Pr[\text{fail}] = \left(1 - \frac{1}{N}\right)^{(1-2f_{\text{secret}})N \cdot C} \leq \exp((2f_{\text{secret}} - 1) \cdot C).$$

(Here, we use the fact that $(1 - x) \leq \exp(-x)$.) If each HSM audits $C = \lambda \approx 128$ chunks, this failure probability is $\ll 2^{-128}$. In other words, some honest HSM will catch a cheating service provider with overwhelming probability. In addition, since all honest HSMs will expect a signature from all honest HSMs, this will cause the updating operation to fail and the system to halt. For this analysis, we assume that the adversary cannot adaptively compromise HSMs while the recovery protocol is running without taking them offline.

Scalability. Each HSM must check the extension proofs on λ chunks, where each chunk contains a $1/N$ fraction of the total updates in each epoch. Thus each HSM checks a vanishing fraction ($\frac{\lambda}{N}$) of log insertions. Each HSM checks one aggregate signature, which requires time independent of the number of HSMs [14]. Thus, the total work that each HSM performs per epoch decreases as the number of HSMs N increases.

Because we use the log primarily to limit the number of PIN attempts, garbage collection is straightforward. The service provider simply creates a new empty log, effectively resetting the number of PIN attempts for every user (old copies of the log can still be inspected to monitor recovery attempts). To ensure that the service provider does not run garbage collection and clear the state too frequently, each HSM will run garbage collection for a fixed number of times (e.g. the expected number of garbage collections over two years) before refusing to respond to further requests. This bounds the number of times the service provider can garbage collect the log.

6.3 Transparency and external auditability

Our log design allows *anyone* to audit the log to ensure that the service provider correctly maintains the log's append-only property. Additional auditors only add to the security of the system by adding another layer of protection, as they can detect log corruptions in the event that more than f_{secret} HSMs are compromised. In particular, for any two log digests d and d' , an auditor can ask the data center for the entire logs L and L' corresponding to both of these digests. The auditor

confirms that d is the root of the log tree for L and that d' is the root of the log tree for L' . Finally, the auditor checks that L' extends L .

As an extra precaution, users could specify external parties (e.g., Let's Encrypt) as designated auditors during backup. During recovery, the HSMs would only complete the recovery if these auditors sign the latest log digest. In this way, mounting a brute-force PIN-guessing attempt against a user would require compromising the user's external auditors as well.

The transparency log can also help with PIN re-use. As discussed in Section 8, instead of storing the salt directly with the service provider, the salt itself can be encrypted using a second round of location-hiding encryption and a null PIN. After recovery, the salt will be destroyed as discussed in the next section. Once the salt has been destroyed, the device restoring a backup can use the log to determine if anyone else has ever fetched the salt. If not, then it is safe for the user to re-use the old PIN.

As described in Section 4, the log contains usernames, which could be sensitive. To prevent leaking usernames, we would replace usernames with random device identifiers that are rerandomized when the device is factory reset. However, even with this modification, the log still leaks information about when and how often users restore backups, which the service provider may not wish to make public. While we hope that organizations would make their logs public, we acknowledge that some may only share their logs with several hand-picked organizations for auditing or may not share their logs at all. In these cases, our security guarantees still hold, although some of the transparency benefits are lost.

7 Forward security by puncturable encryption

We would like our encrypted-backup system to provide forward secrecy [18]. During the recovery process, the client reveals the identity of the $n \ll N$ HSMs that can decrypt its backup. Without forward secrecy, an attacker can break into these n HSMs to recover the client's backed-up data. Forward secrecy ensures that after recovery, an attacker, even one who compromises all HSMs in the data center, learns no information about the client's backup.

One seemingly straightforward way to provide forward secrecy would be to use a new keypair for each backup. However, because the client cannot interact with the HSMs it is encrypting to during backup (as this would reveal their identities), using a unique keypair for every backup would require every HSM in the data center to generate a new keypair for every backup, running counter to our scalability goals.

7.1 Background: Puncturable encryption

We instead achieve forward secrecy using puncturable public-key encryption [38, 39, 25, 21, 19, 26]. A puncturable encryption scheme is a normal public-key encryption scheme (KeyGen, Encrypt, Decrypt), with one extra routine:

Puncture(sk, ct) \rightarrow sk_{ct}. Given a decryption key sk and a ciphertext ct, output a new secret key sk_{ct} that can decrypt

all ciphertexts that sk could decrypt except for ct .

Puncturable encryption for forward secrecy. To achieve forward security in SafetyPin, after an HSM decrypts its share of a client’s recovery ciphertext ct , the HSM *punctures* its secret decryption key. The punctured key allows the HSM to decrypt all ciphertexts except for ct . Thus, if an attacker compromises *all* HSMs in the data center after a client has recovered its backup, the attacker will be unable to decrypt any backup images that clients have already recovered. Furthermore, if an attacker compromises at most $f_{\text{secret}} \cdot N$ HSMs total, where f_{secret} is a parameter of the system that we define in Section 3, then the attacker will not be able to recover any backed-up data whatsoever.

Existing tool: Bloom-filter encryption. Our implementation uses a puncturable encryption scheme called Bloom-filter encryption [25]. There are only two details of Bloom-filter encryption that are important for this discussion.

1. *The secret key is large.* If a key supports $P \in \mathbb{Z}^{>0}$ punctures and we want decryption to fail with probability at most $2^{-\lambda}$, then the secret key for Bloom-filter encryption is an array of roughly λP elements of a cryptographic group \mathbb{G} . After P punctures, the secret key may no longer decrypt messages and it is necessary to rotate encryption keys.
2. *Puncturing is simple.* Puncturing the secret key just requires deleting λ elements in the data array that comprises the secret key.

Concretely, when we set the Bloom-filter-encryption parameters to suitable values for experimental evaluation, each Bloom-filter encryption secret key has size over 64 MB. Even high-end HSMs have only 1–2 MB of storage (Table 2), so storing such large keys on an HSM would be impossible.

7.2 Outsourced storage with secure deletion

We show how to efficiently outsource the storage of this large secret key in a way that preserves forward secrecy of the punctured key. In particular, the HSM can outsource the storage of its secret-key array to the untrustworthy service provider, while still retaining the ability to delete portions of the key. Our technique applies to outsourcing the storage of any data array—not just secret keys—so we describe our secure-deletion approach in general terms.

Desired functionality. At a high level, the HSM has access to (a) a small amount of internal storage and (b) a large external block store, run by the service provider. The HSM wants to store an array of D data blocks at the provider ($data_1, \dots, data_D$). The HSM should be able to subsequently *read* or *delete* these blocks.

The following security properties should hold, even if the attacker, controlling the service provider, may choose the data-array and sequence of operations the HSM performs:

- **Integrity.** If the service provider tampers with the stored data in a way that could cause a *read* to return an incorrect result, the read operation outputs \perp . Otherwise, the read

Figure 6: Our outsourced-storage scheme uses a tree of keys. An arrow $a \rightarrow b$ denotes that value b is stored encrypted under key a . A service provider that stores all values it sees and later compromises the HSM state (sk') still does not learn the deleted $data_3$ value.

operation for a block i returns the value of the last data that the client wrote to block i .

- **Secure deletion.** If the service provider compromises the HSM after the HSM has run the *delete* operation for the i th data block, the attacker learns nothing about the data stored in block i . (This property implies a confidentiality property: the service provider learns nothing about the outsourced data.)

For efficiency, the HSM storage requirements must be small (constant size) and the *read* and *delete* routines should run quickly (in time logarithmic in the size D of the data array). Unlike in ORAM [33, 34], our goal is not to hide the HSM’s data-access pattern from the service provider. We aim only to hide the contents of the array.

7.3 Our secure outsourced storage scheme

We explain our construction here in prose. See the full version [24] for a more formal description.

Running the setup phase. During the setup phase, our outsourced-storage scheme builds a binary tree with D leaves. Every node of the tree contains a fresh symmetric encryption key. During setup, for each node in the tree with key sk_i , we encrypt the keys of the child nodes sk_{i0} and sk_{i1} with sk_i and store this ciphertext $\text{AE.Encrypt}(sk_i, sk_{i0} || sk_{i1})$ in outsourced storage. At the leaves of the tree, we encrypt the i th data block with the key sk_i at the i th leaf and we store the ciphertext $\text{AE.Encrypt}(sk_i, data_i)$ in outsourced storage.

For example, in Figure 6, we use sk_0 to encrypt sk_{00} and sk_{01} and we store the result in outsourced storage. We use key sk_{01} to decrypt data item 2. Thus, knowing the root key sk is enough to decrypt the entire tree and access every data element in the array.

Reading a data block. To retrieve the data block at index i , the HSM reads in the ciphertexts along the path from the tree root to leaf i . The HSM then decrypts the chain of ciphertexts

from the root down to recover the data block at index i . For example, in Figure 6, to retrieve data block 3, the HSM can use sk to decrypt sk_1 , and sk_1 to decrypt sk_{10} , which it can use to decrypt data item 1.

Deleting a data block. To delete the data block at index i , the HSM recovers (as in retrieval) the keys along the path from the root to leaf i . At the node containing the key to decrypt data block i , the HSM deletes the key. It then chooses a fresh key and re-encrypts the other key at that node using the fresh key. To maintain the ability of the parent key to decrypt the child ciphertext, the HSM updates the parent of that node to contain the fresh key for its child and re-encrypts the parent's keys under a new key. It continues this up the path to the root, where the HSM chooses a new key sk' to encrypt the root. The HSM replaces sk with sk' , deleting the old sk , and then sends the new ciphertexts along the path from the root to leaf i back to the service provider. For example, in Figure 6, to delete data item 3, the HSM decrypts the keys $(sk_0||sk_1)$ and $(sk_{10}||sk_{11})$. The HSM then deletes sk_{10} , chooses a new key sk'_1 to encrypt sk_{11} , and then chooses a new key sk' to encrypt sk_0 and sk'_1 . The HSM then replaces sk with sk' .

Efficiency. The setup time is linear in the size of the data array D . The runtimes of retrieval and deletion are both logarithmic in D , and require only symmetric-key operations. The HSM stores only the constant-sized root encryption key sk .

Security intuition. An HSM can always recover the keys necessary to decrypt a data item, provided the HSM did not previously delete any of the keys necessary for decryption. Integrity follows immediately from the security of the underlying authenticated encryption scheme. Finally, we ensure secure deletion by deleting the key necessary to decrypt a certain data item and updating the root key. Without the old root key, it is impossible to access the key necessary to decrypt the deleted data item.

Putting it together. To summarize: the HSMs use a puncturable encryption scheme to prevent the compromise of HSM secrets at time T from allowing an adversary to learn about backed-up data that was recovered any time before T . We implement puncturable encryption using Bloom-filter encryption and outsource the storage of the large secret decryption key using our new technique for outsourcing with secure deletion.

8 Extensions and deployment considerations

The full SafetyPin implementation has to deal with a number of additional issues, which we discuss now.

Failure during recovery. As discussed in Section 7, after participating in recovery, HSMs revoke their ability to decrypt the recovered ciphertext. One consequence is that a client cannot recover the same backup ciphertext twice. This raises the question of what happens if a replacement device fails during or shortly after recovery, or if a communication failure during recovery prevents the new device from receiving the replies from the HSMs.

To solve this problem, when a client initiates recovery, it first generates a fresh per-recovery keypair (sk, pk) for a public-key encryption scheme. The client backs up this secret key sk using SafetyPin before initiating its recovery. Next, the client sends the public key pk to each HSM and then begins the backup-recovery process. Each HSM encrypts its replies to the client under pk , and each HSM sends a copy of each reply to the data center. If a client device fails during recovery, a second, replacement client device can retrieve the backed-up secret key sk and use these to decrypt the replies stored at the data center. This scheme nests arbitrarily, thereby handling any number of consecutive device failures during recovery.

Incremental backups. In practice, mobile devices often generate incremental backups rather than encrypting the entire disk image for each backup. SafetyPin supports incremental backups in the following way. The user uses SafetyPin to store a single AES key, which the user also keeps on her phone. The user can then encrypt incremental backups under this AES key and upload the resulting ciphertext to the data center. When the user recovers, she recovers her AES key and can use this key to decrypt the incremental updates.

Multiple recovery ciphertexts. Clients back up their phones regularly (e.g., every three days), and will thus generate a series of recovery ciphertexts. We want to ensure that after a client recovers her backup from time t , the HSMs involved in recovery puncture their secret decryption keys so that they cannot decrypt that client's backups from earlier times $t' < t$, even if an attacker compromises all HSMs in the data center. To achieve this, in the puncturable-encryption step (Section 7), we have the client use the same salt for each recovery ciphertext it generates. In this way, the client will encrypt its series of backups to the same set of HSMs. When these HSM puncture their secret keys during the recovery process, they will destroy their ability to decrypt any previous recovery ciphertexts from the given client. After recovery, the client chooses a new salt to generate subsequent backups on its new device.

Preventing post-recovery PIN leakage. As we have discussed, an attacker that watches the client recover can learn a salted hash of the user's PIN, which can be used to mount an offline brute-force attack to learn the user's PIN.

One approach to protect against this attack would be to have each user store their salt in secret-shared form at a random set S_{salt} of HSMs, where S_{salt} is included in the client's recovery ciphertext. Then, provided that the attacker does not compromise this set of HSMs, the attacker would learn no useful information on the user's PIN, even after recovery. An attacker could always compromise every HSM in S_{salt} , but an attacker that can compromise only a f_{secret} fraction of HSMs in the data center would not be able to mount this attack against too many clients' salts. We hope to model and prove this multi-user PIN-protection property in future work.

Operation	Ops/sec	Operation	Ops/sec
Pairing	0.43	HMAC-SHA256	2,173.91
ECDSA ver	5.85	AES-128	3,703.70

		RTT, CDC (32b)	2,277.90
		Flash read (32b)	$\approx 166,000$

Table 7: Microbenchmarks on SoloKey. Pairing is on BLS12-381 curve using the JEDI library [49]. Other public-key operations use NIST P256 curve.

9 Implementation and evaluation

We implemented SafetyPin on an experimental data cluster of 100 hardware security devices (Figure 1).

HSM. For the HSMs, we used SoloKeys [72], a low-cost open-source USB FIDO2 security key. SoloKeys use a STM32L432 microcontroller with an ARM Cortex-M4 32-bit RISC core clocked at 80MHz and 265KB of memory. The device is not side-channel resistant, but has a true random number generator and can lock its firmware. We add roughly 2,500 lines of C code to the open-source SoloKey firmware [71].

By default, SoloKeys communicate with the USB host via USB HID, an interrupt-based USB class used typically for keyboards and mice that has a maximum throughput of 64KBps. To improve performance, we rewrote parts of the firmware to use USB CDC, a high-throughput USB class commonly used for networking devices. This gave a roughly 32 \times increase in I/O throughput (Table 7).

For the puncturable-encryption scheme (Section 7.1), we use a variant of Bloom-filter encryption [25] that avoids the need for pairings [13] but increases the size of the HSMs' public keys. For the aggregate signature scheme needed for the log, we use BLS-style multisignatures [12] over the JEDI [49] implementation of the BLS12-381 curve.

Our implementation does not encrypt communication between the client and HSMs. Based on the time to run AES-128 and ElGamal encryption on the SoloKeys, we estimate that transport-layer encryption would add two ElGamal decryptions and 2KB of AES operations per recovery, increasing recovery time by approximately 0.3 seconds, or 30%. This overhead is comparatively high because processing a recovery only requires a handful of symmetric and public key operations.

Service Provider. Our service provider host is a Linux machine with an Intel Xeon E5-2650 CPU clocked at 2.60GHz. Our service-provider implementation is roughly 3,800 lines of C/C++ code (excluding tests) and uses OpenSSL.

Client. Our client device is a Google Pixel 4. Our implementation is roughly 2,300 lines of C/C++ code (excluding tests) and uses OpenSSL.

9.1 Microbenchmarks

Log. Figure 8 demonstrates how increasing the number of HSMs reduces the log-digest update time. We assume that the

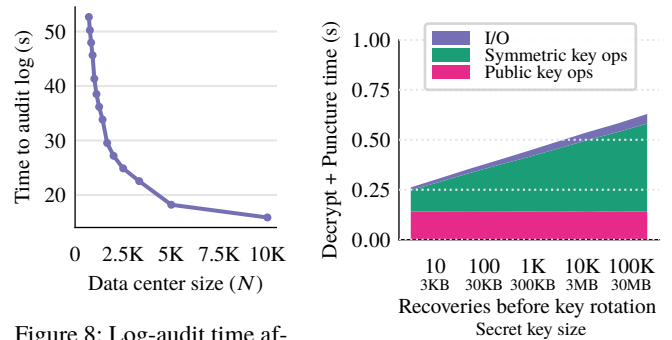

Figure 8: Log-audit time after inserting 10K recovery attempts for a log with roughly 100M recovery attempts. We only measure the auditing time for 100 HSMs as we only had 100 SoloKeys; we distribute the work as if there were N HSMs.

Figure 9: Time to run puncturable encryption on a single HSM as the maximum number of allowed punctures (and also secret key size) grows. The cost of our outsourced storage scheme dominates, though the access time is logarithmic in the size of the key.

log is periodically garbage collected (i.e., approximately once a month), so that it holds at most a hundred million recovery attempts at once. If the HSMs run the log-update process every 10 minutes, each HSM spends approximately 11% of its active cycles auditing the log. The choice of how often to update the log is a tradeoff between how long users must wait to recover their backups and the total number of write cycles to non-volatile storage permitted by the hardware.

Puncturable encryption. Figure 9 shows the cost of performing a decrypt-and-puncture operation as the number of supported punctures increases. The AES operations associated with our scheme for outsourced storage with secure deletion (Section 7.2) dominate the cost.

Another way to implement outsourced storage with secure deletion would be to have the HSM store the outsourced array encrypted under a single AES key k . To delete an item, the HSM would read in the entire array, delete the item, and write out the entire array encrypted under a fresh key k' . With this approach, a deletion takes 48 minutes for a 64 MB array (the size of our outsourced secret keys). Our scheme thus improves system throughput by roughly 4,423 \times .

Each HSM punctures its secret key (Section 7.1) once after each decryption it performs. Since our puncturable-encryption scheme only supports a fixed number of punctures, each HSM must periodically rotate its encryption keys. We configure our puncturable-encryption scheme to allow each HSM to perform roughly 2^{18} decryptions before it must rotate its keys (rotation is triggered when half of the elements of the secret key have been deleted). Key rotation is expensive: we estimate (based on the number of public-key operations required) that key rotation on our HSMs will take roughly 75 hours. Each HSM spends approximately 139.4 hours processing recoveries and maintaining the log between key rotations. Therefore, each HSM spends roughly 56% of its cycles rotating its keys, and

Figure 10: Breakdown of time to save (on Android Pixel 4 phone) and recover (using our SoloKey cluster). We do not consider the time to encrypt or decrypt disk images.

each HSM can process 1,503.9 recoveries per hour on average.

9.2 End-to-end costs

Parameters. We estimate that on average, each user will run recovery once a year. (There are 3.8B smartphone users [73] and 1.5B smartphones sold annually [74], so we expect $1.5/3.8 = 0.39 \ll 1$ recovery/user/year.) We calculate that a SafetyPin deployment of $N = 3,100$ HSMs could support one billion users. So, we treat our small cluster of 100 HSMs as a representative slice of a larger data center of $N = 3,100$ HSMs. Within this larger data center, each client shares its recovery keys among a cluster of $n = 40$ HSMs. This choice of n is based on the size of the data center N and PINs with six decimal digits, and is dictated by bounds we prove in the full version [24]. We set the puncturable encryption keys to allow 2^{20} punctures, as we found this provides a reasonable tradeoff between the time to decrypt and puncture and the time between key rotations. With these parameters, we maintain secrecy if at most an $f_{\text{secret}} = \frac{1}{16}$ fraction of the HSMs are compromised (or $f_{\text{secret}} \cdot N \approx 194$ total). We allow data recovery if at most an $f_{\text{live}} = \frac{1}{64}$ fraction fail due to benign hardware failures (or $f_{\text{live}} \cdot N \approx 48$ total).

Baseline. We compare against an encrypted-backup system modeled on the ones that Google and Apple use [82, 47]. To backup, the client selects a fixed cluster of five HSMs and encrypts her recovery key and a hash of her PIN under the cluster’s public key. At recovery, the client sends the recovery ciphertext and a hash of her PIN to the cluster, and any HSM in the cluster can decrypt the ciphertext, check that the PIN hashes match, and return the recovery key. To defeat brute-force PIN-guessing attacks, each HSM independently limits the number of recovery attempts allowed on a given ciphertext.

Client overhead. Figure 10 gives the overhead of generating a backup in SafetyPin, compared to the baseline. The backup process takes 0.37 seconds. SafetyPin recovery ciphertexts are 16.5KB, versus 130B for our baseline, though we expect encrypted disk image to dominate the ciphertext size.

SafetyPin increases the bandwidth cost at the client. In the baseline scheme, the client downloads five public keys—one from each of its five chosen HSMs. In SafetyPin, the client must fetch a copy of all HSMs’ public keys. (This way, the

service provider does not learn the subset of HSMs to which the client is encrypting its backup.) So, when a client first joins the system, the client must download all these keys (11.5MB). Whenever an HSM rotates its puncturable-encryption keys, clients must download the HSM’s new public key. In a deployment of $N = 3,100$ HSMs supporting one billion recoveries annually, we estimate that each SafetyPin client must download 1.97MB of keying material daily. Increasing the puncturable encryption failure probability would decrease client bandwidth, although this would require decreasing the fraction of HSMs allowed to fail, f_{live} . If a client goes offline for several days, it must download the rotated public keys for each day it spent offline (roughly 2MB/day), up to a maximum of 11.5MB (the size of all HSMs’ keys). However, the client only needs to store the public keys for the n HSMs comprising its chosen recovery cluster which amounts to 9.02KB.

Recovery time. At a cluster size of $n = 40$ HSMs, Figure 11 shows that the end-to-end recovery time takes 1.01 seconds. Puncturable-encryption operations dominate recovery time (Figure 10), since these require expensive elliptic-curve operations for ElGamal decryption and many I/O and AES operations in order to perform secure deletion (Section 7.2).

Tail latency. In a deployment of SafetyPin, it will be important to consider not only the average throughput of the SafetyPin cluster, but also the request latency. Since recovery requests will arrive concurrently and in a bursty fashion, we will need to overprovision the system slightly to ensure that request tail latency does not grow too high, even under large transient loads. In Figure 13, we model how many HSMs are required to achieve various 99th-percentile latencies, while handling different average throughputs. We compute these values by modeling incoming requests using a Poisson process and each HSM using a M/M/1 queue with service times derived from our experimental results. As the figure demonstrates, by increasing the total number of HSMs, we can reduce the tail latency even when accounting for request contention. We anticipate that recovery time will in practice be dominated by the time to download the encrypted disk image, and so as long as the tail latency is less than or close to this time, any delay is unlikely to be noticed by the user.

Financial cost. Figure 12 shows how throughput scales as the outlay on HSMs increases and Table 14 presents dollar-cost estimates for SafetyPin deployments with different types of HSMs. For a configuration that tolerates the compromise of 50 high-quality HSMs, we estimate that adding SafetyPin to an unencrypted backup system would increase the system’s dollar cost by 2.5%.

10 Related work

Today’s encrypted-backup systems rely either on the security of hardware security modules [37, 47], secure micro-controllers [3], or secure enclaves [55, 57]. Vulnerabilities in these hardware components leave encrypted-backup systems

Figure 11: Recovery time grows slowly as cluster size n increases. The bits of security lost refers to the difference between the advantage of an attacker against a SafetyPin deployment with the given value of n and an attacker trying to guess the user’s PIN.

Figure 12: Estimated number of SafetyPin-protected recoveries per year supported by clusters of different HSM models and costs. We use g^x/sec to compute the expected throughput of more powerful HSMs based on our measurements using SoloKeys (Table 2).

Figure 13: Data center sizes necessary to process different request rates with various 99th-percentile latency requirements.

open to attack. And there is ample evidence of vulnerabilities in both HSMs [66, 60, 63, 41, 46, 17, 31, 2] and enclaves [79, 16, 36, 53, 28, 80, 81, 61, 20, 40, 52, 11], and reason for concern about hardware backdoors as well [76, 83, 7, 48].

Many companies including Anchorage [5], Unbound Tech [78], Curv [22], and Ledger Vault [51], offer systems for secret-sharing cryptocurrency secret keys across multiple hardware devices. Unlike SafetyPin, these solutions use a small fixed set of HSMs, so they cannot simultaneously provide scalability and protection against adaptive HSM compromise.

In recent theoretical work, Benhamouda et al. show how to scalably store secrets on proof-of-stake blockchains when an adversary can adaptively corrupt some fraction of the stake [10]. They face many of the same cryptographic challenges that we tackle in Section 5; their theoretical treatment complements our implementation-focused approach. While they use proactive secret sharing to periodically re-share the secret and hide the secret from an adversary controlling some fraction of the stake, our approach allows a party with some low-entropy secret to recover the high-entropy secret.

Transparency logs inspire our log design [6, 50, 58, 1, 54]. While these logs allow a powerful auditor to verify correctness,

	HSM Qty.	f_{secret}	N_{evil}	Cost

<i>Estimated cost of storing $4\text{GB} \times 10^9$ users per year:</i>				\$600M

Table 14: The estimated hardware cost of a SafetyPin deployment supporting one billion users, if each user recovers once per year. The N_{evil} number is how many corrupt HSMs the deployment tolerates.

We estimate the storage cost using AWS S3 infrequent access [4] (\$0.0125 per GB/month). We estimate YubiHSM2 and SafeNet HSM throughput using their data sheets (Table 2). When computing the number of HSMs necessary to service a billion users, we account for key-rotation time. A cluster of 40 SafeNet HSMs can meet the throughput demands of one billion users, so we also consider larger deployments tolerating more compromised HSMs.

they do not easily allow distributing the work of auditing across many less powerful participants. The proofs we provide to the HSMs about the state of the log draw on work on authenticated data structures [75, 56, 65] and cryptocurrency light clients [62]. Kaptchuk et al. show how public ledgers can be used to build stateful systems from stateless secure hardware [45], and they show how their techniques can be applied to Apple’s encrypted-backup system. This work is complementary to ours, as they show how to securely manage state in cases where HSMs do not have secure internal non-volatile storage (an assumption we make in SafetyPin).

11 Conclusion

SafetyPin is an encrypted backup system that (a) requires its users to only remember a short PIN, (b) defeats brute-force PIN-guessing attacks using hardware protections, and (c) provides strong protection against hardware compromise. SafetyPin demonstrates that it is possible to reap the benefits of hardware security protections without turning these hardware devices into single points of security failure.

Acknowledgments. We would like to thank Raluca Ada Popa and Bryan Ford for their support throughout this project. Albert Kwon, Anish Athalye, Christian Mouchet, David Lazar, Dima Kogan, and Lefteris Kokoris-Kogias, offered thoughtful criticism on drafts of this work. We thank our shepherd Sebastian Angel for his work reviewing our camera-ready. We thank Dan Boneh for useful suggestions on how to simplify the security analysis of our location-hiding encryption scheme, we thank Vinod Vaikuntanathan for the suggestion to avoid pairings in our puncturable-encryption scheme, and we thank Keith Winstein for early brainstorming on passwords and PINs. Conor Patrick and Nicolas Stalder gave helpful suggestions for modifying the SoloKey firmware to support USB CDC, and Vivian Fang provided advice on assembling the system. Finally, we thank the anonymous reviewers of USENIX Security 2020 and OSDI 2020 for their thorough and detailed feedback. This research is also supported in part by the RISELab, a Facebook Research Award, and a NSF GRFP fellowship.

A Artifact Appendix

A.1 Abstract

The SafetyPin implementation is split into two components:

- **HSM:** The HSMs (hardware security modules) are used to recover user secrets. Our implementation uses SoloKeys, which are low-cost HSMs. We add roughly 2,500 lines of C code to the open-source SoloKey firmware.
- **Host:** The host implements functionality for the user and data center, including saving secrets, maintaining the log, and coordinating HSMs. Our implementation is roughly 3,800 lines of C/C++ code.

We implement the protocol described in the paper above. To improve performance, we rewrote parts of the SoloKey firmware to use USB CDC, a high-throughput USB class commonly used for networking devices. This results in roughly a 32× increase in I/O throughput. Our artifact is available at:

<https://github.com/edauterman/SafetyPin>

A.2 Artifact check-list

- **Hardware:**
 - 100 SoloKeys
 - 10 Anker SuperSpeed USB 3.0 hubs
 - 2 4-port USB PCIe controller cards
 - Linux machine with Intel Xeon E5-260 CPU clocked at 2.60GHz
- **Compilation:** The ARM compiler for the SoloKeys, and gcc for the host.
- **Metrics:** Latency
- **Experiments:** Log-audit time, puncturable encryption overhead, breakdown of recovery time, cluster size vs. recovery time
- **Required disk space:** 14MB
- **Expected experiment run time:** 50 minutes
- **Public link:** <https://github.com/edauterman/SafetyPin>
- **Code licenses:** Apache v2

A.3 Description

A.3.1 How to access

We provide reviewers with credentials to remotely access our system. Instructions for assembling a similar system are available here:

<https://github.com/edauterman/SafetyPin/blob/master/SETUP.md>.

A.3.2 Hardware dependencies

Our artifact uses SoloKeys as low-cost HSMs. We use 100 SoloKeys for our experiments, although other deployments

could use a different number of HSMs. Because of limitations in the Intel XCHI controller, which supports a maximum of 96 endpoints (each USB 3.0 device has 3 endpoints), we installed PCIe cards to support additional endpoints. This is not necessary for smaller-scale deployments, but larger deployments should choose a host that supports installing such PCIe cards or find another solution. We also recommend USB hubs with an external power source such as the Anker hubs.

A.3.3 Software dependencies

The firmware for the SoloKeys builds on the original SoloKey firmware, which already includes several libraries for cryptographic primitives on embedded devices:

<https://github.com/solokeys/solo>.

To support pairings for aggregate signatures, we use the jedi-pairing library for embedded devices:

<https://github.com/ucbrise/jedi-pairing/>.

For USB HID support, we use the Signal11 library:

<https://github.com/signal11/hidapi>.

We implement our cryptographic primitives that do not require pairings at the host using OpenSSL.

A.4 Installation

Instructions for building the host are available under `host/`. Instructions for building the firmware and flashing the SoloKeys are available under `hsm/`. The SoloKey documentation provides additional details and troubleshooting for building and flashing the SoloKeys:

<https://docs.solokeys.io/>.

When experimenting with SafetyPin, you should not boot SoloKeys in DFU mode, as this locks the firmware and will prevent you from modifying the firmware later (e.g. to load an updated version of the SafetyPin source).

A.5 Experiment workflow

Reviewers can remotely access our machine and run all experiments by executing `./runAll.sh` in `bench/`. More detailed instructions for running individual experiments are available here:

<https://github.com/edauterman/SafetyPin#instructions-for-artifact-evaluation>.

A.6 Evaluation and expected result

Run all experiments by executing `./runAll.sh` in `bench/`. This will produce figures in `bench/out` that match Figure 8, Figure 9, Figure 10, and Figure 11. Note that we only reproduce the recovery time breakdown in Figure 10. Additionally, the configuration we set up for the reviewers only uses 90 HSMs for Figure 8 and Figure 11. We do this to keep different firmware on the remaining 10 HSMs to measure the breakdown in puncturable encryption time as the secret key size increases (Figure 9). For the experiments we show in the body of the paper, we re-flashed HSMs between experiments so that we could use all 100 HSMs to generate Figure 8 and Figure 11.

A.7 Experiment customization

The experiment for Figure 8 can be modified to measure different data center sizes without changing the firmware on the HSMs. The experiment for Figure 9 can likewise be modified to measure different secret key sizes, although this requires changing HSM firmware. If we had more HSMs, we could easily expand Figure 11 to show the effect of larger cluster sizes. We do not measure cluster sizes less than 40 because our analysis shows that our security guarantees begin to break down below this point.

A.8 Notes

To switch between USB CDC and USB HID, change the HID flag on both the host and the HSMs (this requires loading new firmware on the HSMs). More detailed instructions are available here:

<https://github.com/edauterman/SafetyPin/blob/master/SETUP.md>.

Note that rather than generating puncturable encryption secret keys on the HSM (a process we estimate would take roughly 75 hours), to run our experiments efficiently, we generate the secret key on the host (for security, a real-world deployment would need to generate this secret key on the HSM).

A.9 AE Methodology

Submission, reviewing and badging methodology:

Efficiently Mitigating Transient Execution Attacks using the Unmapped Speculation Contract

Jonathan Behrens, Anton Cao, Cel Skeggs, Adam Belay, M. Frans Kaashoek, and Nickolai Zeldovich
MIT CSAIL

Abstract

Today’s kernels pay a performance penalty for mitigations—such as KPTI, retpoline, return stack stuffing, speculation barriers—to protect against transient execution side-channel attacks such as Meltdown [21] and Spectre [16].

To address this performance penalty, this paper articulates the *unmapped speculation contract*, an observation that memory that isn’t mapped in a page table cannot be leaked through transient execution. To demonstrate the value of this contract, the paper presents WARD, a new kernel design that maintains a separate kernel page table for every process. This page table contains mappings for kernel memory that is safe to expose to that process. Because a process doesn’t map data of other processes, this design allows for many system calls to execute without any mitigation overhead. When a process needs access to sensitive data, WARD switches to a kernel page table that provides access to all of memory and executes with all mitigations.

An evaluation of the WARD design implemented in the sv6 research kernel [8] shows that LEBench [24] can execute many system calls without mitigations. For some hardware generations, this results in performance improvement ranging from a few percent (huge page fault) to several factors (getpid), compared to a standard design with mitigations.

1 Introduction

Over the last two years, transient execution has emerged as a powerful new side-channel attack technique. Vulnerabilities have proliferated [5, 12], with examples now including Meltdown [21], Spectre [16], L1 Terminal Fault [4], RIDL [29], Fallout [6], ZombieLoad [25], CrossTalk [23], and SGAXe [28]. In contrast with conventional timing-based side-channel attacks [17], where the victim must access its data in a specific pattern in order to leak it, transient execution attacks are more serious because they often allow an attacker to precisely control which memory locations are leaked, including memory that might not be accessed on the committed execution path. This is of particular concern to OS kernels, which have access to all of physical memory, and therefore could leak data from any process through transient execution bugs. In a public cloud, where it is common for mutually distrustful tenants to share a single machine [30, 35], the threat of transient execution is especially concerning.

A key challenge in addressing transient execution attacks lies in minimizing the performance overheads. CPU and OS

designers have implemented a range of mitigations to defeat transient execution attacks, including state flushing, selectively preventing speculative execution, and removing observation channels [5]. These mitigations impose performance overheads (see §2): some of the mitigations must be applied at each privilege mode transition (e.g., system call entry and exit), and some must be applied to all running code (e.g., retpolines for all indirect jumps). In some cases, they are so expensive that OS vendors have decided to leave them disabled by default [2, 22]. Recent processor designs have also incorporated mitigations into hardware, which also reduces performance compared to earlier processor designs that do not perform such hardware mitigations.

To address the above challenge, this paper proposes a new hardware/software contract, called the *unmapped speculation contract*, or USC for short. USC allows the OS kernel to significantly reduce the overhead of mitigating a particular subset of transient execution attacks—namely, those that leak arbitrary memory contents. The USC says that physical memory that is unmapped (i.e., physical memory that has no virtual address) cannot be accessed speculatively. The benefit of USC is two-fold. From the OS designer perspective, it provides bounds on what data can be leaked through transient execution, and, as we show in the rest of this paper, can significantly reduce the cost of mitigations. From the hardware designer perspective, USC allows the CPU to keep many of the current speculative execution optimizations and their associated performance benefits. Most processor architectures already adhere to USC; AMD states that “AMD processors are designed to not speculate into memory that is not valid in the current virtual address memory range defined by the software defined page tables” [1, pg. 2], and Intel issued hardware and microcode fixes for bugs that violate USC [14, 15].

To demonstrate the benefits of the unmapped speculation contract, this paper presents WARD, a novel kernel architecture that uses selective kernel memory mapping to avoid the costs of transient execution mitigations. WARD maintains separate kernel memory mappings for each process, and ensures that the memory mapped in the kernel of a process does not contain any data that must be kept secret from that process. As a result, privilege mode switches (e.g., system call entry and exit) no longer need to employ expensive mitigations, since there are no secrets that could be leaked by transient execution. When the WARD kernel must perform operations that require access to unmapped parts of kernel memory, such as opening a shared file or context-switching between processes, it explic-

itly changes kernel memory mappings, and invokes the same mitigation techniques used by the Linux kernel today.

A key challenge in the WARD design lies in re-architecting the kernel and its data structures to allow for per-process views of the kernel address space. For example, a typical `proc` structure in the kernel contains sensitive fields, such as the saved registers of that process, which should not be leaked to other processes. At the same time, every process must be able to invoke the scheduler, which in turn may need to traverse the list of `proc` structures on the run queue. This paper presents several techniques to partition the kernel: transparent switching of kernel address spaces when accessing sensitive pages through page faults; using temporary mappings to access unmapped physical pages; splitting data structures into public and private parts; etc.

To evaluate the WARD design, we applied it to the `sv6` research kernel [8] running on x86 processors. The `sv6` kernel is a monolithic OS kernel written in C/C++, providing a POSIX interface similar to (but far less sophisticated than) Linux. The simplicity of `sv6` allowed us to quickly experiment with and iterate on WARD's design, since some aspects of WARD's design require global changes to the entire kernel. Since `sv6` is a monolithic kernel, our prototype was able to tackle hard problems brought up by kernel services such as a file system and a POSIX virtual memory system.

We evaluate the performance of our WARD prototype using `LEBench` [24], which represents the most important system calls for a range of application workloads: Spark, Redis, PostgreSQL, Chromium, and building the Linux kernel. `LEBench` allows us to precisely measure the impact of mitigations on system calls that matter for applications. The most recent Intel CPUs (such as Cascade Lake) include hardware mitigations that cannot be fully disabled; however, some of these mitigations are not needed in WARD. To avoid the performance overhead of such unnecessary mitigations, we run experiments on the previous generation of Intel CPUs (Skylake).

WARD can run the `LEBench` microbenchmarks with small performance overheads compared to a kernel without mitigations. For 18 out of the 30 `LEBench` microbenchmarks, WARD's performance is within 5% of the benchmark's performance without any mitigations (but at the cost of some extra memory overhead). In the worst case, the overhead is $4.3\times$ (context switching between processes, where mitigations are unavoidable). In contrast, standard mitigations incur a median overhead of 19%, and a worst case of nearly $7\times$. To confirm that `LEBench` results translate into application performance improvements, we measured the performance of `git status`, which incurs 11.2% overhead in WARD, compared to 24.6% with standard mitigations.

One of the limitations of USC is that it does not cover all possible transient execution attacks. In particular, attacks where the sensitive information is already present in the architectural or microarchitectural state of the CPU are not covered by USC. For instance, the Spectre v3a attack can leak the sen-

sitive contents of a system register (MSR), instead of leaking sensitive data from memory. USC does not cover sensitive data that is stored outside of memory, and WARD applies other mitigations (e.g., as in Linux) to address those attacks.

2 Motivation

Transient execution mitigations harm kernel performance in two ways. First, they place overhead on code execution by disabling speculation. For example, the Linux Kernel uses a `retpoline` patch to mitigate Spectre V2, which replaces each indirect branch with a sequence of instructions that prevent the CPU from performing branch target speculation [13]. Second, these mitigations increase the privilege mode switching cost incurred during each system call: upon entry into the kernel, they either flush microarchitectural state or reconfigure protection mechanisms. For example, KPTI [11, 20] switches to a separate page table before executing kernel code to prevent Meltdown attacks [21]. Workloads that are system call intensive (e.g., web servers, version control systems, etc.) are impacted by this type of overhead, while non-kernel intensive workloads see little performance impact [11].

Collectively, these and other mitigations can result in large slowdowns. To better understand this problem, we run `LEBench` [24], a microbenchmark suite of system calls that impact application performance the most. We evaluate the Linux kernel (version 5.6.13), comparing two configurations: one where all mitigations are disabled and one where all are enabled. Figure 1 shows the relative slowdown between the two configurations for 13 kernel operations of `LEBench` that don't involve networking (i.e., without `send`, `recv`, `epoll`). There are two sets of bars, representing two generations of Intel CPUs: the older Skylake, and the newer Cascade Lake. On the older Skylake CPUs, system calls that perform the least kernel work are impacted the most (e.g., `getpid()`), but a wide range of operations are impacted significantly (25%-100% slowdowns). These observations are similar to those made by Ren et. al.; they find that KPTI and Spectre V2 mitigations are the root cause of slowdowns in the Linux Kernel over the last two years [24].

The newer Cascade Lake CPUs exhibit lower relative overheads, partly because the processors include hardware mitigations for some of the transient execution vulnerabilities. However, these lower overheads are also in part due to the newer Cascade Lake CPUs being *slower* in the baseline case when software-controllable mitigations are disabled. Figure 2 shows the performance of the microbenchmark on Cascade Lake (Intel Xeon Silver 4210R) relative to the earlier Skylake CPU (Intel Xeon E5-2640 v4). Our experiment uses CPUs with identical clocks (2.4 GHz), and nearly identical other hardware (Dell PowerEdge T430 vs. T440), which allows the comparison to be meaningful. The results demonstrate that, although the new CPU is faster at some microbenchmarks, it is slower for many others: e.g., context-switching is about 20% slower. Although it is impossible for us to separate slowdowns

Figure 1: Linux slowdown due to mitigations on LEBench, for two generations of Intel CPUs: Skylake and Cascade Lake.

Figure 2: Performance regression on the newer Cascade Lake CPU, compared to the older Skylake CPU, for LEBench on Linux, with all software-controllable mitigations disabled.

due to mitigations from speedups due to architectural improvements, the results suggest that the overheads of mitigations implemented in hardware (e.g., for Meltdown, L1TF, or MDS) could still be significant.¹

3 Goal and threat model

WARD’s goal is to reduce the performance cost of mitigations for transient execution attacks. In principle, WARD’s techniques can reduce not only the cost of software mitigations, but also allow processor designers to avoid costly mitigations in hardware. Practically, however, it is difficult for us to disable hardware mitigations in the newest processors. Therefore, this paper focuses on reducing the overhead of software mitigations, and experimentally measures their effect on the

¹One indication that this regression may be related to hardware mitigations is that measured branch mispredictions are around 40% higher on LEBench.

previous generation of CPUs, where we can avoid mitigations altogether. We hope that WARD’s design can allow processor designers to regain some of the absolute performance lost due to hardware mitigation costs.

Our threat model targets scenarios where the adversary and the victim are both running code on the same computer. This might arise either in a server setting, where both are running on a cloud computing platform, or in a client device, where the adversary code is a malicious application or web site.

Canella et al. [5] discuss transient execution attacks in detail, but the salient points of the attack boil down to four steps. First, the processor speculatively executes some code, which accesses sensitive data that the victim wants to keep secret. Second, during the speculative execution, the processor updates microarchitectural state in a way that depends on the sensitive data (e.g., bringing in cache lines into a shared L3

cache whose addresses depend on the sensitive data). Third, the processor aborts the speculative execution, but does not fully roll back all of its side effects (e.g., changes to the L3 cache), because doing so would be prohibitively expensive in hardware. Fourth, the adversary observes these side effects (e.g., using timing measurements), which allows the adversary to infer the sensitive data.

What makes transient execution attacks challenging to mitigate in an OS kernel is a combination of two factors. The first is that an adversary can trigger an OS kernel to speculatively execute code that leads to leakage of sensitive data. Even though the adversary cannot inject their own code to execute in the kernel, the adversary can often have significant influence on what existing kernel code gets executed in speculative execution, by specifying particular system call arguments or setting up micro-architectural CPU state such as the branch predictor. The second factor is that an OS kernel has access to all of the state on the computer. This means that an adversary running in one process can trick the kernel into leaking state from any other process on the same computer.

Current OS kernel designs, such as Linux, have two approaches for mitigating transient execution attacks. The first approach is to make sure that the CPU does not speculatively execute any code that could end up accessing sensitive data. This approach includes techniques such as retpolines and other speculation barriers. The second approach is to make sure that sensitive data is flushed from microarchitectural state, such as flushing CPU caches and buffers when returning from a system call or when context-switching between processes. Both incur significant performance overheads.

Transient execution attacks can leak data across many protection domain boundaries, such as leaking secrets from the kernel to an adversary’s process, or leaking secrets from one process to a different process, or even leaking secrets within a single process that implements its own internal protection domains. Much like in the Linux kernel, the focus of WARD is on preventing leakage between processes, as well as preventing leakage from the kernel to a process. WARD’s approach to preventing cross-process leakage is the same as Linux (flushing state), but WARD has a novel approach for efficiently preventing kernel-to-process leakage of memory contents, as we describe in the next section.

Although WARD addresses all known transient execution attacks, the focus of this paper is on attacks that allow the adversary to leak the contents of arbitrary memory, which is especially important in an OS kernel. WARD handles other transient execution attacks, such as leaking the contents of sensitive data already present in the CPU (e.g., x86 MSRs), in the same way as Linux does.

Attacks that do not leverage transient execution to leak data are also out of scope for this paper, since they are orthogonal to the key challenge of transient execution leakage. In particular, we do not consider attacks that leverage physical side channels (such as Rowhammer or RAMbleed), cache side channels

(such as cache timing attacks), power side channels, etc.

4 Approach: Unmapped speculation contract

WARD’s design for mitigating transient execution attacks relies on page tables. Specifically, if a page of physical memory is not referenced by any entry in the current page table or TLB, speculative execution cannot access any sensitive data stored in that page, because the page doesn’t have a virtual address to access it by.

A contribution of this paper lies in articulating a hardware/software contract—which we call the *unmapped speculation contract*—that captures the above intuition. The contract aims to provide a strong foundation for keeping data confidential, which is typically stated as non-interference. Non-interference can be thought of by considering two system states, s and s' , that differ only in sensitive data, which should not be observable by an adversary. A system ensures non-interference if an adversary cannot observe any differences in how the system executes starting from either s or s' .

Single-core USC. To formally state the unmapped speculation contract, we start with a single-core definition. We use $A(\cdot)$ to refer to the state of the CPU, including all architectural and micro-architectural state, but excluding the contents of memory, and we use $M(\cdot)$ to refer to the contents of *mapped* memory, i.e., the contents of every valid virtual address based on the committed page table in that state. We define the contract by considering a single clock cycle of the processor’s execution, $\text{step}(\cdot)$, which includes any speculative execution done by the processor on that cycle, and require that unmapped pages cannot influence it:

$$\begin{aligned} &\forall s, s', \\ &\text{if } A(s) = A(s') \text{ and } M(s) = M(s'), \\ &\text{then with } S := \text{step}(s) \text{ and } S' := \text{step}(s'), \\ &\text{it must be that } A(S) = A(S') \end{aligned}$$

In plain English, the definition considers a pair of starting states s and s' that should look the same, as far as speculative execution is concerned, because they have the same CPU state and the same contents of mapped pages. They might, however, differ in the contents of some unmapped physical pages, which contain sensitive data that we would like to avoid leaking. The definition then considers the state of the CPU at the next clock cycle ($S := \text{step}(s)$ and $S' := \text{step}(s')$ respectively), and requires that the CPU architectural and micro-architectural state $A(\cdot)$, which the adversary might observe, continues to be the same in those two states. As a result, the microarchitectural state could not have been influenced by any sensitive data not present in $M(s)$.

If the OS kernel does not change the mapped memory in that clock cycle, $M(\cdot)$ remains the same, and the contract will continue to hold on the next cycle too. However, if the OS kernel changes the mapped memory, the contract allows speculative execution from that point on to use the newly mapped memory, and the kernel will need to use other mitigations

to defend against transient execution leaks from the newly mapped memory, if necessary.

The contract specifies how the micro-architectural state, $A(\cdot)$, can evolve, but does not say anything about how $M(\cdot)$ can change. This is because the focus of the contract is on transient execution, which cannot affect the committed architectural state of the system; the contents of memory is described by the ISA, since it is architectural state. In other words, changing the memory requires committing the execution of some instruction, at which point this is no longer a transient execution.

Multi-core USC. In a multi-core setting, the CPU state can be thought of as consisting of per-core state (e.g., registers, execution pipeline, and root page table pointer), which we denote with $A_i(\cdot)$ for core i , and the uncore state (e.g., the hardware random number generator [23]), which we denote with $U(\cdot)$, shared by all cores. Similarly, since each core has its own page table, we index the mapped memory by the core i whose page tables we are considering, $M_i(\cdot)$. Finally, we consider the multi-core system executing a clock cycle on one core at a time, $\text{step}_i(\cdot)$. We assume that $\text{step}_i(\cdot)$ does not change $A_j(\cdot)$ for any $i \neq j$. With this notation, the multi-core contract says:

$$\begin{aligned} &\forall s, s', i, \\ &\text{if } A_i(s) = A_i(s'); U(s) = U(s'); \text{ and } M_i(s) = M_i(s'), \\ &\text{then with } S := \text{step}_i(s) \text{ and } S' := \text{step}_i(s'), \\ &\text{it must be that } A_i(S) = A_i(S') \text{ and } U(S) = U(S') \end{aligned}$$

This means that speculative execution on core i is allowed to depend on the state of core i , the uncore state, and the memory mapped by core i . This multi-core formulation allows transient execution to affect both the core state $A_i(\cdot)$ as well as the uncore state $U(\cdot)$, at the micro-architectural level. However, transient execution cannot affect either of these states in a way that depends on unmapped memory.

Although hardware threads appear to provide separate execution contexts, with a separate page table for each hardware thread, they have extensive sharing of core resources. To capture that, we consider $A_i(\cdot)$ to include the state of all hardware threads on core i , $\text{step}_i(\cdot)$ to include the execution of any hardware thread on core i , and $M_i(\cdot)$ to be the union of memory mapped by all of the hardware threads on core i (i.e., the union of the page tables of the threads). With this model, the contract allows leakage of mapped memory across hardware threads.

Benefits of the USC. The contract helps reconcile security and performance of speculative execution. On the one hand, hardware can keep the high performance provided by out-of-order execution, because the contract allows almost all forms of speculative execution, as long as data during speculative execution is accessed through non-speculative TLB entries. On the other hand, software can precisely specify what data can and cannot be used for speculative execution, by configuring page tables. For example, if the mapped pages never contain sensitive data, then no mitigations are needed to defend

against transient execution vulnerabilities. Finally, because OS developers expect page faults and TLB misses to be quite expensive (compared to memory references), USC doesn't change their performance expectations: developers already have adapted their designs to avoid excessive page faults or TLB invalidations.

Although the contract is aspirational, one appealing property of the contract is that modern computer architectures already effectively aim to provide such a guarantee. AMD explicitly states in bold font that their “processors are designed to not speculate into memory that is not valid in the current virtual address memory range defined by the software defined page tables” [1, pg. 2]. Intel has no explicit position about this contract, but it appears that they treat violations of this contract as bugs to be fixed in hardware or microcode, as evidenced by their fixes for Meltdown and L1TF, described below.

USC and attacks. The contract captures a common pattern that emerges in many transient execution attacks: an adversary can only leak micro-architectural state that is already present on the CPU, as well as the contents of mapped memory, but not the contents of memory that is not present in a page table. As one example, consider the MDS family of attacks [6, 25, 29]. These attacks allow an adversary to trick the kernel into leaking the contents of mapped memory, through careful orchestration of transient execution. Linux prevents this class of attacks by clearing CPU buffers when crossing the user-kernel boundary. This is needed because, when executing in kernel mode, all system memory is mapped and therefore could be leaked through transient execution. The contract, however, captures the fact that only mapped memory is at risk with this attack. This allows for a more efficient mitigation of such attacks, as we demonstrate in WARD, by avoiding kernel mappings of sensitive memory.

In contrast to the example of MDS attacks, which leak sensitive data from memory, the USC does not help mitigate attacks that leak sensitive data already present in the CPU state. For instance, the Spectre variant that leaks the contents of x86 MSRs (Spectre 3a) is not precluded by the contract, since the sensitive data being leaked is not present in memory at all. As a result, an OS kernel must apply other mitigations to deal with such attacks.

More generally, the contract helps categorize existing attacks based on which part of the system state they leak, as shown in Figure 3. For attacks that leak core or uncore state, the contract has little to say in terms of how those attacks can be mitigated, as shown in the “Mitigated by USC” column. As a result, WARD defends against these attacks much in the same way as Linux. In contrast, for attacks that leak the contents of memory, the contract gives a more efficient mitigation approach: simply avoid mapping memory that contains sensitive data. This allows WARD to efficiently mitigate attacks such as some variants of Spectre and MDS.

As shown in the “Consistent with USC” column, all of the

Attack	Leaked state	Mitigated by USC	Consistent with USC
Spectre variants	Memory	Yes	Yes
Meltdown		Yes	Yes (ucode)
MDS		Yes	Yes
PortSmash		Yes	Yes
L1TF		Yes	Yes (ucode)
Spectre variants	Core state	No	Yes
LazyFPU		No	Yes
System reg. read		No	Yes
Spectre variants	Uncore state	No	Yes
CrossTalk		No	Yes
SGAxe		No	Yes

Figure 3: Transient execution attacks categorized based on the state leaked by the attack.

attacks in Figure 3 are consistent with the contract’s requirements on the underlying hardware. This is good in two ways. First off, this means that none of the known attacks violate the contract, and thus, the contract is a reasonable approach for mitigating transient execution attacks. Second, this means that USC can mitigate the class of attacks that it covers—namely, attacks that leak memory contents.

There are two special cases: Meltdown and L1TF. When originally discovered, these attacks bypassed the page table protections and allowed an adversary to obtain the contents of memory that was not mapped. In both of these cases, the hardware manufacturer (Intel) considered them to be hardware bugs, as evidenced by the fact that both of them were fixed through hardware and microcode revisions [14, 15], as confirmed by Canella et al. [5].²

5 Design

Under the assumption of the unmapped speculation contract, this section describes how WARD can reduce the cost of mitigations for system calls. §5.1 provides an overview of WARD’s design with subsequent sections providing more detail about WARD’s switch between protection domains (§5.2), about the mitigations used by WARD when mitigations are necessary (§5.3), WARD’s kernel text (§5.4), WARD’s memory management modifications (§5.5), WARD’s process management split (§5.6), and WARD’s file system split (§5.7).

5.1 Overview

WARD’s design maintains two page tables per process. One page table defines a process-specific view of kernel memory. When a process is running with that page table, we say it is running in its *quasi-visible* domain (or Q domain for short), and with its Q page table. Following the unmapped speculation contract, WARD assumes any kernel memory mapped by the

²Canella et al. state that some variants of the Meltdown attack, such as Meltdown-BR, are still possible even with the most recent microcode. Those variants, however, are bypassing software checks, rather than the hardware page table, and therefore do not violate the unmapped speculation contract.

Figure 4: Overview of WARD’s address space layout with two processes (indicated by the colors green and purple). Each process has a Q and K domain. Q domains have access to public data (the grey color) and per-process kernel data; the white private region is unmapped kernel data. Each domain also has its own stack and kernel text. In the Q domain, the kernel text has no mitigations. The K domains map all memory, including sensitive memory (indicated by red); all K domains have the same memory layout. Data structures that are shared across processes, such as pipes or file pages, can be mapped in multiple Q domains, as indicated by the yellow color.

Q page table can be leaked to the currently running process. Instead of using mitigations to prevent leaks of kernel memory, WARD arranges for the mappings in the Q page table to be such that they contain no sensitive data of other processes.

When the process needs to access data that is not mapped in the Q page table, it can switch to its other page table, which maps all physical memory, including memory that contains sensitive data. When a process is running with this page table, we say the process is executing in its *K* domain with its *K* page table. In its *K* domain, the process runs with the same mitigations as Linux currently uses.

This design allows many system calls to execute in the Q domain, with no mitigation overhead. As a simple example, `getpid` does not access any sensitive data; it needs access to only the kernel text and its own process structure. A more interesting example is mapping anonymous memory: it requires access to the process’s own page table and to the memory allocator, but not other processes’ page tables or pages.

Figure 4 shows the address space layout in WARD in more detail. Each process has a Q and K view of memory. When a process is running in user space it runs in its Q domain (with no secrets mapped in the Q page table). When a user process makes a system call it enters the kernel but stays in its Q domain. The Q domain maps public kernel memory, Q-visible

kernel memory, the process's Q domain stack, and the kernel text without mitigations.

If a system call needs access to memory in the K domain, WARD performs a switch from its Q domain to its K domain. We refer to the switch from a Q domain to a K domain as a *world switch*, because kernel code in a Q domain runs without most mitigations and the kernel code in the K domain runs with full mitigations. Furthermore, the process switches from its Q domain stack to its K domain stack. The K domain, with access to all kernel memory, can then execute the rest of the system call with full mitigations.

Achieving good performance in WARD depends on avoiding world switches. To reduce the number of world switches, WARD maps kernel data structures that contain no sensitive data into every Q domain. For example, all Q domains map x86 configuration tables (IDT, GDT), some memory allocator state, etc. On the other hand, kernel data structures that contain application data, such as process memory or saved register state, are not mapped into Q domains unless that process should have access to that data.

5.2 World switch

One of the challenges in WARD's design is that a system call often does not know upfront whether it will need to execute in the Q domain or in the K domain. For example, a read system call might be able to execute purely in the Q domain, or might need access to sensitive data from the K domain, depending on the file descriptor that the process is reading from, and depending on whether this Q domain already has some sensitive data mapped or not. To support this, WARD's design allows a system call to start executing in the Q domain, and switch to the K domain later as needed.

WARD allows the Q domain to trigger a world switch either *intentionally* or *transparently*. If the code determines that it must switch to the K domain, it can intentionally invoke the function, `kswitch()`, to perform a world switch. When `kswitch()` returns, the kernel thread is now executing in the K domain, and has access to all memory. If the Q domain needs access to specific sensitive data which might or might not be already mapped, the Q domain can attempt to access the virtual address of that data. If the data is already mapped in the Q domain, the access will succeed, no world switch happens, and the Q domain can continue executing. If the data is not mapped, the Q domain triggers a page fault, which transparently triggers a world switch. Once the page fault returns, the kernel thread is now executing in the K domain, as if it called `kswitch()`. Compared to making an intentional call to `kswitch()`, the transparent approach incurs a slight overhead for executing the page fault, but allows large sections of the kernel to be kept completely unmodified, and allows the Q domain to elide a world switch altogether if the data is already mapped in the Q domain.

The above design requires that a kernel thread can start executing in the Q domain and transparently switch to exe-

Transient execution vulnerability	U/Q	K	Ctx

Figure 5: The mitigations implemented in software by WARD.

cuting in the K domain. This means that any addresses that the kernel thread is referencing, including pointers to data structures, stack addresses, and function pointers, remain the same. To achieve this, WARD ensures that the layout of the Q domain and the K domain match. In particular, all data structures in the Q domain must appear at the same address in the K domain, and the kernel code (text) is located at the same address (even though the code is slightly different, as described in §5.4).

The stack requires particular care because a kernel thread that is processing sensitive data in the K domain could inadvertently write that data to the stack. For example, a `read()` system call from `/dev/random` needs to switch to the K domain to access the system-wide randomness pool. However, the pseudo-random generator code might spill some of its state to the stack, depending on the compiler's choices. If the stack is accessible from the Q domain, the sensitive data could in turn be leaked during the next entry into the Q domain by any thread within the same process. At the same time, if the K domain stack was separate from the Q domain stack, pointers to stack locations before a world switch would no longer work after a world switch. To reconcile these constraints without having to rely on any dedicated compiler support, WARD maps a distinct kernel stack for each domain at the virtual address range and copies the Q domain stack contents to the K domain stack during a world switch.

5.3 Mitigations

Figure 5 shows the known transient execution attacks [5, 12], organized by the mitigations needed to address those attacks in WARD's design. The columns (U/Q, K, and Ctx) indicate where the mitigations are needed: respectively, while executing in user-mode or Q domain; while executing in the K domain; and when context-switching between processes.

The L1TF attack allows leaking the contents of the L1 cache

if there are partially-filled-in entries in the page table. We think of this attack as a violation of the USC (see Figure 3), but a simple microcode fix, as well as clearing unused page table entries, makes the system agree with the USC, and avoids the L1TF attack. Since L1TF allows leaking the contents of any data, WARD applies the mitigations both in user-space, Q domain, and K domain.

The next category of attacks requires no mitigations in either user-space or Q domain. Specifically, Spectre variants that bypass bounds checks require mitigation in the K domain, since there is sensitive memory contents that could be leaked as a result of a speculative check bypass. However, there is no sensitive data that can be leaked in the Q domain, owing to USC. Similarly, no mitigations are required on a context switch, since these attacks can only leak data from the current protection domain.

Meltdown also falls in this category, but for a different reason. Meltdown allows an adversary to bypass the user-kernel boundary check in the page table. WARD's use of a separate page table for the Q and K domains ensures that Meltdown cannot leak any confidential data, since no confidential data is available in the Q domain. Recent microcode from Intel fixes the Meltdown attack in a way that avoids the need for software mitigations.

The next category of attacks require mitigation both in the K domain and on context switch. Spectre v2 and MDS attacks can allow an adversary to obtain sensitive data either from the OS kernel or from another process. However, no mitigations for these attacks are needed in the Q domain due to USC: there is no sensitive data to leak in the Q domain of the currently running process.

For some attacks, such as LazyFPU and SpectreRSB, mitigations are only required on context switch, because the attacks involve process-to-process leakage.

Finally, a number of attacks are not applicable to WARD's simpler design, in contrast to Linux. For example, WARD does not support SGX, does not support running virtual machines, and does not use certain hardware features (such as hardware bounds-check instructions or protection keys).

5.4 Kernel text

Some of the mitigations involve changes to the executable kernel code (text), such as the use of retpolines in place of indirect jumps. These mitigations impose a performance cost, but they are not needed when executing in the Q domain.

A naïve approach might be to compile the kernel code twice, with different compiler flags for mitigations, and load the two different kernel binaries in the Q and K domains respectively. However, this would break WARD's page fault triggered world switches because after completing the switch, execution would resume with the same instruction pointer and stack contents from before the switch but neither would be meaningful in the new text segment.

Instead we need the two version to have matching instruc-

tion addresses and stack layouts. WARD achieves this by compiling the kernel only once, but then making two copies of the code at runtime. One copy is mapped into all the K domains, and the other into all the Q domains *but at the same virtual address as in the K domains*. Switching between the two is seamless.

At boot time, in a process inspired by Linux's `ALTERNATIVE` macro [9], WARD locates each `call` or `jmp` in the Q text segment pointing to a retpoline thunk, and replaces them with the instruction that retpoline emulates. One complication is that indirect call instructions are only 2 or 3 bytes, compared to the 5 that a direct call instruction takes. If we tried to pad with a NOP instruction before or after, the pair would not execute atomically, so instead we prepend indirect calls with several repetitions of the CS-segment-override prefix, which is always ignored in 64-bit mode.

5.5 Memory management

Memory allocation in WARD is complicated by the fact that the contents of free pages may contain sensitive data. In particular, if a page was freed by one process, its contents must be erased before the page can be mapped in another Q domain. Zeroing out pages on every allocation would be costly, in particular when allocating kernel data structures, which do not otherwise require the memory to be zero-filled.

To avoid the overhead of repeatedly zeroing kernel pages, WARD implements a sharded allocator for kernel memory. Each Q domain has its own pool of pages for allocation, and the K domain keeps all of the kernel memory that is not part of any Q domain. WARD transfers memory between these shards in batches to amortize the world switch overhead. Keeping a pool of kernel memory in a Q domain allows the kernel to repeatedly allocate and free memory within a Q domain with little overhead.

The other category of memory managed specially by WARD is public memory. WARD maintains a single pool of public pages, with separate functions, `palloc()` and `pfree()`, for allocating and freeing in that pool. All public-pool pages are mapped in every Q domain.

5.6 Process management

When the WARD kernel switches from executing one process to another, it must perform a world switch, to ensure that confidential data does not leak across processes (such as the saved CPU registers that the kernel might save on the stack). However, if a multi-threaded application is running, there is no security reason to perform a world switch when switching between multiple threads in the same process—all of the threads have the same privileges and have access to the same process address space.

To avoid mitigation overhead when switching between threads in the same process, WARD splits the process descriptor, `struct proc`, into two parts. The first part stores sensitive process state, such as the saved CPU registers, and is not public. The second part stores metadata about the process,

such as the PID, the run queue, the scheduler state, etc. This part is public and is used by the scheduler when deciding what thread to execute next. As a result, the scheduler can pick the next thread without incurring a world switch. Furthermore, if the next thread happens to be from the same process, the context switch code can also avoid performing a world switch. Existing scheduler policies that favor picking threads from the same process mesh well with this approach.

5.7 File system

File system workloads involve access to several kernel data structures, including the inode cache and the page cache (containing file data). Inodes are challenging for WARD to deal with because they are smaller than a page, so it is not feasible to map them individually into a Q domain. However, achieving good performance for file system operations requires being able to access an inode without a world switch. To reconcile this conflict, we chose to make all inode structures public in WARD, similar to our approach for splitting the `proc` structure above. If the inode had sensitive data (such as extended attributes), that part of the inode structure would need to be split off into a separate private structure, along the lines of how we split off the part of the `proc` structure storing saved CPU registers.

File data pages are not public, because their contents might be sensitive. WARD implements an optimization that allows it to access file contents without a world switch. In particular, after WARD checks the permissions on a file, it reads or writes the contents of a file page by temporarily mapping the corresponding physical page of memory into its Q domain's address space. This allows the Q domain to access that specific memory page without the risk of leaking other pages; as a result, no mitigations or world switches are needed. When the Q domain is finished with the file read or write, it unmaps the page and issues a TLB shutdown, in case the file is later truncated and the page gets reused for other data.

5.8 Pipes

Pipes are different from many of the other kernel data structures discussed so far in that their contents shouldn't be visible globally, but their state can be associated with multiple processes at a time. WARD's goal is to ensure that if a reader and writer of a pipe run on different cores, then they don't incur world switches when they access the pipe. To achieve this, we store a pipe's data structures in shared memory regions between Q domains. These shared regions are lazily mapped into Q domains the first time a process accesses a pipe (doing the mapping on `fork` would cause unnecessary overhead), and unmapped when the last reference to the pipe within a Q domain is closed.

When a pipe becomes full or empty, the caller blocks on a condition variable. Subsequent reads or writes can observe which processes are blocked and add them to the scheduler run queue if appropriate. Neither of these operations requires access to any secret data so no world switch is triggered until a

new process is scheduled. Thus, if the core remains idle until the blocking thread is added back to the run queue, the cost of a world switch is avoided.

5.9 Discussion

WARD's design assumes that there are no secrets in the Q domain that need to be hidden from the user-level process. For many secrets, they can be protected by placing them in the K domain, such as the seed of a system-wide randomness generator. However, address-space layout randomization (ASLR) for the kernel address space is difficult to protect in this fashion, because kernel addresses must be used in the Q domain, and the addresses must match up between the Q domain and the K domain in order for world switches to work. (Note that the initial seed that is used to randomize layout could be protected in the K domain, but the resulting randomized layout cannot be protected.) As a result, kernel ASLR in WARD is susceptible to leakage of addresses through transient execution side-channels.

Our WARD prototype does not include an optimized in-kernel network stack, but a reasonable approach might be to treat all network data as public, leaving it up to the application to encrypt any sensitive information sent over the network. This meshes well with the recent trends in widespread use of TLS for network security, and allows for network operations to achieve high performance in WARD because no mitigations or world switches are required, and all network processing can stay in the Q domain.

Hyperthreading is a source of many possible transient execution leaks, because a significant amount of microarchitectural state is shared between the execution contexts. However, many Linux systems continue to run with hyperthreading *enabled*, despite these risks, because of the high performance overhead they would incur if hyperthreading was entirely disabled. WARD does the same.

6 Implementation

To demonstrate the feasibility of the WARD design, we implemented a prototype of WARD starting from the `sv6` research kernel. The kernel is monolithic, implementing traditional OS services such as virtual memory, processes and threads, file systems, fine-grained concurrency using RCU-like techniques, etc. The `sv6` kernel, is written in C/C++, runs on x86 processors (both AMD and Intel), and has decent uniprocessor performance and great multicore performance and scalability [8].

Kernel changes. WARD's design affects most core kernel subsystems, including the memory allocator, virtual memory, context switching and the scheduler, and the file system. The simplicity of `sv6` allowed for rapid experimentation with kernel designs to enable WARD, which would have been challenging to do in a more complex kernel like Linux, since it is time-consuming to make changes to core subsystems in the Linux kernel, which would have made design iterations far slower.

Transient execution variant	Strategy	Support
V1 (Bound Check Bypass)	bounds clipping	partial
V1.1 (Bounds Check Bypass Store)	lfence	partial
V1.2 (Read-only Protection Bypass)	lfence	n/a (no in-kernel software sandbox)
V2 (Branch Target Injection)	retpoline	yes
—"	speculation barrier	yes
—"	return stack buffer filling	yes
—"	disable spec before BIOS calls	n/a (no calls to BIOS in WARD)
V3 (Meltdown)	Kernel page table isolation (KPTI)	yes
V3a (System Register Read)	microcode	yes
V4 (Speculative Store Bypass)	disable spec. or ctx. switch	yes
LazyFPU	hardware-assisted save/restore	yes
SpectreRSB	return stack buffer filling	yes
L1TF	cache flush, no SMT	n/a (no VM entry in WARD)
—"	no invalid PTEs	yes
PortSmash	no SMT	no
Microarchitectural Data Sampling (Fallout, RIDL, Zombie Load, etc.)	CPU buffer clearing	yes
Load Value Injection	no SMT	no
	lfence	n/a (no SGX in WARD)
Meltdown-PK (protection key bypass)	address space isolation	n/a (no protection keys)
Meltdown-BR (bounds check instr. bypass)	lfence	n/a (no bounds check instructions)

Figure 6: Transient execution mitigations implemented in WARD.

To help partition the kernel data structures across Q domains, we developed Warden, a tool for tracking down the cause of world switches. Warden instruments page faults from the Q domain that lead to a world switch, and records a stack trace for each of them. Examining the profile of these world switches allows the kernel developer to quickly understand what kernel data structures need to be partitioned or sharded to reduce the number of world switches, as well as the operations that need to be supported on these data structures within a Q domain. Although Warden identifies the data structures that are causing world switches, it is up to the kernel developer to identify an appropriate plan for partitioning the data structure so that no sensitive data can leak through side channels.

To run applications on top of the WARD prototype kernel, we changed the WARD system call interface, including system call numbers, data structure layout, etc, to match that of Linux. This allows unmodified Linux ELF executables to run on top of WARD, and ensures that WARD implements (a subset of) the same system calls that are available on Linux.

We modified `sv6` to use PCIDs to reduce the cost of switching page tables (see §5.2). To improve TLB shutdown performance, we modified `sv6` to use Linux’s shutdown strategy. This is important, for example, for removing temporary mappings in a `read` and `write` systems calls (see §5.7).

Mitigations. WARD implements side-channel mitigations for known transient execution attacks [5, 12], as shown in Figure 6. WARD mostly copies the mitigation strategies and their implementation from the Linux kernel [19]; the most interesting exception is that WARD does not apply some of these mitigations to the Q domain, as described in Figure 5.

For Spectre V1, WARD, adds an `lfence` instruction when

copying from user code, and when taking an interrupt, exception, and NMI entry. WARD uses bounds clipping in fewer cases than Linux for two reasons: WARD has less code and we haven’t performed a careful audit of the complete source code. For Spectre V2, we compile WARD to use retpolines (by specifying the “`-mretpoline-external-thunk`” flag to `clang`). WARD also uses Linux’s `FILL_RETURN_BUFFER` macro to fill the return stack buffer, and issues an indirect branch predictor barrier `IBPB` instruction on a context switch. For Spectre V3, WARD uses separate page tables (as described in §5.1) and uses process-context identifiers (PCIDs) to avoid TLB flushes.

For Spectre V4, WARD issues an `lfence` on context switch. (If WARD supported generating code at runtime, the JITs would also have to be hardened.) For LazyFPU, WARD uses the `xsaveopt` instruction to save/restore floating point state. For SpectreRSB, WARD fills the return stack buffer on context switch. For L1TF, WARD avoids invalid PTEs. Like Linux, WARD doesn’t address PortSmash; the default for the Linux kernel is to allow SMT, and WARD does too. For microarchitectural data sampling attacks, WARD issues the `verw` instruction for clearing CPU buffers.

Some attacks aren’t applicable to WARD, because WARD doesn’t support virtualization, secure enclaves, and hardware transactional memory; does not call into the BIOS; and does not implement in-kernel software sandboxes such as BPF.

Like Linux, WARD also zeroes unused CPU registers on kernel entry, to reduce the avenues of attack available to an adversary. To determine whether mitigations are necessary, WARD maintains a special variable called `secrets_mapped` whose value is 0 in the Q domain and 1 in the K domain; this allows the rest of the kernel code to determine if it needs to perform mitigations just by using `if (secrets_mapped)`

... (as long as interrupts are disabled, to avoid races). To help evaluate the performance impact of side-channel mitigations, WARD's implementation allows switching individual mitigations on and off at runtime, rather than at compile time or boot time.

To improve performance, a few system calls invoke the world switch intentionally to avoid the extra overhead of a transparent world switch. For example, `open`, and `fork` always invoke world switch intentionally. The `read` and `write` system calls invoke a world switch intentionally when they are reading or writing large amounts of data, since the cost of a world switch is less than the cost of shooting down the temporary mappings for that many file pages. A page fault on a Copy-On-Write (COW) page also intentionally invokes a world switch.

Lines of code. The WARD prototype consists of about 34,000 lines of C++ code (for `kernel/` and `include/`), compared to 24,000 lines of C++ code for the `sv6` kernel that WARD was derived from. `git diff -stat` reports roughly 17,000 lines of insertions and 5,000 lines of deletions between `sv6` and WARD. It is difficult to further break down WARD's lines of code, since many aspects of WARD's design required small changes throughout the kernel's source code. For example, splitting up the kernel memory allocator required the use of C++ placement `new` in many parts of the kernel. Similarly, implementing the Linux binary compatibility layer required making changes to the implementation of many system calls.

7 Evaluation

To demonstrate the benefits of WARD's design, this section answers the following questions:

- Do WARD's techniques reduce the overhead of mitigations for system calls? (§7.2)
- How do mitigations affect the cost of a world switch? (§7.3)
- What are the memory overhead associated with WARD's design? (§7.4)

7.1 Experimental methodology

To answer these questions, we consider three different configurations of WARD:

- Baseline: WARD with no mitigations against side channels.
- Linux-style: WARD with standard mitigations against side channels, mirroring the approach taken by the Linux kernel. This configuration does not use separate Q domains; all system calls directly enter the K domain.
- USC-based: WARD with fast mitigations that take advantage of the split between the Q domain and the K domain, leveraging the USC. The K domain implements the same mitigations as in Linux-style.

WARD's design is aimed at reducing the overhead of mitigations associated with system calls. To zoom in on the system call overhead, we evaluate WARD's performance using `LEBench` [24], a collection of system call workloads representative of a range of real applications. This allows us to precisely report and explain the effect of WARD's techniques on individual system calls. We don't report results for the networking benchmarks in `LEBench`, because the WARD prototype doesn't have a suitable in-kernel network stack.

All benchmarks were run on a Dell PowerEdge T430 with two E5-2640 v4 CPUs and 64 GB of RAM.

One potential concern with the use of recent microcode is that it makes the baseline slower, which in turn makes the cost of mitigations appear lower than they really are. This is similar to the significant effect we observed with newer CPUs, as described in §2. However, with newer microcode, we find that the performance of the baseline is not significantly affected: it achieves similar performance even when we use old microcode. The reason for this is that the recent microcode updates add mitigations that can be specifically enabled (e.g., through the `SPEC_CTRL` MSR), but almost nothing is enabled by default. The Linux and WARD baseline experiments do not enable these mitigations, and thus the performance effect is minimal.

For the Linux measurements of `LEBench`, we use the 5.4.0 kernel on Ubuntu 20.04.

7.2 WARD's USC-based fast mitigations

LEBench. Figure 7 shows the benefit of WARD's fast mitigations on `LEBench`. The figure compares WARD with USC-based and Linux-style mitigations, relative to the baseline with no mitigations. As shown, WARD with fast USC-based mitigations is often able to match the unmitigated baseline. The reason is that many of the microbenchmarks can execute with no or very few world switches, as shown in Figure 8.

Many microbenchmarks (`getpid` through `huge pagefault` in Figure 8) have nearly 0 transparent and intentional world switches. They execute completely in the Q domain. The reason that some have near 0 world switches, but not exactly 0, is that during the measurement they were interrupted by a timer interrupt, which requires a world switch to the K domain to run the scheduler (the remainder of the syscall is then executed in the K domain too).

Another cause for fractional numbers of transparent world barriers is that some operations might have a slow path that requires secrets but only gets triggered infrequently (i.e. because a memory allocator pool ran empty). A strength of the WARD approach is that these sorts of cases don't have to be manually annotated and in fact it is harmless to completely ignore them provided they are executed infrequently enough.

There are several microbenchmarks (e.g., the bigger `read` and `write` ones) that perform one intentional world switch per system call. These system calls immediately enter the K domain and thus perform identical to WARD with full mitiga-

Figure 7: Performance of WARD with fast USC-based mitigations and with Linux-style mitigations, normalized against the baseline performance of WARD without any mitigations.

tions, and have the same overhead. These system calls also perform much work in the kernel and the overhead of the 1 world switch is amortized by that work.

The `thr create` and `thr create-child` do multiple syscalls per iteration, but average one world barrier per iteration. Specifically, the `thr create` microbenchmark makes three systems calls: one `clone` that requires a world switch and a call to each of `sigprocmask` and `set_robust_list` which don't. The `thr create-child` microbenchmark includes an additional call to `(sigprocmask)` from the child process, for which WARD can also avoid the world switch.

The `fork` and `fork-child` benchmarks each do a single syscall with an intentional world barrier that takes the vast majority of execution time, but also raise a handful of page faults to populate page table entries (which need secrets if they are copy-on-write related or if the kernel runs out of zeroed memory pages and has to prepare more).

An interesting case is the `context switch` microbenchmark. This microbenchmark measures context switching by writing and reading a byte over a pipe between two processes pinned to the *same* core. The `write` calls avoids a world switch because the scheduler can wake other processes while in the Q domain, but the `read` call causes a context switch and (since the two processes are mutually distrusting) thus requires a world switch.

When we modify the microbenchmark to pin the two processes to *different* cores we observe that it runs without world switches and that the overhead is about 25 times lower than Linux-style mitigations.

Application: git. To confirm that the improved performance of WARD's fast mitigations seen in LEBench translates into

	# sys calls	World switches		
		T	I	Sum
getpid	1	0	0	0
small write	1	0	0	0
small read	1	0	0	0
small mmap	1	0	0	0
small munmap	1	0	0	0
small page fault	1	0	0	0
mid mmap	1	0	0	0
mid munmap	1	0	0	0
mid page fault	1	0	0	0
big mmap	1	0	0	0
big page fault	1	0	0	0
huge mmap	1	0	0	0
huge page fault	1	0	0	0
context switch	2	0	1	1
thr create	3	0	1	1
thr create-child	4	0	1	1
mid read	1	0	1	1
mid write	1	0	1	1
big read	1	0	1	1
big write	1	0	1	1
big munmap	1	1	0	1
huge read	1	0	1	1
huge write	1	0	1	1
huge munmap	1	1.001	0	1.001
fork	2	0	2	2
big fork	2	0	2	2
huge fork	2	0	2	2
huge fork-child	17	0	7	7
big fork-child	17	0.006	7.02	7.026
fork-child	17	0.012	7.065	7.077

Figure 8: The microbenchmarks, sorted by the sum of the number of transparent (T) and intentional (I) world switches per iteration, along with the number of system calls invoked (including page faults).

Configuration	Transparent	Intentional
None	2457 cycles	1082 cycles
SpectreV2	2453 cycles	1075 cycles
MDS	3337 cycles	1980 cycles
MDS+SpectreV2	3363 cycles	1992 cycles
MDS+SpectreV2+Q_retpoline	3406 cycles	2014 cycles

Figure 9: The costs of transparent and intentional world switches for different configurations.

application-level performance improvements, we evaluated the performance of `git`. For this benchmark, we ran `git status` in a 100 MB repository that we cloned from GitHub; all of the file system state was cached in memory. The average runtime for Linux-style mitigations took 24.6% longer than the unmitigated baseline, and USC-style mitigations took 11.2% longer than the unmitigated baseline. Much of the speedup is due to the fact that `git status` invokes frequent `lstat` system calls, which can execute in the Q domain. The remaining overhead is due to system calls like `openat` that require a world barrier for accessing potentially sensitive file contents.

7.3 World switch

§7.2 shows that the mitigation overhead is dominated by the cost of a world switch. This section breaks down this cost.

An intentional world switch via `kswitch()` takes around 644 cycles on a shallow stack, plus 50 cycles or so for every KB of stack used (the cost of a `memcpy`). A transparent world switch using a page fault adds 1372 cycles.

Figure 9 measures the cost of a null system call that invokes an intentional or a transparent world switch, and returns. It shows the cost for different configurations: no mitigations, MDS mitigations, SpectreV2 mitigations, and with `retpoline` in Q domain. The configuration with Q_retpolines runs with retpolines in both the Q and K domains. It shows the benefit of WARD patching them out at runtime: the retpoline that disables branch prediction for indirect jumps through the system call table costs 22 cycles.

7.4 WARD memory overhead

Because the memory protection mechanisms that WARD uses to expose non-secret data to Q domains operates on a 4KB or 2MB granularity, WARD’s approach incurs some additional memory overhead. Figure 10 lists some of these cases. In general we face a trade-off when filling small dynamic memory allocations for Q domain state: either we use an entire page each time, or we tolerate higher memory fragmentation because all chunks of memory on a page must be only used by the same Q domain.

7.5 Security

To validate that WARD’s mitigations work, we implemented a demonstration program that attempts to execute a Spectre V2 attack against the WARD kernel. While running with applicable mitigations disabled (i.e. each Q and K domain retpoline replaced with a normal indirect jump) the attack

Component	Overhead	Explanation
Kernel text	2 MB	Separate text segments for Q and K domains
Public kernel data	< 4 KB	Padding to a page boundary
Process structure	4 KB / process	Allocated on its own page
Thread structure	~6 KB / thread	Split between a Q domain page and a K domain page
Q domain stack	32 KB / thread	Smaller stacks possible by avoiding deep recursion
Page tables	<i>varies</i>	Q domain mappings require additional PTEs
Inodes	–	Many public allocations
Scheduler state	–	packed into a single page

Figure 10: Memory overhead of different WARD components.

succeeds in exfiltrating secret kernel data. However, when our Spectre V2 mitigations are re-enabled (by re-enabling retpolines in the K domain) the attack is thwarted. It is of course impossible to be certain that all variations on the attack would be blocked, but this test provides some confidence both that the unmitigated baseline is vulnerable to transient execution attacks, and that WARD is able to prevent them.

8 Discussion

Future vulnerabilities. It is likely that there are further transient execution attacks either under embargo or yet to be discovered. Based on trends in the existing attacks, we believe that WARD should be well positioned to address them: so far, mitigations developed for Linux have been suitable to directly copy into WARD. Since many need to run only at K domain entry/exit instead of every user-kernel boundary crossing, the same defenses in WARD might be cheaper to apply than they would be for Linux.

Linux. We are optimistic that WARD’s techniques could also benefit monolithic production kernels for two reasons. First, WARD and Linux are in the same ballpark in terms of system call performance on LEBench. Out of the 30 microbenchmarks, WARD is faster than Linux on 18 of them, and slower on 12. Second, as shown in Figure 1 (§2) Linux incurs a significant overhead for mitigations on LEBench and that overhead is in line with the overhead that WARD’s Linux-style mitigations incur on LEBench (see Figure 7). Some systems calls experience more overhead in WARD, because they implement less functionality (e.g., `getpid`), but the corresponding calls in Linux also incur significant overhead. Some systems calls in WARD have less overhead than Linux, because they are not as efficient; for example, `big` and `huge mmap` in WARD requires an update of its radix-tree VM data structures [7], while Linux just inserts the new region into a list. Linux may see a bigger pay for those system calls with WARD’s design than WARD.

A question is how much effort is required to incorporate WARD’s techniques into a production kernel such as Linux. Our preliminary efforts have proven encouraging: we found that we could leverage existing infrastructure for KPTI to

maintain Q domain and K domain page tables. We implemented a `switch_world` function in Linux, which switches to the K domain and copies the Q stack to the K stack. We modified the Linux page-fault handler to call this function when it encounters a page fault while running with the Q page table. This allows the Linux kernel to run as normally with a transparent world switch on each system call. We refactored the `struct task_struct` into a Q-private and secret part, allowing the `gettid` system call to run completely in the Q domain. This gives us some indication that the basic approach of WARD could be made to work in Linux, although an open question is how to best re-design the data structures in the Linux kernel to fit WARD's design.

9 Related work

This paper is motivated by the papers that show how secret kernel data can be leaked through micro-architectural state (e.g., [4, 6, 16, 21, 25, 29]). In particular, two survey papers were helpful by categorizing the known attacks [5, 12].

This paper relies heavily on the mitigation work in the Linux community [19]. WARD adopts Linux's techniques and their optimized implementation in the K domain. WARD uses, for example, Linux's `nospec` macro for bounds clipping, `FILL_RETURN_BUFFER` to fill the return buffer, and `retpoline`. WARD's hotpatching of its kernel text to remove `retpolines` in the Q domain was inspired by Linux's `ALTERNATIVE` macro [9].

In addition to the software/microcode approach currently used by Linux and other production operating systems, there are several proposed hardware-only defenses that delay the use of speculative data until it is safe [3, 31, 34]. While these defenses are more comprehensive, they have higher overheads that impact performance whenever speculation occurs. By contrast, the USC constrains speculation in a more targeted way based on memory mappings. `ConTeXt` also proposes constraining speculation based on memory mappings, but introduces a new PTE bit to explicitly mark pages that contain secret data [26]. WARD instead keeps secrets in separate address spaces, and allows speculation after employing its defenses to switch to the K domain. Finally, `SpecCFI` proposes to enforce control-flow integrity during speculative execution [18]. This idea strengthens Spectre defenses, and is complementary to WARD.

The Q page table is inspired by the shadow page table in KAISER [11] and KPTI [20]. In Linux, when a process executes in user space, the process runs with a shadow page table, which maps only minimal parts of kernel memory: the kernel memory to enter/exit the kernel on a system call. As soon as the process enters the kernel, it switches to the kernel page table that maps all of physical memory. WARD, however, executes complete system calls while running under the Q page table; this requires a significant redesign of the OS kernel, which is a major focus of this paper.

The use of virtual-memory to partition the kernel address

space has a long history in operating systems research. One example is Nooks [27], which runs device drivers in separate protection domains with their own page table in kernel space to provide fault isolation between drivers and the kernel. Another example is the use of Mondrian Memory Protection [32] to isolate Linux kernel modules in different protection domains within the kernel address space [33]. The most recent example is Mike Rapoport's work on kernel address space isolation [10] in Linux. These designs use similar techniques to introduce isolation domains within the kernel, but focus on traditional attacks (e.g., code execution through a buffer overflow) as opposed to transient execution.

10 Conclusion

This paper articulates the unmapped speculation contract (USC) for a division of labor between hardware and software. This contract allows hardware to speculate on many values (but not the values of page table entries) and provides software with a mechanism to prevent leaking secrets through micro-architectural state. The WARD design shows how USC can be used to reduce the performance costs of mitigations on system calls using per-process Q domains and global K domains. WARD transparently switches from Q- to K-domain through page faults, uses temporary mappings to access unmapped physical pages, and splits data structures into public and private parts. An evaluation shows that WARD can run the microbenchmarks of LEBench with small performance overhead compared to a kernel without mitigations: for 18 out of 30 LEBench microbenchmarks, WARD's performance is within 5% of the performance without mitigations. Although WARD is research kernel, we are hopeful that its ideas can carry over to production monolithic kernels.

Acknowledgments

We'd like to thank the anonymous reviewers and our shepherd, Chris Hawblitzel, who provided comments that helped improve this paper. We also want to thank our artifact evaluators for their diligent examination of our artifact submission.

Abstract

When a failure occurs in production systems, the highest priority is to quickly mitigate it. Despite its importance, failure mitigation is done in a reactive and *ad-hoc* way: taking some fixed actions only after a severe symptom is observed. For cloud systems, such a strategy is inadequate. In this paper, we propose a preventive and adaptive failure mitigation service, NARYA, that is integrated in a production cloud, Microsoft Azure’s compute platform. Narya *predicts* imminent host failures based on multi-layer system signals and then decides smart mitigation actions. The goal is to *avert* VM failures. Narya’s decision engine takes a novel online experimentation approach to continually explore the best mitigation action. Narya further enhances the adaptive decision capability through reinforcement learning. Narya has been running in production for 15 months. It on average reduces VM interruptions by 26% compared to the previous static strategy.

1 Introduction

Failures are common in large systems. High-availability system designs require techniques that address a key question: *once a failure occurs, how to quickly detect and mitigate it so the system can continue running?* Mitigating a failure here means attempting to make the failure symptom disappear without necessarily diagnosing and fixing the underlying bugs first. However, for a large cloud infrastructure like Microsoft Azure that serves millions of customers running virtual machines and various software atop, only employing post-failure detection and mitigation techniques is insufficient.

This is because if a system only takes mitigation actions after a failure is detected, users may already be having bad service experience as the system runs in a degraded mode (not completely failing) [15, 17, 29]. Moreover, when a failure is detected, the system will be under intense pressure to mitigate the failure fast in order to minimize downtime; but in practice failure mitigation takes time for large systems, and expediting mitigation could even worsen the situation [12]. In addition, our experience suggests that even short, mitigated failures can

be impactful to customers due to the interruptions themselves.

Therefore, cloud systems should also design techniques to address the question of, *whether a failure may be imminent, and if so, what preventive actions should be taken to avert this failure?* Several recent works tackle the failure prediction problem [14, 27, 38] in the context of disk failures. But they focus on prediction alone, with the goal of alerting operators or providing allocation hints [25]. The questions of how much benefit does the prediction bring, and more importantly what preventive mitigation actions should the system take in response to predicted failures remain open. Answering these questions requires a holistic solution—one that is closely integrated in the system’s control loop, which not only predicts host failures in real time, but also automatically decides the proper mitigation actions, measures the benefits, and continuously adjusts its actions based on the measured benefits.

In this paper, we present NARYA to fill this aforementioned gap. Narya is an end-to-end service with predictive and smart failure mitigation fully integrated in the Azure compute platform for its Virtual Machine (VM) host environment. The design goal of Narya is to *prevent* VM failures ahead of time and enhance the self-managing capability of the Azure compute platform for providing smooth VM experience to customers.

Narya’s design is informed by several observations we had. First, while failure mitigation is a crucial step in cloud operation, the current practice is *ad-hoc*. To mitigate a (predicted) failure, developers use static policies that prescribe actions based on the symptoms and domain knowledge. While this approach works for simple systems, it does not work well at Azure scale. With multi-tenancy, heterogeneous infrastructure components, and diverse customer workloads, it is difficult to comprehensively categorize different failure scenarios in a large cloud system beforehand and determine good mitigation actions (or their parameters), especially without trying it.

Moreover, as the cloud system is constantly changing (software/hardware updates, customer workload changes), some mitigation action that worked well in the past may no longer be optimal. As a result, developers keep reactively adjusting the actions based on hind sights from service incidents.

For example, initially restarting a host node upon receiving a predictive failure signal may be effective as the system failures tend to be caused by some transient hardware issues; but gradually permanent node failures become more common so restarting is not the best mitigation action anymore—live migrating the virtual machines from the node predicted to fail to a healthy node may be a better action. Therefore, for cloud-scale systems, we need smart and adaptive failure mitigation.

Our insight is that the effectiveness of taking some mitigation action in a complex and changing system is often probabilistic as there are too many factors affecting it (network condition, VM size, applications, hardware health, customer activities, etc.), which may not be thoroughly accessed or assessed. We usually do not know beforehand whether some mitigation action is good or not, or whether there is a better action, unless we try it. Consequently, explorations with *production* workload is indispensable to determine the (near-)optimal failure mitigation action. Nevertheless, we should ensure that the actions taken maximize the expected effectiveness (minimize the potential customer impact) over time.

Based on this insight, Narya takes a novel online experimentation approach. In particular, Narya predicts whether host nodes in the production fleet will likely fail and then leverages A/B testing to continually experiment with different mitigation actions, measure the benefits, and discover optimal actions. The rationale behind the A/B testing strategy is that it, in essence, introduces randomization that avoids biased pivots of the diverse nodes, which helps surface the statistically significant effective actions.

One important drawback of the A/B testing strategy is its cost of exploring each action until statistical significance is found and then always choosing the estimated best action. This problem is essentially the classic *exploration–exploitation* trade-off [32] in learning systems that need to make decisions with incomplete information (about the system stack, customer workloads, etc.), constant changes, and uncertain pay-offs (whether the action will prevent future failures). The dilemma is whether the learning agent should repeat a mitigation action that has worked well so far, *i.e.*, *exploit*, or it should try some novel choices in the hope of getting better rewards, *i.e.*, *explore*. We address this issue by enhancing the Narya decision engine using a dynamic assignment learnt through a multi-armed Bandit model [2, 33]. This helps decrease overall cost by better leveraging the early cost estimation of each action and by continuously exploring each of them to adapt to system changes.

Narya has been running in production for 15 months in Azure as part of the Gandalf [24] suite. Narya successfully prevents many VM interruptions for customers. In nine production experiments that Narya runs for different failure types, Narya on average reduces VM interruptions by 26% compared to the previous static strategy. This reduction is close to what the oracle optimal strategy could achieve (35%).

The major contributions of this work are:

- We propose a holistic failure avoidance solution that includes failure prediction, new failure mitigation actions, and intelligent mitigation strategies.
- We design a novel approach of using A/B testing for online experimentation with production workload to automatically identify good failure mitigation actions.
- We explore a more advanced reinforcement learning approach to optimize choice of mitigation action.
- We evaluate the proposed solution in a large-scale, production cloud service, Azure, to validate its effectiveness.

2 Background and Motivation

A traditional system’s operation cycle is as follows: a failure is detected; developers diagnose the failure and find out the root cause; a patch is written; the system is re-deployed. For cloud systems, operating in this exact sequence is problematic because the time it takes to identify the root cause and develop a fix is usually long and exceeds the downtime budget. Instead, once a failure is detected, some *mitigation* action like restart will be applied first without necessarily knowing the bug.

2.1 Target System and Goal

We tackle the problem of preventive and smart failure mitigation for cloud systems. Our specific target system is the VM host environment, a node, in the Azure compute platform. The host environment is a complex stack consisting of guest OSes, guest agents, hypervisor, host OS, host agents, firmware, and hardware. The node is backed by locally attached disks and remote virtual disks. Each node is connected to various compute services, together referred to as controller, that is responsible for provisioning resources and performing management actions such as creating and destroying VMs.

Azure already employs layers of monitoring mechanisms to actively detect if a host node has failed (e.g., via periodic pings), and mitigate the failure with actions such as rebooting the node. We aim to further develop techniques that *predicts* whether a host environment might fail soon and *automatically* decides an appropriate mitigation plan among multiple choices. The end goal is to *avoid* future VM failure events.

2.2 Are Failures Predictable?

To predict failures, there are two basic requirements: (i) the imminent failure is not abrupt; and (ii) there is telemetry recorded to indicate the degradation. One type of predictable hardware issue is certain hardware parts wear out. We could predict using the age or the wear-out rate. Combined with other system signals such as workload patterns, we can predict if a host will fail soon. Resource leak, including memory/file handle/network ports leak, is a common type of predictable software failure. We could predict them using the resource usage trend. If failures are correlated with certain hidden factors such as timeout settings, bugs related to timers, and release schedule, they may also occur on a predictable basis.

Timestamp	Event
03-14 18:00:00	A node with 16 VMs was predicted to fail with 0.7 prob.
03-16 01:09:12	Node agent crashed, 17 VMs offline
03-16 01:15:26	Controller probes to node agent timed out, retry
03-16 01:31:00	Node state marked by controller as unhealthy
03-16 02:07:37	Controller tried to recover the node through restart
03-16 02:23:02	Failed to receive node reboot success signal
03-16 02:23:33	VMs in the node were recreated in another node
03-16 04:40:17	Node was sent out for repair
03-16 06:13:21	Offline diagnosis finished, disk fault was suspected

Table 1: Events timeline for a production node.

2.3 Why Reacting on Predicted Failure?

Since predicted failure is about something (complete failure) that has not occurred yet, one option is to only treat it as an early warning and not act on it. After all, it is developers' common mindset that *"If It Ain't Broke, Don't Fix It"*. However, for cloud services, this mindset puts customers and their VMs at the risk of suffering interruptions. With techniques such as live migration which can migrate a VM from one node to another with minimal customer impact, cloud vendor is in a better position to help customer avoid failures.

To give an example, Table 1 shows a production case of the timeline for events in a node. In this case, the node was predicted to fail with a relatively high probability, but no preventive action was taken. So both the existing VMs and new VMs still run in this node. Later, this node indeed failed (OS crash), which caused 17 VMs including 1 new VM to be offline. The controller tried to probe the VMs and timed out. Then it tried to reboot the node but failed. Finally, the controller decided to recreate the VMs in another node. Subsequent offline diagnosis confirmed the disk on the node was indeed problematic. Had we taken some mitigation action when receiving the failure prediction signal, we could have saved the long VM disruptions and customer impact.

2.4 Why Static Mitigation Is Insufficient?

Intuitively each predicted failure should be handled in the same way using an optimal method. Indeed, initially we used a static strategy where all predicted bad nodes would be mitigated using the same plan: 1) block allocation on the node; 2) try to live migrate VMs; 3) wait for 7 days for short-lived VMs to be destroyed by customers; 4) force migration of remaining VMs; 5) mark the node offline and send it for repair. Although this plan looks reasonable, it quickly faces limitations. Blocking allocation results in capacity pressure while for some predicted failures, avoiding allocation may be better. Some failures may be too severe to do live migration (*e.g.*, broken disks). Forced migration causes unnecessary customer impact if nodes are still healthy after 7 days. Marking nodes offline is also suboptimal when capacity is low.

Using static assignment prevents us from knowing what would have happened if we had chosen a different action, and therefore from knowing how much customer pain we saved or if we were using the best action. In addition, static

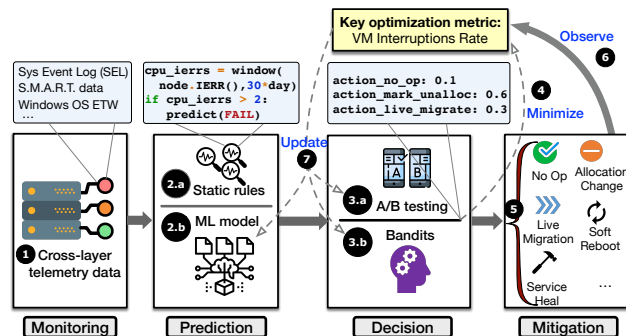

Figure 1: High-level workflow of Narya.

mitigation get affected by system changes over time. With the complexity of our cloud system, the effect of a rule, as well as the telemetry that a rule relies on, is constantly changing. In these cases, since static mitigation does not try other actions, it could increase customer pain without us realizing it. For example, a low CPU frequency can be a defense mechanism from a CPU to indicate an imminent failure; detecting such drop in CPU frequency and applying a mitigation action can be beneficial. However, new improvements in the system could voluntarily decrease CPU frequency to conserve energy. In this case, the original rule could have a high number of false positive in prediction results, and applying the same action will very likely cause more harm than good.

Another limitation of static failure mitigation is that it creates tendency for developers to make *ad-hoc* modifications to the mitigation assignment based on some isolated cases. No mitigation action can be perfect and customers may complain if they suffer from such mitigation. In such case, developers tend to modify the rule to satisfy the customers. However, without testing if that change does reduce the *overall* customer pain, it is possible that the situation gets worse and the policy might be switched back again when another customer complains about this new policy.

3 Overview

We design Narya, an end-to-end service that is integrated in the Azure compute platform, to predict host failures and automatically decide what mitigation actions to take for each predicted failure. The design goal of Narya is to *avert* potential VM failures while minimizing the impact to customers. Narya advances the current practice of failure mitigation in two ways: (i) replacing existing static and *ad-hoc* mitigation assignment to adaptive and systematic decision algorithms; and (ii) transforming the traditionally reactive, post-failure mitigation activity to proactive failure avoidance mechanisms.

3.1 Narya Workflow

Narya takes a novel online experimentation and learning approach to the failure mitigation problem. Figure 1 shows overview of the high-level workflow in Narya.

Each node in Azure is deployed with monitoring agents that

collect various telemetry signals about the host environment (❶, §4.1). The prediction component in Narya continuously consumes these signals and predicts whether some node will fail soon (❷). The prediction is made by both static domain rules (❷.a, §4.2) and running machine learning inference (❷.b, §4.3). Each prediction result is streamed into the decision component in Narya as a mitigation request. Narya supports two decision schemes: A/B testing (❸.a, §6.1), and Bandit model (❸.b, §6.2). The decision component computes a probability distribution of applicable mitigation action choices (❹, §5) and then picks an action based on the distribution. The mitigation controller applies the chosen mitigation action to the suspected node (❺). This whole process is an automated feedback loop that optimizes a key objective metric—VM interruption rate (§3.2). Narya observes (❻) the effect of the mitigation actions and adapts (❼) future prediction and mitigation decisions based on the observations from production.

Building Narya to work for a production cloud requires both algorithm designs and systems support. We first describe the core prediction and mitigation algorithms in Section 4 and Section 6, respectively. Section 7 describes the Narya systems design and implementation.

3.2 Key Optimization Metric

Narya’s objective is to reduce and minimize the overall customer impact caused by node failures on the fleet. Defining a good cost metric for customer impact is critical for the Narya’s decision engine to optimize that metric. In Azure, we focus on the Annual Interruption Rate (**AIR**) defined as:

$$AIR = \frac{\text{VM interruption count in } T}{\text{Total VM lifetime in } T} \times 365 \text{ days} \times 100 \text{ VMs}$$

T is any given measured interval duration in days. VM interruption in this paper mainly refers to reboots or loss of heartbeats. Internally, we also measure performance drop with a sub-metric we call *AIR-blips*.

We optimize this metric instead of the traditional availability metric for a few of reasons. First, long-duration incidents are now rare in Azure. VM interruptions become more common that require addressing. Second, short VM interruptions can significantly disrupt user experiences, e.g., for gaming-type applications. Third, for VMs that run applications like databases, even if the VM only experiences a short interruption, the applications take time to recover, which translates into a longer user-perceived interruption. Fourth, based on communications with customers, customers can be more annoyed if their VMs get frequently interrupted when compared to a single longer-time interruption.

3.3 Challenges

We need to address several design challenges. First, failure mitigation has to act with incomplete information since the underlying root cause is not known. For Narya, this challenge is even more pressing since the failure has not occurred yet.

Second, due to the massive scale of a cloud system, there are many factors to consider in the decision logic. A decision

may work well for some nodes but not others. If not careful, some corner cases can mislead or bias the decision logic. Narya must be robust enough while still being flexible.

Third, our experience suggests that when incorporating failure prediction into a production cloud system, false positives are unavoidable due to the complex system environment, large number of noisy signals, unexpected customer workloads, etc. If the system blindly trusts the failure prediction results and reacts, it could cause unnecessary disruptions. When consuming the prediction results, the mitigation mechanisms should take this into account and operate in a way that minimizes the impact due to unavoidable false positives.

Lastly, failure mitigation is a mission critical procedure. If not designed well, a decision engine may do more harm than good. Ensuring safety should be a top priority for Narya.

4 Predicting Node Failures

The first step in Narya is to predict a host failure before it occurs. In this Section, we describe two prediction methods Narya uses: (1) static threshold rules written by domain experts; (2) machine learning model-based prediction.

4.1 Input Signals

Narya consumes telemetry signals from the entire stack of the host environment to make informed prediction. For hardware and firmware, the monitoring agents collect low-level logs from disk SMART attributes, memory (e.g., uncorrectable errors), CPU (e.g., machine check error), motherboard (e.g., bus error), etc. A higher-level source of signals comes from device drivers, e.g., timeout events. Repetition of such events is often an indicator of an imminent failure. Faults in individual component do not necessarily cause customer impact. Some could be transient that would go away after retries. Others may be tolerated by redundancy. Narya further consumes critical OS events and aggregate application performance counters.

Another important source of signals used by the predictor are results from the control-plane operations. For example, repetitive VM creation operation errors could indicate serious host issues even if the host still appears to be running. Such signals help reduce the observability gap [16].

4.2 Rule-based Prediction

Rule-based prediction leverages domain knowledge from hardware, firmware and software experts. We analyze the common failure patterns and the available telemetry signals to predict failures that have significant customer impact. For example, in some cases, CPU Internal Error (IERR) is a good indicator that the node will fail *again* soon; a prediction rule could be marking the node if IERR occurs twice within 30 days. Rules are typically written as Json files, Python scripts or sometimes C++. Since rules are manually written, they are simple and easy to understand. The prediction rules are deployed directly in the host and can be executed fast.

Figure 2: Prediction horizon and label timeline. t_1 : host failure time. t_2 : component permanent failure time.

Rule-based prediction works best for definitive signals that indicate some severe issue with high confidence. An example is the AvailableSpare signal in NVMe device health log. When it drops below a certain threshold, we know the device is almost at the end of its life.

Since many failure signals are not definitive, rule-based prediction cannot cover a wide range of imminent failures. In addition, the prediction may come late and do not provide enough lead time for the mitigation engine. The number of prediction rules also keeps growing, which becomes a burden to manage and tune. We have a total of 51 rules in use.

4.3 Learning-based Prediction

To address the limitation of rule-based prediction, Narya employs an additional learning-based predictor, which analyzes more signals and patterns during a larger time window. It can predict many complex host failures. It also can predict earlier, thus leaving longer time for the mitigation engine to react.

Prior work predict disk failures [14, 27, 38] and node faults [25] with supervised learning. Our learning-based prediction aligns with prior solutions. A main difference is that we focus on overall host health and failures that result in customer impact, instead of failures of individual components. Because of this, Narya analyzes more diverse signals across layers such as control-plane operation signals.

Prediction Horizon and Label. Deciding the labels to use for learning is crucial for Narya. In prior work that predicts hardware failures for alerting, the positive labels are signals close to when the hardware is completely broken. For Narya, the host view of a failure is different from individual components' view. The host failures could be unresponsive host, VM creation failure, host OS crash, *etc.* In our observation, they happen much earlier than the permanent failure of a component (e.g., disk unusable). As Figure 2 shows, if we assign positive labels from time t_2 (permanent component failure), it can yield late prediction which comes after host failure at time t_1 . The consequence is that the prediction does not give enough time for Narya to take proper mitigation actions.

Additionally, certain faults might not be a problem to the source component but could be problematic from host's view. For example, a series of memory correctable errors might seem fine for an ECC DRAM because they are corrected. But the host may already suffer slowness and impact VMs.

To get accurate and useful prediction result, we only use host failures that result in customer impact and are later confirmed to be caused by some hardware component faults during diagnosis. For a given host failure, if it occurs at time t , we

Figure 3: Deep learning model structure.

assign positive (failure) labels for signals from $t - 1$ to $t - n$, where n is the prediction horizon and using an hour unit. We assign negative (normal) labels for signals from $t - (n + 1)$, ... We also sample negative labels from healthy nodes.

In production, our prediction horizon is set to 7 days. We made the choice based on how discriminative the feature will be given different horizons. Specifically, we looked at the feature distribution of failed nodes and measured the same distribution of healthy nodes. We then measure the similarity between the two distribution groups. Beyond 7 days, we could not observe a significant difference.

Machine Learning Model. With the signals, labels, and host metadata, Narya trains a binary classifier. The predictor outputs the failure probability of a host (we use 0.5 as the cutoff).

To train the classifier, we use the gradient boosted tree model [18] commonly used in supervised learning, which combines decisions from a sequence of simple decision trees with a model ensembling technique called gradient boosting [10]. This simple model works fine for our scenario in terms of its predictive power, but we have to carefully craft aggregated features from the signals. We engineer 2k+ features from 100+ time series data. Those engineered features are combined with other categorical features to build the learning-based model feature set.

We further explore reducing the feature engineering efforts by directly learning the features with an attention-based deep learning model [20, 35]. At a high level, we aim to learn both spatial features and temporal features. Spatial features compare one component to its neighbors. For example, one host often has multiple disks configured under RAID 0, thus they are expected to perform similarly. If one disk performs worse than its neighbors, it could indicate imminent host failures. Attention-based deep models are designed to capture such patterns so that more weights (attention) are assigned to anomalous neighbors. The temporal features characterize changes in components over time.

Figure 3 shows the structure of this model. First, we use a dimension adapter layer to unify the dimension of signals from different sources. Next, we employ a spatial information encoder based on self-attention. It calculates weights of a component's neighbors. The weighted sum of the neighbors' feature vector represent its spatial information. Then, we use the temporal information encoder, which consists of positional encoding, self-attention, and location-based attention layers. Finally, we employ a fusion layer to do binary classification. We omit the attention implementation details as they are based on an existing technique proposed by Lee *et al.* [20].

	Action	Description
Primitive	Avoid	Deprioritize new VM alloc. on this node
	Unallocatable (UA)	Block new VM allocations on this node
	Live Migration (LM)	Migrate VMs to other nodes on the fly
	Service Healing (SH)	Discon. VMs, move them to healthy nodes
	Soft Reboot (SR)	Reload host OS kernel, VM states preserved
	Human Investigate (HI)	Shut down node and send it to diagnostics
Composite	UA-LM-HI	Block alloc., attempt LM and HI after T
	UA-SR	Block alloc., attempt soft reboot
	UA-LM-RH	Block alloc., LM and unblock after T
	Avoid-RH	Avoid alloc. to this host if possible

Table 2: Primitive and composite mitigation actions for Narya. Composite actions are sorted by decreasing priority.

Overall, this model achieve 5–10% improvement compared to the decision tree model with hand-crafted features.

5 Mitigation Actions

When a host is predicted to fail, Narya chooses among several possible actions. Table 2 lists the main *primitive actions* in Azure. Mitigating a failure often requires multiple primitive actions. An aggressive goal for Narya is to explore the actions arbitrarily and figure out the optimal combination. But this could potentially bring significant customer impact. Instead, Narya mitigation engine focuses on exploring pre-defined *composite actions* (Table 2). This set of composite actions is constantly enriched with new combination and by modifying parameters (e.g., unallocatable duration).

Live Migration moves a running VM from one host to another with minimum disruptions. The migration process involves transfer of the VM’s memory, processor and virtual device state [7]. The LM engine iteratively copies the VM’s memory pages while maintaining a dirty page set for the VM on the source host. Based on the dirty page rate, network bandwidth, the engine determines the maximum iterations to stop the VM. After the VM is stopped, the LM engine synchronizes the dirty state with the target and resumes the VM on the target host. Note that not all VMs are eligible for LM and LM could fail for various reasons.

VM Preserving Soft Reboot preserves the VM state across a reboot of the host OS. At a high level, the host OS kernel is reloaded into memory, the VM memory and device state are persisted to the newly loaded kernel. The host reboots into the loaded kernel while preserving the persisted state. Once the reloaded kernel starts, the persisted state is restored and the rest of the state in the prior kernel are discarded. The restored VM experiences a brief pause similar to the live migration.

Service Healing is used to restore the service availability of unhealthy or faulted VMs. Live Migration can move running VMs transparently, but it could fail or cannot be applied due to certain constraints such as network boundary. Service healing works for more general scenarios. The VMs will be isolated by powering down or disconnecting from network. The controller generates new assignment of the VM to healthy nodes. During the process, there is some interruption.

Mark Unallocatable blocks allocation of new VMs to a host for some time T (default 7 days). Composite actions typically start with marking a suspected host unallocatable. In *UA-LM-HI*, after marking host unallocatable, the controller attempts to live migrate the VMs on this host to other hosts. After all VMs have been migrated or destroyed by customers or this host fails, the host will be sent to diagnostics. If at the end of the unallocatable period T some VMs are still running (e.g., because they are not eligible for LM) we service heal them before pushing the host to diagnostics. *UA-LM-RH* is a variant of *UA-LM-HI* where we unblock allocation (reset node health) at the end of T . In *UA-SR*, the controller blocks the allocation and then try the kernel soft reboot action. If the soft reboot succeeds, the controller unblocks allocation. Otherwise, we use a fallback strategy, typically *LM-HI*.

Avoid informs the allocator to try to avoid adding new VMs on this host. Blocking allocation has a strong impact on capacity since the host is not eligible for getting new VMs. Thus, the number of hosts that can be marked unallocatable at the same time is limited. *Avoid* action provides a weaker constraint. The behavior on host failure is still to send it to diagnostics. At the end of T , we reset the node availability.

NoOp is a special action for predicted failure, in which the controller does not take any action. This is the baseline to measure the benefits of prediction and taking actions.

6 Decision Logic for Adaptive Mitigation

With different prediction rules/models as well as different mitigation actions, relying on static assignment based on domain knowledge to map each prediction to an action can soon get intractable and ineffective. This motivates the design of Narya decision engine for adaptive mitigation.

6.1 Online Experimentation with A/B testing

One straightforward way for choosing mitigation action is to *estimate* offline the impact for each possible action for a predicted failure. In our experience, given the complexity of cloud systems, it is extremely hard to estimate the impact of actions and know which one performs best without trying them in production. Based on this insight, Narya takes an online experimentation approach to evaluate different mitigation actions by testing them at scale.

A/B testing, also called online experiments, is widely used [19] in front-end designs to test the effect of UI features. Narya adopts the A/B testing methodology and adapts it for discovering good mitigation actions. In classic A/B testing, one experiment is about one UI feature and each unit is a user. For Narya, one experiment is about the mitigation of one failure prediction (e.g., CPU IERR, slow memory access latency), and each unit is a failure mitigation request about a node marked by the corresponding prediction rule/model.

The workflow of the A/B testing in Narya is as follows: (1) each predicted node is assigned to different action groups with

Figure 4: Hash node ID and experiment name for sticky assignment.

equal probability (2) after taking each action, we measure the customer impact within an observation window; (3) we use hypothesis testing to test if an action yields significantly less customer impact than others; (4) once statistical significance is reached, we consider this least-impacting action optimal and apply it for all nodes; (5) we keep monitoring the customer impact per node for the used action; (6) if customer impact significantly increases, we run a new A/B testing experiment to validate that the action is still optimal.

Cost. The cost ($= -1 \times \text{reward}$) models the customer impact. It should balance the trade-off between key metrics of our system. The pros and cons of each action should be modeled into the cost to correctly optimize for the mitigation action. We use the number of VM interruptions in the node during an observation window and the VM interruptions in nodes to which we migrated VMs in live migration or service healing.

An additional constraint we need to consider is capacity. As capacity does not directly impact customers and is not visible at the node level, it cannot be easily added into the cost. We currently incorporate the constraint by limiting the number of nodes that can be marked unallocatable for the same rule in the same cluster at the same time. With this, capacity indirectly impacts the cost of marking nodes unallocatable.

Assignment Strategy. A crucial point for A/B testing is to decide for each node marked by the failure predictor, in which experiment group should it go to. In classic A/B testing, each experiment unit is assigned randomly, based on the assumption that the units are independent and identically distributed (i.i.d). For Narya, we make several changes.

The same node can be marked by the same prediction rule multiple times during an A/B experiment. In this case, if Narya assigns it different mitigation actions, e.g., assigns node X in action A group at time t_1 and then to action B at time t_2 , the i.i.d assumption can be violated. This is because the underlying node condition at t_1 and t_2 could be highly correlated, especially for hardware issues. Then the observations from the treatment and control group are correlated.

To address this issue, we introduce **sticky assignment**: for each node, the group is determined through the hash of the node Id and experiment name (Figure 4); then, if a node is assigned to action A for an experiment, it will always take action A for subsequent requests.

Classic A/B experiments are typically done sequentially. In our case, sequential experimentation takes too long; so Narya allows different experiments to take place concurrently. While most experiments are independent, some experiments could have prediction rules that are correlated. In this case, it

Figure 5: Using decision time as the start of observation window.

is important to test all possible action combinations to analyze their compound effect later. For example, with experiment X testing actions $\{a, b\}$ and a correlated experiment Y testing actions $\{c, d\}$, we need to have observations that take each of the four scenarios: (a, c) , (a, d) , (b, c) , (b, d) .

Action Overriding. Since many fault handling policies, including our A/B experiments, can take place concurrently, a host can potentially be marked by several prediction rules. As a result, the host might need to follow different composite actions at the same time. A common reason for this is the incomplete information factor (Section 3.3). To handle this situation, Narya uses a specific override logic based on the priority from the order in Table 2. When we try to assign a node with a lower-priority action than its current one, we skip it. In case of equal priority, Narya honors the older actions. The rationale is that later prediction can often be a side effect of the earlier one. Since we often do AB testing between actions with different priorities, it is critical to also observe cases where the action was skipped or later overridden.

Effect Observation and Attribution. Depending on the complexity of the actions, some need longer time to get triggered. In the time between the decision and the start of the action, unrelated VM interruptions can happen. However, to fairly compare action, we should still count the cost in this time gap because, for instantaneous actions, it would be impossible to differentiate the costs caused by the action from the unrelated ones. Like for overrides, we monitor decision instead of action, hence we use the decision time instead of the action time as the start of the observation window. Figure 5 shows an example where if we used the actual action time we would ignore some unrelated reboots for one action and not the other, while they happen in both groups.

Hypothesis Testing. After collecting the cost metrics for each action, the decision engine performs hypothesis testing to decide whether an action is optimal and the experiment can be stopped. Since our cost function is complex and depends on external variables, we simplify the hypothesis testing by assuming that the number of VM reboots per node is i.i.d and follows a normal distribution. Since different actions can highly change the VM reboots per node, we will not assume equal variance for the different actions. Under these assumptions, we use Welch's t-test [36] when testing for two actions and Welch ANOVA test for 3 and more. In the latter, we use post-hoc analysis to remove all statistically worse actions until one action remains.

6.2 Bandit Modeling

One drawback of A/B testing is its static group assignment. Before statistical significance, we do not leverage the estimated difference between the groups to minimize our cost,

and once an experiment reaches statistical significance, we will almost always use the discovered optimal action. This is essentially the classic *exploration-exploitation* dilemma. Naturally, we explore modeling the adaptive mitigation as a *Multi-Armed Bandits* problem [32, 33], where we aim to minimize the customer impact over time by ensuring a balance between exploring potential better actions and exploiting the discovered best action. At training time, we observe tuples (node, rule, chosen action, cost) to estimate the probability to choose each action, while at serving time, we match a request tuple (node, rule), to the learnt action.

Actions. The output of the bandit model is the composite action we want to attempt. The available actions are typically defined per experiment based on offline analyses of the prediction signals characteristics: false positive ratio, time to failure/impact and actions feasibility (Section 5).

Exploration Algorithm. To minimize customer impact over time, we face the classical exploration-exploitation trade-off. We need to explore different actions to see which one minimizes the customer impact but at the same time we want to use the action with minimum estimated cost as much as possible. In other words, we need to balance between short-term and long-term benefits. We experimented with multiple different exploration models including Epsilon Greedy and UCB, and decided to use *Thompson Sampling* model since it provides more explainability and continuous probability changes. In Thompson Sampling, we model the reward as a function of actions and a model parameter and choose the action according to the probability that it maximizes expected rewards. This Bayesian approach updates the prior using observations of actions taken and chooses each action with probability equal to the chance that it minimizes the expected cost:

$$P(a^*) = \int I(E(c|a^*, \theta) = \min_a E(c|a, \theta)) P(\theta|obs) d\theta$$

where $P(a^*)$ is the probability to choose action a^* , θ is a hidden parameter, c is the cost and obs are the past observation as list of tuples (a_i, c_i) . Our technical report [?] describes in more detail the Thompson Sampling algorithm in Narya.

6.3 Extension to Bandits

Compared to traditional Bandits, our system faces several challenges. In addition to the effect observation solution described in Section 6.1, we made 4 main adaptations as follows.

Accommodate Temporal Changes. Since our system can change in time, older observations will gradually become less and less relevant. To account for this factor, we use an exponentially decaying weight for observations to focus on recent data. We will apply a multiplying weight to past observation in the format of $decay = \sigma^{T-T_{obs}}$, where σ is the decaying factor, T is the current time and T_{obs} the time of the observation. We set σ by default to 0.99 based on simulation-based experiments and so that the weight would be close to 0 after 3 months which is our typical retention policy. In the case of

Thompson Sampling with Gamma Prior, the distribution to sample from becomes:

$$P(\theta|a, obs) \sim \Gamma\left(1 + \sum_{i, a_i=a} c_i \sigma^{T-T_i}, 1 + \sum_{i, a_i=a} \sigma^{T-T_i}\right)$$

Delayed Reward Collection. A key challenge in our settings is the potential long time between the action taken and its impact. This forces us to observe for at least 10 days and up to 30 days the impact of choosing each action. This observation window highly depends on the duration of the action and its effect: UA-LM-HI for 7 days would require around 10 days while Avoid-RH for 15 days would require a full 30 days to observe potential failures following the health reset. The drawback of a long observation window is the delay for the reward to be integrated into the model. Thus, wrong estimation could be used for a while before the observed cost can readjust the probabilities. One way to counteract this effect is to observe the reward as it comes. But we can suffer from the opposite effect of getting biased by reboots close to the decision time. Our experience suggests that we need to wait for the full initial observation window and then can collect partial rewards incrementally.

Bandit stickiness. Since the probability to choose each action over time changes, we cannot rely on a hash function like in A/B testing to ensure a node is always assigned to the same action. We define the bandit stickiness for time T as reusing the previously chosen composite action if the node has an available decision for the same rule within the T time window.

Deal with Unexpected Spikes. Another potential issue in our system is the unexpected spike of VM interruption events that could affect one action group more than the other. One approach would be to perform an outlier removal step before using such observation, but in that case it could also filter out spikes inherent to a specific action, which should be integrated into our learned model. We address the issue with the safe guards mechanism described below.

6.4 Safe Guards

Safety is a top priority in Narya mitigation decision logic. We take several measures to ensure safety. In addition to action overriding (Section 6.1), we also apply *safety constraints*—domain-specific restrictions to prohibit certain actions in some failure scenarios. Narya decision engine also requires a minimal number of observations before following the recommendation from the Bandit. The Bandit model will output a *premature* flag for insufficient observations, in which case we would fall back to default action probabilities similarly to A/B testing. This also helps dilute the potential effect of spikes in a larger observation set.

Moreover, we support configuration of minimum and maximum constraints for each action probability. The maximum constraint limits the possible reactions to high cost, while the minimum constraint guarantees some exploration for actions that could seem irrelevant at a specific time. In practice, any

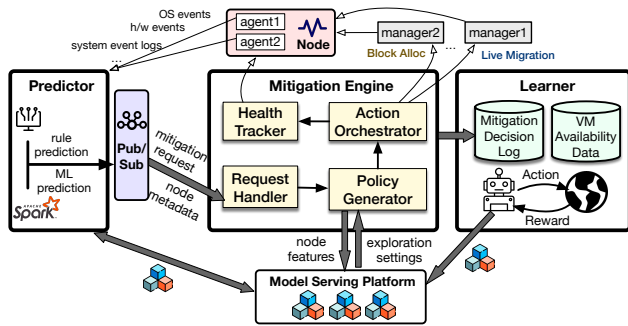

Figure 6: Narya system architecture, which consists of the predictor, mitigation engine and learner. The ML models for the prediction and mitigation are stored in a model serving platform [8].

experiment for which we expect a potential change in the system should keep a minimum probability for each of the allowed action so that it will continue observing the effect of such action. Experimentally, We found that using 10% exploration when nodes flagged per day is less than 100 and 5% when it is higher yielded the best results.

7 Narya System Design and Implementation

In this Section, we describe the system support for Narya. Figure 6 shows the system architecture. Narya is deployed in each data center region of Azure compute. The Narya system must be able to process the massive signals and requests from the entire fleet with low latency and reliability.

7.1 Failure Predictor

Azure deploys various agents in each node to monitor the health of the host environment. The Narya predictor ingests health signals from these monitoring agents and runs rule-based prediction and ML-based prediction (Section 4).

Rule-based prediction has low cost and high priority. Thus its prediction logic is executed directly in the host. The ML-based prediction inspects much more signals such as performance counters and runs more complex prediction logic. Thus, the ML predictor is implemented as a centralized service. It collects raw signals from monitoring agents using micro-batches (small groups) and incrementally processes them. Open source technologies are used for ML modelling. LightGBM is used for decision tree model and PyTorch for deep learning model. The ML inference tasks run as an hourly Spark job, which reads the most recent signals and the trained ML model to compute failure probability for each host.

Pub/Sub Service. A *mitigation request* is created if a node is predicted to fail with high probability. The predictor publishes the request along with metadata information about the host (e.g., hardware generations, OS version) to a central pub/sub service, which we implement on top of Kafka [1]. We choose Kafka because it allows scalable, low-latency, and real-time streaming processing to deliver the mitigation requests quickly. Also, our computation pattern involves many

data producers for a small number of consumers, which is a main scenario Kafka is designed for.

7.2 Mitigation Engine

The mitigation engine is a core component of Narya. Internally, it is composed of four major microservices. These microservices communicate with each other and other services in Azure using REST APIs.

Create Mitigation Job. The *Request Handler* microservice consumes mitigation requests from the Pub/Sub service. Upon receiving a mitigation request, it creates a mitigation job with a job Id. This job Id is used by other micro-services to track the mitigation and query its progress.

Instantiate Mitigation Policy. For a new mitigation job, the *Policy Generator* creates a *mitigation policy*, which maps the information from the request to the action to take. It is represented as a decision tree. There are two types of tree nodes: a Selection node, which chooses the tree node to visit next based on some C# predicate; an Action node, which executes a user-defined C# function. The decision tree structure allows us to easily specify the decision logic. For example, we can decide mitigation actions based on failure types (software or hardware), fault codes (e.g., `Req.FaultCode == 0x123`), cluster types (storage or compute), hardware generations (e.g., `HostNode.Gen != "ABC"`), etc. Figure 7 shows an example.

The policy is derived from a template (Json configuration file). For A/B testing, the action distribution is specified in the template. In the Action tree node matching a mitigation request, the node's C# function samples one mitigation action from the distribution. For Bandit, the Action tree node dynamically generates the distribution based on contextual information. In particular, it calls a ML model serving platform, Resource Central [8], with relevant features such as the fault code, VM count, etc. The platform returns an exploration setting—a probability distribution over mitigation actions.

The policy generator then applies safety constraints on the retrieved exploration setting to obtain an adjusted action probability distribution. Additionally, the mitigation policy allows imposing *rate limit* for a tree node to avoid excessive mitigation that could cause capacity issue or cascading failures.

Walk Policy Tree. The policy generator further traverses the

policy tree in DFS order and creates an *action plan*. During this process, the generator performs many steps such as checking predicates, checking rate limit condition etc. If a node is entered, the generator first checks if we need to apply *sticky* mitigation action (Section 6.1) and if there were decisions made within certain period of time for the same experiment and tree node. In that case, the last mitigation action is retrieved from a distributed storage service.

Otherwise, one action is sampled based on the probability distribution from the config if in A/B testing mode and from Resource Central if in bandit mode. If there is insufficient data learned in bandit mode, a specific flag is returned to indicate the Bandit model is pre-mature. The generator then falls back to use the action probabilities from A/B testing mode. This allows us to bootstrap bandit learning from A/B testing safely, especially considering the delayed cost in the feedback loop. We follow the same fallback strategy if there is any error in calling the model serving platform.

Carry out Action Plan. The *Action Orchestrator* microservice is responsible for carrying out the action plan from the policy tree walk session. This step involves making API calls to the corresponding compute managers since different actions may be implemented by different managers. The orchestrator executes actions asynchronously to avoid blocking.

Log Actions. Logging in general is very important for data analysis, Bandit training, and counterfactual evaluation of different mitigation policies. The logging format for Bandit learning is special since it requires not only recording the chosen action but also the associated probability. In particular, the mitigation engine will log the action timestamp, experiment name, model type, model name, model version, action distributions, chosen action, chosen action parameters, etc.

Track Node Health. The *Health Tracker* tracks node and VM health information during the mitigation process. For example, while rebooting a node, if we get a new signal (e.g., a `WindowsEvent`) that it is a hardware issue, then we can HI the node early instead of waiting for reboot to fail/timeout.

7.3 Learner

Learner is a centralized component in Narya. It learns the effect of mitigation action across different data center regions. Compared to a regional learner design, a global learner has the advantage of observing more data points and hence more confidence in the cost estimation. Additionally, a mitigation effect change in certain region due to software/firmware updates could be quickly learned and applied to other regions rolling out the same updates.

The learner runs two main jobs: cost collection and Bandit model training. The cost collection job retrieves the mitigation engine's decisions from the logs. This information is then correlated with the VM availability measurements and other important information (LM status, VM workload, etc.) to determine the cost of the mitigation action for training. The

Figure 8: AIR improvement of all A/B testing and Bandit experiments in March 2020, breakdown per experiment.

Figure 9: AIR improvement per month.

Bandit model training runs on a Spark cluster. The output model of the learner is a categorical distribution, which the model server can easily draw samples from.

8 Evaluation

Narya has been running in production since June 2019 to prevent VM interruptions in Azure compute platform. Our evaluation answers several questions: (1) how effective is Narya in averting VM interruptions? (2) how accurate and timely is the failure prediction? (3) how does Bandit model compare with A/B testing?

8.1 VM Interruption Savings

The main metric we use to evaluate the effectiveness of Narya is the VM Annual Interruption Rate (AIR) (Section 3.2). We measure the delta between the AIR using the old static assignment and the AIR under new mitigation decisions from Narya. We specifically compute three metrics: the estimated daily AIR savings, the oracle daily AIR savings (savings if we already knew what was the best action), the regret (how much additional AIR we could have saved). The estimated daily AIR savings (\hat{S}) is obtained by comparing the impact of each tested action to the impact of the original action projected on the whole fleet. The oracle daily AIR savings (S^*) is estimated by mapping the best performing action to the whole population compared to the original action on the whole fleet. Our technical report [?] shows the formulas to calculate \hat{S} and S^* . The regret is the expected difference between the reward sum associated with an optimal strategy and the sum of the collected rewards. We consider $R = S^* - \hat{S}$ to be our AIR regret, meaning how much additional AIR we could have saved if we knew the best action all along.

Due to the confidentiality nature of AIR, we report \hat{S}, S^*, R as relative percentages compared to the overall AIR contributed by all of our target failure types (host failures caused by various hardware problems). For the month of March 2020, \hat{S} is a **26.2% improvement**, i.e., Narya successfully

Figure 10: Contrib. of different features.

Figure 11: ML prediction time to failure.

Figure 12: Prediction timeliness.

decreases AIR by about 26.2% compared to the static strategy. We also provide the per-experiment improvements in Figure 8. This shows, for each AB or bandit experiment what percentage of VM interruptions were prevented compared to using the original strategy. 63019E11 constitutes the largest savings since the AB testing experiment was already using the best action. For the same period, S^* is 35.4%, meaning the best AIR reduction percentage we could possibly achieve (if we use the optimal action); R is 9.2%.

Although a 26% might not seem big, given Azure’s scale, it represents a large number of VM reboots, each highly impacting to customers. The ad-hoc mitigation strategy has already been tuned for years, and the overall availability of Azure is already high. Therefore, the comparison baseline is not low. Also note that the oracle saving 35% is only with respect to the online experiments we have run. With new prediction rules for more failure types and new actions, Narya can potentially yield further improvement.

8.2 Savings Trend Over Time

Figure 9 shows the AIR improvements over time. Overall, the savings fluctuate between 20% to 40%. July saw a sudden jump. This is because one major firmware fix occurred in the June-July time period. One rule started marking much more nodes, including nodes considered false positives (not likely to fail soon). This largely increased \hat{S} as the old policy was very sensitive to false positives. However, our anomaly detection caught this issue. We probably would have fixed the policy if we were using it. We report in Figure 9 the corrected savings assuming that fix. In addition, this firmware deployment fixed a driver issue for which our mitigation was reducing much AIR by predicting failures in advance. As a result, our savings decreased in July and August.

8.3 Accuracy and Timeliness of Prediction

We first measure the precision and recall of the Narya failure predictor. There are multiple rules or models to predict different types of host failures. For a prediction rule/model r , we define the prediction precision as $\frac{F+D}{N}$, where N is the total number of hosts marked by r ; F is number of hosts that fail and are diagnosed to be indeed caused by the suspected fault; D is number of hosts that Narya successfully mitigate and the suspected fault is later confirmed. The recall is defined as $\frac{F+D}{M}$, where M denotes the number of host failures that are diagnosed to be caused by fault type that r represents.

The overall precision is 79.49%, while the overall recall is 50.7%. While the false positive rate (20.51%) is not small,

we note that failure prediction in a large-scale, complex, and frequently changing cloud like Azure is an extremely challenging problem. Narya is designed with the expectation that false prediction is unavoidable and employs several measures such as low impact actions, safety constraints, longer observation window to minimize the impact of false prediction.

We further evaluate the contribution of different signals (features) to the prediction accuracy. We calculate the feature importance using the SHAP method [28], sort features by their importance, and group them into 10 bins. We then evaluate the precision and recall (F1-score) using individual bins or aggregate bins (features from bin #1 to #N). Figure 10 shows the result. We can see that some features are more important than others. The first bin in particular contributes significantly. Examples of features in the first bin include read error rate, flush count, AvailableSpare, HostReadCommands, etc.

Besides precision and recall, for Narya, It is crucial to consider the prediction lead time (or time to failure) defined as the duration between the prediction time and the failure time. A larger lead time gives Narya more time to take preventive actions. Figure 11 shows the CDF of the ML prediction time to failure with a median lead time of 2.44 days. Figure 12 compares the timeliness between the ML-based prediction and rule-based prediction: ML-based prediction provides significant advantage in timeliness.

We measure the quantitative benefit of early prediction to live migration success. For nodes predicted to fail, the average successful live migration per node is 5.57. With a smaller lead time, the successful live migration per node gets down to 3.

8.4 Comparing AB Testing and Bandit

Next we compare Narya Bandit and A/B testing in finding the optimal mitigation action. To do so, we compare the used strategy to the other possibilities. For mitigation requests that go through A/B testing, we use off-policy learning of Bandit based on observed A/B data. Similarly we compare the Bandit output to a static A/B policy. We then use counterfactual estimation [32] with Inverse Propensity Score to estimate the cost of running Bandit in place of A/B testing. Over the 2 months period of February and March 2020, using Bandit instead of A/B testing for ongoing experiments could have helped decrease the number of VM interruptions by 14.4%. The breakdown per experiment can be found in Figure 13. Note that A/B testing compared to bandit is safer and allows for more than one cost metric.

Figure 13: Cost metric (VM interruptions, units anonymized) under Bandit vs. AB testing.

Figure 14: Median probability of choosing each action using Bandit and A/B testing over 1000 re-sampling simulations based on production data.

Figure 15: Distribution of reboots using Bandits or A/B testing in 1000 simulations based on production data.

Min	Median	Max	No Convergence	Ongoing
12 days	29.5 days	140 days	2 experiments	3 experiments

Table 3: AB testing experiments convergence time.

8.5 Convergence to Optimal Action

Table 3 shows the convergence time of A/B testing for different experiments. The variance of the convergence time is big, because we need to accumulate enough samples. For different rules, the time it takes to collect the samples differs a lot. Two experiments did not reach convergence at the end of experiments. No convergence usually indicates that there is no significant difference among the experimented actions. For Bandit, we compare its behavior with A/B testing through simulation with production data (details in report [?]). Bandit can achieve a much faster convergence to the best action. Figure 14 shows the result. Bandit converged in around 50 steps, while AB testing would converge in 125 steps. Faster convergence also yields more AIR savings. As Figure 15 shows, Bandits yields much fewer reboots than AB testing.

8.6 Case Studies

Blobcache error is a symptom that can be caused by hardware issues or some recoverable faults. The original mitigation policy was *UA-LM-HI*. We wanted to test if we could avoid the impact of service healing at the end of the unallocatable period and try to reset node health (unblock allocation) instead. We used an AB testing experiment to compare the VM reboots per node when using *UA-LM-HI* and *UA-LM-RH*. The experiment started on 03/10 and statistical significance was reached on 03/25 and observed on 04/02. We were able to save 25.2% AIR compared to the old policy during this period. Once, we adopted the new policy (config change to make it 100%) and deployed it to production, it saved 50.3% of AIR associated with this type of failure.

E11 is a Windows event indicating a disk controller error. When this event occurs, it generally means that the hard disk is experiencing some issues most likely indicating an imminent failure. Using offline correlation analysis on non-empty nodes with no prediction from other rules/models, we found that 85% failed in the following 7 days, with a majority in the first few hours. Although the lead time was small, it should have sufficed to migrate some VMs in each of these nodes.

We started our first AB testing experiment on 2019-07-25 to try our *UA-LM-HI* policy over *NoOp*. To our surprise,

Figure 16: Action probability change using Bandit decisions.

we did not see the significant impact we imagined. Upon analysis, it appeared that few of the VMs could live migrate, mostly because the node failed too quickly or the disk state was already too bad to succeed in live migrating the VMs. However, after a few months of AB testing, the difference in reboots revealed to be significant mostly through short lived VMs getting stopped and repeated failure being avoided by the unallocatable policy. The experiment was ended on 2019-12-12 with approximate daily AIR savings of 28% for such signature.

We started another AB testing experiment on 2020-01-11 to test the use of soft reboot to mitigate some of these issues, following a few positive offline test. Contrary to our belief, we observed no significant improvement, even a slightly larger VM reboot per node in the *UA-SR* action. In total, 51 nodes tried the *SR* primitive action, with none of them succeeding because some pre-checks were not met. This shows the importance of AB testing all potential new actions before using them on the whole fleet.

I/O Timeout We started an AB experiment between *UA-LM-RH* and *NoOp* actions on 2020-01-11 for an I/O timeout prediction rule. At first, *NoOp* seemed to be the better option, although not significantly. In late March, the *UA-LM-RH* action started being consistently better and led to us to switch to Bandit. As Figure 16 shows, we can see a clear switch from choosing *NoOp* to choosing *UA-LM-RH* for that time. Even though we are unsure as to what system changes trigger the probability change, our Bandit model picks up the changes and adapts. Using counterfactual estimation, the results show the Bandits adaptation yields savings of 3.7%–13.9% compared to both static policies.

8.7 Reward Collection Schemes

We compare three possible reward collection schemes: (a) delayed reward collection; (b) immediate reward collection; (c) incremental reward collection.

Delayed reward collection (§6.3) is our default scheme. In (b), we associate VM interruption costs with an action on the

Figure 17: Probabilities in taking two actions using delayed versus immediate reward collection. Action1 is optimal.

day where the action is completed, and we update the Bandit model. In (c), we update and associate the cost daily.

Across different A/B testing experiments we run, the three schemes have varied effectiveness. But overall delayed reward collection outperforms immediate scheme. In particular, (b) yields an average 7.12% AIR improvement, while (a) yields an average 8.50% AIR improvement. This is because immediate reward collection can be easily affected by noises and does not account for action impact that takes a while to manifest itself. Figure 17 illustrates the comparison in one experiment.

We expected that the incremental scheme (c) would perform slightly better than (a), since it could use more information and would not need to wait for the full observation. Contrary to our expectation, in our experiments, the incremental scheme performs slightly worse than the delayed scheme, with a 8.45% AIR improvement. One reason is that, if the environment is relatively steady, adding partial observation does not provide much new information. Additionally, the collected cost from the partial schema might not be distributed evenly across the observation window. In this case, the incremental scheme would be misled by partial observations. However, the incremental scheme does have the advantage of a faster response to system changes, since it can make decisions based on the latest cost data.

8.8 Safe Guards

The safe guards can influence the system in many ways. First, it allows a constant exploration of all action to enable timely adaptation to system changes. In the I/O time out case studies, the bandit could not have readjusted to use *UA-LM-RH*, hence losing 3.7% of cost. Second, it prevents early convergence to a wrong policy. In the E11 case study, when simulating the bandit without safe guards, we converged (probability > 0.95) to use a single action in 27% of cases, 19% of which was *UA-SR*, the worst action. Third, safe guards decrease the impact of unexpected spikes. In the IO timeout experiment, on 2020-04-25, cascading failures resulted in 106 VM interruptions on a single node for the *NoOp* group. Although this significantly impacted the probability to choose *NoOp*, we still keep exploring that option.

8.9 Scale and Performance

Narya runs in each data center region of Azure. The mitigation engine handles hundreds to thousands of requests daily. The failure predictor processes tens of TBs of health signals per day. Figure 18a shows the number of daily mitigation request

Figure 18: Mitigation request handling sessions

sessions (including all fault handling), and the number of requests that go through our A/B testing experiments and requests handled by our Bandit model. Figure 18b shows the CDF of the session duration of the mitigation actions.

9 Discussion and Limitations

Lessons. We share some operational issues and summarize the lessons we learned from running Narya in production.

First, given the sheer complexity of Azure cloud infrastructure, it is inevitable that some Narya decision could go wrong. We encountered two kinds of service misbehavior: (1) some prediction rules are outdated and incorrectly mark many nodes in a short period of time; (2) an increase of customer impact that is not incorporated within the cost model. For (1), the issue would impact AB testing and cause Bandit to take time to adjust. Our rate limit mechanism described in Section 7.2 would help. We also designed a separate anomaly detection algorithm to catch such misbehavior so we can pause and refine the offending prediction rules. To overcome (2), we added monitoring of the support tickets filed by customers.

Second, as Narya consumes telemetry signals from the whole stack, Narya may be broken if the updates of host OS, firmware, and hardware involve uncoordinated schema changes. We recently had an issue in which the schema change of a few critical OS signals was not captured by Narya. Our monitoring component caught the issue and we had to patch Narya. Besides schema changes, the data and label quality may also fluctuate due to improvements or regressions of tracing capability introduced by different component teams.

The aforementioned challenges can be addressed if the cross-team collaboration and communication are perfect, which unfortunately is not realistic in large organizations. Through continuous learning from failures, we build multiple channels based on social alignment principles to include relevant component teams, so that the right team can be involved in time to avoid broken contract, adjust prediction rules, etc.

While we try to ensure sufficient communication, we cannot just rely on it. We build a comprehensive monitoring pipeline that detects anomalies at all layers for Narya, from input data to prediction results, mitigation actions, etc. We proactively investigate alerts and follow up on issues caused by external dependencies or fix Narya's own defects. Moreover, we re-train our ML model on a regular basis to accommodate the evolution of telemetry data and label quality.

Third, Narya may output unexpected decisions, which require verifying its correctness and diagnosing the root cause.

In general, diagnosing issues in Narya's Bandit decisions is easy. The exploration model is explainable and solely depends on the total VM reboots observed and the total nodes observed. Any unexpected change in probability can be traced down to the observations that had large customer impact.

Limitations. We describe several limitations of Narya. While Narya can be fully automated, it currently still involves some human intervention to analyze the experiment results and update the system. This is because our cost model for customer impact is incomplete. We believe limited human intervention is key to catch any gaps in customer complaints and improve.

We currently focus on predicting and mitigating hardware or firmware-induced VM failures. We plan to extend Narya to software-induced VM failures. While generic software failure prediction is very challenging due to their frequent changes and complex dependencies, there are potentials for addressing issues like memory leak, repeated crashes, and timeout bugs.

The multi-armed Bandits model we use has the advantage of simplicity and easy explainability of the mitigation decision. However, this model can segment the data. In particular, Narya divides nodes into different experiments based on fault code and node metadata (e.g., h/w generation). But mitigation actions for nodes from different experiments may share the same characteristics, which may not be learned because each model is trained separately. We are exploring the contextual Bandit model [23] to leverage context information like node features to the model input.

10 Related Work

Our work is related to three subareas in system resilience: failure detection, prediction and mitigation. Failure detection has been extensively studied, while failure prediction and mitigation are not as well explored. Narya's major contribution is improving the latter two in the context of a large-scale, production cloud VM infrastructure, and designing an end-to-end preventive mitigation service to achieve failure *avoidance*.

Detecting crash failures reliably and quickly in asynchronous distributed systems is a classic topic [3, 5, 6, 9, 13, 22, 34]. Recent work has discussed the prevalence of gray failures [11, 17, 26] in cloud. Panorama [16] proposes to leverage observability to detect gray failures [17]. Narya focuses on predicting failures ahead of time. Many of the failures we target fall into gray failure category. But our aim is to identify risky hosts *before* they cause customer impact.

Several recent work proposes using machine learning to predict disk failures [14, 27, 38] and node faults [25]. Narya predictor aligns with these solutions' basic approach. But we focus on predicting failures in the complex VM host environment as a whole and only those with customer impact. Additionally, we design the prediction pipeline to closely integrate with the mitigation engine.

The Recovery-Oriented-Computing project [31] advocates the importance of failure mitigation, particularly reboot [4]. Piegon [21] proposes to expose uncertainty of failures to

allow better failure reactions for applications. But applications have to manually decide whether to wait or start recovery. IASO [30] is a framework for detecting fail-slow issues and supports mitigating slow issues with multiple options such as process restart or VM shutdown. But it relies on customers to manually configure the mitigation option.

NetPilot [37] aims to automate the failure mitigation in a data center network by determining the suspected network devices and mitigating failures based on estimated impact. Narya differs with NetPilot in several ways. First, Narya targets automating the failure mitigation of a system with heterogeneous components and complex stack. In our setting, estimating the impact of an action offline is challenging and often mismatches with production observations. Narya takes an online exploration and learning approach. Second, the mitigation actions available in NetPilot are few and simple like device restart. Narya needs to consider diverse and complex actions. Third, Narya aims to *avoid* failures whereas NetPilot focuses on mitigating failures that have occurred. Lastly, Narya is deployed in production at large scale.

A/B testing experimentation is a common practice to test the effects of UI features using production data (user requests). The idea is simple, but it often yields surprising power [19]. Thus, leading companies conduct thousands of A/B experiments annually. Narya mitigation engine adopts the A/B testing methodology in a novel way to the failure mitigation scenario with several changes. Narya also adopts multi-armed Bandits reinforcement learning [32]. Our contribution is addressing several unique challenges and the system support that make the approach work in a large-scale, production cloud infrastructure to avert real cloud VM interruptions.

11 Conclusion

We investigate an important topic in fault-tolerant system designs—failure avoidance—in the context of cloud infrastructure. Drawing from our experience in operating a large production cloud system, we propose a novel online experimentation and learning approach to tackle this problem. We present Narya, an end-to-end service consisting of failure prediction and smart mitigation. Narya continually evaluates the optimal action in production using A/B testing and Bandit models. Narya has been running in Azure compute infrastructure for 15 months and yields a 26% improvement in reducing VM interruptions compared to previous static strategy.

Acknowledgments

Abstract

Clock synchronization is critical for many datacenter applications such as distributed transactional databases, consistent snapshots, and network telemetry. As applications have increasing performance requirements and datacenter networks get into ultra-low latency, we need submicrosecond-level bound on time-uncertainty to reduce transaction delay and enable new network management applications (e.g., measuring one-way delay for congestion control). The state-of-the-art clock synchronization solutions focus on improving clock precision but may incur significant time-uncertainty bound due to the presence of failures. This significantly affects applications because in large-scale datacenters, temperature-related, link, device, and domain failures are common. We present Sundial, a fault-tolerant clock synchronization system for datacenters that achieves $\sim 100\text{ns}$ time-uncertainty bound under various types of failures. Sundial provides fast failure detection based on frequent synchronization messages in hardware. Sundial enables fast failure recovery using a novel graph-based algorithm to precompute a backup plan that is generic to failures. Through experiments in a >500 -machine testbed and large-scale simulations, we show that Sundial can achieve $\sim 100\text{ns}$ time-uncertainty bound under different types of failures, which is more than two orders of magnitude lower than the state-of-the-art solutions. We also demonstrate the benefit of Sundial on applications such as Spanner and Swift congestion control.

1 Introduction

Clock synchronization is increasingly important for datacenter applications such as distributed transactional databases [12, 32], consistent snapshots [11, 16], network telemetry, congestion control, and distributed logging.

One key metric for clock synchronization is the *time-uncertainty bound* for each node, denoted as ϵ in this paper, which bounds the difference between local clock and other clocks. This concept is used by TrueTime in Spanner [12]. Spanner leverages TrueTime to guarantee the correctness properties around concurrency control and provide consis-

tency in distributed databases. Another example is consistent snapshots, which are commonly used for debugging or handling failures in distributed systems. To ensure consistency among snapshots, each node needs to wait for its time-uncertainty bound (ϵ) before recording the states.

Traditional clock synchronization techniques provide ϵ at the millisecond level (e.g., $<10\text{ms}$ in TrueTime [12]), which is no longer effective for modern datacenter applications with increasing performance requirements and ultra low latency datacenter networks (e.g., with latency around $5\mu\text{s}$ [25]). Today's applications can benefit significantly from submicrosecond-level ϵ . For example, FaRMv2 [32], an RDMA-based transactional system, observes the median transaction delay can drop by 25% if we improve ϵ from $\sim 20\mu\text{s}$ to 100ns . CockroachDB [3] can significantly reduce the retry rate when ϵ drops from 1ms to 100ns based on an experiment in [13].

Providing submicrosecond-level ϵ can also enable new network management applications. For example, with submicrosecond-level clock differences across devices, we can measure one-way delay, locate packet losses, and identify per-hop latency bursts [23, 24]. It also enables synchronized network snapshots [37] which are useful for identifying RTT-scale network imbalance and collect global forwarding state. Accurate one-way delay provides a better congestion signal to delay-based congestion control [17, 29] to differentiate between forward and reverse path congestion.

There are several systems that achieve submicrosecond-level clock precision. The state-of-the-art commercial solution on precise clock synchronization is Precision Time Protocol (PTP) [4]. PTP is widely available in switches and NICs [6, 8, 9]. Each switch or NIC has a hardware clock driven by an oscillator, generates timestamped synchronization messages *in software*, and sends them over a spanning tree to synchronize with other nodes. Normally, oscillator drifts stay within $\pm 100\mu\text{s}$ per second and the devices synchronize every 15ms to 2seconds [4, 8]. A recent proposal DTP [21] sends messages in the physical layer every few microseconds and can also achieve $\sim 100\text{ns}$ precision. Huygens [13] is a clock-synchronization system built in software that achieves $<100\text{ns}$

precision by using Support Vector Machines to accurately estimate one-way propagation delays.

While these works provide high clock precision under normal cases, the time-uncertainty bound ϵ grows to 10-100s of μ s as datacenters are subject to a variety of failures. In large-scale datacenters, there are common temperature-related failures which affect oscillator drifts. There are also frequent link, device, and domain failures (i.e., a domain of links and devices that fail together) that affect the synchronization across nodes (see §3).

In this paper, we present Sundial, which provides ~ 100 ns time-uncertainty bound (ϵ) under failures including temperature-related, link, device and domain failures and reports ϵ to applications – two orders of magnitude better than current designs. Even in cases of simultaneous failures across domains, Sundial provides correct ϵ to applications. Sundial achieves this with a hardware-software codesign that enables fast failure detection and recovery:

Fast failure detection based on frequent synchronous messaging on commodity hardware: Sundial exchanges messages every $\sim 100\mu$ s in hardware without changing the physical layer. The frequent message exchange enables fast failure detection and recovery, and frequent reduction of ϵ . To ensure fast failure detection for remote nodes in the spanning tree, Sundial introduces *synchronous* messaging which ensures that each node sends a new message only when it receives a message from the upstream.

Fast failure recovery with precomputed backup plan that is generic to all types of failures: To enable fast failure recovery, Sundial controller precomputes a backup plan consisting of one backup parent for each node and a backup root, so that each device can recover locally. The backup plan is generic to different types of failures (i.e., link, device failures, root failures, and domain failures) and ensures that after failure recovery, the devices remain connected without loops. We introduce a new search algorithm for the backup plan that extends a variant of edge-disjoint spanning tree algorithm [35] but with additional constraints such as no-ancestor condition (the edge in the current tree cannot be a forward edge in the backup tree) and disjoint-failure-domain condition (no domain failure can take down both the parent and the backup parent for any device). Our algorithm only takes 148ms on average to run on an example Jupiter [33] topology with 88K nodes.

We evaluate Sundial with experiments in a >500 machine prototype implementation and via large-scale simulations. Sundial achieves ~ 100 ns time-uncertainty bound both under normal time and under different types of failures, which is more than two orders of magnitude lower than the state-of-the-art solutions such as PTP [4], Huygens [13], and DTP [21]. Sundial reduces the commit-wait latency of Spanner [12] running inside a datacenter by 3-4x, and improves the throughput of Swift congestion control [17] by 1.6x under reverse-path congestion.

2 Need for *Tight* Time-uncertainty Bound

A clock synchronization system for datacenters need not only a current value of time but also time-uncertainty bound that is used by applications for correctness as well as performance. We describe several datacenter applications and how tight time-uncertainty bound benefits them below.

Distributed Transactional Databases: Spanner [12], FaRMv2 [32] and CockroachDB [3] are some examples of distributed databases deployed at scale in production that directly use time-uncertainty bound to guarantee consistency – transactions wait out time-uncertainty bound before committing a transaction. Spanner is the first to use ϵ in production transactional systems. While it is globally distributed, its idea of using ϵ is adopted in many intra-datacenter systems such as FaRMv2 [32]. However, inside datacenters, with recent software and hardware improvements such as RDMA, NVMe, and in-memory storage, transaction latencies are going towards microsecond level. For example, FaRMv2 is built atop RDMA for datacenters and has ϵ of $\sim 20\mu$ s which already accounts for 25% of median transaction latency! Tight ϵ improves the performance of these systems both in terms of latency and throughput.

Consistent snapshots: Consistent snapshots [11, 16] is another important application for datacenters for debugging, failure handling, and recovery for cloud VMs. The consistency across servers can be guaranteed by waiting out ϵ to ensure the scheduled snapshot time is passed. With recent software and hardware improvements, ϵ becomes a performance bottleneck at a similar level as in distributed databases, limiting the frequency of taking snapshots.

Network telemetry: As network latency reduces to the order of a few microseconds, millisecond-level ϵ is too coarse-grained. Tight ϵ enables a wide range of fine-grained network telemetry. For example, per-link latency or packet losses can be measured by comparing the timestamps or counters at both ends of a link read at the same time [23, 24, 40]. Synchronized network snapshots at RTT scale can be enabled with tight time-uncertainty bound, and can be used for various telemetry needs such as measuring traffic imbalance across different links/paths in the datacenter [37]. To achieve these, switch clocks also need to be synchronized.

One-way delay (OWD): Synchronized clocks enable the measurement of one-way delays. Small ϵ provides a tighter bound on the error in the measurement especially under failures. Measurement of OWD is useful for many applications including telemetry and congestion control. For example, OWD differentiates between forward and reverse-path congestion improving performance of delay-based congestion control algorithms such as Swift [17] (§6.3).

Distributed logging: A key challenge for debugging large-scale distributed systems is to analyze logs collected from different devices with clock differences. Tighter ϵ enables more useful analysis and opens up more distributed debug-

Figure 1: Message exchanges to synchronize B to A.

ging opportunities. Our $\sim 100\text{ns}$ ϵ is about the same as L3 cache miss time, so it can help order all log messages in a datacenter. We note that this class of applications has an additional requirement in that the synchronized clocks follow a master clock that reflects the physical time of day (§4.5).

3 Failures in Clock Synchronization System

In this section, we discuss the different failure scenarios affecting a clock synchronization system and their respective impacts. We start with a brief background on clock synchronization to aid the discussion.

3.1 Background on Clock Synchronization

The clock is driven by a crystal oscillator. Every device has a clock, whose value is incremented on every tick of a hardware oscillator. Different oscillators, even of the same type, have slightly different frequencies. The frequency of an oscillator may change over time, due to factors such as temperature changes, voltage changes, or aging resulting in clocks to drift away over time. As an example, oscillators in production networks can have a frequency variation of ± 100 ppm (parts per million) [7], meaning that the oscillator can drift within the range of $\pm 100\mu\text{s}$ per second compared to running at the nominal frequency. More stable oscillators (e.g., atomic clocks based on Cesium, Hydrogen or Rubidium particles or oven-controlled oscillators) are too expensive to deploy on every device in production.

Clocks exchange messages with each other for synchronization. To ensure that clocks remain close to each other, we need to periodically adjust the clocks to account for potential drift. Figure 1 shows an example where clock B synchronizes to A. A sends a synchronization message (abbreviated as sync-message in this paper) with a timestamp T_1^A based on A’s clock, and B records the receiving time (timestamped by B) of the sync-message T_1^B . Now, if B knows the message delay d_{AB} from A to B, B can compute the *offset* between A and B as $T_1^A + d_{AB} - T_1^B$. To know d_{AB} , B sends another message to A to measure RTT, and use half of RTT to estimate: $d_{AB} = (T_2^A - T_1^A - (T_2^B - T_1^B))/2$. B uses *offset* to adjust its clock. A periodically sends out these sync-messages at an interval denoted by sync-interval. The accuracy of d_{AB} depends on multiple factors and we discuss them below.

A network of clocks synchronize using a synchronization structure. A common way to do this is to construct a spanning tree over which sync-messages are sent, e.g., PTP which is the most widely available system for datacenter clock synchronization uses a spanning tree with one device serving as the root (called master or grandmaster). The model for best case synchronization is that each device’s parent is one of its

Figure 2: Benefit of synchronization between neighbors: symmetric forward and backward paths, and no noises from queuing delay.

direct neighbors in the physical network and sync-messages flow periodically from the root across the spanning tree.¹ This has two advantages. First, it allows switch clocks to also be synchronized enabling additional telemetry applications (§2). Second, it significantly improves the measurement of d_{AB} as shown in Figure 2. Noises in estimation of d_{AB} by halving the RTT can arise due to (1) asymmetric propagation delays of the forward path and the reverse path, and (2) queuing delays. For direct neighbors in the physical network, propagation delay asymmetry is near zero, and there is no queuing delay². There are proposals that do not use a spanning tree as the synchronization structure but either they don’t reflect the physical time [21] (§4.5) or they cannot provide submicrosecond-level precision [12, 27, 28] (§7).

Time-uncertainty bound. As clocks can drift apart over time, time-uncertainty bound (ϵ) can be calculated as:

$$\epsilon = \epsilon_{base} + (now - T_{last_sync}) \times max_drift_rate \quad (1)$$

ϵ of a clock exhibits a sawtooth function. T_{last_sync} is the last time when the clock is synchronized to the *root* (not just its direct parent), $now - T_{last_sync}$ increases with time and goes back to zero after synchronization to the root, and max_drift_rate is a constant representing the maximum possible drift rate between the local clock and the root’s clock. The ϵ_{base} is a small constant (a few nanoseconds) that accounts for other noises (e.g., timestamping errors, bidirectional delay asymmetry of physical links, etc.).

We will show that in the face of failures in production environments, max_drift_rate should be conservatively derived (§3.2.1), and $now - T_{last_sync}$ can be large (§3.2.2).

3.2 Impact of Failures on ϵ

We classify failures affecting clock synchronization into three categories and study their impact on ϵ – failures that induce large frequency variations and need a conservative setting of max_drift_rate , connectivity failures that affect T_{last_sync} , and incorrect behaviors due to broken clocks and message corruption that need to be detected and addressed.

3.2.1 Failures that Induce Large Frequency Variations

An oscillator’s frequency can incur a large variation in the event of sudden temperature or voltage fluctuation. Cooling failures are common and can affect thousands of machines.

¹Note that PTP doesn’t require this to be the case.

²While the devices may have local queues, the timestamp is marked at dequeue/egress time and is not subject to local queuing delay.

In an cooling incident that occurred in production recently, it resulted in errors related to clock synchronization in a large fraction of machines (and not just the ones affected by the failure). The temperature variation resulted in oscillator frequency variation to exceed max_drift_rate and the operator had to shut down many machines.³ Thus, the max_drift_rate needs to be set very conservatively (e.g., 200ppm in True-Time [12]) to tolerate frequency variations under a wide range of temperature (e.g., up to 85 °C) even though in normal cases, temperature variations occur slowly [13]. This entails that in order to keep ϵ small, we need to reduce $now - T_{last_sync}$ through frequent messaging – ϵ of 100ns with max_drift_rate of 200ppm needs sync-interval to be $<500\mu s$. Software cost of reducing sync-interval to such low values is high – PTP takes one core to process thousands of sync-messages and associated computations per second [1], and Huygens consumes 0.44% CPU for a sync-interval of 2s (which grows proportionally as the interval is reduced). We need hardware support for efficiency (§4.1).

3.2.2 Connectivity Failures

Failures that break the connectivity of the spanning tree also affect ϵ . For example, if a device or a link in the spanning tree fails, the whole subtree under this device or link loses connectivity to the root⁴, until a new spanning tree is reconfigured by the SDN controller. ϵ grows proportionally to the time it takes for recovery – if it takes 100 ms, ϵ grows to more than $20\mu s$. Even a distributed spanning tree protocol supported by PTP (best master clock algorithm) is slow to converge.

What is worse, is that the inflation of ϵ is not only for a device affected by the failure at a given time; instead, **almost all devices have to report high ϵ , all the time** and not only during the failure duration. This is because a device cannot distinguish whether it is affected by a failure or not. Consider a 3-node setup as depicted in Figure 3 with A as the root of the spanning tree and B and C as A’s child and grandchild respectively. When A fails, B detects the failure but C continues synchronizing to B without noticing the failure. This means at any time, there is no way for C to tell if it is in-sync or not, no matter if there is an actual failure or not and thus, it has to **always** report large ϵ (i.e., $> 20\mu s$) even during normal periods.⁵ Another way to look at this is in the context of Equation 1, C cannot set T_{last_sync} to the time it receives the last sync-message from its parent T_{last_msg} ; instead, for correctness, C has to **always** set $T_{last_sync} = T_{last_msg} - T_{recovery}$, where $T_{recovery}$ is the maximum time to recover from any failure that may break its connectivity to the root. All non-direct descendants of the root are affected by this.

³Normally, after a cooling system failure, operators let machines continue running for 10s of minutes before the recovery of cooling system or a gradual shutdown of machines, because this is usually safe and a sudden total shutdown should be avoided as much as possible.

⁴PTP is configured on a per-port basis (not per-device), so sync-message cannot bypass the failed link or the link associated with the failed device.

⁵Without changing the PTP standard, B cannot explicitly communicate to C about the failure.

Figure 3: Challenge of determining T_{last_sync} . Node C cannot determine if it is synchronized to the root or not, so C has to always set T_{last_sync} conservatively early to account for possible down time.

Figure 4: Number of link down events per second in a 1000-machine cluster during a near two-minute window of a failure incident.

There are many possible causes of connectivity failures: besides the common link or switch down, there are incidents that can take down massive (10s to 100s) devices or links, such as failures related to patch panels, link bundles, power domains, or human operations [38, 39]. Figure 4 shows the time series of link down events in a 1000-machine cluster during a failure incident. The suspected cause was a software bug related to a patch panel but its impact on device/link failures lasted across nearly two minutes – a total of 133 links go down. Thus, in order to provide small ϵ , the system must recover from connectivity failures quickly.

3.2.3 Broken Clocks and Message Corruption

Clocks may break and stop functioning well resulting in actual drift rate to exceed max_drift_rate . While this is rare relative to more severe hardware problems – statistics from production show that broken CPUs are 6 times more likely than broken clocks [12] – they need to be taken care of to provide correct ϵ to applications. Similarly, sync-message corruption may garble the associated timestamp and affect correctness of reported ϵ . A fault-tolerant clock synchronization system must detect and address such anomalies.

4 Sundial Design and Implementation

Motivated by the discussion above, we identify two key requirements to build a fault-tolerant clock synchronization system for datacenters that achieves performant time-uncertainty bounds. First is a small sync-interval (§3.2.1) – this is well served with a hardware implementation to avoid high CPU overhead of receiving and transmitting synchronization messages in software. Second is fast failure recovery so that ϵ continues to be small even when failures happen (§3.2.2). The challenge here is that recovering solely via a centralized controller is slow for our target ϵ requirements. Instead, as we show later, we can recover from most failures locally by adding redundancy to the synchronization graph, where in

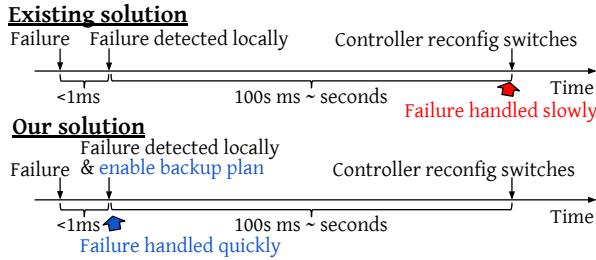

Figure 5: Fast failure recovery using precomputed backup plan.

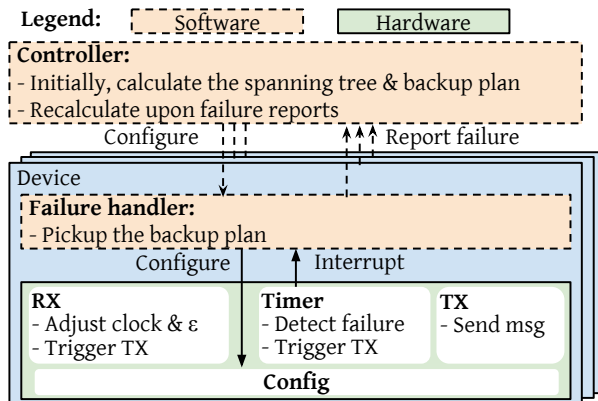

Figure 6: Sundial Framework. Solid arrows are the fast local recovery. Dashed arrows are slower but non-critical paths of recovery.

addition to the primary spanning tree, each device maintains a backup parent, such that it can transition to the backup parent locally upon detecting a failure. As shown in Figure 5, this takes the round trip time to the controller and the computation time out of the critical path of failure handling.

Thus, Sundial uses a hardware-software codesign. Figure 6 depicts Sundial’s framework, which has three main components. Sundial implement the most essential functions of exchanging synchronization messages and detecting failures in hardware such that it can synchronize frequently and quickly detect failures. Sundial relies on software components to take action once a failure is detected, by invoking a failure handler in software which reconfigures the hardware to transition to the backup parent pre-programmed by a centralized controller (also in software). We use the topology in Figure 7(a) as a toy example to aid with the discussion in this section with Figure 7(b) as an example spanning tree.

4.1 Sundial Hardware Design

Sundial’s hardware has three main components. It implements *frequent* transmission of sync-messages in a *synchronous* fashion, i.e., sync-messages are sent downstream only upon their receipt. The hardware is also responsible for detecting failures and triggering software handlers for quick recovery. Finally, the hardware maintains the current value of ϵ . We detail out these components below.

4.1.1 Frequent Synchronous Messaging

Sundial’s hardware supports frequent message sending to prevent clocks from drifting apart significantly. On the root, this is done via a hardware timer maintaining a counter that

Figure 7: Failure cases in a $k=4$ FatTree. (a) is the raw FatTree. To show the spanning tree clearer, we draw an equivalent topology in (b) and a spanning tree in it. An arrow is from a parent to its child, and a dashed line indicates an edge not used in the spanning tree. (c) shows one way of adjusting the spanning tree when the link between 4 and 8 fails; not only the directly impacted nodes (node 8), but also other nodes (node 5) have to change parent. (d) shows one way of adjustment when node 4 fails; the way node 5 changes its parent (to node 3) is different from the case in (c) (change to node 9).

increments on every oscillator cycle, and triggers message transmission when the time since last transmission exceeds the configured sync-interval. We configure sync-interval on the root device to be around $100\mu s$. The sync-messages are sent at the highest priority, but the network overhead remains extremely small – a 100-byte packet every $100\mu s$ only consumes less than 0.01% bandwidth and adds at most 10ns queuing delay for other traffic.

For non-root devices, a challenge is that an upstream failure can affect all devices in that subtree. Consider the case in Figure 7(c), if link 4-to-8 goes down, 8 needs to switch to 5 as its parent, which needs 5 to change its parent as well. A potential solution is explicit notification of failures to other devices, but this has two issues – not only can this be unreliable (since the notification messages may get dropped), it also adds complexity to the hardware. Instead, we solve this via *synchronous messaging* where message transmission is triggered only upon receipt of a message from upstream. In this way, an upstream failure implies that messages stop propagating downstream, and devices can take corrective actions.

4.1.2 Fast Failure Detection

Sundial’s hardware uses a timeout to detect if it stops receiving messages indicating an upstream failure. The timeout is set to span multiple sync-intervals, such that occasional message drop or corruption doesn’t trigger it. It’s implemented using a counter that is incremented on every oscillator cycle, and cleared on receiving a sync-message – once it’s exceeded, the hardware issues an interrupt to the software.

To detect broken clocks and message corruption, each de-

vice verifies the incoming timestamp (adjusted for link delay). If the adjusted value lies outside the local ϵ , the message is marked invalid and doesn't trigger an update and message transmissions. A broken clock can cause continuous invalid messages and thus, we don't reset the timeout counter on their receipt. Once a broken clock is detected, the failure handler in device software is triggered to handle it (§4.2.2).

4.1.3 Time-uncertainty Bound Calculation

The hardware maintains ϵ according to Equation 1. In our implementation, we configure $\text{max_drift_rate} = 200\text{ppm}$ and $\epsilon_{\text{base}} = 5\text{ns} \times \text{depth}$ where depth is the distance of the device from the root in the tree.

$T_{\text{last_sync}}$ is updated when receiving a sync-message. In PTP, $T_{\text{last_sync}}$ should be set to earlier than $T_{\text{last_msg}}$. Thanks to synchronous messaging, Sundial sets it to $T_{\text{last_msg}}$ since a device stops receiving messages on an upstream failure. This lowers $\text{now} - T_{\text{last_sync}}$ which in turn lowers ϵ .

4.2 Sundial Software Design

There are two main components to round out the fault-tolerant design of Sundial – a centralized SDN controller that pre-calculates backup plans and programs them on the devices and a failure handler in device software that quickly moves to the backup when a failure is detected by the hardware.

4.2.1 Centralized Controller

The centralized controller in Sundial is responsible for computing the primary spanning tree along with the backup plan based on the current topology and configures the devices accordingly. Comparing Figure 7(c) and 7(d), we see that not all neighbors of a node (e.g., node 5 in the figure) can be the backup parent under different failures. Sundial uses a search algorithm (detailed below) to compute a fault-tolerant backup plan that is *generic* to link, non-root node, root node, and domain failures (which can take down multiple links or devices). We break down this requirement into 5 properties.

Properties of a fault-tolerant backup plan. We briefly introduce the terminology used. The **primary spanning tree** is one that is currently being used to propagate sync-messages. The **backup plan** consists of a backup-parent for each node/device and a backup root. Terms like parent, edges, paths, and ancestors apply separately to the primary and the backup graph (graph formed by the edges in the backup plan).

(1) No-loop condition: *For any primary subtree, the backup edges of nodes in the subtree do not form a loop.* This is a necessary and sufficient condition to be generic to any single link failure. The necessity is obvious: if there is a loop, the nodes in the loop do not synchronize to the root after a failure. We prove the sufficiency by induction as follows. Suppose a k -node subtree is affected by a link failure, and the k backup edges do not form a loop (Figure 8); the nodes other than the k nodes are unaffected and still form a tree (called the *main tree*). At least one of the k nodes' (say, C) parent is in the main tree; otherwise, all k nodes' parents are in the k nodes, which must form a loop, contradicting the no-loop condition.

Figure 8: No-loop condition. It is sufficient to guarantee connectivity after any link failure.

We can now expand the main tree to include C since C is connected to the main tree via its backup edge. We can then iteratively add the remaining $k - 1$ nodes to the main tree.

(2) No-ancestor condition: *The backup parent of a node is not its ancestor.* This and property (1) together ensure that the backup plan is generic to any non-root node failure. Otherwise, if that ancestor fails, that node has no backup parent.

(3) Reachability condition: *The backup root must be able to reach all nodes through backup paths.* This is necessary and sufficient to be generic to the root failure. When the root fails, all nodes change to their backup parents, and the backup root will become the new root. To synchronize all nodes, they must be reachable from the backup root.

(4) Disjoint-failure-domain condition: Domain failures present a unique challenge, because they may take down multiple devices or links. If a domain failure breaks the connectivity of a device s to the root, s will turn to its backup parent; but if the domain failure also takes down its backup parent, then s cannot recover its connectivity.

The following property solves this problem: *for any node s , there shouldn't be a single domain failure that both breaks s 's connectivity to the root and takes down the backup parent or backup edge, unless that failure also takes down the node s .*

Formally, if the set of failure domains that can break s 's connectivity to the root⁶ is D_p , the set of failure domains that can take down s 's backup parent or backup edge is D_b , and the set of failure domains that s belongs to is D_s , we should have $D_p \cap D_b \subseteq D_s$.

The necessity is obvious. We present the intuition behind the proof of the sufficiency. If a domain failure happens, s has two possibilities: either s 's connectivity is unaffected, or s connects to its backup parent b . If it is the latter, then the question is whether b is connected to the root, which also has two possibilities. Doing this recursively, s keeps connecting to more nodes along a backup path. The backup path will not go indefinitely due to the no-loop condition, so it finally reaches either an unaffected node or the root.

(5) Root failure detection: Upon root failure, the backup root needs to collect sufficient information to elect itself. Figure 9 describes the approach – the backup root is chosen amongst root's children so it has one source of information by itself.

To get information from additional sources, we set up the backup graph to have a backup path from the subtree of another child of the primary root (i.e., the backup path from node

⁶Any device or link failure along the primary path from the root to s can break s 's connectivity.

Figure 9: Root failure detection. Under any non-root failure, the backup root continues receiving messages, which can be used to distinguish other failures.

2 to 1 in Figure 9). In this way, if the link between the primary root and the backup root fails (link from 0 to 1), the backup root knows the primary root is still alive because it continues receiving sync-messages that come through the backup path. We can continue this backup path to cross more subtrees of children of the primary root to get additional sources of information (e.g., crossing node 3 and 4 in Figure 9).

In this way, as long as the root is alive, the backup root continues receiving sync-messages. Only when the root fails, the backup root stops receiving messages. So the backup root can detect the primary root failure using a second timeout of not receiving messages after it first turns to its backup parent, and it elects itself as the new root after the second timeout.

Putting all 5 properties together. Only non-root nodes have backup parents, so there are $N-1$ nodes and $N-1$ edges in the backup graph (N is the total number of nodes), so there must be exactly one loop⁷ in the backup graph, and each node in the loop has a backup subtree (can be a single node) under it (Figure 10). With property (3), the backup root must be in the loop, so that the backup root can reach all nodes. The loop should cross multiple primary subtrees of root's children, so it meets both property (1) and property (5) (it delivers multiple sources of primary root's information to the backup root). Lastly, the backup graph should meet properties (2) and (4).

Figure 11(a) shows an example of primary tree and backup graph for the topology in Figure 7. Note that the computed primary tree is different to support a backup graph. The backup graph has a loop (between node 4 and 8) with the backup root 4 on it; the loop crosses the two primary subtrees of root's children (node 8 is under node 6's primary subtree). To show how property (4) handles domain failures, we add a failure domain that includes both node 11 and 3 (primary and backup parents of node 7 in Figure 11(a)). Now in the new backup graph (Figure 11(b)), to meet property (4), node 7's backup parent becomes node 2, so that even if both node 3 and 11 go down, node 7 (and other nodes) is still connected.

We want to highlight how the system recovers when the root fails. All backup edges get enabled forming a loop, but no sync-messages flow at this time. At the second timeout, the backup root elects itself and ignores incoming messages, effectively disabling the edge towards it (Figure 10). In this way, sync-messages do not loop.

⁷A graph with equal numbers of nodes and edges has at least one loop. In addition, if there is more than one loop, then the graph is not fully connected.

Figure 10: Backup Graph. There is exactly one loop with the backup root in it. Each node in the loop is the root of a subtree.

Figure 11: (a) A primary tree and a backup graph that meet all properties in Figure 7. But if node 3 and 11 are in the same domain, node 7 cannot have them as its primary and backup parents, so its backup parent becomes node 2 in (b).

Algorithm for computing backup plan. Sundial uses a search algorithm to calculate the backup plan which includes a primary tree and the backup graph. Note that not every primary tree has a valid backup graph. Thus, the goal is to search for a primary tree and its backup graph together. The search heuristic is based on the *score* of a primary tree – the maximum number of edges in the backup graphs it supports. The corresponding backup graphs are called the largest backup graphs (of the primary tree).

Algorithm 1 describes the algorithm. *pending* is the set of primary trees that are pending to be checked, initialized with a simple BFS (Line 1). After initialization (Line 2), we start the SEARCH function (Line 3) that will return a pair of primary tree and backup graph. In SEARCH, each time, we pick the primary tree p with the highest score (Line 6) – the most promising one – and find the largest backup graphs for it (Line 7). If some backup graph is complete, i.e., every device (including the backup root) has a backup parent, the search successfully returns (Line 8 - 9). Otherwise, we update the best score so far (Line 10), and mutate p (Line 11) to get a new set of primary trees in *pending* and iterate.

In MUTATE, for each backup graph b (Line 14), we try to expand b to include edge $\langle x, y \rangle$ (Line 15). Since $\langle x, y \rangle$ is not usable in backup graphs of p ⁸ (i.e., $\text{USABLEINBACKUP}(\langle x, y \rangle, p)$ is false), we IMPROVE p to make $\langle x, y \rangle$ usable (Line 16). We then add each improved version p' to *pending* if not already tested (Line 19). After all the mutations, p is removed from *pending* (Line 22). We will discuss the optimizations in Line 20 - 21 later.

FINDLARGESTBACKUP and IMPROVE are the key functions. FINDLARGESTBACKUP conforms to the 5 properties. Properties (2) and (4) decide what edges can be used in backup graphs given a primary tree p , as expressed in function

⁸ $\langle x, y \rangle$ is not usable for sure; otherwise b is not the largest because it can readily include $\langle x, y \rangle$.

Algorithm 1 Searching for a primary tree and a backup graph.

```
1:  $pending = \{BFS(prim\_root)\};$ 
2:  $tested = \emptyset; best\_score = 0;$ 
3: return SEARCH();
4: function SEARCH
5:   while  $pending$  is not empty do
6:      $p = pending.get\_best(); tested \cup = \{p\};$ 
7:      $backup\_set = FINDLARGESTBACKUP(p);$ 
8:     if  $\exists b \in backup\_set | b$  is complete then
9:       return  $p, b;$ 
10:     $best\_score = \max\{best\_score, calc\_score(p)\};$ 
11:     $MUTATE(p, backup\_set);$ 
12:  return NotFound;
13: procedure  $MUTATE(p, backup\_set)$ 
14:  for  $b$  in  $backup\_set$  do
15:    for each  $\langle x, y \rangle | x \in b, y \notin b$  do
16:       $new\_prim\_set = IMPROVE(p, \langle x, y \rangle, b);$ 
17:      for  $p'$  in  $new\_prim\_set$  do
18:        if  $p' \notin tested$  then
19:           $pending \cup = \{p'\};$ 
20:          if  $calc\_score(p') > best\_score$  then
21:            return ;
22:   $pending -= p;$ 
```

Algorithm 2 Check if $\langle x, y \rangle$ is usable in backup graphs of p .

```
1: function  $USABLEINBACKUP(\langle x, y \rangle, p)$ 
2:  return ( $x$  is not  $y$ 's ancestor in  $p$ ) && ( $y$ 's ancestor in  $p$  and
 $x$  meet disjoint-failure-domain condition);
```

USABLEINBACKUP (Algorithm 2). Properties (1), (3), and (5) decide how the backup graph should look like. We can simply use BFS starting from the backup root (property (3)) to find the tree (property (1)) that is largest, and then enumerate the backup parent for the backup root and see if it forms a loop that meets property (5). IMPROVE's goal is to change p to p' so that $\langle x, y \rangle$ becomes usable (i.e., USABLEINBACKUP($\langle x, y \rangle, p'$) is true). It finds the set of p' that meets this goal.

As long as FINDLARGESTBACKUP and IMPROVE are exhaustive, the search is exhaustive – it will find a solution if one exists. The search process is similar to an algorithm that finds two edge-disjoint spanning trees [35], because our backup graph is composed of a more restricted spanning tree that is edge-disjoint with the primary tree, and an extra edge towards the backup root. The problem seems to be NP-hard although we don't have a proof yet.

In practice, our implementation of SEARCH is extremely fast – it only takes 148ms on average in a simulated Jupiter topology with 88,064 nodes [33] leveraging the following three strategies. (i) In Line 20 - 21 of Algorithm 1, we prune enumerations as per Line 14 - 15 as long as we find a p' that is heuristically better than any primary trees so far (including p). This significantly speeds up the search, as we can immediately make progress – after return (Line 21), the search immediately starts a new iteration at Line 6 based on p' , which is heuristically better than continuing mutating p . Note this strategy does not miss any primary trees, as the

Algorithm 3 Finding the largest backup graph of p .

```
1: function  $FINDLARGESTBACKUP(p)$ 
2:   $b = BFS\_ForBackup(backup\_root, p);$   $\triangleright$  BFS uses
   $USABLEINBACKUP$  to avoid unusable edges.
3:  Find  $\langle y, backup\_root \rangle$  where  $y \in b$  &&  $USABLEIN-$ 
   $BACKUP(\langle y, backup\_root \rangle, p)$  && the loop crosses multiple
  subtrees of  $prim\_root$  in  $p$ ; Add  $\langle y, backup\_root \rangle$  to  $b$ ;
4:  return  $\{b\};$ 
```

Algorithm 4 Changing p to make $\langle x, y \rangle$ usable and keep as many b 's edges usable as possible.

```
1: function  $IMPROVE(p, \langle x, y \rangle, b)$ 
2:  if  $x$  is  $y$ 's ancestor in  $p$  then
3:    for each edge  $\langle u, v \rangle$  on the path  $x \rightsquigarrow y$  in  $p$  do
4:       $new\_prim\_set \cup = RECONNECT(v, x, p, b);$ 
5:  if  $\langle x, y \rangle$  fails disjoint-failure-domain condition then
6:     $new\_prim\_set \cup = RECONNECT(y, x, p, b);$ 
7:  return  $new\_prim\_set;$ 
8: function  $RECONNECT(v, x, p, b)$ 
9:  BFS from  $v$  along reverse edges, and stops at nodes outside
   $x$ -subtree in  $p$ , while keeping as many  $b$ 's edges usable as pos-
  sible. It gives a set of paths  $S = \{w \rightsquigarrow v | w \text{ is outside } x\text{-subtree in } p\}$ 
10: for  $path$  in  $S$  do
11:   For each  $\langle i, j \rangle \in path$  set  $j$ 's parent to  $i$  in  $p$  to get  $p'$ ;
12:    $new\_prim\_set \cup = \{p'\};$ 
13: return  $new\_prim\_set;$ 
```

original p remains in $pending$. (ii) FINDLARGESTBACKUP only returns one of the largest backup graphs, rather than all of them. This is sufficient as all largest backup graphs for a primary tree connect the same set of nodes and we use this strategy in Algorithm 3. (iii) IMPROVE just returns the set of p' that keeps the largest number of b 's edges usable. This tries to keep as many useful fruits of past iterations as possible, so it speeds up the search. Algorithm 4 is based on this strategy.

These three strategies significantly reduce the computation time per iteration (Line 6 - 11). While the latter two strategies make the search non-exhaustive, all practical datacenter topologies have high redundancy such that in our experiments, we quickly found a backup-plan even after injecting 50 successive failures. Also owing to the high redundancy in practical topologies, the number of iterations is small since the initial p already has a very high score, only a few hundreds below the total number of nodes. Finally, another consequence of high redundancy is that in practice, the search iterates with almost monotonically increasing scores⁹, sometimes with jumps of tens or hundreds, reaching the final backup plan in tens of iterations on average.

Mutation for meeting property (5) follows a similar process as MUTATE. We omit the details due to limited space.

Calculating $\epsilon_{base, backup}$. When a node turns to its backup parent, its *depth* may change, so we also precompute $\epsilon_{base, backup}$

⁹IMPROVE can easily find paths while keeping all b 's edges usable, because of the high redundancy.

Figure 12: Node A’s *depth* is dependent on the failure. If node 1 fails, A’s *depth* is 3 (A, B, 2, root). But if node 2 fails, A’s *depth* is 4 (A, B, 4, 3, root).

Figure 13: A has 6 possible paths to the root, of 3 types. (1) **Backup path:** if the root is down, the backup path (A, 1, 2, 3) is in effect. (2) **Primary path:** when A is unaffected by failures. (3) **Mixed path:** when failures affect A and some other nodes on the loop, A connects to the root first along the loop for one or more hops, and then along the primary path (e.g., A, 1, 2, ..., root). There are 4 possible mixed paths, starting the primary paths from respective node 1, 2, 3, and 4.

to which a device set ϵ_{base} upon timeout. The exact *depth* is failure-dependent as shown in Figure 12.

So we calculate the maximum possible *depth* for each node after *any* failures. A naive approach is to enumerate all possible combinations of failures, which can be slow. Instead, Sundial uses a simple dynamic-programming (DP) based scheme. If a node s turns to its backup parent b , we calculate s ’s maximum possible *depth* $s.depth_{backup}$:

$$s.depth_{backup} = 1 + \max(b.depth_{primary}, b.depth_{backup})$$

where the max function considers two possible cases: b is unaffected by failures ($b.depth_{primary}$ denotes b ’s depth in the primary tree, a deterministic value), or affected by failures. $depth_{backup}$ can be calculated top-down.

DP works for all nodes except the nodes on the loop in the backup graph, whose DP calculations inter-depend. But we can easily calculate their maximum possible depths. On an L -node loop, for each node we enumerate all $L + 1$ possible ways it connects to the root (Figure 13). So the overall time complexity is $O((N - L) + L(L + 1))$ for a total of N nodes.

4.2.2 Failure Handler in the Device Software

A daemon running in firmware serves as the failure handler and responds to interrupts generated by the hardware once it detects a failure – the hardware is reconfigured to move to the backup parent based on the backup plan and set ϵ_{base} to $\epsilon_{base, backup}$. For the backup root, if an interrupt is triggered, the failure handler also continues to monitor incoming sync-messages for the second timeout. At the second timeout, the device sets itself as the primary root.

Handling broken clocks. If a clock is broken [12], it can drift away faster than max_drift_rate . In Sundial, we detect such clocks in two steps: (1) detect the existence of a broken clock when receiving an invalid message, and (2) confirm which one is broken. Figure 14 illustrates the process. As such, a broken clock is isolated without affecting other clocks.

The failure handler is triggered by a hardware interrupt upon receiving an invalid message to handle broken clocks.

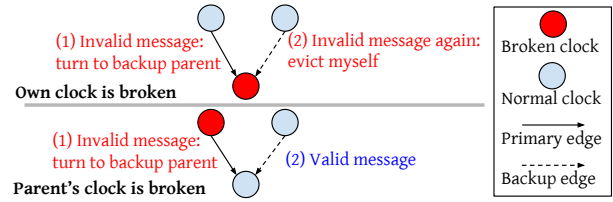

Figure 14: Handling a broken clock in two steps. If a node’s own clock is broken, the messages from both its primary and backup parents are marked invalid by itself (the timestamp is outside local ϵ), so it evicts itself. If a node’s parent’s clock is broken, after receiving an invalid message it turns to its backup parent, and continues synchronization thereafter.

For the node with a broken clock, it evicts itself (no longer participates in synchronization). For the node whose parent has a broken clock, it turns to its backup parent.

4.3 Implementation

Controller. We implement a module in the network controller. The module registers a function to be called by the controller framework for failure notifications. When notified, this module reads the current device/link/port states, and computes a new backup plan. For each device, it compares the existing configuration and the new configuration, and only re-configures the devices whose configuration changes, through RPC. It also configures the TX side of both primary and backup edges to send sync-messages.

RPC Interface between the Controller and Device Firmware. The controller and the device firmware communicates through RPCs. These RPCs have the following parameters: backup parent, first timeout, and second timeout which are used to configure the device hardware.

Firmware. The RPC handler configures the backup parent, the first timeout, and the second timeout accordingly. The backup parent and the second timeout are maintained in the firmware, and the first timeout is maintained in the hardware registers to enable failure detection in hardware. Only the backup-root has a non-zero value for the second timeout.

The firmware also registers a handler function for the interrupt triggered by the first-timeout. This function first reconfigures the hardware to accept sync-messages from the backup parent; then, if the second-timeout is non-zero, it waits for the timeout to see if it receives any new sync-messages; if not, it configures the hardware to become the root.

We cannot reveal hardware details due to confidentiality.

4.4 Practical Considerations

Concurrent connectivity failures may happen in practice, and may not be recovered by the backup plan, which needs to involve the controller. Sundial maintains the correctness of ϵ in this case. The only impact is that ϵ grows larger before being recovered by the controller: if it takes 100ms to recover, ϵ grows up to $20\mu s$ during this time (still $\sim 100ns$ during normal time). The impact is negligible, because compared to single failures, concurrent failures are already rare, and only a very small subset of them cannot be recovered by the backup

plan, as discussed below.

The most commonly seen concurrent failures are caused by a domain failure, which is not an issue because of the disjoint-failure-domain condition of the backup plan (§4.2.1).

If cross-domain failures happen, whether they impact Sundial depends on their locations and time proximity. For the nodes whose connectivity is affected, the backup plan is ineffective only if these failures also take down their backup parents/edges (special locations) within a short period of time before the controller recomputes a new backup plan (time proximity). The chance is very small, because cross-domain failures are random in locations and time proximity.

Small window of error before evicting a broken clock.

The broken clock detection only happens when messages arrive. There is a small time window between when the failure actually happens and when the next message arrives, during which errors could arise. This can be solved via hardware redundancy – each node physically keeps two clocks, and each clock query reads the two clocks and checks if they match (their time-uncertainty ranges overlap). Once a clock is broken, the next read immediately detects it. Additionally, Sundial prevents this failure to affect other clocks, because its children ignore the invalid messages.

False positives. If a device timeouts without a failure, it will turn to the backup parent. Such false positives are harmless, except extra controller processing. We do not observe false positives in our experiments.

4.5 Sundial’s Position in the Design Space

4.5.1 Design Space of Clock Synchronization

At the submicrosecond level, Sundial is the first to support time-uncertainty bound. We identify three key aspects of the design that a clock synchronization system must answer.

1. Type of message: There are multiple options, synchronization messages can either be sent directly with specialized physical layer (PHY) with zero-overhead messages, or at higher layers (L2, L3, L4) with increasing bandwidth overhead and increasing ease of deployment.

2. Noise due to message delay between a pair of clocks.

The message delay in the forward and reverse directions may be unequal due to queuing or asymmetric paths. There are three options to deal with such noise: (1) Only synchronize between neighboring devices, such that there is no noise (§3.1). (2) Use multiple messages to filter out noise; (3) Tolerate the noise. Option (1) is the best if all devices (switches and hosts) can participate. Otherwise, option (2) and (3) face a tradeoff between noise and overhead.

3. Network-wide synchronization structure: three options.

(1) *Master clock distributed through a tree.* A master clock distributes its time to other clocks through a tree. The master clock can synchronize to the physical time (e.g., via GPS), so that all clocks reflect the physical time.

(2) *Master clock distributed through a mesh.* Similar to (1), but instead of a tree, each clock receives sync-messages from

(a) Synchronous messaging: exponential inflation of sync-messages. (b) Asynchronous messaging has much smaller inflation of sync-messages. larger ϵ .

Figure 15: Mesh structure: higher ϵ due to asynchronous messaging.

multiple other clocks, forming a mesh.

(3) *No master clock (no physical time).* Clocks synchronize independently with each other without regards to a master clock. For example, in DTP [21] each clock follows the fastest of its neighbors. In this option, all clocks converge to a function (e.g., $\max()$ in DTP) of all clocks, which has nothing to do with the physical time. This option is worse than (1) and (2) because access to physical time is important for many datacenter applications.

Tradeoff between (1) and (2). While (2) is clearly more fault-tolerant, it cannot get ϵ as low as (1). The reason is that mesh-based solutions cannot use synchronous messaging. As shown in Figure 15a, if a clock receives sync-messages from k other clocks, synchronous messaging inflates the number of messages by k per hop, causing exponential inflation. So mesh-based solutions have to use asynchronous messaging, which has much larger ϵ – as shown in Figure 15b, ϵ increases per hop from the master to the participant clocks. On the other hand, tree-based solutions can use synchronous messaging, achieving much lower ϵ . §6.2 evaluates this effect.

4.5.2 Sundial’s Design Choices

Sundial’s key contribution is in the third design choice, which exhibits fundamental tradeoff between small ϵ and fault-tolerance. Sundial aims to achieve the best of both worlds, by combining tree and mesh topologies: Sundial sends messages through a mesh, such that it still has available edges upon failures; but the effective synchronization only happens over a primary tree, enabling it to use synchronous messaging.

The first two design choices have clear best options, and they are mainly determined by hardware availability. In our implementation, Sundial synchronizes neighboring devices at the L2 level as the specialized PHY layer is not available. That said, Sundial can benefit from such a layer if it’s available. Comparison with other schemes is in §7.

5 Application Access to Synchronized Clocks

In Sundial, the primary mechanism to access synchronized clocks is via hardware Rx/Tx timestamps. Additionally, for applications that want to access host clock directly, Sundial provides local host to NIC clock synchronization.

Access via hardware timestamps. NIC and switch hardware timestamps marked on the packets [29] are the primary access mechanism, for which it provides $\sim 100\text{ns}$ time-uncertainty bound. Applications such as distributed databases

Figure 16: PI controller based on clock-skew; offset and skew are measured periodically and an adjustment is computed using suitable P and I constants.

that have strict ϵ requirements rely directly on NIC-Rx-timestamps marked on the last packet in a message to order them to provide consistency properties. Networking stacks such as Snap [26] provide op-stream interface to applications (preventing out-of-order delivery) and export the NIC timestamps. Telemetry and congestion control applications also rely directly on NIC timestamps to measure one-way delays.

Host clock synchronization. We also synchronize the local host clock to the NIC clock for applications that want to directly read the host clock (and don't require strict guarantees on ϵ). We use a Proportional-Integral controller based on clock-skew between the host and NIC clocks as depicted in Figure 16. We measure the offset, $o(t)$ and skew, $s(t)$, every T time-units (we use $T=10\text{ms}$) and apply the rate adjustment to the host clock to tick faster or slower. The constants P and I need to be tuned in production. One challenge is that the two clock-measurements are subject to local delays such as PCIe jitter and we use linear regression to filter the noise out.

6 Evaluation

Through experiments in a >500-machine testbed-prototype (§6.1) and through large-scale simulations (§6.2), we show that Sundial's time-uncertainty bound is $\sim 100\text{ns}$ under different types of failures, and discuss application improvements enabled by Sundial in §6.3.

6.1 Time-uncertainty Bound (ϵ) in Testbed

6.1.1 Methodology

Testbed. The testbed consists of 23 pods, 276 switches and 552 servers. A pod including 12 switches and 24 servers acts as a failure domain. The oscillators used in the hardware have a frequency specification of $\pm 100\text{ppm}$. The depth of the base spanning tree in the topology is 5.

Schemes for comparison. We compare Sundial with recent submicrosecond-level clock synchronization schemes: PTP [4], Huygens [13], and DTP [21]. While they do not consider time-uncertainty bound (ϵ) and how it is reported to applications, we augment the designs to provide ϵ , according to Equation 1 in §3.1 and describe them below.

Sundial: We set the sync-interval to $90\mu\text{s}$.¹⁰ The timeout is $185\mu\text{s}$ ($>2 \times \text{sync-interval}$). The second timeout for the backup root to elect itself is set to $180\mu\text{s}$ ($185+180 > 4 \times \text{sync-interval}$). The backup plan has a maximum $\text{depth}_{\text{backup}}$ of 6.

PTP+ ϵ : PTP is the most common submicrosecond-level syn-

chronization protocol with a default sync-interval of two seconds. To add ϵ , we set ϵ_{base} to $5\text{ns} \times \text{depth}$, and max_drift_rate to 200ppm . $T_{\text{last_sync}}$ is updated as follows – for root's children, we set $T_{\text{last_sync}} = T_{\text{last_msg}}$; but for other descendants, we set $T_{\text{last_sync}} = T_{\text{last_msg}} - T_{\text{recovery}}$ to account for possible out-of-sync duration caused by remote connectivity failures that are oblivious to them (§3.2.2). We set T_{recovery} to 2s, since it takes 2s to recover from failure.¹¹

PTP+DTP+ ϵ : What if we could set lower sync-interval in PTP+ ϵ ? We evaluate another scheme that leverages DTP – DTP allows very small sync-interval (a few microseconds) with low bandwidth overhead by modifying the physical layer protocol. Since DTP requires hardware support, we emulate it in our testbed by setting $5\mu\text{s}$ sync-interval (much smaller than $90\mu\text{s}$).¹² All devices that are not direct children of the root set $T_{\text{recovery}}=100\text{ms}$, where 100ms is the typical connectivity failure recovery time measured from datacenters.¹³

Huygens+ ϵ : Huygens gathers network-wide sync-messages during each 2-second sync-interval, and uses machine learning to decide the best adjustment for each device at the beginning of the next sync-interval. While we do not have its implementation, we report the best possible ϵ it can achieve. Specifically, we assume it is not affected by connectivity failures because of its use of network-wide information, so $T_{\text{last_sync}}$ is set to the beginning time of each sync-interval (without minus T_{recovery}). We also assume it can filter out delay noises entirely and optimistically set ϵ_{base} to 0.

Failure injection. We evaluate the impact of failures on ϵ in Sundial and above schemes by injecting link failures, non-root device failures, root failures, and domain failures (where multiple devices can go down).

Metrics and measurement approach. We measure ϵ on every device by running a daemon in the firmware to read ϵ every $10\mu\text{s}$. After a failure, the controller sends an RPC to configure the devices for recovery. The frequent monitoring interferes with processing RPCs that are sent by the controller in the event of failures. As a workaround, we set a stop time which allows the controller RPC to execute after the monitoring stops. In this way, the monitoring tells us which devices are affected by failures and their ϵ . But it also inflates the controller delay, which is unfair to other schemes as they heavily rely on the controller for failure recovery. With knowledge of the expected controller delay, we can easily restore the expected ϵ based on the measured ϵ (Figure 17), because ϵ 's behavior is deterministic during failures recovery: ϵ keeps increasing, and goes back to normal when the failure is recovered.

¹¹In favor of low ϵ , $T_{\text{recovery}} = 2$ seconds is already a very optimistic setting for PTP+ ϵ , because recovery may take longer if the next sync-message is also dropped by another failure that just happens at that time. Setting T_{recovery} larger results in even higher ϵ . But we show that even with this optimistic setting, PTP+ ϵ still has much higher ϵ than Sundial.

¹²This is sufficient to show the improvement of ϵ , even though we don't have the physical layer protocol to keep the bandwidth overhead low.

¹³This is already friendly to PTP+DTP+ ϵ because to *guarantee* correct ϵ , T_{recovery} should be the maximum recovery time, which is several seconds.

¹⁰ $90\mu\text{s}$ is just enough for $\sim 100\text{ns}$ ϵ , although lower ϵ is achievable.

Figure 17: Restoration of ϵ under inflated controller delay.

Figure 18: CDF of ϵ measured across devices without failures.

ered. To get the expected controller delay, we use its lower bound, the delay on the controller (without network delay), which is more friendly to schemes other than Sundial.

6.1.2 ϵ Distribution without Failures

Figure 18 shows the distribution of ϵ over all devices under different schemes. In Sundial, $\epsilon \leq 43\text{ns}$, which matches the calculated value – the deepest device in the tree has ϵ_{base} of 25ns , and $90\mu\text{s}$ sync-interval leads to an additional 18ns .

In contrast, all other schemes have a much higher ϵ . In PTP+ ϵ and PTP+DTP+ ϵ , devices that do not directly synchronize to the root have to set $T_{\text{last_sync}}$ earlier than $T_{\text{last_msg}}$ by 2s and 100ms respectively, to account for possible failure-induced out-of-sync periods, so their ϵ can go up to $800\mu\text{s}$ and $20\mu\text{s}$ respectively during a sync-interval. Devices directly synchronizing to the root can set $T_{\text{last_sync}}$ to $T_{\text{last_msg}}$ and achieve lower ϵ . So their ϵ increases from 5ns (1-hop ϵ_{base}) to $\sim 400\mu\text{s}$ and 6ns respectively (2s and $5\mu\text{s}$ sync-intervals lead to $400\mu\text{s}$ and 1ns additional ϵ respectively at the end of each sync-interval). For these devices ($\sim 6.3\%$ of all), PTP+DTP+ ϵ 's low ϵ shows the benefit of extremely small sync-interval when failure is not a concern. Note that if available, Sundial can also benefit from DTP's physical layer design to further reduce sync-interval. In Huygens+ ϵ , during each 2s interval, ϵ increases from 0 to $400\mu\text{s}$. Reducing sync-interval comes with CPU cost (Huygens already consumes 0.44% CPU of the whole cluster). However, even if the sync-interval was halved, ϵ is still 3 orders of magnitude higher than Sundial's.

6.1.3 ϵ Distribution during Failures

To understand the behavior under failures, we inject 50 random failures over a course of 6 minutes including 24 single link failures, 23 non-root single device failures, 2 domain failures and 1 root failure.

Figure 19 shows the time series of ϵ of a device affected by a link failure. In Sundial, ϵ is sawtooth between 15ns and 33ns during normal time, because this device has a depth of 3 in the tree.¹⁴ When the link failure happens, ϵ increases

¹⁴Figure 21 shows the behavior at smaller timescales.

Figure 19: Time series of ϵ of a device affected by a link failure. The failure happens at 1s and the controller reacts to it near 1.1s .

Figure 20: Blast radius of failures under different schemes. Impacted device time is the summation of per-device impacted time – duration when a device stops receiving sync-messages – over all devices.

to a maximum of 84ns and goes down in just $270\mu\text{s}$ (after the $185\mu\text{s}$ timeout, the next message is at $270\mu\text{s}$). After that, ϵ is sawtooth between 30ns and 48ns , because its ϵ_{base} is set to $\epsilon_{\text{base,backup}}$ by the local recovery, which is 30ns ($\text{depth}_{\text{backup}}=6$). Once the controller reconfigures the spanning tree, ϵ goes back to between 15ns and 33ns because its depth is 3. In PTP+ ϵ , since the sync-message is dropped due to this failure, ϵ continues to increase for the next 2 seconds. Even if the sync-message was not dropped, ϵ for PTP+ ϵ (w/o failure) remains high. PTP+DTP+ ϵ 's ϵ increases to $40\mu\text{s}$ and recovers to $20\mu\text{s}$ when the controller recovers the connectivity. However, even if the controller delay was lower (50ms), it only reduces the peak ϵ to $30\mu\text{s}$, but the normal ϵ is still around $20\mu\text{s}$. Huygens+ ϵ is not affected by failures, but its ϵ is normally very large ($200\mu\text{s}$ at median and up to $400\mu\text{s}$).

The behavior is similar under other failures – ϵ depends on the recovery time. For PTP+ ϵ and PTP+DTP+ ϵ , the recovery time depends on how long it takes for the controller to recover from it. For Sundial, the recovery time is much smaller as it's local. Any non-root failure recovery time is around $270\mu\text{s}$, as is the case in Figure 19. The root failure takes slightly longer to recover from ($365\mu\text{s}$ after the two timeouts) and ϵ increases to up to 103ns . The devices at different levels in the tree have slightly different ϵ (discussed in §6.1.4).

We now study the spatial and temporal impact range (blast radius) of failures. Figure 20 shows that Sundial's blast radius is very small. Even after 50 failures, the total impacted time summarized over all devices is only 131ms . The most significant jump happens when the root fails (40-th failure). PTP+ ϵ and PTP+DTP+ ϵ 's blast radius is much higher owing to their longer recovery time. Note that more devices are affected by

failures under Sundial (401 in total) than under PTP+ ϵ (3 in total) and PTP+DTP+ ϵ (55 in total) as Sundial’s backup-plan-based recovery can affect remote devices as well (those under the subtree of the failure). Even then the total impacted time for Sundial remains significantly smaller.

PTP+ ϵ exhibits a step function because only failures occurring close to sync-interval boundaries affect it as the sync-interval of 2s is longer than the time to recover in most cases. The impact, however, is larger than in other schemes because it takes 2s for the next sync-message. PTP+DTP+ ϵ ’s sync-interval is only 5 μ s and thus, every failure affects it. While Huygens+ ϵ is not affected by connectivity failures, its ϵ remains high as shown before.

6.1.4 Microbenchmarks

How Sundial’s different techniques improve ϵ . We zoom into details of how each technique improves ϵ . Specifically, starting with PTP+ ϵ , we add (1) frequent sync-messages, (2) synchronous messaging, and (3) backup plan to it one by one, resulting in four schemes: PTP+ ϵ , PTP+ ϵ +freq_msg, PTP+ ϵ +freq_msg+sync_msging, and Sundial itself.

Figure 21 shows the time series of ϵ during a link failure. Frequent sync-messages improve ϵ by an order of magnitude. Synchronous messaging further reduces ϵ during normal time as it helps each device detect connectivity failures: as long as a device receives a sync-message, it is connected to the root, so T_{last_sync} can be safely set to T_{last_msg} . Finally, adding the backup plan significantly speeds up the failure recovery – ϵ only increases for 270 μ s to a maximum of 84ns before the backup plan is activated, two orders of magnitude lower.

To show how Sundial’s backup plan handles domain failures, we also run Sundial without considering domain failures (called Sundial w/o domain). We find that if a domain failure simultaneously takes down both the primary and backup parents of a device, the device’s ϵ is like PTP+ ϵ +freq_msg+sync_msging in Figure 21. This is expected because a down backup parent is equivalent to no backup parent. But if the failure domain is considered in the backup plan, ϵ is similar to Sundial in Figure 21, because the backup plan guarantees that no device loses both its primary and backup parents due to this domain failure. We also try another domain failure, which gradually takes down the primary and backup parents of a device, mimicking the domain failure that gradually takes down multiple devices or links (e.g., Figure 4). The result is similar.

Distribution of ϵ at different levels of the tree. We plot the maximum ϵ across devices at different depths, under different scenarios, shown in Figure 22. Root’s ϵ is always 0. ϵ increases linearly with depth, which is expected as each level increments ϵ_{base} by 5ns.

6.2 Large-scale Simulations

We compare Sundial vs Marzullo’s algorithm [27], an agreement algorithm for fault-tolerant clock-synchronization which is used by NTP [28] and TrueTime [12]. Marzullo’s algorithm

Figure 21: A link failure happens at 50 ms. The controller reacts to the failure at around 150 ms.

Figure 22: Distribution of ϵ at different levels in the tree.

also introduces time-uncertainty bound (ϵ) (called as error-bound in the original version). Since it is not supported in hardware due to its complexity, we use large scale simulations to demonstrate the performance characteristics.

Marzullo’s algorithm synchronizes clocks through a mesh, so it can tolerate connectivity failures but has higher ϵ (§4.5). To reconcile the different time values and ϵ from multiple clocks, each node does intersection of time-uncertainty ranges of different clocks as the correct time should be within all ranges. A set of master clocks (1 or more clocks synchronized via GPS) serve as the source of synchronization, whose ϵ is always close to zero. Broken clocks can also be detected when the intersection result is empty. We simulate in a Jupiter topology [33] with 88,064 devices, where each node sends sync-messages to all its neighbors to maximize the tolerance to failures. We set 2 masters to tolerate master failures. The sync-interval is 90 μ s, same as Sundial. Figure 23 shows that during the normal time, Sundial has smaller ϵ than Marzullo’s algorithm. Under failures, Marzullo’s algorithm’s ϵ is affected insignificantly. For Sundial, ϵ increases during failure recovery; the largest ϵ is 178ns, which is under the root failure.

Figure 23: CDF of ϵ during normal time in Jupiter in simulation.

Message type	DTP [21]	Huygens [13]	Marzullo [27]	PTP boundary clock [4]	Sundial
Dealing with delay noises	<i>Special PHY</i>	L3	Unspecified	L2	L2
Synchronization structure	<i>Neighbor</i>	Multi. msg	Unspecified	<i>Neighbor</i>	<i>Neighbor</i>
Support time-uncertainty bound	No master	Master, mesh	Master, mesh	Master, tree	<i>Master, mesh+tree</i>
	No	No	<i>Yes</i>	No	<i>Yes</i>

Table 1: Design choices of state-of-the-art clock synchronization schemes. Italic options are the best.

6.3 Application Performance Improvement

Distributed transactional system. We evaluate the impact of smaller time-uncertainty bound using a load-test provided to us by Spanner team [12]. We run the load-test inside a datacenter. The load-test does 4KB transactions and we measure commit-wait gap – time to wait out time-uncertainty before committing the transaction. Results are in Table 2 where we show that our system improves performance by $3\text{--}4\times$ not only in the median but also at the 99-th percentile.

	Baseline	With Sundial
Median	211 μ s	49 μ s
99-%ile	784 μ s	238 μ s

Table 2: Sundial improves commit-wait latency by $3\text{--}4\times$ for Spanner running inside a datacenter.

Congestion Control. Delay-based congestion control such as Swift [17] is widely used in datacenters relying on end-to-end RTT measurements to control sending rate. A key challenge with such schemes is how to differentiate between forward and reverse-path congestion. As an example, congestion in the reverse path can also inflate RTT causing a sender to slow down even though there is no congestion in the forward path.¹⁵ Synchronized clocks solve this problem as they enable the measurement of one-way delay (OWD) which can pinpoint the direction in which congestion is occurring.

We perform a microbenchmark with 3 servers – A, B and C with Swift congestion control. First, we only send traffic from A to B which achieves line-rate throughput. Next, we introduce reverse-path congestion by adding traffic from B and C to A. In Table 3, we observe A’s throughput goes down to 50Gbps even though there was no congestion in the forward path. Replacing RTT with OWD as measured using Sundial resolves this completely and A continues to send at line rate.

	RTT	OWD
No reverse congestion	80.1 Gbps	80.5 Gbps
Reverse congestion	50.5 Gbps	80.9 Gbps

Table 3: Using one-way delay (OWD) improves throughput in the presence of reverse-path congestion.

7 Related Work

Other clock synchronization systems. Table 1 compares state-of-the-art solutions, in the design space outlined in §4.5.

¹⁵While prioritizing the ACK may solve the problem, it is impractical in production because of two reasons. (1) Network priorities are typically tied to business priorities; and we simply cannot send ACKs for lower business priority traffic on a higher network priority. (2) Sending ACKs on a higher network priority precludes ACK piggybacking on data packets, thereby increasing the packets-per-second to process. This is especially detrimental for CPU-efficient networking stacks such as PonyExpress in Snap [26].

DTP [21] introduces a specialized PHY layer to achieve zero bandwidth overhead of sync-messages. If this modified PHY can be standardized and productionized in the future, Sundial can readily benefit from it to have even lower sync-interval and ϵ . However, DTP does not reflect physical time since it doesn’t have a master clock.

Huygens [13] does not synchronize switches, so it uses multiple messages between each pair to filter out noises. As a result, Huygens’ sync-interval is limited, so it cannot achieve tight ϵ . Huygens’ main advantage is that it is implemented completely in software and doesn’t require hardware support (other than hardware timestamps) but it does not consider ϵ ; and if incorporated, Huygens’ ϵ is large primarily due to the large sync-interval. While it assumes clocks drift slowly during normal time, it cannot set a small *max_drift_rate* as the maximum drift is subject to failures (§3.2.1); otherwise it risks datacenter-wide application-level errors (e.g., inconsistent transactions), which is unacceptable.

Marzullo’s algorithm [27] is the first to introduce ϵ but its ϵ is high because it sends messages through a mesh. PTP boundary clock [4] is based on a tree, and is not fault-tolerant.

Other solutions are too expensive (e.g., GPS [22]), too complex [18, 20, 31] or do not provide physical time [30, 34, 36].

Fault tolerance in other systems. In distributed systems and networking, fault tolerance is provided through redundancy [5, 10, 14, 19, 33, 38]. However, Sundial’s backup plan cannot be chosen arbitrarily and needs to satisfy a set of properties (§4.2.1) to be generic to different types of failures.

Ethernet uses spanning tree protocols [2, 15] that can recompute a spanning tree in a distributed fashion after a failure, but they usually take up to a few seconds to converge [15].

8 Conclusion

Sundial is the first submicrosecond-level clock synchronization system that is resilient to failures. It uses hardware-software codesign to quickly detect failures and recover from them. Our evaluation shows that Sundial provides ~ 100 ns time-uncertainty bound under different types of failures, and improves performance in Spanner and in Swift.

Abstract

This paper introduces Beldi, a library and runtime system for writing and composing fault-tolerant and transactional stateful serverless functions. Beldi runs on existing providers and lets developers write complex stateful applications that require fault tolerance and transactional semantics without the need to deal with tasks such as load balancing or maintaining virtual machines. Beldi's contributions include extending the log-based fault-tolerant approach in Olive (OSDI 2016) with new data structures, transaction protocols, function invocations, and garbage collection. They also include adapting the resulting framework to work over a federated environment where each serverless function has sovereignty over its own data. We implement three applications on Beldi, including a movie review service, a travel reservation system, and a social media site. Our evaluation on 1,000 AWS Lambdas shows that Beldi's approach is effective and affordable.

1 Introduction

Serverless computing is changing the way in which we structure and deploy computations in Internet-scale systems. Enabled by platforms like AWS Lambda [2], Azure Functions [3], and Google Cloud Functions [18], programmers can break their application into small functions that providers then automatically distribute over their data centers. When a user issues a request to a serverless-based system, this request flows through the corresponding functions to achieve the desired end-to-end semantics. For example, in an e-commerce site, a user's purchase might trigger a product order, a shipping event, a credit card charge, and an inventory update, all of which could be handled by separate serverless functions.

During development, structuring an application as a set of serverless functions brings forth the benefits of microservice architectures: it promotes modular design, quick iteration, and code reuse. During deployment, it frees programmers from the prosaic but difficult tasks associated with provisioning, scaling, and maintaining the underlying computational, storage, and network resources of the system. In particular, app developers need not worry about setting up virtual machines or containers, starting or winding down instances to accommodate demand, or routing user requests to the right set of functional units—all of this is automated once an app developer describes the connectivity of the units.

A key challenge in increasing the general applicability of serverless computing lies in correctly and efficiently composing different functions to obtain nontrivial end-to-end applications. This is fairly straightforward when functions are state-

less, but becomes involved when the functions maintain their own state (e.g., modify a data structure that persists across invocations). Composing such *stateful serverless functions* (SSFs) requires reasoning about consistency and isolation semantics in the presence of concurrent requests and dealing with component failures. While these requirements are common in distributed systems and are addressed by existing proposals [8, 28, 33, 35, 46], SSFs have unique idiosyncrasies that make existing approaches a poor fit.

The first peculiarity is that request routing is stateless. Approaches based on state machine replication are hard to implement because a follow-up message might be routed by the infrastructure to a different SSF instance from the one that processed a prior message (e.g., an “accept” routed differently than its “prepare”). A second characteristic is that SSFs can be independent and have sovereignty over their own data. For example, different organizations may develop and deploy SSFs, and an application may stitch them together to achieve some end-to-end functionality. As a result, there is no component in the system that has full visibility (or access) to all the state. Lastly, SSF workflows (directed graphs of SSFs) can be complex and include cycles to express recursion and loops over SSFs. If a developer wishes to define transactions over such workflows (or its subgraphs), *all* transactions (including those that will abort) must observe consistent state to avoid infinite loops and undefined behavior. This is a common requirement in transactional memory systems [20, 23, 32, 37, 38], but is seldom needed in distributed transaction protocols.

To bring fault-tolerance and transactions to this challenging environment, this paper introduces *Beldi*, a library and runtime system for building workflows of SSFs. Beldi runs on existing cloud providers without any modification to their infrastructure and without the need for servers. The SSFs used in Beldi can come from either the app developer, other developers in the same organization, third-party open-source developers, or the cloud providers. Regardless, Beldi helps to stitch together these components in a way that insulates the developer from the details of concurrency control, fault tolerance, and SSF composition.

A well-known aspect of SSFs is that even though they can persist state, this state is usually kept in low-latency NoSQL databases (possibly different for each SSF) such as DynamoDB, Bigtable, and Cosmos DB that are already fault tolerant. Viewed in this light, SSFs are clients of scalable fault-tolerant storage services rather than stateful services themselves. Beldi's goal is therefore to guarantee *exactly-once* semantics to workflows in the presence of clients (SSFs) that fail at any point in their execution and to offer *synchro-*

nization primitives (in the form of locks and transactions) to prevent concurrent clients from unsafely handling state.

To realize this vision, Beldi extends Olive [36] and adapts its mechanisms to the SSF setting. Olive is a recent framework that exposes an elegant abstraction based on logging and request re-execution to clients of cloud storage systems; operations that use Olive’s abstraction enjoy exactly-once semantics. Beldi’s extensions include support for operations beyond storage accesses such as synchronous and asynchronous invocations (so that SSFs can invoke each other), a new data structure for unifying storage of application state and logs, and protocols that operate efficiently on this data structure (§4). The purpose of Beldi’s extensions is to smooth out the differences between Olive’s original use case and ours. As one example, Olive’s most critical optimization assumes that clients can store a large number of log entries in a database’s *atomicity scope* (the scope at which the database can atomically update objects). However, this assumption does not hold for many databases commonly used by SSFs. In DynamoDB, for example, the atomicity scope is a single row that can store at most 400 KB of data [14]—the row would be full in less than a minute in our applications.

Beldi also adapts existing concurrency control and distributed commit protocols to support transactions over SSF workflows. A salient aspect of our setting is that there is no entity that can serve as a coordinator: a user issues its request to the first SSF in the workflow, and SSFs interact only with the SSFs in their outgoing edges in the workflow. Consequently, we design a protocol where SSFs work together (while respecting the workflow’s underlying communication pattern) to fulfill the duties of the coordinator and collectively decide whether to commit or abort a transaction (§6).

To showcase the costs and the benefits of Beldi, we implement three applications as representative case studies: (1) a travel reservation system, (2) a social media site, and (3) a movie review service. These applications are based on Death-StarBench [12, 16], which is an open-source benchmark for microservices; we have ported and extended these applications to work without servers using SSFs. Our evaluation on AWS reveals that, at saturation, Beldi’s guarantees come at an increase in the median request completion time of $2.4\text{--}3.3\times$, and 99th percentile completion time of $1.2\text{--}1.8\times$ (§7.4). At low load, the median completion time increase is under $2\times$.

In summary, Beldi helps developers build fault-tolerant and transactional applications on top of SSFs at a modest cost. In doing so, Beldi simplifies reasoning about compositions of SSFs, runs on existing serverless platforms without modifications, and extends an elegant fault-tolerant abstraction.

2 Background and Goals

In this section, we describe the basics of serverless computing (sometimes known as Function-as-a-Service), the challenge of deploying complex serverless applications that incorporate state, and a list of requirements that Beldi aims to satisfy.

2.1 Serverless functions

Serverless computing aims to eliminate the need to manage machines, runtimes, and resources (i.e., everything except the app logic). It provides an abstraction where developers upload a simple function (or ‘lambda’) to the cloud provider that is invoked on demand; an identifier is provided with which clients and other services can invoke the function.

The cloud provider is then responsible for provisioning the VMs or containers, deploying the user code, and scaling the allocated resources up and down based on current demand—all of this is transparent to users. In practice, this means that on every function invocation the provider will spawn a new *worker* (VM or container) with the necessary runtime and dispatch the request to this worker (‘cold start’). The provider may also use an existing worker, if one is free (‘warm start’). Note that while workers can stay warm for a while, running functions are limited by a timeout, after which they are killed. This time limit is configurable (up to 15 min in 1 s increments on AWS, up to 9 min in 1 ms increments on Google Cloud, and unbounded time in 1 s increments on Azure) and helps in budgeting and limiting the effect of bugs.

Serverless functions are often used individually, but they can also be composed into *workflows*: directed graphs of functions that may contain cycles to express recursion or loops over one or more functions. Some ways to create workflows include AWS’s *step functions* [41] and *driver functions*. A step function specifies how to stitch together different functions (represented by their identifiers) and their inputs and outputs; the step function takes care of all scheduling and data movement, and users get an identifier to invoke it. In contrast, a driver function is a single function specified by the developer that invokes other functions (similar to the main function of a traditional program). Control flow can form a graph because functions (including the driver function) can be multi-threaded or perform asynchronous invocations.

Stateful serverless functions (SSFs). Serverless functions were originally designed to be stateless. As such, state is not guaranteed to persist between function invocations—even when writing to a worker’s local disk, the function’s context can be terminated as part of dynamic resource management, or load balancing might direct follow-up requests to different or new instances. Accordingly, a common workaround to persist data is to store it in fault-tolerant low-latency NoSQL databases. For example, AWS Lambdas can persist their state in DynamoDB, Google cloud functions can use Cloud Bigtable, and Azure functions can use Cosmos DB. Through these intermediaries, *stateful serverless functions* (SSFs) can save state and expose it to other instances.

Unfortunately, the above approach to state interacts poorly with the way that serverless platforms handle failures. If a function in a workflow crashes or its worker hangs, the provider will either (1) do nothing, leaving the workflow incomplete, or (2) restart the function on a different worker,

potentially incrementing a counter twice, popping a queue multiple times, or corrupting database state and violating application semantics. Indeed, serverless providers currently recommend that developers write SSFs that are idempotent to ensure that re-execution is safe [17]. While helpful, these recommendations place the burden entirely on developers. In contrast, Beldi simplifies this process so developers need only worry about their application logic and not the low-level details of how serverless providers respond to failures.

2.2 Requirements and assumptions

We strive to design a framework that helps developers build serverless applications that tolerate failures and handle concurrent operations correctly. Our concrete goals are:

Exactly-once semantics: Beldi should guarantee *exactly-once* execution semantics in the presence of SSF or worker crash failures. That is, even if an SSF crashes in the midst of its execution and is restarted by the provider an arbitrary number of times, the resulting state must be equivalent to that produced by an execution in which the SSF ran exactly once, from start to finish, without crashing.

SSF data sovereignty: Beldi should support SSFs that are developed and managed independently. For example, multiple instances of an SSF may all access the same database, but they might not have access to the databases of other SSFs, even those in the same workflow. Instead, state should only be exposed by choice through an SSF’s outputs. This type of encapsulation is important to support a paradigm in which different developers, organizations, and teams within the same organization are responsible for designing and maintaining their own SSFs. An application developer can then contract with SSF developers (or teams) to integrate their SSFs into the application’s workflow via the SSF’s identifier (§2). Furthermore, data sovereignty is key to enabling developers to offer proprietary functions-as-a-service to others, and is a best practice in microservice architectures [11, §4]. For example, Microsoft’s eShopOnContainers [29] serves as a blueprint for applying these ideas to real-world applications.

SSF reusability: Beldi should allow multiple applications to use the same SSFs in their workflows at the same time. This may require each SSF to have different tables or databases to maintain the state of each application separately, though cross-application state should also be supported.

Workflow transactions: Beldi should support an optional transactional API that allows an application to specify any subgraph of a workflow that should be processed transactionally with ACID semantics. We target *opacity* [20] as the isolation level. Opacity ensures that (1) the effects of concurrent transactions are equivalent to some serial execution, and (2) every transaction, including those that are aborted, always observes a consistent view of the database. We discuss why these requirements are important in SSFs in Section 6.2.

FIGURE 1—Beldi’s architecture. Developers write SSFs as they do today, but use the Beldi API for transactions and externally visible operations. At runtime, operations for each SSF are logged to a database, which, when combined with a per-SSF intent and garbage collector, guarantees exactly-once semantics.

Deployable today: Beldi should work on existing serverless platforms without any modifications on their end. This allows developers to use Beldi on any provider of their choosing (or even a multi-provider setup), and lowers the barrier to switch providers. Additionally, developers should not need to run any servers in order to use Beldi. After all, a big appeal of serverless is that it frees developers from such burdens.

Assumptions. To achieve these goals, Beldi makes some assumptions about the storage provided to SSFs: that it supports strong consistency, tolerates faults, supports atomic updates on some atomicity scope (e.g., row, partition), and has a scan operation with the ability to filter results and create projections. These assumptions hold for the NoSQL databases commonly used by SSFs: Amazon’s DynamoDB, Azure’s Cosmos DB, and Google’s Bigtable.

3 Design Overview

Beldi consists of a library that developers use to write their SSFs and a serverless-based runtime system to support them. Beldi’s approach to handling SSF failures is based on an idea most recently explored by Olive [36] and inspired by decades of work on log-based fault tolerance [19, 30]. Specifically, Beldi executes SSF operations while atomically logging these actions and periodically re-executes SSFs that have not yet finished. The logs prevent duplicating work that has already been done, guaranteeing *at-most-once* execution semantics, while the re-execution ensures *at-least-once* semantics.

Figure 1 depicts Beldi’s high-level architecture. Beldi consists of four components: (1) the Beldi library, which exposes APIs for invocations, database reads/writes, and transactions; (2) a set of database tables that store the SSF’s state, as well as logs of reads, writes, and invocations; (3) an *intent collector*, which is a serverless function that restarts any instances of the corresponding SSF that have stalled or crashed; and (4) a *garbage collector*, which is a serverless function that keeps the logs from growing unboundedly.

To ensure data sovereignty (§2.2), the runtimes and logs

of different SSFs are independently managed and stored; however, all instances of *related* SSFs may share the same Beldi infrastructure. An app developer composes multiple SSFs into a workflow by chaining them together using a driver function, a step function, or a combination of the two. In the following sections we expand on each of these components.

3.1 Initial inspiration: Olive

Olive [36] guarantees exactly-once execution semantics for clients that may fail while interacting with a fault-tolerant storage server. This is a similar objective as ours, though our setting makes applying Olive’s ideas nontrivial. An intent in Olive is an arbitrary code snippet that the client intends to execute with exactly-once semantics. Each intent is assigned a unique identifier (*intent id*), which Olive uses as the primary key to save its progress. A client in Olive enjoys *at-most-once* semantics by checking the intent’s progress and skipping completed operations during re-execution. Intents consist of local and external operations. For example, incrementing a local variable is a local operation, whereas reading a value from storage is an external operation. Each external operation in the intent is assigned a monotonically increasing *step number*, starting at 0, that uniquely identifies it.

There are two key requirements for intents. First, intents must be deterministic; developers can make non-deterministic operations (e.g., a call to a random number generator) deterministic by logging their results and replaying the same values in the event of a re-execution. Second, intents must be guaranteed to always complete in the absence of failures (e.g., they must be free from bugs such as deadlock or infinite loops).

After an intent has been successfully logged, the client in Olive executes the intent’s code normally until it reaches an external operation (e.g., reading or writing to the database). Then, the client: (1) determines the operation’s step number; (2) performs the operation (e.g., writes to the database); (3) logs the intent id, step number, and the operation’s return value (if any) into a separate database table called the *operation log*. When the client completes all operations, it marks the intent as ‘done’ in the intent table.

To ensure at-most-once execution semantics, the client in Olive must perform actions (2) and (3) above atomically. This ensures that if Olive re-executes an intent, there will be a record in the operation log showing that a particular step has already been completed and should not be re-executed. Instead, the entity re-executing the intent should resume execution from the last completed step, using logged return values from previous steps as needed. To make these two actions atomic, Olive introduces a technique called *Distributed Atomic Affinity Logging* (DAAL), which collocates log entries for an item in the same *atomicity scope* (the scope at which the database supports atomic operations) with the item’s data. For example, in a storage system where operations are atomic at the row level, Olive would store the item’s value and its log entries in different columns of the same row.

Beldi Library Function	Description
<code>read(k) → v</code>	Read operation
<code>write(k, v)</code>	Write operation
<code>condWrite(k, v, c) → T/F</code>	Write if <i>c</i> is true
<code>syncInvoke(s, params) → v</code>	Calls <i>s</i> and waits for answer
<code>asyncInvoke(s, params)</code>	Calls <i>s</i> without waiting
<code>lock()</code>	Acquire a lock
<code>unlock()</code>	Release a lock
<code>begin_tx()</code>	Begin a transaction
<code>end_tx()</code>	End a transaction

FIGURE 2—Beldi’s API for SSFs, which includes all of Beldi’s primitives and its transactional support (§6).

Intent collector. To guarantee *at-least-once* semantics, Olive must ensure that some entity finishes the intent if the client crashes. This is the job of the *intent collector* (IC), which is a background process that periodically scans the intent table and completes unfinished intents by running their code. Before the IC executes an external operation, it consults the operation log table with the operation’s step number to see if the operation has already been done and to retrieve any return value; regular clients also perform this check between actions (1) and (2). If the operation has not been done, the IC atomically executes the operation and logs the result to the operation log table. Even if multiple IC instances execute concurrently, or if the IC starts executing the intent of a client that has not crashed, this is safe because of Olive’s assurance of at-most-once semantics.

Beldi vs. Olive. Beldi is inspired by Olive’s high-level approach but makes key changes and introduces new data structures and tables, support for invocations so that SSFs can call each other (Olive only supports storage operations), and garbage collection mechanisms to keep overheads low.

An important difference between the two is the definition of an ‘intent.’ In Olive, intents are code snippets—logged by the client—and all intents are logged in the same intent table. In Beldi, the *client* (which is the SSF) is the code snippet. As a result, an intent in Beldi is not code but rather the parameters that identify a particular running instance of the SSF: its inputs, start time, whether it was launched asynchronously, etc. Accordingly, Beldi uses the term ‘instance id’ instead of ‘intent id’ to capture this distinction.

Another critical difference is that, as shown in Figure 1, each SSF in Beldi is backed by a different database and Beldi runtime to ensure data sovereignty, though different SSFs developed by the same engineering team may reuse these components if desired. We will expand on these details in the following sections, but we begin by introducing Beldi’s API.

3.2 Beldi’s API

Beldi exposes the API in Figure 2, which includes key-value operations such as `read`, `write`, and `condWrite` (a write that succeeds only if the provided condition evaluates to true), and functions to invoke other SSFs (`syncInvoke` and

Log	Key	Value
intent	instance id	done, async, args, ret, ts
read	instance id, step number	value
write	instance id, step number	true / false
invoke	instance id, step number	instance id of callee, result

FIGURE 3—Beldi maintains four logs for each SSF. The intent table keeps track of an instance’s completion status, arguments, return value, type of invocation, and timestamp assigned by its garbage collector (ts). The read log stores the value read. The write log stores true for writes, or the condition evaluation for a conditional write. The invoke log stores the instance id of the callee and its result.

asyncInvoke). These operations are meant as drop-in replacements for the existing interface used by SSFs. Furthermore, Beldi supports the ability to begin and end transactions; operations between these calls enjoy ACID semantics.

Beldi’s API hides from developers all of the complexity of logging, replaying, and concurrency control protocols that take place under the hood to guarantee exactly-once semantics and support transactions. For example, an SSF using Beldi’s API automatically determines (from the input, environment, and global variables) the SSF’s instance id, step number, and whether it is part of a transaction. Beldi takes actions before and after the main body of the SSF as well as around any Beldi API operations.

3.3 Beldi’s runtime infrastructure

Developers write SSF code as they do today, but link Beldi’s library and use its API. The rest of Beldi’s mechanisms happen behind the scenes.

Intent table. Beldi associates with every SSF invocation an *instance id*, which uniquely identifies an intent to execute a given SSF. For the first SSF in a workflow, the instance id is the UUID assigned by the serverless platform to the initial request. For example, in AWS this UUID is called the ‘request id,’ in GCP it is called the ‘event id,’ and in Azure it is the ‘invocation id.’ For subsequent SSFs in the workflow, each caller in the graph will generate a new UUID to be used by the callee as its instance id. A new id is generated even if the SSF has been invoked earlier in the workflow or if the callee is another instance of the caller SSF (in the case of recursive functions). Thus, every SSF instance will have a distinct instance id, even if the instances are of the same SSF and in the same workflow.

Beldi keeps an intent table that contains the instance id, arguments, completion status, and other information listed in Figure 3 for every SSF instance that users and other SSFs intend to execute. It does this by modifying SSFs to ensure that the first operation is to check the intent table to see if their instance id is already present and, if not, to log a new entry. Beldi performs a similar modification to set the intent as ‘done’ at the end of the SSF execution.

Operation logs. In addition to the intent table, Beldi maintains three logs for each SSF: a *read log*, *write log*, and *invoke*

log. Their schema is also in Figure 3. For each operation, the key into the log is the combination of the executing SSF’s instance id and the step number, which (like in Olive) is a counter that identifies each unique external operation. Each read operation adds the value read from the database into the read log. Writes, meanwhile, write to the write log with a boolean flag that states whether the write operation took effect. Regular writes always set this flag to true, while conditional writes set it to the outcome of the condition at the time of the write. The actual data being written is stored in a data table, although in Section 4 we discuss a data structure that generalizes Olive’s DAAL and collocates the write log in the same table as the data to avoid cross-table transactions. The invoke log is new to Beldi and ensures at-most-once semantics for calls to other SSFs; we describe it in Section 4.5.

Intent and Garbage Collectors. For each SSF, Beldi introduces a pair of serverless functions that are triggered periodically by a timer. The first function acts as the SSF’s *intent collector* (IC). The IC scans the SSF’s intent table to discover instances of the SSF that have not yet finished (lack the ‘done’ flag). The IC restarts each unfinished SSF by re-executing it with the original instance id and arguments. Note that it is safe for the IC to restart an SSF instance even if the original instance is still running and has not crashed, owing to Beldi’s use of logs to guarantee at-most-once semantics for each step of the SSF. We implement two natural optimizations for the IC. First, the IC restarts instances only after some amount of time has passed since the last time they were launched to avoid spawning too many duplicate instances in cases where the IC runs very frequently. Second, the IC speeds up the process of finding unfinished instances among all instance ids in the intent table by maintaining a secondary index.

The second function acts as a *Garbage Collector* (GC) for completed intents, taking care to ensure safety in the presence of concurrent SSF instances, IC instances, and even GC instances. This component is described in Section 5.

4 Executing and Logging Operations in Beldi

As we mention in Section 3.1, guaranteeing exactly-once semantics requires atomically logging and executing operations. This section discusses how Beldi achieves this.

4.1 Linked DAAL

The logging approach taken by Olive (§3.1) requires an *atomicity scope* with high storage capacity, as otherwise few log entries can be added. In the context of Cosmos DB (the successor of the database used by Olive), the atomicity scope is a database partition, and the atomic operation is a transactional batch update. Olive’s DAAL is a good fit for Cosmos DB because partitions can hold up to 20 GB of data [10], which is enough to collocate a data item and a large number of log entries. However, other databases adopt designs with more limited atomicity scopes. For example, the atomicity scope of DynamoDB and Bigtable is one row, which can hold up to

FIGURE 4—Linked DAAL for a single item. Each row contains the item’s key, previous values (except the last row which contains the current value), lock information (used for transactions), a log of recent writes, and information for traversal and garbage collection.

400 KB [14] and 256 MB [7], respectively; the recommended limits are much lower. If we were to use Olive’s DAAL with DynamoDB, an SSF could only perform hundreds of writes to a given key before filling up the row. At such point, Olive would be unable to make further progress until the logs are pruned. This is hard to do in our setting: reaching a state of quiescence where it is safe to garbage collect logs is challenging since existing platforms expose no mechanism to kill or pause SSFs (§5).

To support all common databases, Beldi introduces a new data structure called the *linked DAAL* that allows logs to exist on multiple rows (or atomicity scopes), with new rows being added as needed. There are three reasons why this simple data structure is interesting for our purposes: (1) linked DAALs continue to avoid the overheads of cross-table transactions and work on databases that do not support such transactions; (2) linked DAALs are a type of non-blocking linked list [21, 42, 47], allowing multiple SSFs to access them concurrently with the operations supported by the atomicity scope (e.g., atomic partial updates); (3) even with frequent accesses, our garbage collection protocol can ensure that the length of the list for each item is kept consistently small (§5).

Structure. Figure 4 gives an example of a linked DAAL for an item with two rows of logs. Every row stores the item’s key, value, owner of the lock (used for transactions in Section 6), the log of writes, and metadata needed to traverse the linked DAAL and perform garbage collection. The first row is the ‘head,’ which has a special RowId and is never garbage collected. The primary key for rows is RowId + Key, the hash key is Key, and the sort key is RowId. When a row is full and the SSF issues a write operation, a new row is appended with the updated value and a log entry describing the write; the previous row’s value and logs are not modified once filled. Thus, the tail always has the most recent value.

Traversal. Most operations in Beldi require traversal to the tail of the list. The simplest way to accomplish this is to start at the designated head row and iteratively issue read requests for each NextRow until the field is empty. While this procedure will eventually reach the tail, the number of database operations grows with the length of the list. Garbage collection can control this length, but Beldi applies an additional optimization that leverages the scan and projection operations available in the three NoSQL databases that we surveyed. Specifically, Beldi issues a single scan operation to

```
def read(table, key):
    linkedDAAL = rawScan(table,
        cond: "Key is {key}",
        project: ["RowId", "NextRow"])
    tail = getTail(linkedDAAL)
    val = rawRead(table, tail)
    logKey = [ID, STEP]
    STEP = STEP + 1
    ok = rawCondWrite(ReadLog, logKey,
        cond: "{logKey} does not exist"
        update: "Value = {val}")
    if ok:
        return val
    else:
        return rawRead(ReadLog, logKey)
```

FIGURE 5—Pseudocode for Beldi’s read wrapper function. Functions beginning with “raw” refer to native (unwrapped) access to the database tables storing the data or the logs. Identifiers starting with capital letters indicate a member of the log structures.

the database that returns every row containing a target Key. On its own, the scan operation returns all contents of each row (including the values, write logs, etc.). To reduce this overhead, Beldi applies a projection that filters out all columns except for RowId and NextRow. This combination of scan and projection allows Beldi to download only 256 bits per row of the linked DAAL. From these rows, Beldi constructs a skeleton version of the linked DAAL locally, which it can quickly traverse to find the RowId of the tail.

We note that the individual reads in a scan are not executed atomically. For example, Beldi might see a row with no NextRow, and also receive a row that was subsequently appended to it. This operation might even retrieve rows that are orphaned from a failed append operation. Regardless, when these databases are configured to be linearizable [6, 9, 13], the set of rows traversed from the head to the first instance of an empty NextRow form a consistent snapshot of the linked DAAL—any write that completes strictly before the scan begins will be reflected in the constructed local linked DAAL.

While the linked DAAL is structurally simple, operating on it requires care. The following sections detail how Beldi’s API functions read and modify the linked DAAL.

4.2 Read

We begin by discussing Beldi’s read operation. While read has no externally visible effects on its own, the potential use of its non-deterministic results in a subsequent external operation means that Beldi must record the result of every read in a dedicated *ReadLog*. Unlike write operations, however, the read from the database and the log to the ReadLog need not happen atomically—if the SSF crashes before logging the outcome, it is fine to fetch a fresh value as the previous result did not have any externally visible effect.

Figure 5 shows the pseudocode of the read API function, which involves two steps: (1) read the most recent value of the key from the tail of the linked DAAL, and (2) log the result

```

def write(table, key, val):
    logKey = [ID, STEP]
    linkedDAAL = rawScan(table,
        cond: "Key is {key}"
        project: ["RowId", "NextRow",
            "RecentWrites[{logKey}]"])
    if logKey not in linkedDAAL:
        tail = getTail(linkedDAAL)
        tryWrite(table, key, val, tail)
    STEP = STEP + 1
def tryWrite(table, key, val, row):
    logKey = [ID, STEP]
    ok = rawCondWrite(table, row[RowId],
        cond: "({logKey} not in RecentWrites)
            && (LogSize < N)",
        update: "Value = {val};
            LogSize = LogSize + 1;
            RecentWrites[{logKey}] = NULL")
    if ok: # Case B
        return
    row = rawRead(table, row[RowId])
    if logKey in row[RecentWrites]: # Case A
        return
    elif row[NextRow] does not exist: # Case D
        row = appendRow(table, key, row)
    else: # Case C
        row = rawRead(table, row[NextRow])
    tryWrite(table, key, val, row)

```

FIGURE 6—Pseudocode for Beldi’s write wrapper function.

to the ReadLog if it has not yet been completed. For the first step, Beldi retrieves the tail as described in Section 4.1. For the second step, Beldi uses an atomic conditional update to efficiently log the operation without overwriting a previously executed read. If it encounters a conflict during the update, it returns the previous result from the ReadLog.

4.3 Write

A write is more complex as the update and logging must be done atomically—within the same atomicity scope—and Beldi needs to handle cases where other SSFs are accessing and appending to the linked DAAL concurrently. At a high level, the write operation must find the tail of the linked DAAL, check if the write has been previously executed, log/update the tail if it has not, and extend the linked DAAL if the current tail is full. Like read, Beldi can use scan and projection to assemble a minimal local version of the linked DAAL. Unlike read, Beldi cannot skip directly to the tail; instead, Beldi must check that none of the scanned rows contains a record of the current operation. Furthermore, once Beldi has a candidate for the tail, Beldi needs to update its value and add an entry to its log atomically. For a given tail candidate there are exactly four possible scenarios:

- A. The operation has already been executed and the [instance ID, step number] tuple can be found in the current row. Beldi can return immediately in this case.
- B. The operation is not in the log and there is still space. This indicates that Beldi is at the tail, the operation has

FIGURE 7—Possible cases for the state of a candidate tail in the linked DAAL during a write and its potential transitions.

never been executed previously, and there is room in the current row to execute/log the write.

- C. The operation is not in the log, but the log is full and there is a pointer to the next row. Beldi should follow the provided pointer toward the tail.
- D. The operation is not in the log and the log is full, but there is no next row. Beldi should append a new row and advance to that new row.

We formulate a lock-free algorithm to handle all the cases above by examining the transitions induced by concurrent SSF accesses. For example, if Beldi is in case B, where the operation is not in any log and there is still space to execute it in the current row, a concurrent SSF can, without warning, execute the current operation (\rightarrow A) or fill the remaining space in the log (\rightarrow C/D). The reverse is not true: once there is a NextRow pointer, the linked DAAL will never revert to having extra space for logs. The cases and their transitions are summarized in Figure 7, where N is the maximum number of log entries that can fit in a row when accounting for the size of the key, value, and other metadata. The exception is garbage collection (not covered in Figure 7), whose operation and correctness we describe in Section 5. An arrow in Figure 7b indicates a possible effect of concurrent SSF instances.

To safely identify the state of a row, Beldi checks for each case starting at the node(s) in the transition graph without incoming edges. In this case there is only one such node (B), so Beldi performs a conditional write with the condition given in case B of Figure 7a (i.e., that the logKey is not in the logs, that the logSize is less than N , and that there is no nextRow). If the conditional check fails, the state of the row will not revert back to case B later because B has no incoming edges. Therefore, it is safe to remove B from the transition graph and check the remaining cases. Beldi repeats the above process with cases A and D (in any order) because they have no incoming edges in the remaining graph. Finally, if all prior conditions fail, the row is in case C.

4.4 Conditional write

Beldi also provides support for conditional writes, which only execute if a user-defined condition is true at the time of the write. The initial scan and subsequent scenarios are similar to the scenarios for unconditional writes. The only exception is the case where the operation has not previously executed and the current row still has remaining space in the log (i.e., case B from Section 4.3). We split this case into two: in B_1 , the condition is true, and in B_2 , the condition is false.

```

def syncInvoke(callee, input):
    calleeId = UUID()
    logKey = [ID, STEP]
    STEP = STEP + 1
    ok = rawCondWrite(InvokeLog, logKey,
        cond: "{logKey} not in InvokeLog"
        update: "Id = {calleeId};
            Result = NULL")

    if not ok:
        record = rawRead(InvokeLog, logKey)
        calleeId = record[Id]
        result = record[Result]
    if result does not exist:
        return rawSyncInvoke(callee,
            [calleeId, input])
# When the Callee is done it issues a callback
# to the caller. Below is the callback handler.
def syncInvokeCallbackHandler(calleeId, result):
    rawWrite(InvokeLog, cond: "Id = {calleeId}",
        update: "Result = {result}")

```

FIGURE 8—Pseudocode for synchronous invocation of other SSFs. Asynchronous invocations are similar, but since they do not have return values, the callback is invoked as soon as the callee logs the intent in its intent table. We give the code for the callee’s actions in Appendix A of our tech report [45].

Beldi handles these cases by first checking B_1 and B_2 with conditional writes before covering the other states exactly as in the unconditional-write case. We give a detailed description in Appendix A of our extended technical report [45].

4.5 Invocation of SSFs and local functions

Finally, Beldi supports three types of function invocations: synchronous calls (`syncInvoke`), which block and return a value; asynchronous calls (`asyncInvoke`), which return immediately; and calls to functions that do not use Beldi’s API (e.g., legacy libraries or legacy SSFs). In the first two cases, Beldi guarantees exactly-once semantics. In the last, it only guarantees that the operation is performed at least once.

Figure 8 shows pseudocode for synchronous SSF invocations. As mentioned in Section 3.3, to help SSFs that are being invoked (“callees”) differentiate between re-executions and new executions, Beldi passes an instance id to the callee (the “callee id”) along with the parameters of the call. In the first invocation, the callee id is generated using `UUID()`; for re-executions, it retrieves the id from the invoke log. If there is already an entry in the invoke log for this caller id and step number, there are two cases: (1) a result is already present, in which case the caller reuses that result; or (2) the entry is present but there is no result, in which case the caller re-invokes the callee with the existing callee id.

Callbacks. Note that `syncInvoke` (Figure 8) does not log the result of the actual call or otherwise mark the call as complete. To see why this is important, consider the example trace in Figure 9, which shows the result of a failure of the callee (SSF2) after it marks itself as done in the intent table

FIGURE 9—SSF1 synchronously invokes SSF2, which then fails to return after logging the operation as done. The callback ensures that SSF1 has the result of SSF2 before SSF2 marks itself as done.

but before it returns the result to the caller (SSF1). Suppose that there is no callback, i.e., that SSF2 logs itself as complete immediately after completing execution. Beldi’s federated setup means that each SSF has a garbage collector running at its own pace. If SSF2 were to fail after logging itself as done, it is, therefore, possible that SSF2’s GC will garbage collect the intent before SSF1 gets any value. Later, when SSF1’s IC re-executes the unfinished SSF1 instance, the caller will see the lack of result in the invoke log, re-invoke SSF2 (with the existing callee id), and SSF2 will mistakenly perform the operation again. In some ways, this is similar to why write operations in Beldi must be atomically logged and executed (§3.1). Unfortunately, there are no mechanisms for atomically logging into a database and executing other SSFs.

We address this issue by decomposing an invocation into two steps: (1) the invocation itself, performed by the caller; and (2) the recording of results, done via a second, automatic invocation by the callee to *some* instance of the caller. We emphasize ‘some’ and ‘original’ because request routing in serverless is stateless: if SSF1 invokes SSF2, and SSF2 then invokes SSF1, the two SSF1 instances could be different (§2.1). We call this automatic invocation a *callback*. When the second instance of the caller receives the callback, it logs the provided result in its invoke log and returns. At this point, it is safe for the callee to mark its intent as done since it knows the caller’s invoke log already contains the result. Note that callbacks only require at-least-once semantics, so there is no need for additional logging of the callback invocation.

Figure 9 illustrates the idea of Beldi’s callback mechanism. The callback ensures that the result of SSF2 is properly received by SSF1. As such, we note that SSF2’s response to SSF1 is merely an optimization and not necessary for correctness. We also note that if SSF2 fails after a successful callback but before logging the completion of the intent, it may result in a case where SSF1 completes, gets garbage collected, and then a re-execution of SSF2 invokes a spurious callback. SSF1 can detect and ignore this case when a callback occurs for an invoke that does not exist.

Asynchronous invocations. This procedure is similar to that of synchronous invocations, but with the two steps flipped

on the callee. The caller first makes a `rawSyncInvoke` call to the callee, but rather than execute the function, the callee (observing an ‘async’ flag) simply registers the intent in its intent table, issues a callback, and then immediately returns to the caller. In the second step, Beldi performs the actual asynchronous invocation of SSF2’s logic. We describe this operation in detail in Appendix A of our tech report [45].

5 Garbage Collection

If left alone, the linked DAAL will grow indefinitely. While Beldi’s use of scans means that the linked DAAL’s length is generally not the performance bottleneck, unbounded growth of the linked DAAL and logs (intent table, read log, invoke log) can lead to significant overheads and storage costs. Beldi ensures that logs are pruned and the linked DAAL remains shallow with a garbage collector (GC) that deletes old rows and log entries without blocking SSFs that are concurrently accessing the list. The GC is an SSF triggered by a timer.

At a high level, the protocol has six parts. First, the GC finds intents that have finished since the last time a GC instance ran and assigns them the current time as a finish timestamp. Second, the GC looks up all intents whose finish timestamp is ‘old enough’ (we expand on this next), and marks them as ‘recyclable.’ Third, the GC removes log entries (in the read and invoke logs) that belong to recyclable intents. Fourth, the GC disconnects, for every item, the non-tail rows of their linked DAAL that have empty logs, marks these rows as ‘dangling’, and assigns them the current time as a dangling timestamp. Fifth, the GC removes all rows whose dangling timestamp is ‘old enough.’ Finally, the GC removes the log entries from the intent table. The algorithm is given in Figure 10, with more details in Appendix A of our tech report [45]. Note that GCs only need at-least-once semantics to avoid memory leaks in the presence of crashes; they do not use Beldi’s exactly-once API. Instead, GCs defer the removal of entries in the intent table until the end.

Assumption. The safety of garbage collection relies on a synchrony assumption. In particular, it assumes that an individual SSF instance terminates, one way or another, in at most T time. This allows the GC to delete the logs of completed intents after waiting T time for all running instances of the completed intents to finish. Note that no new instances will be started by an SSF’s IC after the intent is marked as ‘done.’

Our assumption is based on the observation that serverless providers enforce user-defined execution timeouts on SSF instances (§2.1), but otherwise provide no interface for developers to kill or stop running functions. We can derive a conservative bound for T from these user-defined timeouts. Note that even if providers refuse to kill SSFs after the timeout, we can work around this issue (at high cost) by having the GC change the database’s permissions or rename tables so that ongoing SSF instances (including stragglers that stick around after the intent is done) fail to corrupt the database;

```
def garbageCollection():
    time = now()
    recyclable = []
    for id, intent in IntentTable:
        if intent[Done]:
            if FinishTime not in intent:
                intent[FinishTime] = time
            elif time - intent[FinishTime] > T:
                recyclable.append(id)
    for id in recyclable:
        remove from ReadLog
            where "LogKey[Id] == {id}"
        remove from InvokeLog
            where "LogKey[Id] == {id}"
    for table, key in getAllDataKeys():
        rows = rawScan(table,
            cond: "Key == {key}")
        for row in rows:
            for log in row[RecentWrites]:
                mark if log[Id] in recyclable
            if fullyMarked(row[RecentWrites])
                and row[NextRow] exists:
                prev(row)[NextRow] = row[NextRow]
            if DangleTime not in row:
                row[DangleTime] = time
        rows = rawScan(table, cond: "Key == {key}
            && {time} - DangleTime > T")
        for row in rows:
            if row not reachable from head(key)
                delete row
    for id in recyclable:
        remove from IntentTable
            where "LogKey[Id] == {id}"
```

FIGURE 10—Pseudocode for Beldi’s lock-free, thread-safe garbage collection algorithm. T is the maximum lifetime of an SSF instance.

instances that start after the change are fine.

Safety of concurrent access. With the above assumption, Beldi’s GC preserves exactly-once semantics without needing to interrupt SSF instances. First, observe that an intent is marked as recyclable only after Beldi is sure that no live SSF instance requires the intent. Accordingly, the read log, invoke log, and intent table entries for the intent will never be accessed again. For the linked DAAL, the GC only disconnects a row when all of the contained logs are marked as recyclable and it is not the tail. New traversals of the linked DAAL for read or write operations will not observe the disconnected row (technically the `rawScan` operation will return these disconnected rows, but they will be ignored during the traversal of the local linked DAAL). Running SSF and GC instances, however, may be in the process of traversing the disconnected row—if Beldi deleted it immediately, the SSF or GC might become stranded. To prevent this, Beldi keeps the disconnected row for an additional T time to ensure that instances with such references terminate successfully.

Safety of concurrent modifications. The linked DAAL also supports garbage collection in the presence of concurrent appends from SSFs and deletions from other GC instances ow-

ing to it being a type of non-blocking linked list. In fact, it is simpler than traditional non-blocking linked lists [21, 42, 47] because new rows are always appended to the tail, and GCs never touch the tail. The only interesting case is the concurrent disconnection of neighboring rows such as X and Y in $A \rightarrow X \rightarrow Y \rightarrow B$. In this case, the disconnection of X succeeds, but the disconnection of Y will not be visible because the updated `NextRow` pointer in X is no longer part of the linked DAAL. The next GC run disconnects Y permanently.

6 Supporting Locks and Transactions

In addition to exactly-once semantics, Beldi also provides support for locks and transactions with user-generated aborts.

6.1 Locks

Beldi’s approach to mutual exclusion borrows an abstraction in Olive called “locks with intent”, where locks over data items are owned by an intent rather than a specific client. This means that, if an SSF instance calls `lock(item)` and then crashes, the lock is not lost and held indefinitely; rather, the IC will soon restart the instance. The re-executed instance, upon arriving at the `lock(item)` call, will see that it already acquired the lock and be able to continue with the remaining operations as if the original SSF instance had never crashed.

In Beldi, the ownership of a lock on a given item is kept alongside the data and logs in the “lock owner” column of the item’s linked DAAL. Lock acquisition and release are logged to the DAAL as writes to the item using Beldi’s `condWrite` semantics, where the condition is that the lock is either owned by the current SSF or has an empty lock-owner column in the DAAL. The exactly-once semantics are needed for cases where an SSF is re-run after successfully releasing a lock.

Note that Beldi only guarantees exactly-once semantics—it does not absolve the developer from writing bug-free code. Thus, problems like infinite loops within critical sections and deadlock need to be handled with higher-level mechanisms (like the one below) if the user wishes to guarantee liveness.

6.2 Transactions

Beldi uses an extension of the locking mechanism of the preceding section to implement transactions within and across SSF boundaries. Beldi transactions are based on a variant of 2PL with wait-die deadlock prevention and two-phase commit. Note that the choice of wait-die (rather than something like wound-wait) is deliberate as SSF instances generally cannot kill other instances. To implement this, we need to track the intent-creation time of each SSF. We do so by adding to the lock-owner column an intent-creation timestamp and checking upon lock-acquisition failure whether the existing lock owner is older or younger than the current SSF instance; if older, abort, otherwise, try again (see Figure 11).

There are three main parts to Beldi’s transaction-handling protocol: (1) creating and forwarding a *transaction context*, (2) executing Beldi calls inside a transaction, and (3) prop-

```
def lock(table, key):
    ok = condWrite(table, key,
        cond: "LockOwner = NULL
              || LockOwner.id = TXNID",
        update: "LockOwner = [TXNID, START_TIME]")
    if not ok:
        row = read(table, key)
        ownerId, ownerTime = row[LockOwner]
        if ownerTime <= TXNID:
            abort
        else:
            lock(table, key)
```

FIGURE 11—Pseudocode for the lock operation with wait-die deadlock prevention used during the ‘Execute’ mode of a transaction.

agating abort/commit signals throughout a workflow. Note that Beldi does not currently support `asyncInvoke` in transactions; however, it does support spawning threads that issue `syncInvoke` operations and are then joined.

Transaction contexts. In Beldi, transactions are defined with the `begin_tx` and `end_tx` API calls. Beldi assumes that both the begin and the end statements are placed in the same SSF, but SSFs can invoke other SSFs inside a transaction, so transactions can span across multiple SSFs. When an SSF calls `begin_tx` it creates a new top-level *transaction context* which consists of a unique transaction id and a mode (‘Execute’, ‘Commit’, or ‘Abort’). Contexts start in ‘Execute’ mode. The SSF instance will also, upon creating a new context, execute the transaction’s operations in a new thread/goroutine to catch any runtime exceptions. The matching `end_tx` waits for the result and runs either a commit or abort protocol depending on the outcome of the contained operations.

Transaction contexts are passed along with any SSF invocations that occur inside the transaction. Thus, whenever a Beldi-enabled SSF starts, it first determines whether it is a part of an ongoing top-level transaction by checking whether a context was provided as part of the input. This is necessary even if the SSF never creates a transaction itself. If the SSF does create a transaction, the `begin_tx/end_tx` statements will be ignored and all operations will be inherited by the top-level transaction context. Beldi does not currently support *nested transaction* semantics [31] (e.g., a sub-transaction can abort without causing the top-level transaction to abort).

Opacity. Beldi chooses *opacity* as the isolation level for transactions. Opacity [20] captures strict serializability [5, 34] with the additional requirement that even transactions that abort do not observe inconsistent state. The rationale is that observing inconsistent state can lead to undefined behavior and infinite loops. For example, if an SSF instance reads inconsistent state that results in division by zero, it may crash. Beldi’s IC will restart the SSF instance and deterministically replay the (inconsistent) values to ensure exactly-once semantics, re-triggering the crash. Figure 12 gives another example of how OCC [26], which provides serializability but not opacity,

```

begin_tx()
x = read("x"); y = read("y")
while (x != y):
    // some logic
    x++
write("x", x + 2); write("y", y+4)
end_tx()

```

FIGURE 12—OCC leads to an infinite loop when two instances of the above transaction, T_1 and T_2 , execute concurrently. Suppose $x = 0, y = 1$ initially. T_1 reads $x = 0, y = 1$, executes the logic, acquires locks on x and y , validates the read set, and writes $x = 3, y = 4$. T_2 reads $x = 3, y = 1$ (corresponding to a state after which T_1 updated x but before it updated y), and is stuck in an infinite loop. Even though T_2 is destined to abort, it will never reach the read set validation step.

leads to infinite loops. These issues are not present with isolation levels that guarantee that all transactions read from a consistent snapshot.

Operation semantics inside a transaction. If an SSF is in a transactional context, Beldi modifies the semantics of its API based on the mode to ensure ACID semantics. We have already discussed two operation modifications that occur in ‘Execute’ mode—one to locks in Figure 11 and another to `begin_tx/end_tx`, which are ignored. ‘Execute’ mode also causes Beldi to call `lock` before every `read`, `write`, and `condWrite` operation, using the transaction id as the lock holder. In addition to acquiring locks, Beldi also changes where reads and writes look up and record values. While lock acquisition still goes to the original tables, Beldi redirects written values to a *shadow table* that acts as a local copy of state for the transaction. Like the original table, this shadow table is also stored as a linked DAAL and is garbage collected along with the normal DAAL (except the GC also deletes the head and tail). Unlike the original, the shadow table is partitioned by transaction id, with Key relegated to a secondary index. All `read` operations check the shadow table first before consulting the real table to ensure that transactions read their own writes. If, before an operation, an SSF fails to acquire a lock and must kill itself (due to wait-die), it returns to its caller with an ‘abort’ outcome.

Propagation of commit or aborts. Eventually, a `begin_tx/end_tx` code block will reach the `end_tx` with an abort/commit decision. For commit, Beldi changes the mode of the context to ‘Commit’, flushes the final values of the items in the shadow table to the real linked DAAL, and releases any held locks. Beldi then calls the SSF’s callees and passes them the transaction context in Commit mode. Note that if an SSF instance fails between flushing the shadow table and notifying the callees of the commit decision, Beldi’s exactly-once semantics ensure that once the SSF instance is re-executed, it will pick up from where it left off. For abort, none of the values have been written to the actual table, so Beldi just releases all locks and invokes all callees in ‘Abort’ mode.

When an SSF is invoked with a transaction context that includes a Commit mode, Beldi skips the SSF’s logic, and instead performs only the aforementioned commit protocol: flushes the final value of the items, releases any held locks, and notifies its own callees by invoking them with the provided transaction context. An Abort mode similarly skips the SSF’s logic, releases all locks, and notifies its callees. This recursive invocation of callees with a Commit or Abort mode mimics the role of a coordinator in two-phase commit.

Supporting step functions. The previous discussion assumes a `begin_tx` and `end_tx` in the same SSF. To support transactions across SSFs defined in *step functions*, the developers must introduce ‘begin’ and ‘end’ SSFs in their workflow (we give an example in Appendix A of our tech report [45]). These SSFs create the transaction context and kickstart the commit or abort protocol. SSFs that fall between the ‘begin’ and ‘end’ SSFs in the workflow execute transactionally. If an SSF aborts it sends ‘abort’ on its outgoing edges in the workflow; an SSF that receives an abort as input skips its operations and propagates the abort message on its outgoing edges. This continues until the abort message reaches the ‘end’ SSF, which then sets the transaction context mode to Abort and invokes the ‘begin’ SSF. If ‘end’ executes without receiving any abort message, it sets the context mode to Commit instead. This invocation initiates the second phase of 2PC over the transactional subgraph of the workflow.

Non-transactional SSFs inside transactions. While an SSF that does not use transactions can be invoked inside a transaction by another SSF (which automatically forces the non-transactional SSF to acquire locks before any accesses), app developers must ensure that the non-transactional SSF is *only* used inside transactional contexts. Otherwise, non-transactional instances may access the database without acquiring locks or obeying the wait-die protocol.

7 Evaluation

Beldi brings forth an array of programmability and fault-tolerance benefits, but with these benefits come costs. In this section we are interested in answering three questions:

1. What is the cost of maintaining and accessing the linked DAAL, and how does it compare to applicable baselines?
2. What are the latency and throughput of representative applications running on Beldi, and how does Beldi compare to existing serverless platforms that provide neither exactly-once semantics nor transactional support?
3. What effect does Beldi’s GC have on linked DAAL traversal, and how does it change as we adjust the timeout (T)?

We answer the above questions in the context of the following implementation, applications, and experimental setup.

7.1 Implementation

We have implemented a prototype of Beldi for Go applications that runs transparently on AWS Lambda and DynamoDB. In

total, Beldi’s implementation consists of 1,823 lines of Go for the API library and the intent and garbage collectors.

Case studies. To evaluate Beldi’s ability to support interesting applications at low cost, we implement three case studies: a social media site, a travel reservation system, and a media streaming and review service. We adapt and extend these applications from DeathStarBench [12, 16], which is a recent open-source benchmark suite for microservices, and port them to a serverless environment (using Go and AWS Lambda). This port took around 200 person-hours. Combined, our implementations total 4,730 lines of Go. We provide details of the corresponding workflows in Appendix B of our tech report [45], and give a brief description below.

Movie review service (Cf. IMDB or Rotten Tomatoes): Users can create accounts, read reviews, view the plot and cast of movies, and write their own movie reviews and articles. Our implementation of this app consists of a workflow of 13 SSFs.

Travel reservation (Cf. Expedia): Users can create an account, search for hotels and flights, sort them by price/distance/rate, find recommendations, and reserve hotel rooms and flights. The workflow consists of 10 SSFs, and includes a cross-SSF transaction to ensure that when a user reserves a hotel and a flight, the reservation goes through only if both SSFs succeed. Note that we extend this app to support flight reservations, as the original implementation [12] only supports hotels.

Social media site (Cf. Twitter): Users can log in/out, see their timeline, search for other users, and follow/unfollow others. Users can also create posts that tag other users, attach media, and link URLs. The workflow consists of 13 SSFs that perform tasks like constructing the user’s timeline, shortening URLs, handling user mentions, and composing posts.

7.2 Experimental setup

We run all of our experiments on AWS Lambda. We configure lambdas to use 1 GB of memory and set DynamoDB to use autoscaling in on-demand mode. All of the read and scan operations for Beldi and the baseline use DynamoDB’s strong read consistency. We turn off automatic Lambda restarts and let Beldi’s intent collectors take care of restarting failed Lambdas. Our garbage and intent collectors are triggered by a timer every 1 minute, which is the finest resolution supported by AWS. Note that AWS currently has a limit of 1,000 concurrent Lambdas per account. As we will see in some of our experiments, this limit is often the bottleneck in both the baseline and Beldi. Finally, consistent with our deployability requirement (§2.2), Beldi uses no servers.

The baseline for our experiments is running our ported applications on AWS Lambda without Beldi’s library and runtime. Consequently, these applications will not enjoy exactly-once semantics or support transactions: when running on the baseline, the travel reservation app outputs inconsistent results, and all apps can corrupt state in the presence of crashes.

FIGURE 13—Median latency of Beldi’s operations. Error bar represents the 99th percentile, and “cross-table tx” is an implementation of Beldi that uses cross-table transactions instead of the linked DAAL.

7.3 What are the costs of Beldi’s primitives?

We start our evaluation with a microbenchmark that measures the cost of each of Beldi’s primitive operations: read, write, condWrite, and invoke. The keys are one byte and the values are 16 bytes. We measure the median and 99th percentile completion time of the four operations over a period of 10 minutes at very low load (1 req/s). As baselines, we also measure the completion time (1) without Beldi’s exactly-once guarantees and (2) using a design that logs writes to a separate table using cross-table transactions. Since Beldi’s database operations depend on the length of the linked DAAL, we populate the chosen key’s linked DAAL with a conservative value of 20 rows, which corresponds to the length of the linked DAAL after 30 minutes without garbage collection as described in the experiment of Section 7.5.

Figure 13 shows the overhead of Beldi’s reads/writes compared to those of the baseline stem from two sources: scanning the linked DAAL (instead of reading a single row) and logging. For invoke, the overheads come from our callback mechanism and logging to the invoke log. Consequently, all of Beldi’s operations are around 2–4× more expensive than the baseline. In contrast, the approach using cross-table transactions does not use a DAAL so reads avoid the scan (but not the logging), and writes perform an atomic transaction where the value is written to one table and the log entry is added to another. The cost of this operation is 2–2.5× higher than Beldi’s linked DAAL. Appendix C in our tech report [45] describes the same experiment with a more optimistic setting (5 rows in the linked DAAL); the results are similar.

Note that not all existing databases (e.g., Bigtable) support cross-table transactions. Even for those that do, the performance gain that cross-table transactions have on read operations over using a linked DAAL goes away whenever SSFs use transactions because read locks use condWrite which is a cheaper operation on the linked DAAL.

Other costs. Another consideration beyond performance is the additional storage and network I/O required by Beldi to maintain and access all logs and linked DAAL metadata. For our setup above, the 20-row DAAL for the item takes up

FIGURE 14—Median response time and throughput for our movie review service. Dashed lines represent 99th-percentile response time.

8 MB of storage. Counting all logs and metadata, each operation requires storing between 20 to 36 bytes in addition to the value. In terms of the network overhead introduced by the scan and projection approach that we use to traverse Beldi’s linked DAAL, for a 20-row DAAL, each scan fetches 2 KB more data than a baseline read to a single cell when measured at the network layer. Compared to the baseline, Beldi induces one extra scan and write for each read operation, at least one scan for an unconditional write (and potentially more scans and writes depending on the scenario), and one read and two writes for a function invocation. In DynamoDB’s on-demand mode, each read costs an additional $\$2.5 \times 10^{-7}$, whereas writes cost an additional $\$1.25 \times 10^{-6}$. In provisioned-capacity mode, costs are lower but depend on the specified capacity.

7.4 How does Beldi perform on our applications?

In this section, we discuss the results of our large-scale experiments for the movie review and travel reservation services; the social networking site has similar results, so we defer its results to our tech report [45]. The workloads that we use are adapted from DeathStarBench [12, 16] with a minor modification to support our extended travel reservation service: the transactions to reserve a hotel and flight randomly pick a hotel and a flight out of 100 choices each following a normal distribution. Requests contain random content within the expected schema and are generated and measured using wrk2 [44].

We issue load at a constant rate for 5 minutes, starting at 100 req/s and increasing in increments of 100 req/s until the system is saturated. For our applications, we achieve saturation at around 800 req/s. The primary bottleneck in all cases is compute: AWS enforces a limit of 1,000 concurrent Lambdas per account (even if the Lambdas are for different functions), and the HTTP Gateway (or some internal scheduler) rejects requests in excess of this limit.

Figures 14 and 15 depict the results. In all cases (including the social media app), we observe that, until around 400 req/s (34M per day), Beldi’s median and 99th-percentile response time are each around $2\times$ higher than that of the baseline. At the highest loads that we could test on AWS, Beldi still achieves the same throughput as the baseline at a slightly higher median response time (around $3.3\times$ for the travel

FIGURE 15—Median response time and throughput for travel reservation service. Dashed lines represent 99th-percentile response time. Beldi performs transactions over multiple SSFs to reserve a hotel room and a flight, while the baseline returns inconsistent results.

FIGURE 16—Median response time for an SSF that uses one write operation under different GC configurations. Without GC, the linked DAAL grows over time. As a baseline, we configure Beldi with cross-table transactions that do not use a linked DAAL.

reservation). At this high load, Beldi’s 99th-percentile latency is only 20% higher for the movie review service, and 80% higher for the transaction-enabled travel site. We also test a configuration of the travel site that uses Beldi for fault-tolerance but without transactions. The median latency at saturation for that configuration is 16% lower and the 99th-percentile latency is 20% lower than Beldi with transactions.

7.5 What is the effect of garbage collection?

Finally, we evaluate the importance of the choice of garbage collector timeout (T) on performance. Note that this is different from the 1-minute timer that triggers the GC SSF (§7.2). T is instead proportional to the maximum lifetime of an SSF and determines when a GC can remove a row from the Linked DAAL. Thus, this value is important for safety, whereas the trigger only determines when the GC runs.

Since T is important to ensure exactly-once semantics, we could imagine performing a similar actuarial analysis to those involved in setting the end-to-end timeouts of reliable failure detectors [1, 27]. However, as Figure 16 shows, the median response times for SSFs that access the linked DAAL are only lightly impacted by the choice of T , even as we run the system for 30 minutes at constant load under pessimistic conditions (all SSF instances write to the same key). As a result, we

can be relatively conservative about T . To be clear, this is a testament to the heroic efforts of DynamoDB engineers that have optimized its scan, filter, and projection operations. Nevertheless, we take some slight credit for ensuring that Beldi's linked DAAL is compatible with such operators.

It is worth noting, however, that while T has a minor impact on performance, it does impact storage overhead and I/O, since `read` and `write` operations still fetch a projection of the linked DAAL which scales with the number of rows (§7.3).

8 Discussion

We now discuss a few aspects of Beldi, such as the implication of relying on strongly consistent databases, the potential benefit of using SQL databases like Amazon Aurora, and the security implications of SSF federation and reusability.

Strongly consistent databases. Beldi enables developers to write stateful serverless applications without having to worry about concurrency control, fault tolerance, or manually making all of their functions idempotent. In doing so, Beldi leverages one or more fault-tolerant databases configured to be strongly consistent. If these databases were to become unavailable, for example due to network partitions, SSFs that write to these unavailable databases would also become unavailable until the partition was resolved.

ACID databases. A natural question is whether SSFs that use ACID databases need all of Beldi. For such SSFs, the benefit is not having to maintain a read or write log (or a linked DAAL) since the database does its own logging. However, ACID databases are not enough to guarantee exactly-once semantics for function invocations since they provide atomicity for read and write operations, but have no support for invocations. As a result, Beldi would still need to implement mechanisms such as callbacks (§4.5) to ensure that a failed SSF is not mistakenly re-executed despite independent garbage collectors. Furthermore, workflows that contain transactions *across* SSFs would still need a collaborative coordination protocol such as the one proposed in Section 6.2.

Independence of separate applications. We view SSFs as owning all the data on which they operate, similar to microservice architectures [11]. SSFs can isolate the state of different applications by storing each application's state on a different database. To ensure that a malicious request from one application cannot observe the state of another, standard authentication mechanisms such as capabilities and public key encryption could be used.

9 Related Work

We already discuss Beldi's differences with Olive [36] throughout. To summarize, Beldi builds upon Olive's elegant approach to fault tolerance and mutual exclusion, and adapts it to an entirely new domain. This adaptation is nontrivial and requires us to introduce new data structures, algorithms, and abstractions (e.g., transactions across SSFs). The result of our

innovations is a simple API that SSF developers can use to build exciting applications without worrying about fault tolerance, concurrency control, or managing any infrastructure!

In the context of serverless, the observation that existing designs are currently a poor fit for applications that require state has been the subject of much prior work [15, 22, 24, 25, 43]. For example, Cloudburst [40] proposes a new architecture for incorporating state into serverless functions, and gg [15] proposes workarounds to state-management issues that arise in desktop workloads that are outsourced to thousands of serverless functions. However, the general approach to fault-tolerance in these works is to re-execute the entire workflow when there is a crash or timeout—violating exactly-once semantics if any SSF in the workflow is not idempotent.

AFT [39] is the closest proposal to Beldi and introduces a fault-tolerant shim layer for SSFs. However, AFT's deployment setting, guarantees, and mechanisms are very different. First, Beldi runs entirely on serverless functions, whereas AFT requires servers to interpose and coordinate all database accesses. As a result, Beldi can run on any existing serverless platform (or even in a multi-provider setup) without requiring any modification on their part and without the user needing to administer their own VMs. Second, Beldi seamlessly enables transactions within SSFs and across workflows with opacity, whereas AFT targets the much weaker (but more efficient) read atomic isolation level [4]. Due to the weaker isolation, it would be more difficult to implement our travel reservation system on AFT. Finally, Beldi allows SSFs to be managed independently and to keep their data private from each other, while AFT's servers manage all SSF data, handle failures and garbage collection, and serve as a central point of coordination for transactions.

10 Conclusion

Beldi makes it possible for developers to build transactional and fault-tolerant workflows of SSFs on existing serverless platforms. To do so, Beldi introduces novel refinements to an existing log-based approach to fault tolerance, including a new data structure and algorithms that operate on this data structure (§4.1), support for invocations of other SSFs with a novel callback mechanism (§4.5), and a collaborative distributed transaction protocol (§6). With these refinements, Beldi extracts the fault tolerance already available in today's NoSQL databases, and extends it to workflows of SSFs at low cost with minimal effort from application developers.

Acknowledgments

We thank the OSDI reviewers for their feedback and our shepherd, Jay Lorch, for going above and beyond and providing suggestions that dramatically improved the content and presentation of our work. We also thank Srinath Setty for many invaluable discussions and his help with Olive. This work was funded in part by VMware, NSF grants CNS-1845749 and CCF-1910565, and DARPA contract HR0011-17-C0047.

A Artifact Appendix

A.1 Abstract

Our artifact runs on Amazon AWS Lambda without additional requirements or dependencies. Deploying the code, performing the measurements, generating the plots, and running the benchmarks depend on some third-party frameworks including serverless, gnuplot and wrk2.

A.2 Artifact check-list

- **Program:** Golang
- **Run-time environment:** AWS Lambda
- **Metrics:** Throughput and latency
- **Experiments:** Our serverless port of DeathStarBench
- **Expected experiment run time:** Around 20 hours
- **Public link:** <https://github.com/eniac/Beldi>
- **Code licenses:** MIT License

A.3 Description

A.3.1 How to access

<https://github.com/eniac/Beldi>

A.4 Installation

A.4.1 Set up docker container

1. login to a registry

```
$ docker login
```
2. pull the docker image
for github packages users:

```
$ docker run -it \
```

```
> docker.pkg.github.com/eniac/beldi/beldi:latest
```

```
/bin/bash
```

for docker hub users:

```
$ docker run -it tauta/beldi:latest /bin/bash
```

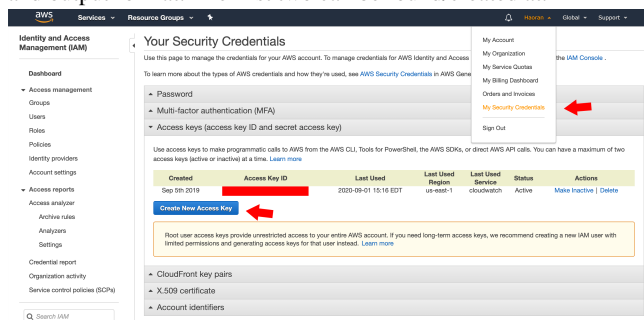

The purpose of this container is to setup the environment needed to run our configuration, deployment, and graph plotting scripts. The actual code of Beldi runs on AWS lambda.

A.4.2 Set AWS Credentials

Inside the container run

```
$ aws configure
```

It will ask you for an access key ID, a secret access key, region and output format. The first two can be found/created at:

Set the region to us-east-1 and the output format to json.

A.5 Evaluation and expected result

A.5.1 Primitives (Figure 13)

To run the experiment

```
$ ./scripts/singleop/run.sh
```

The script has two modes

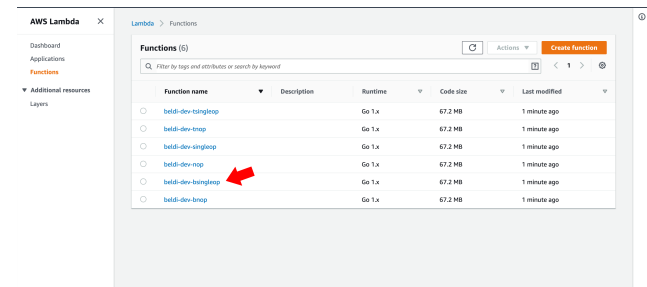

1. fast mode: less time, approximate result (around 5 min)
2. full mode: full experiment (around 30 min)

The script will ask you which mode to run when it starts.

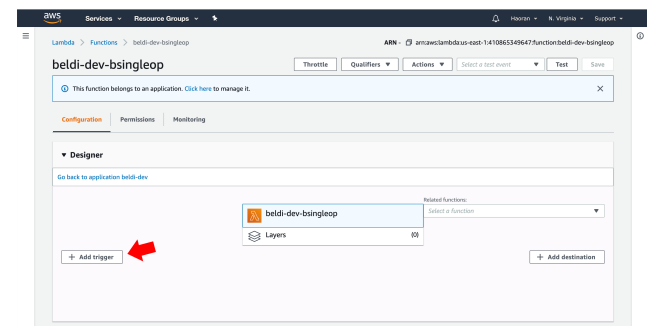

Figure 13 includes three experiments, baseline (without beldi), beldi and beldi-txn. Their function names are bsingleop, singleop and tsingleop respectively. After deployment, the script will ask for the HTTP endpoint for these three lambdas, which needs manual setup at AWS.

Take bsingleop as an example:

1. Go to the lambda console, click the function

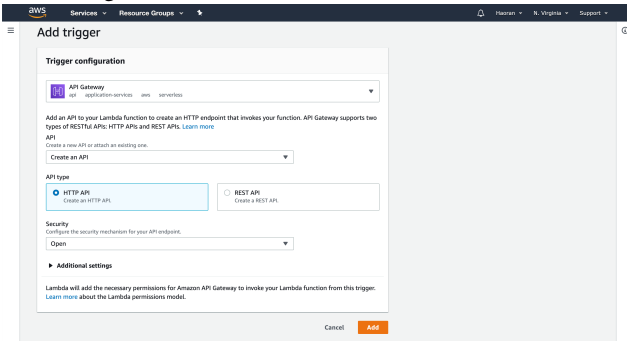

2. Click add trigger

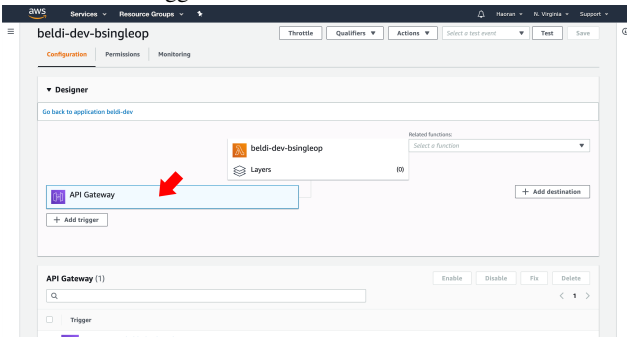

3. Choose API Gateway

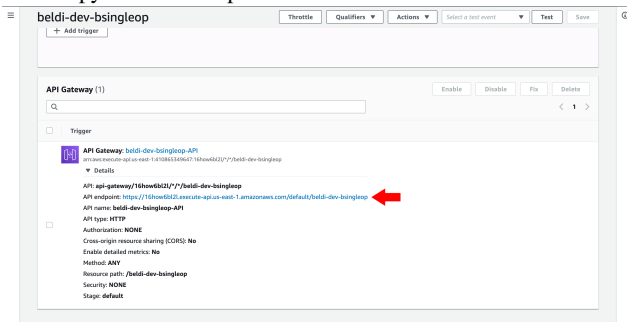

4. Configure as below

5. Click the trigger created

6. Copy the link and paste in terminal

After all three endpoints get set, the experiment will start running. The result will be saved at `beldi/result/singleop/singleop`, which can be loaded by `gnuplot`

```
$ gnuplot < scripts/singleop/singleop.pg
```

The figure will show up as `beldi/result/singleop/res.png`. You can use `docker cp` to copy it to your host.

A.5.2 Garbage Collection (Figure 10)

To run the experiment,

```
$ ./scripts/gctest/run.sh
```

The script has two modes

1. fast mode: less time, prefix of Figure 10 (around 30 min)
2. full mode: full experiment (around 150 min)

The script will ask you which mode to run when it starts.

The script compiles the code and deploys the binary to AWS. After that, it will ask for the HTTP endpoint for **beldi-dev-gctest**. The result will be saved as `beldi/result/gctest/gc`.

To generate the figure,

```
$ gnuplot < scripts/gctest/gc.pg
```

The figure will show up as `beldi/result/gctest/res.png`.

A.5.3 Movie review service (Figure 14)

Baseline.

```
$ ./scripts/media/run-baseline.sh
```

Each data point takes around 20 min.

The script will first ask you for a request rate (the default is 100). After deployment, it will ask for the HTTP endpoint for **beldi-dev-bFrontend**. When it finishes, it will print to the terminal the median and p99 latency. This result will also be saved to `result/media/baseline.json`. Alternatively, you can view the metrics on AWS CloudWatch.

Beldi.

```
$ ./scripts/media/run.sh
```

A.5.4 Travel Reservation (Figure 15)

Baseline.

```
$ ./scripts/hotel/run-baseline.sh
```

Each data point takes around 20 min.

It will ask for the HTTP endpoint for **beldi-dev-bgateway**. When it finishes, it will print to terminal the median and p99 latency. It will also save the result to `result/hotel/baseline.json`.

Beldi.

```
$ ./scripts/hotel/run.sh
```

Unearthing inter-job dependencies for better cluster scheduling

Andrew Chung^{*} Subru Krishnan[†] Konstantinos Karanasos[†] Carlo Curino[†] Gregory R. Ganger^{*}

^{*}Carnegie Mellon University [†]Microsoft

Abstract

Inter-job dependencies pervade shared data analytics infrastructures (so-called “data lakes”), as jobs read output files written by previous jobs, yet are often invisible to current cluster schedulers. Jobs are submitted one-by-one, without indicating dependencies, and the scheduler considers them independently based on priority, fairness, etc. This paper analyzes hidden inter-job dependencies in a 50k+ node analytics cluster at Microsoft, based on job and data provenance logs, finding that nearly 80% of all jobs depend on at least one other job. Yet, even in a business-critical setting, we see jobs that fail because they depend on not-yet-completed jobs, jobs that depend on jobs of lower priority, and other difficulties with hidden inter-job dependencies.

The Wing dependency profiler analyzes job and data provenance logs to find hidden inter-job dependencies, characterizes them, and provides improved guidance to a cluster scheduler. Specifically, for the 68% of jobs (in the analyzed data lake) that exhibit their dependencies in a recurring fashion, Wing predicts the impact of a pending job on subsequent jobs and user downloads, and uses that information to refine valuation of that job by the scheduler. In simulations driven by real job logs, we find that a traditional YARN scheduler that uses Wing-provided valuations in place of user-specified priorities extracts more value (in terms of successful dependent jobs and user downloads) from a heavily-loaded cluster. By relying completely on Wing for guidance, YARN can achieve nearly 100% of value at constrained cluster capacities, almost 2× that achieved by using the user-provided job priorities.

1 Introduction

Data lakes have become core elements of modern data-driven enterprises, providing required data storage and analysis infrastructure (see Fig. 1). Data lakes enhance data processing via a combination of two critical properties: (i) a highly consolidated, multi-tenant infrastructure that enables multiple teams of data scientists and engineers to share resources rather than each having their own, and (ii) low data access barriers that allow easy data sharing between users and various types of data analytics applications. Combined, these properties increase data re-use [4, 27] and reduce overall computational resource-hours consumed [31, 33].

This same data and resource sharing creates a new challenge: hidden inter-job dependencies. We say that Job 2 depends on Job 1 if Job 2 takes as input any output file generated

Figure 1: Data lake overview. Different jobs submitted by different organizations share the same compute infrastructure and read (R) and write (W) to the same storage system, thereby creating *inter-job dependencies* as jobs consume the output of other jobs. e.g., Job 2 (from Org 2) reads a file written by Job 1, so Job 2 depends on Job 1.

and stored into the shared distributed file system by Job 1.¹ For example, in Fig. 1, Job 3 (from Org 3) depends on Job 2, which in turn depends on Job 1. We refer to these as *hidden dependencies*, to contrast them with explicit computation DAGs managed by schedulers within workflow managers [30, 40, 41], because there is no indication of such dependencies indicated in the job submissions—the dependencies are not expressed to the cluster scheduler.

The advent of GDPR [56] forced large companies such as Microsoft to invest in infrastructures to track data provenance and data movement both within the data lake and to external components. This created an unprecedented opportunity to uncover and exploit these inter-job dependencies for scheduling: We analyze data extracted from petabytes of job and data provenance logs for 90 days of a 50k+ server cluster (part of Microsoft’s Cosmos data lake [6, 12]) shared by over 1300 users from more than 150 internal organizations. In total, our analysis covers over 4 million submitted jobs and 16 million inter-job dependencies. We find that almost 80% of submitted jobs depend on output generated by at least one other job. Indicating the breadth of sharing, many dependencies are cross-organization, with 20% of jobs depending on jobs submitted by another organization.

Despite so much inter-job dependence, systems provide little support for addressing associated challenges. For example, in Cosmos, different users and organizations make their own decisions regarding when to submit jobs and how to set job priorities. Ideally, all co-dependent organizations and users would set up clear Service Level Agreements among themselves to ensure timely arrival of input data for business-critical analyses. Yet, we see signs of insufficient coordination

¹Our nomenclature and analyses focus on fundamental dataflow dependencies among batch analytics jobs, not distributed stream processing or artificial inter-relationships caused by resource contention.

to ensure that jobs' outputs are produced in time for consumption by dependent jobs. For example, 13% of submitted jobs depend on output files from jobs that execute at a lower priority, which can result in priority inversion since job schedulers are not dependency-aware. More broadly, 34% of recurring jobs are submitted without checking if inputs they depend on are available, failing immediately if they are not.

The Wing dependency profiler efficiently processes prior job and provenance data to predict the impact of each new job on future jobs and user downloads. Although it is inherently difficult to know what future jobs will depend on the output generated by a current job, Wing finds success by focusing on recurrence. Previous workload studies have shown that > 60% of jobs in data analytics environments are *recurrent* and suggest that dependencies of these jobs can similarly follow certain patterns [34, 51]. Our analyses in Cosmos confirm that inter-job dependencies are recurrent (79% of all inter-job dependencies are recurrent), with jobs of the same template exhibiting recurring input consumption patterns. As such, Wing uses *historically recurring dependencies* to (i) analyze and predict relationships between common, dependent recurring jobs, and (ii) guide a cluster scheduler to value jobs in a way that accounts for hidden dependencies.

To explore Wing's efficacy, we pair Wing with stock YARN scheduling (*Wing-Agg*), replacing user-provided priorities with Wing-guided priorities. Specifically, we use number of downloads attained associated with a job's outputs as an approximation for job value,² and assign priorities to jobs based on *value efficiency* [8, 28, 44] (job-value divided by resource-time-used). We use trace-driven simulation to evaluate Wing-Agg, compared to using the user-provided priorities (as used in Cosmos), when the goal is to maximize the overall value attained. We find that Wing-guided scheduling achieves up to 66% more value than the Cosmos default, under cluster capacity crunch. Further, when organizational cluster resource boundaries are removed, a Wing-guided scheduler can achieve nearly 100% of value at constrained cluster capacities, almost 2× the value achieved by scheduling based on user-provided job priorities.

Contributions. This paper makes three primary contributions: (i) It presents the first detailed public study of hidden inter-job dependencies in a large-scale data analytics cluster, revealing important problems and opportunities; (ii) it describes a novel system for extracting historical inter-job dependencies from provenance data, at scale, and predicting the impact of a newly-submitted job on future jobs and users; (iii) it shows that use of such predictions can allow a modern scheduler, with minimal changes, to better serve the overall workload by prioritizing the highest-impact jobs.

²While job output download-counts are imperfect as ground-truth for job value, a limited check (§4.3) against known important levels for six business-critical jobs indicates that it at least sometimes behaves reasonably.

2 Hidden inter-job dependencies in Cosmos

This section describes and analyzes hidden inter-job dependencies in a large production data lake (Cosmos), highlighting observations that affect resource scheduling decisions and opportunities. It provides an overview of Cosmos and inter-job dependencies, introduces terminology used through the rest of the paper, and quantifies the prevalence and characteristics of hidden inter-job dependencies.

2.1 Cosmos

Overview. Cosmos is one of the largest big data analytics infrastructures in the world. Deployed internally within Microsoft, it is made up of multiple clusters, each with 50k+ nodes [12]. Within Cosmos, more than 80% of infrastructure capacity is dedicated to SCOPE jobs [6, 12], which are batch data analytics jobs similar in nature to Apache Spark [57] and MapReduce [14]. Our work primarily focuses on SCOPE jobs and inter-job dependencies between them.

CosmosFS and operations. SCOPE jobs submitted to a Cosmos cluster read input from and write output to a distributed file system known as the *CosmosFS*. A user can also access CosmosFS through a front-end service to upload or download files directly. We call actions performed on files in CosmosFS, either by SCOPE jobs or through the front-end, *operations*.

Continuous logging. Cosmos continuously tracks and logs data provenance and job telemetry (e.g., compute-hours, submission/completion time, and job structure metadata) into external services: *ProvRepo* stores data provenance and *JobRepo* stores job telemetry. Our analyses and Wing use these logs to figure out inter-job dependencies.

Job template vs job. A job template [32, 34] is a program to be executed (one or multiple times) in Cosmos, while a job is an actual execution of a job template. Each submission of a job template results in a job.

SCOPE job submission patterns. Common patterns used to submit SCOPE jobs within Microsoft include:

- (i) *Manual submissions*: Where a job is manually submitted.
- (ii) *Workflow managers*: Workflow managers allow users to automate SCOPE job submissions using *workflows*. Workflows consist of inter-dependent jobs that often map to a business task, and can be triggered periodically or conditionally. Within Microsoft, there are at least five major production workflow managers, each with thousands of users.
- (iii) *Custom shell scripts*: Scripts can be set up to perform automated job submissions for users. This method is more flexible, but requires specialized management.

2.2 Inter-job dependencies

How are inter-job dependencies formed? We say that a job *A* depends on a job *B* if *A* consumes *any* of *B*'s output as input. As a concrete example of a recurring cross-organization inter-job dependency, periodic jobs deployed by the data compliance team process CosmosFS access logs, which are generated hourly by the CosmosFS team, to detect data compliance

Characteristic	Description	Heuristic
Recurring	<i>Recurring jobs</i> are jobs whose template is submitted many times over time, often to analyze fresh data. <i>Recurring dependencies</i> are dependencies occurring between jobs of two recurrently-submitted job templates.	Borrowing from Morpheus [34], jobs are identified as <i>recurring</i> if (a) jobs of a template are submitted at least three times over a period of three months, with at least one submission each month, (b) templated job names are an exact match, and (c) source-code signatures are an approximate match. Dependencies are identified as recurring if both the upstream and the downstream jobs are recurring.
Ad-hoc	<i>Ad-hoc jobs/dependencies</i> are those not recurring.	<i>Ad-hoc jobs/dependencies</i> are those not identified as recurring.
Periodic jobs	<i>Periodic jobs</i> are recurring jobs that are submitted “on-the-clock” at a fixed cadence (e.g., submitted every hour at the start of the hour).	Jobs of a template are identified as <i>periodic</i> if they are recurring and if job submissions have near-constant inter-arrival time. To determine if inter-arrival times are near-constant, we use the coefficient of variation (CV). Jobs with small CV in their inter-arrival times are identified as <i>periodic</i> , while others are <i>aperiodic</i> .
Polling	Jobs are <i>polling</i> if they scan and wait for their inputs to become available before their submission. Input dependencies of polling jobs are similarly polling.	Jobs are identified as <i>polling</i> if they (a) are not identified as periodic, indicating that they are not submitted on a clock, (b) never fail due to missing files from their recurring upstream jobs, and if (c) they are submitted within 15 minutes of the completion of their latest-completing dependent job. Input dependencies of a polling job are <i>polling</i> .
Hard dependencies	Dependencies are <i>hard</i> if the downstream job requires the output(s) of the upstream job to be able to run successfully. If the input(s) of the downstream job is not ready by the time of its submission, the downstream job fails with a missing file exception.	Dependencies are identified as <i>hard</i> if they are (a) ad-hoc, (b) recurring and > 95% of jobs of the same template consume the output of only one job of the same upstream job template, or (c) if the downstream job consumes the output of the same number of upstream jobs of the same job template all the time, indicating that they expect the same number of inputs from the same number of jobs from the upstream template.

Table 1: Summary of and heuristics to identify and characterize job and dependency types.

issues. There are many ways inter-job dependencies can form, and while some inter-job dependencies form through careful negotiation between users/organizations, most are formed *organically*, such as via:

- (i) *Data discovery through data catalogs*: A user finds an interesting dataset while browsing through Microsoft’s internal data catalog, and sets up a job to analyze the dataset.
- (ii) *Script inheritance*: A user wanting to submit a SCOPE job to analyze a popular dataset often starts with a script written and shared by others, that contains logic to extract the dataset. The new script, while containing custom logic, often retains parts of the original script (e.g., priority settings).
- (iii) *Logically related intra-workflow jobs*: Workflows, which can consist of multiple inter-connected jobs, are often constructed to improve job modularity and manageability. Each run of a workflow potentially creates many inter-job dependencies, as jobs within a workflow are inter-dependent. Note that, although a workflow manager may know about these inter-job dependencies, there is no interface for a workflow manager to express them to Cosmos.

Characteristics of jobs and dependencies. Our analyses uncovered a few major types of dependency and job characteristics based on job submission patterns (Table 1). The three most important job and inter-job dependency characteristics for our purposes are *recurring*, *ad-hoc*, and *hard*.

Challenges. Among the many ways in which inter-job dependencies can form and evolve, most promote loosely maintained (or non-existent) contracts between inter-dependent jobs in favor of developer convenience. This leads to an environment in which most users know little about upstream jobs that produce their input datasets, and even less about downstream jobs that depend on the data their jobs produce. These sub-optimal inter-job dependency configurations are often only exposed as a result of capacity impairment, unexpected

job failures, or data/job audits. Indeed, inter-job dependencies are *hidden* through the availability of the many disaggregated solutions to manage and submit jobs and workflows, prompting us to develop Wing to uncover these dependencies.

2.3 Observations on inter-job dependencies

This section motivates our work on exploiting inter-job dependencies by describing consequential empirical observations about our inter-job dependency data, observed over three months in a single Cosmos cluster.

Observation 1 (Recurring jobs & dependencies): Most jobs and dependencies are recurring. Recurring jobs make up 68% of all submitted jobs (the other 32% of jobs are ad-hoc), while recurring dependencies make up 79% of all dependencies (the other 21% of dependencies are ad-hoc). Recurringness of jobs and dependencies suggest predictability, which we show to be achievable in §3.

Observation 2 (Priority mis-configurations): In Cosmos, jobs are assigned resources in declining priority order, where the priority of a job is assigned by the job’s submitter. Here, we find that potential priority mis-configurations are frequent within Cosmos: jobs of 21% of job templates have the chance to be systematically priority-inverted—i.e., recurring jobs consuming their output have a higher priority. In addition, up to 33% of ad-hoc jobs are assigned higher priority than the average recurring job submitted within the same hierarchical queue,³ where recurring jobs are often production jobs [34].

Observation 3 (Uncoordinated jobs): Many jobs are submitted without explicit coordination with respect to the completion of their upstream jobs—i.e., these jobs do not wait for their input to become available nor are tolerant to missing input, yet they are submitted blind with respect to the avail-

³*Hierarchical queues* designate resource shares of an organization in clusters at Microsoft. Priorities are only comparable between jobs in the same queue.

ability of their inputs. Such jobs make up 34% of recurring jobs, and can be susceptible to failure due to missing input from an upstream job not completing in time.

Observation 4 (Cross-org jobs & dependencies): Cross-org jobs and dependencies are common at Microsoft. Up to 95% of organizations have cross-org dependencies. Of all dependencies, 33% are cross-org, and 17% of template dependencies are cross-org, where a *template dependency* is a dependency between recurring jobs of two job templates. Furthermore, 28% of jobs and 23% of recurring jobs are involved in cross-org dependencies. Cross-org dependencies can be harder to manage because they require coordination between jobs across hierarchical queues and between job owners across different organizations.

Observation 5 (Jobs are highly inter-connected): Modeling jobs and their dependencies as a directed acyclic graph (DAG), where inter-job dependencies represent edges, we find that more than 50% of jobs are inter-connected in a single weakly connected component (CC), and CCs of sizes ≥ 10 cover more than 80% of all jobs. We also find that the larger a CC, the more bottom-heavy it is—the failure of certain jobs in such large CCs can cause significant amounts of cascading failure downstream.

Observation 6 (Many jobs can be load-shifted in time): Analyzing when the outputs of jobs are consumed by both downstream jobs and users, we find significant opportunity to delay, or load-shift jobs in time, which allows cluster operators to mitigate capacity crunches or reduce power cost [2, 3, 36]. A job has the potential to be able to be load-shifted by up to T hours if it is (1) recurring, (2) has a gap of $> T$ hours before its output(s) are consumed, and (3) has run times of $< T$ hours. (1) allows the job to be identifiable in the future, and (2) and (3) ensure that the job has enough slack to be safely delayed by up to T hours. We find that 31, 27, 22, and 14% of all jobs can be potentially load-shifted by up to $T = 1, 3, 6$, and 12 hours, respectively.⁴

Discussion. We have seen failure due to lacking input and priority inversions happen during manual inspection of job logs and dependency graphs, but we can not provide counts. We have also seen that: (1) users can and do fix their jobs, sometimes at the cost of sub-optimal performance and results, to work around issues, such as by consuming stale data; and (2) some of these problematic inter-job dependencies can be masked with sufficiently available resources. A better understanding of inter-job dependencies can help us uncover problematic mis-configurations before they show up.

3 Inter-job dependency predictability

Inter-job dependencies show potential in guiding scheduling; but it is unrealistic to expect job submitters to provide all inter-job dependencies up-front due to the fragmented nature of inter-dependency knowledge (§2.2). While *inter-job*

⁴While load-shifting is an interesting topic for future research, we do not directly address methods for load-shifting in this paper.

dependency recurrence shows promise, for Wing to effectively guide schedulers with inter-job dependencies, recurring inter-job dependencies also need to be *predictable*—i.e., it is important that past dependencies tell us something about the future. In this section, we use a simple model to predict future occurrences of recurring inter-job dependencies, and show that inter-job dependencies can be predictable.

3.1 Prediction model

Given a specific point in time where a job j_u of template J_u ($j_u \in J_u$, where the symbol “ \in ” is used as shorthand for “of instance”) has arrived, for each recurring job template J_d that depends on the output of template J_u in a recurring fashion, our prediction model has two targets: (T1) *whether or not* a recurring job $\in J_d$ will arrive and depend on j_u in the future and (T2) *when* the first instance of such a job will arrive.

Model for (T1): Will a downstream recurring job arrive?

For (T1), our model uses a configurable *prediction threshold* $tr\%$ ranging from 0 to 100 to predict whether or not a job $\in J_d$ will arrive: If $\geq tr\%$ of prior jobs $\in J_u$ have their outputs consumed by a job $\in J_d$, then the predictor predicts `true`; otherwise it predicts `false`.

Model for (T2): When will a downstream job arrive?

For (T2), our model aggregates previously observed recurring dependencies where the upstream job $\in J_u$ and the downstream job $\in J_d$, and computes the median elapsed time from the *submission* of the upstream job to the submission of the first dependent downstream job.

3.2 Predictability evaluation

Dependencies change slowly over time. Dependency patterns of recurring jobs change slowly over time, and making predictions based on inter-job dependencies over longer periods of time presents challenges. For example, in (T1), using a month of inter-job dependency data to train our model to predict the arrival of dependent jobs occurring in the next month only allows us to capture at most 77% of upcoming jobs. Regularly training our model on a week of data to predict for the next week works comparatively well, because (1) it allows us to capture up to 95% of upcoming jobs and (2) it allows us to characterize the dependencies of 89% of job templates (covering 97% of all jobs), since jobs of most templates are submitted with an inter-arrival time of less than a week (with daily submissions being the most common).

(T1) metrics and model performance. We evaluate the prediction quality of our model on (T1) based on precision⁵ and recall.⁶ Fig. 2 examines the tradeoff between precision and

⁵*Precision* is defined as the number of true positives (TPs) divided by the sum of TPs and false positives. Precision can be thought of as the percentage of positive predictions our model makes (i.e., a downstream job will arrive) that are truly relevant (i.e., such a downstream job actually arrives).

⁶*Recall* is defined as TPs divided by the sum of TPs and false negatives. Recall can be thought of as the percentage of relevant results that our model is able to correctly predict.

Figure 2: (T1) precision-recall tradeoff. *Predictor* shows the precision-recall tradeoff our dependency-based job arrival predictor makes. Each point on the curve specifies a different setting for the prediction threshold (tr). As $tr \rightarrow 100\%$ (more selective), a larger fraction of predictions are relevant (more precision), but less relevant jobs are captured in total (less recall).

recall for our model using various settings for the prediction threshold tr . As the model becomes more selective with respect to which downstream jobs will arrive ($tr \rightarrow 100\%$), it retains less relevant dependencies in total, but the dependent recurring jobs it predicts to arrive mostly do show up. The reverse is true as the model becomes less selective ($tr \rightarrow 0\%$).

We discuss the evaluation of our model based on a threshold that balances precision and recall. A common way to identify such a threshold is to select the threshold that maximizes *precision * recall*. We find that $tr = 20\%$ yields the greatest *precision * recall*, and therefore evaluate our model by setting $tr = 20\%$. The threshold used in an online prediction service can similarly be tuned from week-to-week based on observed precision and recall, though the specific target to optimize depends on the penalties associated with making mistakes in recall or precision.

(T2) metrics and model performance. To evaluate the performance of our model on predicting *when* a downstream job $j_d \in J_d$ will arrive at the arrival time of an upstream job j_u , j_d must satisfy two conditions: our model must predict j_d to arrive based on jobs that have already arrived during a point in time in the execution trace *and* it must actually arrive. Our evaluation focuses on jobs that satisfy both above conditions.

To evaluate the performance of our model for (T2), we use the *Root Mean Squared Error (RMSE)* and the *Median Absolute Error (MAE)* metrics to measure prediction error in absolute time units. RMSE measures error by computing the root of the average of squares of errors, while MAE measures error by computing the median of absolute error = $|forecast - actual|$, over all predictions. To measure relative error, we use the *percentage error* metric: it computes $(forecast - actual)/actual$ for each prediction.

While we discuss the evaluation of our model on (T2) setting $tr = 20\%$, we find that confidence in job arrival prediction only slightly affects time-to-dependency prediction quality. This does not mean that the setting of tr is inconsequential, as tr affects the predictions of whether or not a job will arrive. Here, we evaluate the time-to-dependency predictions only for jobs that are both predicted to arrive *and* actually arrive.

Figure 3: (T2) Time-to-dependency (TTD) prediction. This figure shows our predictor’s performance on predicting TTD from the submission time of the upstream job, at different settings of tr in a CDF. f is the *forecasted* TTD, and a is the *actual* TTD. While being more precise ($tr \rightarrow 100$) does not yield better TTD predictions, it does affect predictions on whether or not a job will arrive.

We observe the RMSE and MAE of our model to be 2.5 hours and 22 minutes, respectively: MAE is smaller, as RMSE can be skewed by large mis-predictions at the tail. While our absolute errors can be improved using more sophisticated techniques, we find that our model predictions are reasonable for most jobs in our workload in terms of relative error, as shown in Fig. 3 in the form of a cumulative distribution function (CDF), for different settings of tr : the arrival of 50% of arrived jobs $\in J_d$ are predicted within $\pm 20\%$ of its actual arrival. But, there is also a non-trivial number of significant over-estimates: the arrival of 7% of arrived jobs $\in J_d$ are over-estimated by $2\times$ or more—i.e., the actual jobs arrive more than $2\times$ earlier than predicted. While this may not explain all mis-estimations, we have found that aperiodic recurring jobs (such as those that are manually triggered) and jobs that depend on the outputs of multiple jobs are prone to greater mis-estimates (our simple model presented here only tries to predict the arrival of a future job based on one of its directly upstream recurring jobs).

4 The Wing dependency profiler

This section describes Wing, an end-to-end dependency profiler meant to be run intermittently (e.g., weekly) that uncovers historical, hidden inter-job dependencies from data provenance logs. It performs a series of analyses using these inter-job dependencies in-tandem with historical job telemetry, yielding characterizations of jobs and inter-job dependencies such as signs of misconfigured priorities between recurrently-dependent jobs (§2.3), predictability of upcoming jobs (§3), and estimates of recurring jobs’ aggregate value considering their impact on downstream jobs that rely on their outputs, directly or indirectly (§4.3). These characterizations are ultimately used to inform better scheduling decisions, where its benefits are explored in more detail in §7.

4.1 Architecture

First, we introduce related systems and data sources upon which Wing depends, and provide an overview of Wing’s architecture, shown in Fig. 4.

Input data sources. Wing relies on the following data sources, from which we derive job dependencies and insights thereof: (i) *JobRepo* preserves job telemetry (e.g., compute-hours, submission/completion time, and job structure meta-data) for submitted jobs. Wing uses JobRepo to derive recurring jobs and their historic statistics. (ii) *ProvRepo* tracks data provenance across Microsoft to support auditing and compliance applications [56]. Specifically, it stores data provenance across systems deployed within Microsoft, including but not limited to Cosmos. ProvRepo is used by Wing to uncover historic inter-job dependencies, and from there, infer recurring dependencies between recurring jobs.

Analysis pipeline. Wing’s data analysis pipeline, primarily composed of a workflow of inter-dependent SCOPE jobs, is managed by a workflow manager and is periodically executed in Cosmos. The pipeline reads data from JobRepo and ProvRepo and writes its output to be consumed by WingStore.

WingStore. The *WingStore* is a service that hosts the resulting analyses of Wing’s analysis pipeline, periodically renewed each time a new instance of the pipeline completes. Given a historical job or the identifier of a recurring job, one can look up relevant historical job and inter-job dependency data: Such historical job data include, but are not limited to, distributions of job runtime and compute-time used. Historical inter-job data include distributions of job fan-in/fan-out, recurring inter-job dependencies, and distributions of number of downstream jobs. The WingStore is the interface between Wing’s analysis and a Wing-guided resource manager.

4.2 The Wing pipeline: Single-hop analysis

Wing considers both *single-hop* and *multi-hop* dependencies in its analyses. The former occur when jobs directly consume the output(s) of another job. The latter are indirect dependencies between jobs that are connected by means of intermediate jobs. Here, we focus on the derivation of single-hop dependencies, which multi-hop dependencies are built upon, from historical provenance data stored in ProvRepo.

Single-hop dependency derivation. To derive single-hop dependencies from provenance data in ProvRepo (stored roughly in the form of `<input, operation, output>`, but with much more detailed context), we perform a self-join on the ProvRepo dataset with the condition of $p_1.\text{input} = p_2.\text{output}$. A naïve self-join across multiple months of data is extremely compute intensive and can yield incorrect results, as a single file can be written multiple times by different jobs. To reduce join complexity and ensure correctness, we apply the following additional rules on the join:

- (1) *R/W correctness*: The read must occur after the write. i.e., $p_1.\text{operation}$ must occur after $p_2.\text{operation}$.
- (2) *Last-writer wins*: If multiple writes occur on a single file, the read only depends on the latest write prior to the read.
- (3) *Time windowing*: The time between the read and the write

Figure 4: Wing architecture. A workflow manager periodically submits Wing’s pipeline to Cosmos. Upon pipeline completion, results of its analyses are loaded in to WingStore, which informs Wing-guided schedulers (§6.2) with job and dependency characteristics.

operations are at most T days, where we set $T = 30$.⁷

Time windowing can reduce join complexity and allow our analyses to account for inter-job dependencies more *fairly*—if time windows are not applied over an observation period, operations issued earlier necessarily have a higher chance to be depended-upon. In other words, for each operation between days 31–60⁸ in our dataset, time windows give them equal opportunity (in wall-clock time) to be depended-upon by directly-dependent operations.

Heuristics to identify recurring jobs & dependencies. A key to the analyses that we perform is the identification of recurring jobs, for which we employ the time-tested heuristic proposed in Morpheus [34] and applied in multiple production environments [34, 51]. Through the identification of recurring jobs and uncovered single-hop dependencies, the Wing pipeline further derives recurring dependencies and uncovers dependency characteristics of jobs using similar heuristics, described in Table 1. While ideally, we would like the full semantics of how inter-job dependencies are formed, due to the availability of the many different ways to submit a job (§2.1), our usage of heuristics is necessary. Sampling 25 jobs for manual verification, we confirm that our heuristics categorize jobs and dependencies correctly for 24 of the jobs.

4.3 Motivating multi-hop analysis: Job valuation using aggregate downloads

Companies can benefit more from their infrastructure investment through effective scheduling that prioritizes the completion of the most valuable jobs. But, often times, inter-job dependencies have not been considered when evaluating the importance of jobs—e.g., a job with high value can potentially depend on jobs with low value. In these cases, inter-job dependency awareness is key to ensure that upstream jobs do not disrupt high-value downstream jobs. Here, we look at why inter-job dependency analyses beyond direct dependencies (i.e., *multi-hop analyses*) can inform better, dependency-aware

⁷In retrospect, we should have set $T = 31$ to capture all monthly cycles, but our results based on $T = 30$ remain valid because (1) 98% of dependencies occur within a week, and (2) jobs of 89% of templates (97% of all jobs) have mean inter-arrival times of less than a week.

⁸Operations between days 31–60 are analyzed because we observe fully over time windows of 30 days both operations they depend on (days 1–30) and those that depend on them (days 61–90).

valuation of jobs to improve scheduling, and explore using the *number of downloads attained* associated with the outputs of a completed job as a proxy-metric for job value.

Priority assignments. To prioritize jobs today, schedulers in most production data analytics environments, including in Cosmos, use priority assignments to determine a job’s order in its claim to resources. In this context, the notion of job value is often translated into a priority assignment on the job—the greater a job’s value, the higher its priority. However, priorities in clusters are difficult to set correctly (Observation 2), and even at Microsoft, whose multi-billion dollar clusters are carefully provisioned and whose user-base is highly skilled, incidents triggered by late completion of hand-picked, closely monitored, and highly valued production jobs still occur due to mis-configured priorities.

Multi-hop value impact. The completion of a job can often be associated with some measurement of monetary value to a company. For example, jobs computing Bing’s search indices directly impact the revenue of Microsoft. We term the direct value associated with the completion of a job its *job-local* value. However, the delay or failure of a job may not only affect its users and consumers of its output: through analyses of Cosmos’s job DAG (Observations 3 and 5), we find that the delay or failure of certain jobs impact a lot more jobs and users than others. Hitches in the execution of these jobs are likely to cause much more financial and operational damage to users and organizations within the company due to the ripple effects they can create downstream, yet their impact might not always be obvious. While prior work [18, 34] suggest that finishing jobs prior to the arrival of their first directly-dependent job is important, quantifying the *aggregate value* of a job necessitates inter-job dependency analyses extending beyond a single hop (i.e., *multi-hop analyses*). Fig. 5 shows a toy example that computes such an aggregate value for the root job of a dependency tree.

Approximating value impact with agg. downloads. Although determining the true dollar-value of jobs is difficult, we find it promising to evaluate the importance of jobs based on their historical *aggregate user downloads*, which measures hypothetically if a job fails, how many download operations it will affect (directly or indirectly) in total. In developing Wing, we have also experimented with several alternative metrics e.g., sum of cpu-hours and number of downstream jobs. Number of downloads was preferred by our resource management team because file downloads (1) are the most direct way users interact with a job’s output; (2) can be easily interpreted and understood; and (3) because file downloads can be used to quantify how soon the output(s) of a job are used upon its completion. The properties of file downloads allow aggregate download counts to provide a proxy-measure to how the delayed or failed outputs of jobs can impact users in and out of Microsoft. Aggregate download counts also implicitly capture the number of downstream jobs that can be impacted by the failure of a job through their associated output downloads.

Figure 5: Value aggregation and value decay. In this toy example, jobs A–E are submitted at strict, absolute times, where the x-axis denotes time relative to the submission of job A. B and C have hard dependencies on A, and D and E have hard dependencies on C. The aggregate value of A is the sum of the aggregate values of B and C and A’s own job-local value. With Wing, we can model how the aggregate value of A decays as it fails to complete by the time its downstream jobs arrive, losing the value of B at the time of B’s submission, and collectively losing the values of C, D, and E at the time of C’s submission (D and E depend *indirectly* on A through C, so if C fails, D and E will also fail). In this example, A retains its job-local value until the end.

While further work is required to confirm that aggregate download counts represents job value and to explore how it should be combined with other signals (e.g., user-provided priorities), we use it in this paper as our approximation of value.

Sanity-checking aggregate downloads as job value. We conducted a sanity check, using aggregate download counts for job valuation to see how it matches up with pre-existing notions of job importance. To that end, we obtained a list of six recurring job templates hand-curated by the Cosmos resource management team at Microsoft, each vetted to be significantly important to Microsoft’s operation. We then look at Wing’s ranks of those jobs.

Our results show that our valuation scheme mostly holds up for the most important jobs: We find that jobs of five of the six templates are consistently ranked by our scheme to be among the top 4% of all jobs submitted, with jobs of one template still ranking in the top 11%. We also measure relative rankings by user-specified priority and by our heuristic among jobs submitted to the same organizational queue, since priorities are only relevant when compared to other jobs sharing the same queue. For four out of the six hand-curated job templates, Our heuristic produces organizationally-relative rankings within 5% of priority assignment rankings. For one of the six job templates, our valuation scheme produces a ranking lower than that produced by priority assignments by up to 11%. For the last of the six job templates, however, we produce a ranking *higher* than that produced by priority assignments by 50%. This is surprising because we expected priority assignments for these six job templates, which are all verified to be highly important, to be extremely well-tuned, with highly-ranked priorities assigned to jobs of all six templates. Yet, jobs of the last template are only ranked at the 49th

percentile of all submitted jobs within its queue by priority assignment—this mis-configuration may lead to significant issues once the queue becomes more heavily-loaded.

Future work: Further validating agg. downloads as value.

We acknowledge that accurate job valuation is a difficult problem that requires further study, and that different companies can have different notions of job value. While further efforts are ongoing at Microsoft to validate the efficacy of our job valuation scheme (e.g., conducting surveys of Cosmos users), Cosmos’s resource management team has noted that our valuation scheme is better than any of their existing heuristics used for job valuation, and are considering adopting it to aid in rolling out job upgrades and using it as a weighting function to report certain cluster performance indicators (e.g., reliability).

4.4 The Wing pipeline: Multi-hop analyses

Wing provides a flexible iterative solution implemented on top of SCOPE for performing *downstream multi-hop analyses*, in which for a given job, we analyze properties of its directly and indirectly-dependent jobs. Provided a set of single-hop inter-job dependencies, our framework allows the computation of both the transitive closure and aggregate statistics of all sub-DAGs rooted at each job in an inter-job dependency DAG (defined in Observation 5). Such multi-hop analyses are important to effectively guide scheduling decisions, as it can compactly characterize each job’s downstream impact: i.e., if a job fails or is delayed, how will its downstream jobs and users be affected (§4.3)? Our framework generalizes the algorithm proposed in Owl [9], which allows multi-hop dependency analysis to be applied to other applications, e.g., fixing priority inversions⁹ for Cosmos jobs.

Algorithm input. Our algorithm input is a single-hop job dependency DAG specified as a relational table, where the first column (*job*) holds the dependent job and the second column (*depOn*) holds the depended-upon job.

Algorithm output. Our algorithm outputs a relational table describing multi-hop dependencies. The first column (*job*) holds the downstream job, the second column (*depOn*) holds the (potentially multi-hop) upstream job, and the third column (*agg*) holds Wing-computed weights aggregated along all paths between the pair of up/downstream jobs.

Aggregation Functions (AFs). Each downstream multi-hop analysis specifies the following *Aggregation Functions* (AFs):

- *Weight function* (*wt_fn*): *wt_fn* takes in a job and its in- (or out-) edges as input, and outputs a weight *wt* for each graph edge. This operation is done once to convert the input DAG into an edge-weighted DAG.
- *Edge operation* (*e_op*): For two vertices *t* and *v* connected by an intermediate vertex *u*, *e_op* performs an aggregation of

weights between a pair of (potentially auxiliary) in- (*t*, *u*) and out-edges (*u*, *v*) of *u*, constructing a new auxiliary weighted edge connecting *t* and *v*. Specifically, it computes the weight for an auxiliary edge based on new edges explored in each iteration between two indirectly connected jobs. This operation should be *distributive* over the *p_op* (defined following).

- *Path operation* (*p_op*): *p_op* aggregates weights on all explored paths between two jobs. While a unique path cannot be explored multiple times, the algorithm can make multiple traversals and aggregations between the same pair of up- and downstream jobs if multiple paths between two jobs exist. This operation should therefore be *associative*.

- *Downstream operation* (*ds_op*, optional): The downstream operation is the last step performed, after our iterative algorithm converges. For a job, it performs an aggregation on all of its downstream jobs and aggregated path weights.

Algorithm outline. We first preprocess the job dependency DAG with the AF *wt_fn* to generate the DAG edge weights *wt*. Then, for each job in parallel, our algorithm traverses the DAG and computes transitive closures along all paths, maintaining an “aggregated version” of *wt* using *e_op* and *p_op* along the way. Our algorithm completes in $O(\log(\text{diameter}))$ iterations, where *diameter* is the longest path in the DAG. In each iteration, the algorithm maintains a *frontier* and a *base* table, both with the schema (*job*, *depOn*, *wt*). The frontier table records the set of discovered furthest reachable upstream jobs by *job* in *depOn*, while the base table records the set of all discovered reachable upstream jobs by *job* in *depOn*. The *wt* column of both tables records the aggregated weights along discovered paths from *job* to *depOn*. Each iteration joins and updates the frontier and base tables, extending the “reach” of each job by a maximum of 2×. Our algorithm pseudocode is shown in Algorithm 1.

4.5 Job value aggregation with Wing

4.5.1 Job value aggregation properties

Fair multi-hop time windowing. Aggregating value directly on even a single-hop time-windowed job dependency graph has a critical shortcoming: when considering multiple hops, jobs at the start of the observed trace still hold an advantage over jobs toward the end of the observation window in terms of opportunities to have their multi-hop downstream dependencies also land in the observation window. To better illustrate this, suppose we are given a recurring job template *X* with multiple jobs in our observation window. While ideally all jobs of *X* should have similar amounts of downstream dependencies, jobs of *X* that occur earlier in the trace are more likely to have their downstream dependencies also observed in the trace, while later jobs of *X* in the trace are more likely to have their downstream dependencies cut off due to the limits of using a static-length trace. In the limit of using an infinitely long trace, no time windowing is necessary.

A *multi-hop time window* is therefore needed to further

⁹Wing can fix priority inversions by raising the upstream job’s priority before its dependent high-priority job arrives. Traditional OS methods require both jobs to have arrived at the scheduler, and dependency between the two jobs is communicated through concurrency data structures (e.g., locks). There is no lock-equivalent in Cosmos’s scheduler.

```

// Helper functions
1 Function preprocess(s_hop) is
2   gp_by_job = job  $\mathcal{G}$  wt=wt_fn(depOn)(s_hop);
3   return  $\pi$  job, depOn=wt.s.depOn, wt=wt.s.weights(gp_by_job);
4 end
5 Function extend_reach(t1, t2) is
6   e_agg =  $\pi$  t1.job, t2.depOn, wt=e_op(t1.wt,t2.wt) (
7     t1  $\bowtie$  t1.depOn=t2.job t2);
8   return job, depOn  $\mathcal{G}$  p_op(wt) (e_agg);
9 end
// Computation start
Input: s_hop // Single-hop dependencies
10 i = 0; // Iteration
11 ftr_i = preprocess(s_hop); // Frontier
12 base = COPY(ftr_i); // Base
// base at the end of iter i covers deps up to 2i hops
13 do
14   i++;
15   base_tmp = base - ftr_{i-1};
16   ftr_i = extend_reach(ftr_{i-1}, ftr_{i-1});
17   base_tmp = extend_reach(ftr_{i-1}, base_tmp)  $\cup$  base;
18   base = job, depOn  $\mathcal{G}$  wt=p_op(wt) base_tmp;
19   base = base  $\cup$  ftr_i;
20 while COUNT(ftr_i) > 0;
21 return job, depOn  $\mathcal{G}$  agg=p_op(wt) base; // Converged

```

Algorithm 1: Multi-hop downstream analysis framework. preprocess first assigns weights to DAG edges with wt_fn. In each iteration, it calls extend_reach to further explore the graph from each job in parallel. In extend_reach, auxiliary edges with edge weights specified by e_op are created to denote newly discovered indirect dependencies (through the JOIN, or \bowtie operator). The auxiliary edges are deduplicated with a GROUP BY (\mathcal{G}) operator at the end of each iteration, yielding edge weights of p_op(wt).

restrict the set of jobs eligible for value aggregation. Our multi-hop time windowing method works as follows: we first define a time window size ω smaller than the observation period. For each *valid* job j in the trace, we consider its entire set of directly and indirectly dependent jobs that are submitted by up to ω after its completion time. Here, we define valid jobs as jobs that complete at least ω prior to the end of the observation period. We set ω to *one week* for multi-hop dependency analysis, as the scale of the inter-job dependency graph bottlenecks transitive closure computation as ω increases: increasing ω exponentially increases the number of multi-hop inter-job dependencies to consider, as dependencies fan-out further into the future. ω is set to a week here to capture the majority of recurring dependencies that occur on a sub-weekly cadence (most recurring templates are submitted with inter-job arrival times of a day or less), while allowing our entire analyses pipeline to finish in approximately a day.

Value conservation. To conserve the total amount of value in the system, we employ an *equal contribution* scheme proposed in Owl [9], where each job contributes value to its directly-dependent upstream jobs equally, and the aggregate value of a job in this scheme is computed as the sum of value contributed upstream by all of its downstream jobs plus the value of the job itself. In this scheme, if a job j depends directly on the output of N jobs, it contributes $1/N$ of its

value to each of its jobs directly upstream. Each of the N upstream jobs in turn further propagates j 's (and their own) value upstream in the same fashion; e.g., if each of the N jobs directly depend on the output of M other jobs, j contributes $1/(N * M)$ of its value to each of the $N * M$ jobs two hops upstream. This yields the following equation, as proposed in Owl [9], for computing the aggregate value of a job:

$$agg_val(j) = \sum_{d \in \mathcal{D}_j} \left(\sum_{p \in \mathcal{P}(j,d)} \prod_{e \in p} w_e * k_d \right) + k_j,$$

where \mathcal{D}_j represents *all* downstream jobs of j , $\mathcal{P}(j,d)$ represents all paths from j to d , w_e represents the weight of a directed edge e on the path p , and k_d and k_j represent the job-local values of d and j , respectively.

4.5.2 Wing value Aggregation Functions

We implement Owl's dependency-driven job valuation scheme with Wing's downstream multi-hop analysis framework, specifying Aggregate Functions as follows: the *weight function* wt_fn takes in a job j and its N upstream dependencies as input, and returns $1/N$ as the weight of each in-edge; the *edge operation* e_op multiplies the weights of its two operands; the *path operation* p_op sums the weights of its operands; and finally, for each job j , the *downstream operation* ds_op sums the job-local downloads of each job downstream of j multiplied by the aggregated path weights between the downstream job and j . j 's job-local downloads are finally added to the downloads computed by ds_op, yielding j 's aggregate downstream downloads.

Extensibility. While we elect to use downloads as a proxy for job value, Wing's framework is flexible enough to consider other metrics: e.g., if one day the dollar value associated with a job can be known, computing the aggregate downstream dollar value of a job is as easy as replacing a field in ds_op.

4.5.3 Aggregate value exploration and convergence

Using downloads as a proxy-metric for value, Fig. 6 shows the fraction of aggregate value explored in each iteration for each job on average. Considering the aggregate value of jobs with Wing allows us to uncover 83% of value that would otherwise be hidden if only job-local values (*iteration* = 0) were considered. In the context of value-based job scheduling (§5), this means that nearly 6 \times of value can be hidden from the scheduler if jobs are independently considered. The figure also shows that 99% of average job aggregate value can be explored within four iterations of our algorithm.

5 Wing-Agg: Inter-job value scheduling

Value scheduling. The objective in *value scheduling* is to maximize the value achieved from executing jobs in a workload, where the completion of each job is directly associated with an amount of *job-local value* attained. Job-local value can decay over time, and this behavior is often modeled as a *value function* (VF) in scheduling literature, which expresses value attained as a function of job completion time. In value

Figure 6: Aggregate value convergence. This figure shows the fraction of average aggregate job value uncovered downstream in each iteration of our value aggregation algorithm. 99% of aggregate value is discovered within four iterations.

scheduling, it is therefore important to complete jobs in a timely manner to achieve the most value.

Value and priority. We make a clear distinction between the terms *value* and *priority*. In this paper, we use the term *value* to describe a measure of “goodness” achieved associated with the completion of a job. *Priority*, on the other hand, defines the order in which pending jobs are assigned cluster resources: the higher the priority, the earlier a job receives its requested resources. Most commonly, including currently within Cosmos, the priority of a job is assigned by its submitter.

Wing-Agg. When inter-job dependencies are present, we find that it is important to consider the potential value downstream that can be lost if a job fails or is delayed. To consider the effects of inter-job dependencies, we propose a scheduling policy, *Wing-Agg*, that incorporates Wing’s notion of inter-job dependencies into job priorities: *the goal of Wing-Agg is to achieve the most value for a given workload*.

As suggested in the introduction, completing the most value-impactful job may not lead to a scheduler attaining the most value, as some value-impactful jobs can also require large amounts cluster resource-time to complete. Indeed, prior work [8, 28, 44] has shown that schedulers can often benefit by considering together how much value a job provides and how much resource-time a job uses.¹⁰

Wing-Agg therefore considers the *aggregate value efficiency* of jobs, which measures how much aggregate value per aggregate resource-time a job impacts downstream. Essentially, Wing-Agg replaces user-assigned priorities with what Wing believes is a job’s aggregate value efficiency. When a job arrives, Wing-Agg performs a look-up in the Wing-Store (§4.1). If the job is recurring, Wing-Agg computes the job’s aggregate value efficiency by dividing the job’s median historic aggregate value by its median historic aggregate compute-time, and assigns the quotient as the job’s priority. If the job is ad-hoc, Wing-Agg estimates the job’s aggregate value efficiency based on previous ad-hoc jobs that the same user has submitted. Wing-Agg assigns aggregate value efficiency rather than aggregate value as jobs’ priorities to optimize for high value throughput.

¹⁰ Although Wing-Agg and shortest-job-first both use job resource-time in their decisions, Wing-Agg frequently runs longer, more value-providing jobs ahead of shorter jobs.

6 Experimental setup

This section provides an overview of the Cosmos resource management infrastructure, describes our evaluated scheduling policies, and describes our experimental methodology.

Downloads attained as value. In our experiments, we use the number of downloads associated with the outputs of each job as a proxy for the value attained by a job. We model download attainment using real-world output download traces: if a job j completes at 1PM in the real-world (from the trace) but only completes at 2PM in our experiment, j attains only the output downloads associated with its outputs that occur after 2PM, and loses the downloads that occur between 1 and 2PM. A limitation of our model of value is that it does not reward completing a job early. Further research is required to determine how much additional value the early-completion of a job yields in data lakes.

Cosmos backend: YARN and hierarchical queues. Cosmos uses a *YARN-based resource manager* [12, 54] in the backend and utilizes *hierarchical queues* (queues, for brevity) to delineate resource boundaries between organizations—users/workflow managers can only submit SCOPE jobs to queues belonging to organizations of which they are a part. Cosmos uses a scheduling policy similar to the default policy that the *CapacityScheduler* in stock YARN uses, which orders jobs in each queue based on their (often user-) assigned priorities. A key difference is that jobs are scheduled with gang semantics in Cosmos—a job is admitted only when the scheduler can ensure that a user-provided minimum number of parallel, *job-requested* resources can be granted to it.

6.1 Simulation setup

We evaluate the application of Wing’s analyses to scheduling using simulation-based experiments due to the scale of Cosmos: the Cosmos traces we use contain ~40k jobs per day, and ~160k inter-job dependencies. Experiments at this scale cannot realistically be attempted on research clusters without down-sampling jobs, at which point much inter-job dependency fidelity within the original workload will have been lost. We therefore use simulations to preserve the characteristics of inter-job dependencies in our experiments.

Simulation platform: design and implementation. Our simulation platform takes a discrete-event based approach. To ensure that our experiments retain most properties of YARN/Cosmos, our simulation platform makes minimal changes to the YARN architecture—our implementation only mocks out the real-time clock and the communication layers of the YARN servers. We also use real queue sizes for each hierarchical queue in our Cosmos cluster. The authors plan to contribute this simulator back to the open source community.

Simulation accuracy. To make simulation feasible given the scale of our job logs, the simulator does not model: (1) “internal” dependencies among stages of a job, but rather treat a job as a rigid collection of tasks; (2) resource-sharing through opportunistic execution [35] of job tasks, which allows jobs

Figure 7: Cluster utilization. This figure shows the job-requested and total resource utilizations of our real cluster.

to use more resources than requested when those resources are otherwise idle; and (3) job sizes based on resources used rather than job-requested resources, meaning that our simulations only consider the deep blue area in Fig. 7.

To evaluate the fidelity of our simulator, we measure the absolute differences in job completion times between jobs in our simulations (using the baseline system policies) and the same jobs run in the real cluster. We normalize the deltas by the job’s real-world latency, and observe that even at the 99th percentile, jobs are shifted by only 1.3% of their latencies. Our experiments run at 100% cluster capacity also achieve average resource utilization for job-requested resources within 1.5% of what is observed in the real cluster.

6.2 Evaluated scheduling policies

In addition to Wing-Agg (§5), we evaluate value-attainment on our workload traces on the following scheduling policies. All implement Cosmos’s gang-scheduling semantics.

PRIO represents Cosmos’s current approach, and is the default scheduling policy used by stock YARN in its CapacityScheduler. It orders jobs within each hierarchical queue based on user-specified priorities.

Wing-MIL. Millennium [8] is a VF-aware scheduler that orders jobs based on expected value attained per resource time: For each queued job it computes how much value can be gained at an estimated job completion time, divides the value by total job resource-time, and orders jobs by the resulting quotient. MIL is our implementation of Millennium on YARN, following descriptions in its design as closely as possible.

Wing-MIL is MIL using Wing-informed value functions (VFs): In addition to capturing how the job-local value of a single job decays, a Wing-informed VF captures *potential* value associated with the job lost over time by modeling a job’s full decay of downloads. A job j attains all of j ’s aggregate downloads in the most optimistic case if it completes before or at its real-world completion time; otherwise, it loses value according to when users perform download operations *and* when downstream jobs fail due to it not completing on time (illustrated earlier in Fig. 5). For example, in a Wing-guided VF, if j completes at 1PM in the real-world but only completes at 2PM in our experiment, j loses all the direct downloads that occur between 1 and 2PM, *and* all the *indirect* downloads rooted in jobs that directly depend on j submitted between 1 and 2PM.

Figure 8: Distribution of job value. This figure shows the distributions of job-local value and aggregate job value, along with a Zipfian distribution fitted to job-local value. The distribution of job value deviates from Zipfian at lower job rankings.

Plan-ahead based VF-aware policies. We attempted to evaluate more sophisticated plan-ahead based VF-aware policies, e.g., FirstOpportunityRate [44]. But, we found that one implementation of such a policy couldn’t accommodate workloads at Cosmos scale, and efforts to mitigate bottlenecks by caching and limiting plan-ahead led to less value attainment than simpler policies (e.g., MIL). We therefore do not include our attempts with such a policy, as further work is warranted before conclusions are drawn.

6.3 Workload and predictor descriptions

Dataset. We use data from the final four weeks of our analysis dataset to evaluate our scheduling policies: Within the four weeks of data, Wing uses data in the first and second weeks to establish job and dependency profiles. Experiments are conducted over the third week, and downloads (value) are counted for each job up to one week (into the fourth week) from the completion of the job. Each day of traces contains ~40k jobs and ~160k inter-job dependencies.

Considering inter-job dependencies. Different from prior work, our experiments take characteristics of inter-job dependencies into account to realize more realistic workloads. For example, if a job holds a hard dependency on the output of an upstream job but the output is not available in time, the job fails due to missing input. Other dependency patterns, such as polling behavior (when a job waits for its inputs to become available), are also modeled faithfully. Jobs and dependencies considered in our experiments are described in Table 1.

Job value distribution. Job value, as measured by the number of downloads associated with the timely completion of a job in our experiments, are distributed roughly in a Zipfian fashion ($s = 1$) with deviation at the low end, as shown in Fig. 8. This means that the most valuable jobs are downloaded significantly more times than less valuable jobs. When scheduling for value on a workload that is inter-job dependency aware, schedulers should work to *unblock* the most valuable jobs before they arrive in order to attain their value.

Value efficiency predictor. Wing-Agg and Wing-MIL use a predictor to estimate the aggregate value efficiency associated with upcoming recurring jobs to optimize for value throughput. While §3 shows that direct inter-job dependencies can be predictable, it neither considers predictions on a

Figure 9: Value efficiency prediction. This figure shows the CDF of our predictor’s performance on predicting the value efficiency and aggregate value efficiency of recurring jobs.

job’s subgraph of downstream dependencies, nor a job’s value impact. Evaluating predictions on aggregate value efficiency therefore allows us to better understand the performance of Wing-guided schedulers. For recurring jobs in our experiments, we use a median-based predictor to predict the value efficiency associated with a job. That is, given a recurring job j of template τ , we predict j ’s value efficiency based on the historical median value efficiency for jobs of template τ .

Fig. 9 shows the performance of our value efficiency predictor in a CDF. For predicting the aggregate value efficiency of a job, 39% of our predictions fall within $\pm 20\%$ of the actual value efficiency of a job, while for predicting the value efficiency of a single job, 44% of our predictions fall within $\pm 20\%$ of the actual value efficiency of a job. While we are working on further studies to improve predictor accuracy with more sophisticated methods, we find that the performance of our simple predictor enables Wing-Agg to outperform other evaluated scheduling policies in value attainment (§7).

7 Experimental results

We evaluate the efficacy of each scheduling policy for the actual full Cosmos resource capacity (100%) and for smaller capacities (at 80–20%). Value-attainment results are reported as a percentage of value achievable—i.e., if all jobs in workloads complete before any of their values are lost.

Cluster capacities & consequential policy decisions. Scheduling is most interesting when cluster capacity is constrained and schedulers need to make difficult decisions regarding which jobs to provide resources. Indeed, at 100% capacity, the baseline and more advanced schedulers perform similarly, completing $> 99\%$ of all jobs in the trace. We find that the lower cluster capacities (i.e., $\leq 40\%$) best exemplify the consequences of decisions a scheduler makes. We therefore focus the discussion of our results at these capacities to maximize observable differences.

Takeaways. Our experiments yield the following key takeaways. First, policies guided by Wing are better at achieving value when clusters are heavily-constrained. In particular, Wing-Agg outperforms all other compared policies at all capacities and improves value attained by up to 21% as capacity declines. Second, understanding the downstream impact of a job is crucial in constrained clusters, and that

Figure 10: Benefits of Wing guidance. This figure shows the value attained for each scheduling policy, normalized to total value achievable. Wing-guidance (exemplified in Wing-Agg and Wing-MIL) is significantly beneficial at constrained capacities.

Wing-guided inter-job dependency predictions are accurate enough to be practical: Wing-Agg can effectively complete the prerequisites of the most consequential jobs. Finally, we demonstrate significant opportunity in applying inter-job dependency awareness in Wing to a cluster-wide queue and establishing a cluster-wide value metric: Wing-Agg achieves up to 93% of all value in our workload when using a single cluster-wide queue, using only 20% of cluster capacity.

7.1 Benefits of Wing guidance

Fig. 10 shows that policies guided by Wing beat PRIO at all capacities, with value attainment gaps widening as the cluster is increasingly stressed. At 60% capacity, Wing-Agg achieves 87% of value (vs PRIO’s 80%). At 40% capacity, Wing-Agg achieves 77% of value (vs PRIO’s 62%). Even at 20% capacity, Wing-Agg is able to capture more than half of all value (55%), while PRIO only captures 35% of value.

Considering aggregate value gives Wing-guided schedulers a two-fold benefit over PRIO. First, it naturally “fixes” priority mis-configurations, such as priority inversions, by propagating job value upstream, such that downstream jobs with high value are not blocked. Second, it guides schedulers toward sub-DAGs of high value efficiency jobs effectively, allowing schedulers to achieve more value with less resources.

Are ad-hoc jobs disadvantaged? Since Wing-Agg focuses on recurring jobs, we examine our logs to see if ad-hoc jobs are at a disadvantage when scheduled by Wing-Agg vs recurring jobs, where the priority of ad-hoc jobs are determined by the median aggregate value efficiency of previous jobs submitted by the same user. We find, from results at 20% cluster capacity, that 25% of recurring jobs fail, compared to 42% of ad-hoc jobs. However, recurring jobs also carry 9× more value than ad-hoc jobs. To optimize for value, Wing-Agg necessarily needs to complete larger fractions of recurring jobs. Indeed, recurring jobs are more often production jobs [34].

Dynamic priorities (Wing-MIL). Intuitively, policies using dynamic priorities (e.g., value functions, or VFs) such as Wing-MIL should perform better than static policies such as Wing-Agg, as VFs can express both importance and urgency while priorities only allow the expression of one of the two dimensions; but, we observe that Wing-Agg outperforms

Wing-MIL at all capacities, albeit only slightly.

Unlike Wing, which only depends on aggregate value-efficiency predictions, Wing-MIL also depends on the time-to-dependency predictions of directly-dependent jobs (§3) to determine when aggregate job value decays. But, while a part of this underperformance is indeed caused by imperfect predictions of time-to-dependencies, we find that providing Wing-MIL with perfect job value and time-to-dependency information does not help much. Further analyzing our results, we find that this underperformance is mainly due to Wing-MIL’s failure to consider the *properties* of inter-job dependencies. For example, a downstream job that polls for the arrival of its inputs will not fail if its upstream jobs complete late. But, VFs constructed from historical data will still reflect a drop in value at the time the polling downstream job is expected to arrive, leading Wing-MIL to believe that it should give up prematurely on scheduling the job. This shortcoming can be addressed by considering dependency properties *explicitly*, but our attempted implementation of such a policy does not significantly improve over Wing-Agg: both Wing-Agg and our attempted implementation can complete the most impactful, value-efficient jobs in a timely manner.

Practicality of Wing-Agg. The simplicity of Wing-Agg is desirable from an engineering standpoint, as Wing-Agg is both highly practical and highly scalable: Integrating Wing-Agg into a production cluster requires minimal changes to the existing resource management framework, and all the information needed for Wing-Agg to determine a job’s priority can be pre-computed offline in Wing’s analysis pipeline (§4). Adoption of Wing-Agg into production can therefore be straightforward, upon confirming job valuation schemes.

7.2 Sensitivity and ablation studies

Aggregate vs. job-local value. This section discusses benefits of understanding job value at an aggregate vs job-local level by comparing Wing-Agg against Wing-Direct, where *Wing-Direct considers the job-local value efficiency of a job*: i.e., Wing-Direct only considers direct-downloads associated with the outputs of and the compute-time of a single job only.

The patterned bars in Fig. 11 show the normalized value attained by Wing-Agg and Wing-Direct. While Wing-Direct outperforms PRIO, Wing-Agg maintains significant benefit over Wing-Direct at the tightest capacities: Wing-Agg attains 13% more overall value than Wing-Direct at 20% capacity. Our analysis finds that Wing-Direct’s knowledge of job resource consumption allows it to effectively complete jobs at the head of queue, enabling it to complete a similar amount of jobs as Wing-Agg. But, with knowledge of historical aggregate value efficiency, we find that Wing-Agg completes jobs in the more value-heavy sub-DAGs of the inter-job dependency DAG, yielding significant improvements over Wing-Direct.

Wing predictions vs. Oracle knowledge. We examine how much potential benefit better predictions can provide to each Wing-aided policy. *Oracle Wing-Agg* represents Wing-Agg

Figure 11: Benefits of aggregate job value. *Aggregate* (corresponding to aggregate download-aware) vs *Job-local* (corresponding to direct download aware only) bars show the benefits of aggregate value, compared to only scheduling based on job-local value. The solid portion of the bars show the benefits of Oracle knowledge.

endowed with perfect knowledge of aggregate value efficiency, and *Oracle Wing-Direct* represents Wing-Direct provided with perfect knowledge of job-local value efficiency.

While we find that having better predictions are beneficial, the differences between the solid (representing policies with Oracle knowledge) and the patterned bars (representing policies with Wing-provided predictions) in Fig. 10 and Fig. 11 show that at most capacities, Wing-guided schedulers achieve close to the value attained by their Oracle variants. However, having more accurate information presents opportunity for significant gain in value attained for Wing-Agg at 20% capacity: e.g., Oracle Wing-Agg improves value realized over Wing-Agg by 8% of overall value. Conversely, although Oracle Wing-Direct is granted exact knowledge of how value-efficient each job is, its view of the overall inter-job dependency graph leads to only incremental benefits.

Oracle benefits to aggregate value aware policies come from a more accurate knowledge of a summarized view of the inter-job dependency graph: compared to single job value-aware policies with Oracle knowledge, a policy such as Oracle Wing-Agg can efficiently complete the most consequential jobs in the job dependency graph, increasing value attained (by up to 18% of overall value vs Oracle Wing-Direct) and reducing the number of jobs failed due to missing input (by 3% of all jobs vs Oracle Wing-Direct).

Sensitivity to mis-predictions. We examine the sensitivity of Wing-Agg to aggregate value efficiency mis-predictions on our workload by running experiments that introduce artificial shifts in aggregate value efficiency provided by Oracle Wing, using 20% cluster capacity. Each experimental run is associated with a maximum artificial shift s , where $s \in \{1.1, 1.25, 1.5, 2, 5, 10\}$. For each job j within each run, we scale the aggregate value efficiency e_{val} of j provided by Oracle Wing by multiplying e_{val} by a randomly sampled multiplier m between $1/s$ and s . Our results show that Wing-Agg is not sensitive to mis-predictions in value on our workload: For $s \leq 5$, value attained is only reduced by at most 4% vs Oracle Wing-Agg. For $s = 10$, value attained is only reduced by 11%. This insensitivity is because job values in our workload are distributed in a Zipfian fashion (§6.3), where the most

Figure 12: Benefits of Wing-guidance with a cluster-wide queue.

This figure shows the value attained for policies from 60–20% cluster capacities in a cluster with a merged cluster-wide queue. All policies complete all jobs at 60% capacity. Wing-guidance (exemplified by Wing-Agg) is increasingly beneficial at lower capacities. The solid portion of the bars show the benefits of Oracle knowledge.

valuable jobs are much more valuable than other jobs.

Reducing transitive closure computation. At 20% capacity, Wing-Direct (0 iterations of Wing’s multi-hop analysis) attains 42% of all value, while Wing-Agg (9 iterations executed) attains 55% of all value. In Fig. 6 in §4.5.3, we find that 99% of aggregate value of most jobs can be explored in four iterations of Wing’s multi-hop analysis. We therefore believe that four iterations of exploration would be sufficient to similarly attain 55% of all value, and that two iterations of exploration would allow us to attain close to 50% of all value.

7.3 Cluster-wide queue and value metrics

Our earlier results correspond to a simplified view of Cosmos using strictly enforced queue boundaries. Hard queue boundaries restrict placement more than in the real system, where resource-sharing (§6.1) softens queue boundaries, which might exaggerate Wing-Agg’s benefits. To confirm that Wing-Agg’s improvements are not due to hard queue boundaries, we evaluate a boundary-free alternative with experiments run using a single global, cluster-wide queue.

Evaluation. Fig. 12 shows the value attainment of our evaluated scheduling policies using a single cluster-wide-queue. We note that all jobs are able to complete for all scheduling policies at 60% cluster capacity. Indeed, the dark blue area in Fig. 7 show that these requests peak at around 60%. At 40% capacity, the cluster still has more capacity than needed most of the time: Wing-Agg achieves 99% of value, and Wing-Direct and PRIO achieve 97 and 93% of value, respectively.

Under extreme capacity crunch (e.g., 20% capacity), removing restrictions of hard queue boundaries improves value attained of all policies. But, a Wing-guided scheduler sees significantly more benefit in terms of absolute value achieved. With a cluster-wide queue at 20% capacity, Wing-Agg attains 93% of value, whereas Wing-Direct attains 84%, and PRIO only attains 47%. Furthermore, Wing-Agg fails fewer jobs compared to both Wing-Direct and PRIO (11% vs 13% and 25% of jobs, respectively).

We find that understanding inter-job dependencies is critical, as Wing-Direct with Oracle knowledge did not signifi-

cantly outperform Wing-Direct with predicted values, both in terms of value attained and in terms of number of jobs failed; yet, we find that Wing-Agg with Oracle knowledge, in this setting, can achieve up to 98% of all value (comparable to performances at 100% capacity), while failing only 7% of all jobs (compared to 26% in a multi-queued setting at 20% capacity). One of the reasons why Wing-Agg is able to attain 93% of all value using only 20% of cluster capacity is due to its ability “unblock” the most valuable downstream jobs.

Recall that the simulated job sizes in our experiments are based on job-requested resources, rather than job-used resources, which may be higher because of opportunistic execution. As a result, cluster utilization is lower in our experiments. But, we believe that the rankings of the different schedulers are not affected, because the number of opportunistic resources highly correlate with that of allocated job-requested resources, both across the top 10% of most valuable jobs (Spearman correlation of 0.85) and across all jobs (Spearman correlation of 0.84). Indeed, the amount of opportunistic resources available to a job is capped with a max proportional to the number of allocated job-requested resources [49]. So, the relative differences shown for 20% cluster capacity may instead be for 30% cluster capacity in the heavier workload.

Toward establishing a cluster-wide value metric. Our results confirm that removing queue boundaries would be beneficial. Partitioning resources into queues naturally introduces resource fragmentation, but usage of queues is often viewed as a “necessary evil,” as certain organizations are willing to pay more to have guaranteed access to their share of compute. Yet, naïvely removing queue boundaries without a quota-system [55] in place may introduce resource competition, where users across different organizations assign increasingly high priorities to their jobs to acquire guaranteed resources. A cluster-wide, automated arbitrator that understands both system-internal (e.g., aware of downstream number of affected jobs and user-downloads) and organizational/user-defined notions of importance is therefore required. We see this as an exciting direction for further research.

Current state of deployment. Instead of immediately deploying Wing-Agg as described, the Microsoft Cosmos resource management team has asked us first to deploy an inter-job dependency advisory tool using analyses from Wing, to aid users on better configuring their jobs. The tool will allow us to gather user feedback on our recommendations.

8 Related work

Workflow managers. Workflow management for batch analytics jobs is a widely studied area in the fields of databases and data management [30, 40, 41]. Our work differs in two primary ways: (1) workflow managers often assume the availability of a dependency graph up-front, while Wing infers properties of inter-job dependencies from job history; and (2) workflow managers optimize only a single pipeline of jobs submitted by one user at a time, while Wing considers inter-

dependent jobs across workflow and organization boundaries. **Cluster workload analysis.** Although much work has been done on cluster workload analysis from many different perspectives (e.g., resource/workload heterogeneity [1, 11, 26, 37, 45], failure analysis [7, 17, 46], job predictability [43, 50, 52], and intra-job task dependency [23, 24, 51]), most prior work assumes (implicitly or explicitly) that each job is independent of other jobs. This paper fills the knowledge gap with analyses of inter-job dependencies and application of this knowledge in cluster scheduling.

Cluster scheduling. Although a variety of work has been published in the area of cluster scheduling, each trying to address scheduling woes of different kinds of workloads (e.g., support for general batch analytics [5, 10, 18, 21, 22, 29, 34, 43, 53, 54], low latency scheduling [15, 16, 35, 42], and strategies to handle mixes of workloads [12, 19, 20, 48, 55]), most work in cluster scheduling similarly assume the independence of jobs. Our work shows that incorporating knowledge of inter-job dependencies can improve cluster scheduling in an environment with a lot of data and work product sharing, and we believe that considering inter-job dependencies can help future schedulers better tackle challenges, such as enabling better job task placement and learning better scheduling policies [38, 47].

Task-DAG schedulers assign resources to inter-dependent tasks within a job based on knowledge of the overall task-DAG [18, 23, 24, 38]. Such techniques and our proposed policies can be complementary, as task-DAG schedulers drill into job-level details while our schedulers (e.g., Wing-Agg) work at a higher level and treat jobs as black boxes. In particular, schedulers that predict the arrival of future jobs [34, 38] can benefit from the availability of inter-job dependency context to refine their predictions. Some task-DAG scheduling techniques could also be applied to the problem of inter-job dependency scheduling; but, these task-DAG schedulers generally assume upfront availability of task-DAGs, while full inter-job dependency graphs are rarely available ahead of time. An interesting direction for future research is in combining task-DAG scheduling techniques with some form of Wing-provided “probabilistic inter-job dependency” DAGs.

Jockey and Morpheus. Jockey [18] uses the direct dependencies of jobs to illustrate the importance of maintaining low job latency variance, but uses a step-function with value=1 until the *user-provided deadline* as each job’s value function (VF). Morpheus [34] improves upon Jockey’s notion of VFs by deriving deadlines based on a job’s first consumer (as observed from historical instances of that job), but still considers all jobs as equal in value. In addition to our characterization of inter-job dependencies in a large analytics cluster, our work extends Morpheus and Jockey in two ways: (1) jobs no longer all have the same value—instead, Wing derives each job’s value (and therefrom priority) as the sum of a chosen value metric (e.g., downloads) for all downstream dependencies, and (2) value is no longer a step-function with a single deadline based on a job’s first direct consumer, but a rich decay

proportional to the aggregate value of dependency sub-DAGs rooted in each direct consumer. While we do not directly compare against Morpheus, in §7.1, we find, in the context of Wing-MIL, that a premature drop in aggregate value can lead to the scheduler giving up early when dependency properties are not considered, leading to lower value attainment. Considering value as a step-function with a single deadline can therefore potentially be detrimental when inter-job dependencies are present in cluster workloads. While Wing-Agg uses only the initial “height” of the aggregate value VF of each job to set priorities, we believe that full aggregate value VFs can still better guide other scheduling decisions, such as determining which jobs to load-shift.

Systems using job recurrence and data provenance. There has also been much prior work on systems that efficiently collect provenance data [13, 39] and systems that both exploit job recurrence and data provenance on other problems [25, 33], such as garbage-collecting shared computation results. Our work uses similar ideas, but focuses on facilitating better value attainment in resource scheduling.

Owl and Guider. Our previous work Owl [9] and Guider [39] introduced the usage of job dependencies to determine the value of jobs. Wing operationalizes and expands upon prior work by (1) analyzing and characterizing inter-job dependencies in a large cluster, (2) evaluating predictability of recurring inter-job dependencies, (3) integrating inter-job dependencies into cluster schedulers, (4) applying said schedulers to a real scheduling problem, and (5) providing a general aggregate inter-job dependency analysis framework.

9 Conclusion

Complex inter-job dependencies pervade modern data lakes, creating complex problems as cluster schedulers make decisions without knowing of them. The Wing dependency profiler uncovers these dependencies from provenance logs and provides improved guidance to cluster schedulers. Evaluations with real job traces show that significantly more value, in terms of successful user downloads, can be attained by using Wing-guided priority assignments over those provided by users. Wing’s effectiveness opens a new range of resource management possibilities guided by automatically-determined knowledge of the impact of jobs.

Abstract

Low-latency online services have strict Service Level Objectives (SLOs) that require datacenter systems to support high throughput at microsecond-scale tail latency. Dataplane operating systems have been designed to *scale up* multi-core servers with minimal overhead for such SLOs. However, as application demands continue to increase, scaling up is not enough, and serving larger demands requires these systems to scale out to multiple servers in a rack.

We present RackSched, the first rack-level microsecond-scale scheduler that provides the abstraction of a rack-scale computer (i.e., a huge server with hundreds to thousands of cores) to an external service with network-system co-design. The core of RackSched is a two-layer scheduling framework that integrates inter-server scheduling in the top-of-rack (ToR) switch with intra-server scheduling in each server. We use a combination of analytical results and simulations to show that it provides near-optimal performance as centralized scheduling policies, and is robust for both low-dispersion and high-dispersion workloads. We design a custom switch data plane for the inter-server scheduler, which realizes power-of-k-choices, ensures request affinity, and tracks server loads accurately and efficiently. We implement a RackSched prototype on a cluster of commodity servers connected by a Barefoot Tofino switch. End-to-end experiments on a twelve-server testbed show that RackSched improves the throughput by up to $1.44\times$, and scales out the throughput near linearly, while maintaining the same tail latency as one server until the system is saturated.

1 Introduction

Online services such as search, social networking and e-commerce have strict end-to-end user-facing Service Level Objectives (SLOs) [12, 22]. To meet such SLOs, datacenter systems behind these services are expected to provide high throughput with low *tail latency* in the range of tens to hundreds of *microseconds* [12]. Example systems include key-value stores [6, 7, 60], transactional databases [9, 64], search ranking and sorting [13], microservices and function-as-a-service frameworks [17], and graph stores [43, 67].

With the end of Moore’s law and Dennard’s scaling, applications can no longer rely on single-threaded code to execute faster on newer processors with increased clock rates and instruction-level parallelism [31]. This leads to the rise of multi-core machines to scale up computation. Meeting microsecond-scale tail latency is challenging given that the request processing times with single-threaded code on bare metal hardware are already in the same time scale. This means that the operating system (OS) should impose minimal overhead when it manages resources and scales up these applications on multi-core machines.

This calls for new software architectures to efficiently utilize the resources of multi-core machines. One critical component of such architectures is scheduling. Dataplane operating systems have been designed to support low-latency applications with minimal overhead to meet strict SLOs [14, 39, 54, 58, 59]. For example, Shinjuku [39] uses efficient mechanisms to implement preemption and context switching, in order to realize *centralized* scheduling policies to avoid head-of-line blocking and address temporal load imbalance between multiple cores.

However, as application demands continue to increase, *scaling up* a single server is not enough. Serving larger demands requires these systems to *scale out* to multiple servers in a rack, which is termed as rack-scale computers, such as Berkeley Firebox [1], Intel Rack Scale Architecture [5], and HP “The Machine” [2]. Though previous efforts have not fully panned out yet, we believe it is inevitable, as evidenced by the emerging TPU Pods that pack high-density specialized hardware into a rack [8]. Even a traditional rack contains tens of servers and hundreds to thousands of cores, posing a challenge for scheduling microsecond-scale requests.

While dataplane operating systems address intra-server scheduling between multiple *cores*, head-of-line blocking and temporal load imbalance between multiple *servers* arise when the systems scale out. Using a single core for centralized scheduling and queue management is amenable for one server with a few to tens of cores [39]. But the core would quickly become the bottleneck if it were used to queue and schedule requests for a rack with hundreds to thousands of cores.

In this paper, we present RackSched, the first rack-level microsecond-scale scheduler that provides the abstraction of a rack-scale computer (i.e., a huge server with hundreds to thousands of cores) to an external service with network-system co-design. Serving microsecond-scale workloads is particularly challenging because the scheduler needs to *simultaneously* provide high scheduling speed (i.e., high throughput and low latency of the scheduler) and high scheduling quality (i.e., low tail latency to complete requests). Given the scheduling latency of modern OSes on a single server being a few microseconds [19, 39], our goal is to design a rack-level scheduler with comparable scheduling latency that can scale out to hundreds to thousands of cores in a rack. While there has been a long line of work on scheduling and load balancing, existing solutions are not designed for microsecond-scale workloads: software-based solutions [24, 27, 55, 56] suffer from low scheduling throughput and high scheduling latency (at least millisecond-scale); hardware-based ones [25, 51] are coarse-grained (based on five tuple) and server-agnostic, and thus suffer from long tail latency.

The core contribution of RackSched is a novel network-system co-design that *simultaneously* achieves high scheduling speed and high scheduling quality (§2). We propose a two-layer scheduling framework that integrates inter-server scheduling in the top-of-rack (ToR) switch with intra-server scheduling in each server to approximate centralized scheduling policies. This two-layer design, and the line-rate, on-path inter-server scheduling in the ToR switch, are critical for the scheduler to achieve high speed.

To provide high quality scheduling decisions, our key insight is that the two sources of long tail latency—load imbalance and head-of-line blocking—can be decoupled and handled by separate mechanisms. The ToR switch tracks real-time server loads, and schedules requests at *per-request* granularity to realize inter-server load balancing (LB). Each server keeps its own queue, and uses intra-server scheduling to preempt long requests that block pending short ones. It is known that centralized first-come-first-serve (cFCFS) is near-optimal for low-dispersion workloads, and processor sharing (PS) is near-optimal for heavy-tailed workloads or light-tailed workloads with high dispersion [39, 59, 69]. We use a combination of analytical results and simulations to show that our two-layer scheduling framework provides *near-optimal* performance as *centralized* policies, and is robust to different workloads (Figure 1).

Realizing the inter-server scheduler in the ToR switch requires the switch to schedule requests based on *server loads* on *per-request* granularity (§3). Today’s stateful network load balancers map connections to servers based the hash of the five tuple [24, 25, 51, 53, 56], which is *static*, and cannot dynamically adapt the server selection under *microsecond-scale* load imbalance. There are three aspects of our approach to address this challenge. (i) We leverage the switch on-chip memory to store server loads, and use the multi-stage process-

Figure 1: Key idea of RackSched.

ing pipeline to implement power-of-k-choices and to support a variety of practical scheduling requirements, such as multi-queue policies. (ii) We design a *request state table* for *request affinity*, which guarantees the packets of the same request are sent to the same server. To maintain the dynamic mapping between requests and servers, the request state table supports *insert* (after scheduling the first packet), *read* (for sending following packets), and *remove* (when the request is completed) all in the *data plane*. (iii) We leverage *in-network telemetry* (INT) to monitor server loads with minimal overhead. Servers *piggyback* their load information in their *normal* traffic, and the switch tracks the latest reported load for each server.

Recent switch-based solution R2P2 [42] relies on expensive recirculation which does not scale for high request rate, and its scheduling policy has long tail latency under heavy-tailed or high-dispersion workloads due to head-of-line blocking (§4.5). In addition, R2P2 needs an extra round trip for multi-packet requests to ensure request affinity, while RackSched can finish in one round trip. RackSched is also more general in supporting many practical policies (§3.6).

In summary, we make the following contributions.

- We propose RackSched, the first rack-level microsecond-scale scheduler that provides the abstraction of a rack-scale computer to an external service.
- We design a two-layer scheduling framework that integrates inter-server scheduling in the ToR switch and intra-server scheduling in each server. We use a combination of analytical results and simulations to show that it provides near-optimal performance as centralized policies.
- We design a custom switch data plane for the inter-server scheduler, which realizes power-of-k-choices for near-optimal load balancing, ensures request affinity, and tracks server loads accurately and efficiently.
- We implement a RackSched prototype on a cluster of twelve commodity servers with a Barefoot Tofino switch. End-to-end experiments show that RackSched improves the throughput by up to 1.44×, and scales out the throughput near linearly, while maintaining the same tail latency as one server until the system is saturated.

The code of RackSched is open-source and available at <https://github.com/netx-repo/RackSched>.

Figure 2: Simulation results.

2 Design Decisions

In this section, we navigate through the design space of building a microsecond-scale scheduler for rack-scale computers, and highlight the design rationale of RackSched.

Scaling out to a rack. Supporting large application demands requires datacenter systems to scale out to multiple servers in a rack. While existing solutions like Shinjuku [39] solve the problem of scheduling requests to multiple cores (i.e., intra-server scheduling), they do not address the problem of scheduling requests to different servers (i.e., inter-server scheduling). When requests are simply scheduled to the servers randomly, the load imbalance and head-of-line blocking can happen at the server level, causing long tail latency for the entire system.

To motivate our work, we use simulations on representative workloads to show the impact of ineffective scheduling policies. We use the following two request service time distributions: (i) Exp(50) is an exponential distribution with mean = 50 μ s, which is representative for low-dispersion workloads; (ii) Trimodal(33.3%-5, 33.3%-50, 33.3%-500) is a trimodal distribution with 33.3% of requests taking 5 μ s, 33.3% taking 50 μ s and 33.3% taking 500 μ s, which is representative for high-dispersion workloads. The simulations assume eight servers and each server has eight workers (cores). The PS time slice used in the simulations is 25 μ s.

We first compare the baseline policies that randomly send requests to servers and only use cFCFS or PS inside each server (per-cFCFS and per-PS) with the ideal centralized policies across all workers (global-cFCFS and global-PS). Figure 2 shows that the centralized policies perform better than the baseline policies. The tail latencies of per-cFCFS and per-PS quickly go up when the system load exceeds 0.75 and 0.5 respectively, while global-cFCFS and global-PS keep low tail latencies until the system is almost saturated.

Centralized scheduling cannot scale. The policy comparison in Figure 2 shows that there is a substantial gap between the tail latencies of the centralized policies (global-cFCFS and global-PS) and the baseline policies (per-cFCFS and per-PS). However, directly implementing the centralized policies is challenging because they would require a centralized scheduler for the entire rack. While a single core is capable of running a centralized scheduler to handle the requests for a multi-core server, it is unlikely to scale to a multi-server rack.

Figure 3: Two-layer scheduling framework.

Indeed, a single scheduler in Shinjuku [39] can scale to up to 11 cores, which falls well short of the demands of a rack with hundreds to thousands of cores.

Hierarchical scheduling. One natural solution to scale up the rack-scale scheduler is a two-layer hierarchical scheduler consisting of an inter-server scheduler at the high level, and per-server schedulers at the low level (Figure 3). This way, the inter-server scheduler only needs to schedule requests across tens of servers, instead of hundreds or thousands of cores. Each server employs its own intra-server scheduler to schedule requests across its cores.

Scaling the inter-server scheduler. While the inter-server scheduler only needs to schedule requests across the servers in the rack (instead of across all cores), it still needs to handle every request. Assuming a rack with 1000 cores and 10 μ s requests, the inter-server scheduler must handle up to 100 millions requests per second (MRPS) to saturate the rack! Unfortunately, such a scheduler would need to process a request every 10 ns, which exceeds the capability of a general-purpose computer.

To address this challenge, in this paper we propose to leverage emerging *programmable switches*, and have the ToR switch implement the inter-server scheduler. This design has the key benefit that the ToR switch is already on the path of the requests sent to the rack, and thus can readily process all these requests at line rate.

JSQ is near optimal and robust. A natural way to approximate a centralized scheduler with a two-layer scheduler is to implement the same scheduler at both layers. For example, if the global scheduler is cFCFS, in the corresponding hierarchical scheduler all the inter-server and intra-server schedulers will be cFCFS as well.

Unfortunately, the cFCFS scheduler needs to maintain a queue, and existing programmable switches have too limited memory to buffer requests, and are not well equipped to maintain dynamic data structures, such as queues. The join-the-shortest-queue (JSQ) scheduler can address the challenge because it is a bufferless scheduler. Upon a request arrival, it immediately forwards the request to the server with the shortest queue. This way, JSQ achieves fine-grained load balancing across the rack's servers. Figure 2 confirms that JSQ-cFCFS

and JSQ-PS can deliver nearly the same performance as the centralized policies (global-cFCFS and global-PS).

Theoretically, the two-layer scheduling framework implements the A/S/K/JSQ/P models in queueing theory, where A is the inter-arrival distribution, S is the service time distribution, K is the number of servers, JSQ is the join-the-shortest-queue policy implemented by the inter-server scheduler, and P is the intra-server scheduling policy which is either cFCFS or PS in this case. In particular, it is known that JSQ provides near-optimal load balancing, and importantly, is *robust* against request service time distributions. An expanded discussion is in the technical report [74].

Approximating JSQ. While conceptually simple, JSQ cannot be implemented in its definite form in practice, because it requires the switch to know the exact queue length of each server when scheduling a request. It takes a round trip time for the switch to ask each server, during which the queue lengths may have changed for microsecond-scale workloads. Furthermore, imperfect JSQ based on delayed server status is prone to *herding*, where several consecutive requests are sent to the same server before the server load is updated, and this can generate micro bursts and degrade system performance. Note that herding here is not caused by multiple asynchronous load balancers as there is only one load balancer (the inter-server scheduler), but from stale server load information in the load balancer. In addition, the switch can only do a limited number of operations for each request, and finding the shortest queue cannot be implemented for many tens of servers. Thus, we use power-of-k-choices to approximate JSQ, which samples k servers for each request and chooses the one with the minimum load. This approximation provides comparable performance as JSQ in theory [18] (see [74]), and handles these practical limitations well.

Why not a distributed, client-based solution? An alternative solution is to implement distributed scheduling at each client. The clients can use JSQ, power-of-k-choices or more complicated solutions like C3 [63] to pick workers for their requests. Such a client-based solution has two drawbacks. First, it needs client modification and increases system complexity. The clients need to probe server loads and make scheduling decisions. More importantly, the clients need to be notified for *every* system reconfiguration (e.g., adding or removing servers), because they have to know which set of servers a request can be sent to. Notifying a large number of clients of the latest system configuration imposes both a consistency challenge and high system overhead. Putting these functionalities in a scheduler, on the other hand, simplifies the clients and avoids these system complexities.

Second, a distributed, client-based solution provides a worse trade-off between performance and probing overhead than a centralized scheduler for microsecond-scale workloads. This is because microsecond-scale workloads are IO-intensive, and a probing request incurs comparable processing

cost as a normal request at the servers. Thus, probing needs to be minimized to improve the throughput of processing the actual requests. No matter whether probing is done proactively or piggybacked in reply packets, given n clients with the same sending rate, a centralized scheduler can utilize n times as much probing data as that of one client in a client-based solution, resulting in better scheduling quality. Figure 2 confirms the benefit of the centralized scheduler over a client-based solution with a piggyback-based probing mechanism (client-cFCFS and client-PS). The simulation does not model the client software delay and the network delay to get the server loads, which favors the client-based solution. The client-based solution performs worse in real experiments (§4.5). In a multi-pipeline switch, though states are not shared across pipelines, RackSched can approximate JSQ within each pipeline. It works better than the client-based solution because the number of pipelines (e.g., 4) is far smaller than the number of clients (e.g., 1000 or more).

Putting it all together. We propose a two-layer scheduling framework that integrates inter-server scheduling in the ToR switch and intra-server scheduling in each server. The ToR switch uses power-of-k-choices to achieve inter-server load balancing, and each server uses cFCFS or PS to minimize head-of-line blocking. This solution approximates centralized scheduling for the entire rack, and provides the abstraction of a rack-scale computer: the capacity (throughput) of the rack-scale computer is the sum of that of its servers, and the tail latency is maintained as that of one server.

Challenges. Translating the two-layer scheduling framework to a working system implementation presents several technical challenges:

- What is the system architecture to realize this two-layer scheduling framework?
- How does the switch schedule requests based on the server loads, and handle practical scheduling requirements?
- How does the system ensure request affinity (i.e., the packets of the same request are sent to the same server), when the switch processes each packet independently?
- How do servers expose their states to the switch so that the switch can track the real-time loads on the servers efficiently and accurately?

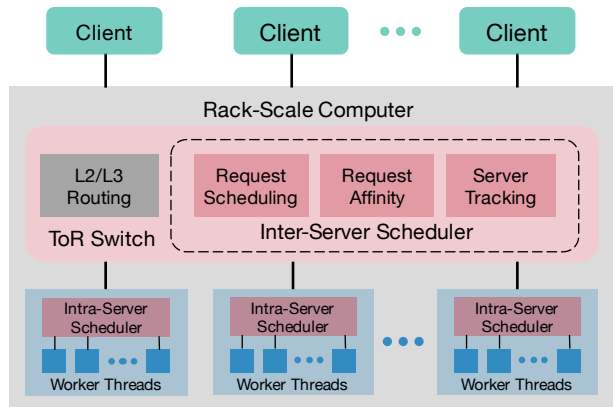

3 RackSched Design

In this section, we present the design of RackSched to address the challenges. We first give an overview of the system architecture, and then describe each component in detail.

3.1 System Architecture

The core of RackSched is a two-layer scheduling framework that combines inter-server scheduling and intra-server scheduling. Figure 4(a) shows the RackSched architecture.

Inter-server scheduling. The ToR switch performs inter-server scheduling at per-request granularity via three modules:

(a) RackSched architecture.

(b) RackSched packet format.

Figure 4: RackSched overview.

a request scheduling module that selects a server for a new incoming request based on server loads (§3.3) and scheduling requirements (§3.6), a request affinity module that forwards the packets of the same request to the same selected server (§3.4), and a server tracking module that tracks the real-time load on each server (§3.5). All three modules are implemented in the switch data plane that enables the inter-server scheduler to run at line rate.

Intra-server scheduling. Each multi-core server in the rack runs multiple worker threads to process requests. Each server has a centralized scheduler to queue and schedule requests to its own workers. The scheduler implements centralized scheduling policies for intra-server scheduling. Each server also piggybacks its load information in reply messages to report its load to the ToR switch.

Deployment options. There are two deployment options for RackSched. (i) The first one is to integrate RackSched with the ToR switch of a rack-scale computer. This option adds additional functionalities to the ToR switch, but does not change any other part of the datacenter network. (ii) The second option is to treat the switch-based scheduler as a specialized server with a programmable switching ASIC. This server can be connected to the same ToR switch as worker servers. It owns the anycast IP address so all requests would be first sent to it for scheduling. By properly updating the addresses, it can also force the reply packets to pass through it before returning to the clients, in order to clear request states and update server loads. This option does not even modify the ToR switch, but has the latency cost of an extra hop by the detour to the switch-based scheduler.

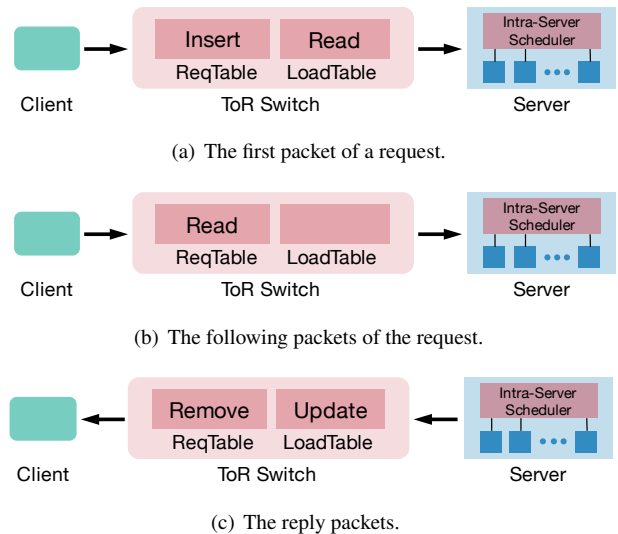

Figure 5: Request processing in RackSched.

3.2 Request Processing

Network protocol. RackSched is designed for intra-datacenter scenarios. It uses an application-layer protocol which is embedded inside the L4 payload. We reserve an L4 port to distinguish RackSched packets from other packets. The network uses existing L2/L3 routing protocols to forward packets. There are no modifications to the switches in the network other than the ToR switch. The ToR switch uses the reserved L4 port to invoke the custom modules to process RackSched packets. Other switches do not need to understand the RackSched protocol, nor do they need to process RackSched packets. RackSched is orthogonal to and compatible with other network functionalities, such as flow/congestion control, which is typically implemented by the transport layer or the RPC layer (e.g., eRPC [41]). RackSched ensures request affinity under packet loss and retransmission by maintaining connection state (§3.4).

RackSched only requires the applications to add the RackSched header between the TCP/UDP header and the payload (Figure 4(b)), so that it can make scheduling decisions based on the RackSched header. Note that for TCP handshake packets that do not have any payload, the RackSched header should be appended after the TCP header to expose necessary information to the switch. We emphasize that RackSched focuses on microsecond-scale workloads. It is not intended to support long-lived TCP connections, which impose unnecessary system overhead to maintain connection states, especially under switch failures (§3.4), and restrict the scheduler from making per-request scheduling decisions to address temporal load imbalance. RackSched does support request dependency for tasks with multiple requests (§3.6).

The RackSched header contains three major fields, which are TYPE, REQ_ID, and LOAD. TYPE indicates the type of the packet, e.g., REQF (the first packet of a request), REQR (a remaining packet of a request), and REP (a reply packet).

Algorithm 1 ProcessPacket(pkt)

```

– ReqTable: on-chip memory for request-server mapping
– LoadTable: on-chip memory for server loads

// first packet of a request
1: if pkt.type == REQ then
2:   server_ip ← LoadTable.select_server()
3:   ReqTable.insert(pkt.req_id, server_ip)
// remaining packets of a request
4: else if pkt.type == RQR then
5:   server_ip ← ReqTable.read(pkt.req_id)
// reply packets
6: else if pkt.type == REP then
7:   ReqTable.remove(pkt.req_id)
8:   LoadTable.update(pkt.srcip, pkt.load)
9: Update packet header and forward

```

REQ_ID is a unique ID for each request. All packets of the same request and the corresponding reply use the same REQ_ID. To ensure a REQ_ID is globally unique, each client appends its client ID in front of its locally generated unique request ID, i.e., a tuple of <client ID, local request ID>. LOAD indicates the load of the server. The server piggybacks its current queue length in the LOAD field in reply packets. LOAD is not used in request packets.

Processing request packets. Clients use an *anycast* IP address as the destination IP to send requests to the rack-scale computer, and are unaware of the number of servers behind the ToR switch. Figure 5 illustrates how RackSched processes packets, and Algorithm 1 shows the high-level pseudo code of the switch. The switch keeps two essential sets of state in the switch on-chip memory. One is *ReqTable* which stores the mapping from the request IDs to the servers, and the other is *LoadTable* which stores the queue lengths of the servers. As shown in Figure 5(a), when the first packet of a request arrives at the switch, the switch selects a server based on *LoadTable*, and remembers this selection by inserting an entry to *ReqTable* (line 1-3). Then in Figure 5(b), when remaining packets of the request arrive, the switch checks the *ReqTable* to get the selected server (line 4-5), which ensures request affinity. The switch uses the selected server IP to update the destination IP in the packet header and sends the packet to the corresponding server (line 9).

Processing reply packets. After a server receives a request, it uses its local scheduler to schedule and processes the request. Then the server generates a reply, and sets the LOAD field with its current queue length. As shown in Figure 5(c), the switch deletes the mapping from *ReqTable*, because the request has completed and the memory space can be freed for other requests (line 7). The switch also updates the server load in *LoadTable* based on the LOAD field (line 8). We do not distinguish the first and following packets for a reply even if the reply contains *multiple* packets (also equivalent to *multi-*

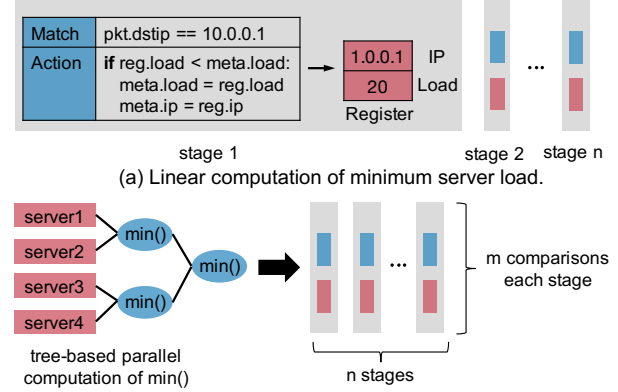

Figure 6: Traditional hash-based random dispatching.

(b) Tree-based computation of minimum server load.

Figure 7: Optimal server selection.

ple replies). Because *ReqTable* checks *req_id* for deletion, if a slot is reused by another request, the following reply packets of the previous request would not be applied. The updates of *LoadTable* only affect server selection of new requests. Note that this is compatible with TCP even if the client initiates the termination of the connection, as the mapping of this request is removed from *ReqTable* when the server receives the request and sends the first reply packet back to the client. The switch control plane periodically checks the data plane to remove *stale* mappings from *ReqTable*, which can be caused by server failures or lost reply packets. In the end, the switch updates the source IP to the anycast IP in the packet header, and sends the packet back to the client (line 9).

3.3 Request Scheduling

The request scheduling module dynamically schedules requests based on server loads. Unfortunately, this is not supported in today's switches. Today's switch-based load balancers such as SilkRoad [51] only support ECMP-like random dispatching based on the five tuple. Figure 6 shows how hash-based random selection is implemented in the data plane. The register array stores a set of server IPs for the anycast IP 10.0.0.1. The rule in the match-action table matches packets with their destination IP being the anycast IP 10.0.0.1, and the action rewrites the destination IP to an IP in the register array, which is selected by computing a hash on the packet header (usually the five tuple). Because the selection is static, and is purely based on the hash, it can cause load imbalance and long tail latency as discussed in §2. We now describe how to realize dynamic request scheduling based on server loads. Handling practical scheduling requirements is in §3.6.

Optimal server selection. We leverage the register arrays to store the server loads together with the server IPs and use the multi-stage packet processing pipeline to compute the minimum. A naive way is to use multiple stages to scan the

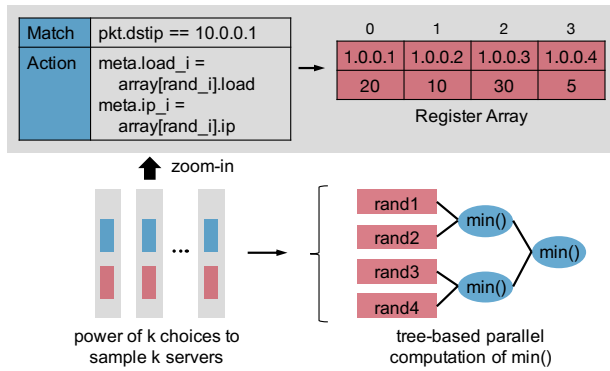

Figure 8: Approximate server selection.

server loads linearly, as shown in Figure 7(a). The number of servers this solution can support is limited to the number of stages. As a switch typically has 10–20 stages and many stages need to be used by other switch functionalities, this solution is not scalable. It can be optimized by computing the minimum in a tree structure as shown in Figure 7(b). The comparisons between two servers in each layer of the tree have no dependencies, and thus can be done in parallel in the same stage. In the ideal case, given n servers, this tree-based solution requires $\log(n)$ stages, while the naive solution requires n stages. Let each stage support up to m comparisons. The comparisons in the first few layers need to be distributed to multiple stages, if they are larger than m .

Approximate server selection. As discussed in §2, always choosing the server with the shortest queue is prone to herding, and due to the limited stages and the need to support other functionalities, the tree-based approach cannot scale to many tens of servers. We design an approximate server selection mechanism based on power-of- k -choices [18], i.e., the switch samples k servers and chooses the one with the shortest queue from them. As shown in Figure 8, the sampling can be done via multiple stages if k is bigger than the number of register read operations supported by one stage. After the k servers are sampled, the tree-based mechanism can be applied to get the one with the shortest queue.

3.4 Request Affinity

Request affinity ensures all packets of the same request are sent to the same server. This is challenging because the switch processes each packet independently. In traditional network load balancers [24, 25, 51, 53, 56], the server selection is solely based on the hash of the packet header, and the switch does not need to keep any state for request affinity. But in RackSched, the selection is dynamic. If the switch performs a server selection for every packet, the packets of the same request might be sent to different servers.

Realizing request affinity requires the switch to keep states. Abstractly, the switch should maintain a request state table to store the mapping from request IDs to server IPs (i.e., *ReqTable* in Algorithm 1). One option is to use a match-

Figure 9: Multi-stage hash table for request affinity.

action table, where the request IDs are stored in the match, and the servers IPs are stored in the action to update the destination IP of the packets (e.g., used by SilkRoad [51]). This option, however, does not work for microsecond-scale requests at million RPS throughput, because updating the match-action table (e.g., adding or removing a request) requires the control plane, which can only do about 10K updates per second [36, 48, 52]. To address this challenge, our design leverages register arrays to realize a multi-stage hash table that implements all necessary operations (i.e., *insert*, *read* and *remove*) for *ReqTable* in the data plane, as shown in Figure 9. Unlike match-action tables, register arrays can only be accessed via an index. We use the hash of the request ID to find the slot for a request, and the slot stores the request state, i.e., the request ID and server IP. To handle hash collisions and the limited array size in each stage, we leverage multiple stages to build a multi-stage hash table. Algorithm 2 shows the pseudo code to implement the three operations on *ReqTable* in Algorithm 1. The switch iterates over the stages to find an empty slot to insert a new request (line 1-5), and to find a matched slot to read the server IP (line 6-9) or remove a completed request (line 10-14). RackSched does not decrease the capability of the system to defend against DoS attacks. The switch has sufficient memory for *ReqTable* to support high throughput (§4.1), and a DoS attack that overwhelms *ReqTable* could have overwhelmed the servers first.

Handling switch failure. There is a relevant notion to request affinity called Per-Connection Consistency (PCC) for stateful layer-4 load balancers, which requires a TCP connection to be kept across load balancer failures and system reconfigurations [24, 25, 51, 53, 56]. We emphasize that RackSched focuses on microsecond-scale requests with strict deadlines (e.g., a couple of the request execution time). Rebooting a failed switch or replacing it with a backup switch takes a few minutes, by the time of which the requests have already *missed* their deadlines. Therefore, different from PCC, maintaining request affinity across switch failures is a non-goal for RackSched. Because of the *fate sharing* between the ToR switch and the rack, it is safe to disregard the *ReqTable* upon a switch failure, and the new switch starts with an empty *ReqTable*. Note that RackSched does not increase the chance of switch failures as a normal ToR switch without RackSched can still fail and make the rack disconnected.

Algorithm 2 Request affinity

```
– ReqTable[n][m]: register arrays to store request state, which spans  $n$ 
  stages and has  $m$  slots in each stage
1: function INSERT( $req\_id, server\_ip$ )
2:   for stage  $i$  in all stages do
3:     if ReqTable[i][h( $req\_id$ )] == None then
4:       ReqTable[i][h( $req\_id$ )] ← ( $req\_id, server\_ip$ )
5:     return
6: function READ( $req\_id$ )
7:   for stage  $i$  in all stages do
8:     if ReqTable[i][h( $req\_id$ )]. $req\_id$  ==  $req\_id$  then
9:       return ReqTable[i][h( $req\_id$ )]. $server\_ip$ 
10: function REMOVE( $req\_id$ )
11:   for stage  $i$  in all stages do
12:     if ReqTable[i][h( $req\_id$ )]. $req\_id$  ==  $req\_id$  then
13:       ReqTable[i][h( $req\_id$ )] ← None
14:   return
```

Handling system reconfiguration. Unlike switch failures, there is no fate sharing between each server and the rack, and RackSched does maintain request affinity across system reconfigurations such as adding or removing servers for an application. Because RackSched uses *ReqTable* to store the mapping, ongoing requests simply check *ReqTable* to go to the correct servers. Only the request scheduling module (§ 3.3) needs to be updated to have the right set of servers to choose from for new requests. We pre-allocate a large number of registers for *LoadTable* at compilation time, and use another register to indicate the number of *active* servers, which is dynamically updated for system reconfigurations. For an unplanned server removal (e.g., a server failure), RackSched uses the switch control plane to update the *ReqTable* and delete the stale entries related to the removed server.

3.5 Server Tracking

The server tracking module updates the server loads (i.e., *LoadTable* in Algorithm 1) for the switch to make scheduling decisions. The challenge is to accurately track the server loads at real-time with low overhead. A straightforward solution is to let the switch control plane periodically poll the queue lengths at each server and update the data plane. However, due to the millisecond-scale delay and the limited rate of control plane updates [37, 52], this solution does not apply to the microsecond-scale workloads targeted by RackSched. To do this in the data plane, a possible solution is to let the switch *proactively* track the server loads, i.e., incrementing and decrementing the counters for queue lengths when processing request and reply packets. This solution suffers from estimation errors due to packet loss and retransmissions, and fixes like decreasing the counters based on the server processing rate [47] cannot handle temporal load imbalance in high-dispersion microsecond-scale workloads.

RackSched leverages in-network telemetry to accurately track server loads with minimal overhead. In-network telemetry is widely used in network monitoring and diagnosis where switches put relevant measurement data into packet headers

in the data plane. RackSched applies this mechanism to track server loads. Then the servers piggyback their loads in the reply packets to update the counters in the switch, which does not introduce new packets and thus minimizes system overhead. A potential problem is the feedback loop delay as stale information can cause herding, which can degrade the scheduling performance and make the system unstable (i.e., swing between overloading different servers). In RackSched, the switch and the servers are directly connected in the same rack, and the server-side data plane implementation bypasses traditional TCP/IP stack to report its queue length to the switch quickly, making the feedback loop delay minimal. And together with power-of-k-choices scheduling, RackSched can effectively avoid herding. An alternative solution that only keeps the server with the minimum load in the switch and updates it based on in-network telemetry cannot leverage power-of-k-choices to avoid herding. We show the impact of different ways to track and represent server loads in §4.6.

3.6 Handling Scheduling Requirements

Multi-queue support. By default, RackSched uses a single-queue policy, i.e., the system does not differentiate a priori between request types and aims to meet a single SLO for tail latency (e.g., a photo caching workload with only *get* requests). RackSched also supports multiple queues if the workload has multiple request types that have distinct service time distributions (e.g., a key-value store workload with both *get* and *range* requests). Applications indicate the request type in the *TYPE* field of the packet header. Each server maintains a separate queue for each type for intra-server scheduling. The switch maintains the counters for each type in *LoadTable*, and schedules requests based on the queue lengths of the request type. We remark that there is no fundamental limit on the number of queues on each server, since the queues are implemented in software and the switch only needs to keep a counter for each queue on each server.

Locality and placement constraints. RackSched handles two types of common locality and placement constraints, which are data locality and request dependency. (i) Data locality requires a request to be processed on a subset of servers that hold the input data. To support data locality, applications set different *LOCALITY* values to represent different locality requirements (i.e., different sets of servers that can process this request), and the switch maintains different mappings, which map a server ID to a server for different *LOCALITY* values. (ii) Request dependency requires multiple requests to be scheduled to the same server, e.g., a task consists of multiple requests and the input of one request is the output of one or more other tasks. Request dependency is supported using request affinity: relevant requests carry the same *REQ_ID* in their headers, so that they will be sent to the same server. Additional information is included in the RackSched header for the number of subsequent requests to expect. The server can send replies to each request separately and independently.

RackSched only requires the server to set `TYPE` to be reply in replies after it has received all requests in the set in order to safely delete the state in the switch. Note that applications can still use different request IDs for different requests and receive replies as soon as some requests are completed, by adding application-specific metadata in the payload.

Resource allocation policies. The scheduler is responsible for allocating resources when the demand exceeds the capacity of the rack-scale computer. RackSched supports two types of common resource allocation policies, which are strict priority and weighted fair sharing. (i) To support strict priority, each server maintains a separate queue for each priority. Similar to the multi-queue support, the switch tracks the queue lengths, and balances the server loads for each priority. Each server uses intra-server scheduling to preempt low-priority requests when high-priority requests arrive, which can be done in $5\ \mu\text{s}$ in our implementation based on Shinjuku [39]. (ii) Supporting weighted fair sharing is similar. Each server maintains a separate queue for each client, and performs weighted fair queueing [23] for intra-server scheduling on the granularity of slice in PS. The switch tracks the queue lengths and balances the server loads for each client.

4 Evaluation

In this section, we evaluate RackSched with a variety of synthetic and real application workloads. We provide additional experiment results, including locality constraints, priority policies and multiple applications, in the technical report [74].

4.1 Methodology

Testbed. The experiments are conducted on a testbed of twelve server machines connected by a 6.5Tbps Barefoot Tofino switch. Each server has an 8-core CPU (Intel Xeon E5-2620 @ 2.1GHz), 64GB memory, and one 40G NIC (Intel XL710). Eight servers are used as workers to process requests, and they run Shinjuku [39] with our extension. Four servers are used as clients to generate requests. The bottleneck of the system is at the workers.

Implementation. We have implemented a RackSched prototype and integrated it with Shinjuku [39]. (i) The switch data plane is written in P4 [16] and compiled to Barefoot Tofino ASIC [11] with P4 Studio [10]. The request state table contains a hash table with 64K slots. The default implementation uses power-of-2-choices. (ii) The worker server is based on Shinjuku [39]. We have extended Shinjuku to support the RackSched packet header, maintain a counter and update the counter upon request arrival and reply departure to track the queue length and append the queue length in reply packets. Both RackSched and Shinjuku preempt requests that exceed $250\ \mu\text{s}$ in our experiments. (iii) The client is open-loop and implemented in C using Intel DPDK 16.11.1 [4]. It can generate requests at high request rate based on synthetic workloads and the RocksDB application, and measure the throughput and latency of RackSched.

Resource consumption. Our prototype uses 13.12% SRAM, 9.96% Match Input Crossbar, 12.5% Hash Unit and 25% Stateful ALUs of the Tofino ASIC resources. We provide an analysis and a back-of-the-envelope calculation to show that RackSched consumes little switch memory. RackSched has two sets of state on the switch, i.e., *LoadTable* and *ReqTable*. (i) *LoadTable* maintains a counter for each queue of each server. Let the counter be 4 bytes, the number of queues in each server be 3 and the number of servers be 32. It only consumes 384 bytes. (ii) *ReqTable* maintains the selected server IPs for the *ongoing* requests, not *all* requests the system have received and processed. Each slot can be *reused* by many times each second because the requests are microsecond-scale. Given an average request processing latency of $50\ \mu\text{s}$, a slot can support 20 KRPS throughput, and a table with 64K slots can support 1.28 BRPS throughput. Let the request ID and server IP both be 4 bytes. A table with 64K slots (our implementation) consumes 256 KB, which is only a few percent of the on-chip memory (tens of MB). Overflowed requests can fall back to hash-based random dispatching which preserves request affinity.

Workloads. We use a combination of synthetic and application workloads. They include the following workloads. By default, the workloads use one-packet requests.

- Exp(50) is an exponential distribution with mean = $50\ \mu\text{s}$, which represents common query and storage workloads, such as *get* requests in photo caching.
- Bimodal(90%-50, 10%-500) is a bimodal distribution with 90% of requests taking $50\ \mu\text{s}$ and 10% taking $500\ \mu\text{s}$, which represents workloads with a mix of simple requests and complex requests, such as *get* and *range* requests in key-value stores.
- Bimodal(50%-50, 50%-500) is a bimodal distribution with 50% of requests taking $50\ \mu\text{s}$ and 50% taking $500\ \mu\text{s}$, which represents workloads with half simple requests and half complex requests.
- Trimodal(33.3%-50, 33.3%-500, 33.3%-5000) is a trimodal distribution with a third of requests taking $50\ \mu\text{s}$, $500\ \mu\text{s}$ and $5000\ \mu\text{s}$, respectively, which represents workloads with more diverse request types, such as *point*, *range* and complex *join* requests in databases.

We also use RocksDB 5.13 [60], an open-source production-quality key-value store, as a real application workload to evaluate RackSched. RocksDB is configured to store data in DRAM to avoid blocking behavior and achieve low latency.

4.2 Synthetic Workloads

We evaluate the system on synthetic workloads that cover large application space. We compare RackSched with that directly runs Shinjuku in the cluster, i.e., the requests are randomly sent to the servers.

Figure 10(a) and Figure 10(b) compare RackSched and Shinjuku under Exp(50) and Bimodal(90%-50, 10%-500) workloads, respectively. In these two figures, both RackSched

Figure 10: Experimental results for synthetic workloads with homogeneous servers.

Figure 11: Experimental results for synthetic workloads with heterogeneous servers.

and Shinjuku use a single-queue policy. Under Exp(50), the 99% latencies of RackSched and Shinjuku are similar at low load. But the 99% latency of Shinjuku quickly goes up after 800 KRPS, while that of RackSched can support the system load up to 950 KRPS. Under Bimodal(90%-50, 10%-500), the 99% latency of Shinjuku quickly increases after 500 KRPS, while that of RackSched stays stable until 650 KRPS. In both workloads, RackSched supports larger request load with lower tail latency, because its inter-server scheduling addresses temporal load imbalance between servers, while Shinjuku experiences short bursts and long queues in individual servers under high request load.

Figure 10(c) and Figure 10(d) show the results for Bimodal(50%-50, 50%-500) and Trimodal(33.3%-50, 33.3%-500, 33.3%-5000) workloads, respectively. In these two figures, both RackSched and Shinjuku have a separate queue for each request type. Again, RackSched significantly outperforms Shinjuku. The improvement of RackSched is larger in Trimodal(33.3%-50, 33.3%-500, 33.3%-5000) than Bimodal(50%-50, 50%-500), because Trimodal(33.3%-50, 33.3%-500, 33.3%-5000) has more diverse service times and can benefit more from effective inter-server scheduling.

Figure 11 shows the results with heterogeneous servers. In this case, four servers have four workers and the other four servers have seven workers (one core used by the scheduler). This evaluates the cases when some servers are slower or some cores of these servers are grabbed for other purposes [15, 54]. We compare RackSched with Shinjuku under the same four distributions in Figure 10. RackSched is load-aware and tends to send requests to the servers with shorter queue lengths, while Shinjuku distributes the requests to the servers uniformly, disregarding the heterogeneity. RackSched can improve the performance further with heterogeneous servers.

Figure 12: Scalability results.

4.3 Scalability

The key benefit of RackSched is that it enables the system to scale out by adding servers, while achieving low tail latency at high throughput. Figure 12 shows the 99% latency under different request load with one, two, four and eight servers, respectively. This figure uses Bimodal(90%-50, 10%-500) workload, and the results for other workloads are similar. With one server, the two systems, i.e., RackSched (1) and Shinjuku(1), have the same performance, as there is no need for inter-server scheduling. With two servers, load imbalance can happen, but the variability is small. With four servers, micro bursts can cause bigger temporal load imbalance, and the improvement of inter-server scheduling is also bigger. When there are eight servers, there is more variability between the loads on the servers, and inter-server scheduling has more opportunities to improve performance. Shinjuku(8) can only maintain low tail latency until 500 KRPS, while RackSched (8) can maintain low tail latency until 650 KRPS. We expect the improvement of RackSched over Shinjuku would be larger with more servers, because there would be more variabilities with more servers.

Figure 13: Experimental results for RocksDB.

Overall, RackSched scales out the total throughput of the system near linearly with the number of servers in the rack. And the throughput improvement is achieved without increasing the tail latency. Even with more servers, RackSched is still able to maintain the same tail latency as one server until the system is saturated.

4.4 Application: RocksDB

We use RocksDB [60] to demonstrate the benefits of RackSched on real applications. RocksDB is an open-source production-quality storage system that is widely deployed to support many online services such as Facebook. In the experiments, RocksDB is configured with an in-memory file system (/tmpfs/) for microsecond-scale request processing. We use two request types. One is *GET* which gets 60 objects with a median request service time of 50 μs. The other is *SCAN* which scans 5000 objects with a median service processing time of 740 μs. Only 326 lines of code are needed to port RocksDB to RackSched and Shinjuku. Figure 13(a) shows the results for the workload that contains 90% *GET* requests and 10% *SCAN* requests. In this experiment, the system uses a single-queue policy. At low request load, RackSched and Shinjuku have comparable 99% latency. But Shinjuku can only maintain low tail latency until 300 KRPS, while RackSched is able to keep low tail latency until 500 KRPS.

Figure 13(b) shows the results for the workload that contains 50% *GET* requests and 50% *SCAN* requests. In this experiment, the system uses a multi-queue policy. RackSched is able to maintain low tail latency at a higher request load than Shinjuku. We further break down the results for each request type for this workload. Figure 13(c) and Figure 13(d) show the 99% latency for *GET* and *SCAN* under different total request load, respectively. Because RackSched uses the switch to balance the load of each request type between the

Figure 14: Comparison with other solutions.

servers, the improvement of RackSched over all requests does not come at the cost of sacrificing any individual request type. For both request types, RackSched is able to deliver comparable tail latency at low load, achieve significantly lower tail latency at high load, and support higher total request load.

4.5 Comparison with Other Solutions

R2P2 [42] is a recent solution that proposes a join-bounded-shortest-queue (JBSQ) policy for request scheduling, and the solution can be implemented on programmable switches. R2P2 does not have preemptive intra-server scheduling and has head-of-line blocking. Thus, it suffers from long tail latency, especially under high-dispersion workloads. Client-based solutions are lack of global view and use power-of-k-choices scheduling based on stale server load information, and thus they suffer from inaccurate scheduling decisions. We emulate 100 clients that generate requests with the same rate in the machines. Each client performs the same policy as RackSched and tracks server queue lengths via piggybacking by its own. The performance of Client(10) (which emulates 10 clients) and Client(1000) (which emulates 1000 clients) are nearly the same as that of Client(100). Figure 14 shows the performance of RackSched, Shinjuku, the client-based solution and R2P2 under Bimodal(90%-50, 10%-500) and Bimodal(50%-50, 50%-500) workloads. In both workloads, RackSched outperforms others by maintaining low latency at higher request rate, and Client(100) has nearly the same performance as Shinjuku. More importantly, R2P2 is not robust to service time distributions. It is close to RackSched under Bimodal(50%-50, 50%-500), and the gap between R2P2 and RackSched is significantly larger under Bimodal(90%-50, 10%-500).

4.6 Analysis of RackSched

We analyze RackSched and show the impact of different design choices, including different scheduling policies of the switch-based inter-server scheduler and different mechanisms to track the server loads.

Impact of switch scheduling policies. Figure 15 evaluates the impact of different scheduling policies under Bimodal(90%-50, 10%-500) and Bimodal(50%-50, 50%-500) workloads. We compare four scheduling policies: *RR* (which

Figure 15: Impact of switch scheduling policies.

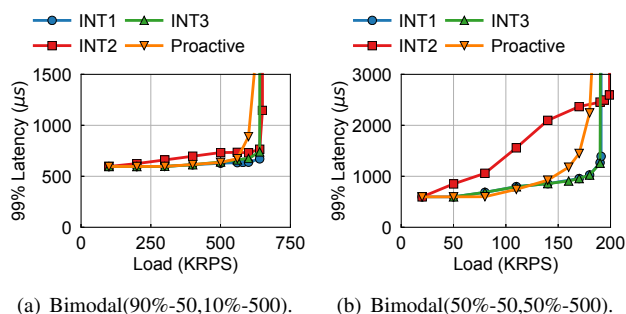

Figure 16: Impact of server load tracking mechanisms.

schedules requests to server with round-robin), *Shortest* (which chooses the server with the smallest queue length), *Sampling-2* (which samples two servers and chooses the one with the smaller queue length), and *Sampling-4* (which samples four servers and chooses the one with the smallest queue length). RR sends an even number of requests to each server, without considering the variability of request service times. Thus, it suffers from long tail latency at high request load. Theoretically, *Shortest* can provide effective load balancing, but it incurs high tail latency in practice, even at low request load. As discussed in §2, the reason is that there is a delay to update the queue lengths in the switch from the servers. When a server becomes the one with the smallest queue length, multiple consecutive requests would all choose this server, causing a micro *herding* behavior. And the queue length of this server has to wait to be updated until the new queue length is piggybacked in the first reply packet to update in the switch. As discussed in §2, this herding behavior can be handled by adding randomization to the scheduling process. The results in the figure confirm the effectiveness of sampling. For the scale of the evaluated scenario, sampling two and four servers have similar performance, because sampling two servers already provides enough choices to avoid hotspots and enough randomization to avoid herding.

Impact of server load tracking mechanisms. Figure 16 evaluates the impact of different mechanisms to track server loads, under both Bimodal(90%-50, 10%-500) and Bimodal(50%-50, 50%-500) workloads. We compare three tracking mechanisms discussed in §3.5: *INT1* (which tracks

Figure 17: Handling failures and reconfigurations.

the number of outstanding requests for each server and computes the minimum), *INT2* (which only tracks the minimum number of outstanding requests and updates on reply packets), *INT3* (which tracks the total service time of outstanding requests for each server) and *Proactive* (which increments and decrements the counters by the switch). *Proactive* cannot precisely maintain the queue length for each server as packet loss and retransmissions can introduce errors on the counters, and as a result, it does not work well as others. *INT2* performs worse than *INT1* because it only keeps one server with the minimum load, resulting in herding. *INT3* is comparable to *INT1*. However, it presumes that the service times are known a priori, which is normally not the case in practice. *INT1* works the best because it accurately tracks server loads, enables randomization to avoid herding for effective load balancing, and does not require any priori knowledge.

4.7 Request Affinity

Handling switch failures. To simulate a switch failure, we first stop the switch manually, then reactivate the switch after several seconds. Figure 17(a) shows the total throughput during this period under Exp(50) workload. At 10 s, the switch is stopped and the total throughput drops to 0. We reactivate the switch after 5 seconds and the total throughput recovers to the initial level. The microsecond-scale requests have already timed out after 5 seconds. So it is safe to start with an empty *ReqTable* after the reactivation, as discussed in §3.4.

Handling system reconfigurations. RackSched maintains request affinity during system reconfigurations. Figure 17(b) shows the 99% latency under system reconfigurations. We use two-packet requests under Exp(50) workload, and start with 500 KRPS load and seven machines as the servers. At time 8 s, we increase the request sending rate, and the 99% latency goes up to around 380 μs . At time 14 s, we add another server to serve the requests, and the 99% latency drops to 310 μs . At

time 28 s, we set the request sending rate back to 500 KRPS. And the 99% latency drops to 280 μ s further. At time 39 s, we remove a server from the rack. Since seven servers are enough for such workload, the 99% latency remains the same. As discussed in § 3.4, the request affinity is maintained by the *ReqTable* in the above process.

5 Discussion

Target workloads. RackSched supports both stateless and replicated stateful services. Examples include microservices, function-as-a-service, stream processing, replicated caches and storage, and replicated machine learning models for high-throughput inference. It is unlikely for a stateful service to be replicated to all servers in a rack. We expect a more practical scenario is that a rack would run multiple such services, where each service is provided by a subset of (overlapping) servers, i.e., locality constraints. The evaluation shows that RackSched can provide significant improvements for a service hosted on just 8 servers (§4). And we provide additional results to show the benefits for multiple services with locality constraints in the technical report [74]. These results demonstrate that RackSched provides significant benefits even when the service is replicated on just a couple of servers.

Going beyond a rack. We focus on a single rack in this paper. A modern rack can already pack hundreds of cores, and a future rack is expected to pack thousands of cores [1, 2, 5], which is sufficient for many services. For planetary-scale services, a single microservice may span multiple racks. In this scenario, there is no central place like the ToR switch in a rack that can see and process all traffic. Yet, the abstraction of a rack-scale computer provided by RackSched provides a useful building block for distributed inter-rack scheduling. This would be an interesting direction for future work.

6 Related Work

Dataplane designs for low latency. Conventional networking stacks and operating systems usually sacrifice low latency for generality. To address the need for low latency, various dataplane designs have been proposed, including optimized networking stacks [4, 21, 34] and dataplane operating systems [14, 20, 32, 39, 54, 58, 59]. RackSched leverages such dataplane designs and enhances them with an inter-server scheduler, realizing low latency in a rack-scale computer.

Scheduling and resource management. There is a long line of research on job scheduling and resource management [26, 28, 29, 32, 38, 40, 42, 55, 57, 65, 66, 71]. Many systems focus on large jobs that can run from seconds to hours, and they can afford running sophisticated scheduling algorithms to make effective decisions. RackSched works at microsecond scale and optimizes the tail latency with network-system co-design.

Programmable switches. Programmable switches bring new opportunities to improve datacenter networks and systems, such as key-value stores [36, 48, 49, 50], coordination and

consensus [35, 45, 46, 70, 73], network telemetry [3, 33], machine learning acceleration [61, 62] and query processing offload [44]. There are also proposals for managing systems built with programmable switches [30, 68, 72]. RackSched is a new solution that leverages the programmable switch as an inter-rack scheduler to optimize microsecond-scale tail latency for rack-scale computers.

7 Conclusion

We present RackSched, a rack-level microsecond-scale scheduler that provides the abstraction of a rack-scale computer to an external service. RackSched leverages a two-layer scheduling framework to achieve scalability and low tail latency. We hope that with the end of Moore’s law and Dennard’s scaling, RackSched will inspire a new generation of datacenter systems enabled by domain-specific hardware and hardware-software co-design.

Acknowledgments We thank our shepherd Ryan Stutsman and the anonymous reviewers for their valuable feedback. We thank Jack Humphries for helping debug Shinjuku issues. Abstract

As the demand for data center capacity continues to grow, hyperscale providers have used power oversubscription to increase efficiency and reduce costs. Power oversubscription requires power capping systems to smooth out the spikes that risk overloading power equipment by throttling workloads. Modern compute clusters run latency-sensitive serving and throughput-oriented batch workloads on the same servers, provisioning resources to ensure low latency for the former while using the latter to achieve high server utilization. When power capping occurs, it is desirable to maintain low latency for serving tasks and throttle the throughput of batch tasks. To achieve this, we seek a system that can gracefully throttle batch workloads and has task-level quality-of-service (QoS) differentiation.

In this paper we present Thunderbolt, a hardware-agnostic power capping system that ensures safe power oversubscription while minimizing impact on both long-running throughput-oriented tasks and latency-sensitive tasks. It uses a two-threshold, randomized unthrottling/multiplicative decrease control policy to ensure power safety with minimized performance degradation. It leverages the Linux kernel's CPU bandwidth control feature to achieve task-level QoS-aware throttling. It is robust even in the face of power telemetry unavailability. Evaluation results at the node and cluster levels demonstrate the system's responsiveness, effectiveness for reducing power, capability of QoS differentiation, and minimal impact on latency and task health. We have deployed this system at scale, in multiple production clusters. As a result, we enabled power oversubscription gains of 9%–25%, where none was previously possible.

1 Introduction

Data centers form the backbone of popular online services such as search, streaming video, email, social networking, online shopping, and cloud. The growing demand for online services forces hyperscale providers to commit massive capital to continuously expand their data center fleet.

The overall capital expenditures for just the top 5 hyperscale providers (Amazon, Google, Microsoft, Facebook, Apple) in 2019 reached \$120B out of a total \$210B for all data centers worldwide [10, 11]. The majority of these investments are allocated towards buying and building infrastructure, such as buildings, power delivery, and cooling, to host the servers that compose the warehouse-scale computer. Power oversubscription is the practice of deploying more servers in a data center than the data center's power supply can nominally support if all servers were 100% utilized. Power oversubscription allows deploying more servers into a data center, and therefore reduces the number of data centers needed to be built. The cost savings potential of power oversubscription amounts to billions of dollars per year and is therefore of great importance to data center operators.

However, power oversubscription comes with a risk of overload during power peaks, and thus often comes with protective systems such as power capping. Power capping systems enable safe power oversubscription by preventing overload during power emergencies. Power capping actions include suspending low-priority tasks [18], throttling CPU voltage and frequency using techniques such as dynamic voltage and frequency scaling (DVFS) and running average power limit (RAPL) [8, 13, 25], or packing threads in a subset of available cores [17]. The action needs to be compatible with the workloads and meet their service-level objectives (SLOs). This, however, is challenging for clusters with throughput-oriented workloads co-located with latency-sensitive workloads on the same servers.

Throughput-oriented tasks represent an important class of computation workloads. Examples are web indexing, log processing, and machine learning model training. These workloads typically have deadlines on the order of hours for when the computation needs to be completed, making them good candidates for performance throttling when a cluster faces a power emergency due to power oversubscription. Nevertheless, missing the deadline can result in serious consequences such as lost revenue and diminished quality, thus making them unamenable to interruption.

Latency-sensitive workloads are a different class. They need to complete the requested computation on the order of milliseconds to seconds. A typical example is an application that handles user requests. High latencies result in bad user experience, eventually leading to loss of users and revenue. Unlike throughput-oriented pipelines, such tasks are not amenable to performance throttling. They often are considered high priority and need to be exempt from power capping.

In our data centers, throughput-oriented and latency-sensitive tasks are co-located on the same server to increase resource utilization [20]. This introduces a need for a fine-grained power capping mechanism that throttles the performance of throughput-oriented tasks to reduce server power usage while exempting high-priority latency-sensitive tasks.

This paper describes a simple, robust, and hardware-agnostic power capping system, Thunderbolt, to address these challenges. It throttles the CPU shares of throughput-oriented workloads to slow them down “just enough” to keep power under specified budget, while leaving latency-sensitive tasks unaffected. It has been deployed in large-scale production data centers.

To our knowledge, Thunderbolt is the first industry system that simultaneously achieves the following goals. All of these are important to scale out mission critical systems.

- A system architecture that enables oversubscription across large power domains. Power pooling and statistical multiplexing across machines in large power domains maximizes the potential for power oversubscription.
- Quality-of-service-aware, hardware-agnostic power throttling mechanism with wide applicability. Our system relies only on established Linux kernel features, and thus is hardware platform agnostic. This enables the flexibility of introducing a variety of platforms into data centers without compromising the effectiveness of power capping. Our task-level mechanisms allow differentiated quality-of-service (QoS). Specifically, Thunderbolt does not affect serving, latency-sensitive workloads co-located with throughput-oriented workloads on the same server, and has the ability to apply different CPU caps on workloads with different SLOs. The platform-agnostic and QoS-aware nature allows the system to be tailored to the requirements of a wide spectrum of hardware platforms and software applications.
- Power safety with minimized performance degradation. A two-threshold scheme with a randomized unthrottling/multiplicative decrease algorithm enables minimal performance impact while ensuring that a large amount of power can be shed to avoid power overload during emergencies.
- System availability in the face of power telemetry unavailability. Power telemetry availability has not drawn

much attention in most previous power capping systems, but we found it to be the availability bottleneck in our system. Thunderbolt introduces a failover subsystem to maintain power safety guarantees even when power telemetry is unavailable.

We have deployed this system in multiple data centers over a period of two years. We have verified proper operation at scale and achieved oversubscription of 9–25% when none was previously possible. At such an oversubscription level, data centers run at high power efficiency and are close to the edge of exceeding their power limits. Power capping is expected to occur a few times a year. [Section 7](#) has more details.

2 Background

Warehouse-sized data centers run very complex and diverse workloads and need a flexible power actuator to handle complicated application scenarios. Google recently published a power capping system [18] that intentionally suspends low-priority tasks which often results in task timeouts and failures. Such interruption is appropriate in certain situations; for instance, some tasks can tolerate occasional downtime but prefer to have consistent performance when they run, and prefer to be interrupted so they can be rescheduled somewhere else rather than being slowed down. However, for throughput-oriented workloads, this is not only wasteful of compute resources but is also disruptive.

Popular software frameworks like Hadoop [19], MillWheel [3], and TensorFlow [1] provide checkpointing functionality to allow tasks to handle failures gracefully. Checkpointing itself, however, incurs non-negligible cost and complexity. Users have to balance between the risk of failure and the overhead of runtime checkpointing. Even with checkpointing, some amount of work is wasted when a task is killed and restarted. For distributed computing that requires synchronization among workers (e.g., synchronized machine learning training), a killed task can easily become a straggler as others have to wait for it to make forward progress. Our system aims to provide a more graceful solution where traditional task killing or suspension is too costly.

Most previous studies control CPU power to affect overall machine power draw. Our system follows this practice, because CPU power draw is much higher than that of memory or storage components (e.g., flash and disk) on the commodity servers in our data centers.

Data center workloads also run at different priorities with varying QoS. It is highly desirable to reflect differentiated QoS even under power capping. Previous industry power capping systems, such as Dynamo [25] and CapMaestro [14], differentiate priorities at the machine level. They assign priorities to individual machines and build a global priority-aware control policy for all machines involved. To provide QoS

differentiation with Dynamo or CapMaestro, tasks with different capping priorities have to be scheduled on different machines. This conflicts with our requirement to run mixed-priority workloads on the same machine to improve resource utilization. In contrast, our approach is designed to provide QoS differentiation when workloads of different priorities run on the same machine.

From a scheduling perspective, our problem may look similar to the classic problem of scheduling latency-sensitive and throughput-oriented tasks on the same machine and optimizing for latency and throughput. However, it is a different form of the problem to which existing scheduling solutions do not directly apply. The constraining resource is power, which neither cluster scheduler nor local node scheduler can directly control or allocate. Instead we control power indirectly by controlling CPU usage. We treat power as a system output, measure it via power meters, and feed it back into the system to build a control loop. We have to care about the availability of power readings that are external signals. Violation of the power budget results in not performance degradation but high-stake physical failures (tripping circuit breakers) and immediate power loss to thousands of machines. Therefore a strong guarantee of power not exceeding the budget is the top priority, requiring fast response and a wide dynamic range of power control. Optimization for latency and throughput must not compromise this guarantee.

3 Terminology

To facilitate the explanation of our system, we define a few key terms summarized here for easy reference.

Thunderbolt. The power capping system as a whole, named after the resulting power curves that look like a thunderbolt (see [Figure 5](#)). The overall architecture is described in [Section 4](#).

Load shaping. The “reactive capping” subsystem and closed-loop control policy using power signals for fine-grained power capping control. It is described in [Section 4.1.2](#). It uses CPU bandwidth control (described below) as the node-level mechanism.

CPU bandwidth control. The node-level mechanism for load shaping. It leverages the CPU bandwidth control feature provided by Linux’s completely fair scheduler to throttle the CPU usage of tasks. It is described in [Section 4.1.1](#).

CPU jailing. The “proactive capping” backup subsystem that takes over when power signals are unavailable and load shaping cannot function. It includes an open-loop control policy of risk assessment and a node-level mechanism that makes use of Linux’s CPU affinity features to limit machines’ CPU utilization. It is described in [Section 4.2.1](#).

Figure 1: Software architecture of Thunderbolt.

4 Architecture and Implementation

Thunderbolt is capable of performing two types of end-to-end power capping actuation tailored to throughput-oriented workloads: a primary mechanism called reactive capping, and a failover mechanism called proactive capping. Reactive capping monitors real-time power signals read from power meters and reacts to high power measurements by throttling workloads. When power signals become unavailable, e.g., due to meter downtime, proactive capping takes over and assesses the risk of breaker trips. The assessment is based on factors such as power in the recent past and for how long the signals have been unavailable. If the risk is deemed high, it proactively throttles tasks.

The reactive capping system depends on power signals provided by power meters installed close to the protected power equipment, like circuit breakers. Meters are installed at every power “choke point” whose limit will be first reached as power draw increases. In our data centers the choke points are typically power distribution units (PDUs) or medium voltage power planes (MVPPs) [18]. This differs from the more widely adopted approach of collecting power measurements from individual compute nodes and aggregating at upper levels. Our approach has several advantages. It is simple. It avoids aggregation and the associated data quality issues such as time misalignment and partial collection failures. It also avoids the need to estimate power drawn by non-compute equipment, such as data center cooling, that does not provide power measurements.

[Figure 1](#) illustrates the software architecture of Thunderbolt. The meter watcher module polls power readings from meters at a rate of one reading per second. It passes the readings to the power notifier module and also stores a copy in a power history datastore. The power notifier is a central module that implements the control logic of reactive and proactive capping. When power readings are available, it uses the readings for the reactive capping logic. When the readings are unavailable, it queries the risk assessor module for the proactive capping logic. The risk assessor uses the historical power information from the power history datastore to assess the risk of breaker trips. If either logic decides to cap, the power notifier will pass appropriate capping parameters to the ma-

chine manager module, which then sends remote procedure call (RPC) requests to the node controller of individual machines concurrently to reduce power. Important data about the power delivery topology, such as the protected power limits and the machines to be throttled under the power domain, are obtained from a power topology datastore.

The scale of a power domain can vary from a few megawatts, such as a PDU, to tens of megawatts, such as a MVPP. One instance of Thunderbolt is deployed for each protected power domain. The instance is replicated for fault tolerance. There are 4 replicas in a 2-leader, 2-follower configuration. Only the leader replicas can read power meters and issue power shedding RPCs. The node controller's power shedding RPC services are designed to be idempotent and can handle duplicate RPCs from different leader replicas. We require two identical leader replicas to ensure power shedding is available even during leader election periods. Followers take over when leaders become unavailable.

The architecture allows Thunderbolt to scale easily. When a new power domain is turned up, a new Thunderbolt instance can be deployed without affecting existing instances for other domains. When machines are added to or removed from a power domain, only the power topology data needs to be updated to include an up-to-date list of machines.

4.1 Primary subsystem: reactive capping

4.1.1 Node-level mechanism: CPU bandwidth control

CPU usage is a good indicator for the CPU power drawn by a running task. We use the CPU bandwidth control feature of the Linux completely fair scheduler (CFS) [21] to precisely control the CPU usage of tasks running on a node, in order to control the power drawn by the node.

Individual tasks run inside their own Linux control groups (cgroups). The Linux scheduler provides two parameters for a cgroup, namely *quota* and *period*. Quota controls the amount of CPU time the workload gets to run during a period and is replenished every period. Quota is shared and enforced by all logical CPUs in the system. The quota and period can be set for each cgroup and are typically specified at millisecond granularity. A separate (per cgroup and per logical CPU), cumulative *runtime_remaining* variable is kept inside the kernel. The cumulative (per logical CPU) *runtime_remaining* is consumed when a thread is running on the CPU. When it reaches zero, it attempts to draw from the per-cgroup quota pool. When the quota pool is empty, the running thread is descheduled and no thread in the same cgroup can run until quota is replenished at the beginning of the next period.

We track the historical CPU usage of all workloads running on the machine. During a capping event, every node in the power domain will receive an RPC to throttle throughput-oriented workloads. The RPC contains parameters describing how much the CPU usage of the tasks should be reduced

(details in [Section 4.1.2](#)). The node controller that receives the RPC uses the historical CPU usage of all throughput oriented workloads to determine how much CPU time to throttle. The new quota and period values are then calculated and configured for each cgroup on the machine.

Different tasks have different cgroups, and we can achieve task-level QoS differentiation by adjusting their cgroup parameters. The Thunderbolt framework is capable of assigning different CPU throttling levels to different cgroups, with more restrictive levels to lower priority cgroups. In our cluster resource management systems, throughput-oriented tasks are typically assigned low priorities while latency-sensitive tasks are assigned high priorities. CPU throttling is applied only to cgroups of throughput-oriented tasks, exempting cgroups of latency-sensitive tasks. This is appropriate for our production environment, where a significant portion of total CPU resources is consumed by throughput-oriented tasks (also known as batch tasks [20]), and it is undesirable to throttle business-critical latency-sensitive tasks. Exempting all latency-sensitive tasks comes with a caution about non-sheddable power, which is explained below. Kernel threads are also exempt from throttling and their CPU usage is very low compared to regular tasks.

Non-sheddable power, the lower bound of the power control range, is an important consideration for power oversubscription and capping. With our implementation of Thunderbolt, non-sheddable power can be attributed to CPU usage by exempt tasks, machine idle power, and other uncontrolled power users such as cooling equipment. We deliberately set the oversubscription level so that non-sheddable power does not exceed the protected power limits. We run continuous monitoring and rigorous analysis to predict and alert on the portion of non-sheddable power in our data centers. In an unlikely event when high non-sheddable power is predicted in a cluster, site operators can leverage global load balancing to redirect traffic of latency-sensitive tasks elsewhere to offset the risk.

The relationship between throttling levels and power draw is nonlinear and workload dependent, therefore we always use CPU bandwidth control in conjunction with power metering and negative feedback to ensure expected power reduction is achieved. The feedback loop is described in detail in [Section 4.1.2](#).

Characteristics of CPU bandwidth control. CPU bandwidth control has two important properties:

Platform-agnostic. CPU bandwidth control is a pure software feature supported by the upstream Linux kernel. It can be switched on for almost any new platform with minimal additional effort.

Task-level control. CPU bandwidth control is at the task (cgroup) level. Specifically, tasks of varying priorities are co-located on the same server and can even run on the same physical core. CPU bandwidth control has the

Table 1: Comparison between CPU bandwidth control, DVFS, and RAPL for power limiting.

	CPU bandwidth control	DVFS	RAPL
Response time	1 ms	100 μ s	100 μ s
Spatial granularity	cgroup	Physical core	Processor socket
Power feedback control	Requires external	Requires external	Processor built-in
Mechanism	Pure software	Requires hardware support	Requires hardware support

required fine-grained visibility and control to provide the differentiated QoS.

These properties make CPU bandwidth control a good fit for our needs. We have also considered other popular hardware-based alternatives, in particular dynamic voltage and frequency scaling (DVFS) and Intel’s running average power limit (RAPL). Below we compare and discuss CPU bandwidth control and the two alternatives, and explain why, despite the merits of the two alternatives, we do not adopt them for Thunderbolt.

We summarize several attributes of CPU bandwidth control, DVFS, and RAPL in [Table 1](#). Given their nature of hardware control, DVFS and RAPL both have faster power response times than bandwidth control. In practice, however, we find that the longer response time of CPU bandwidth control is still fast enough to be an effective load shedding mechanism for safe power oversubscription (see [Section 6](#)).

CPU bandwidth control vs RAPL: RAPL is available only on Intel platforms. More importantly, the power limit can only be set on a per socket basis, which means it does not provide task-level control granularity. Alternative approaches are possible to achieve differentiated task QoS using RAPL if additional support is added to the node controller. For instance, tasks with different QoS may be scheduled on different sockets. Apart from the extra complexity, such a scheduling constraint has a disadvantage of limiting CPU resource over-commitment opportunity, which is undesirable for our cluster scheduler [22].

CPU bandwidth control vs DVFS: DVFS is available on most modern high-performance platforms, bringing its compatibility close to CPU bandwidth control. However, it may also have problems supporting task-level control. For example, per-core DVFS is supported by Intel only for Haswell and later generations, and it is not supported by some non-x86 vendors. In terms of power control and performance impact, as we will show in [Section 5](#), DVFS is incapable of throttling down to very low power levels but it has better power efficiency than bandwidth control.

Operational factors. The platform-agnostic nature of CPU bandwidth control is vital to new platform introductions. Even if a new microarchitecture supports fine-grained DVFS, driver support for new platforms often have issues that require extra

work. More importantly, per-task DVFS setting is not supported by the upstream Linux kernel. It is also not rare to find chip errata that require workarounds. Using CPU bandwidth control as either the main throttling mechanism or as a fall-back mechanism removes these uncertainties in the critical path. It makes us more comfortable about scaling up our data centers with heterogeneous processor microarchitectures.

Overall we consider CPU bandwidth control essential to the success of Thunderbolt. In the future DVFS can be added as a node-level optimization. When Thunderbolt was first deployed, per-task DVFS setting was not available in our Linux kernel. We have recently added per-task DVFS support to the Linux kernel to enable additional trade-offs between performance and efficiency on Intel servers. The same kernel mechanism can be used for power throttling.

4.1.2 Control policy: load shaping

The load shaping control policy determines when and how much the actuator (CPU bandwidth control) should throttle CPU usage in order to control power.

Formally, the power draw of a power domain can be written as

$$p(t) = \sum_{i=1}^N f_i(c_i(t) + u_i(t)) + n(t) \quad (1)$$

where t is (discrete) time, p is the total power draw, N is the number of machines, f_i is the power drawn by machine i as a monotonic function of the normalized machine CPU utilization (in the range of $[0, 1]$), c_i is the CPU used by controllable tasks, u_i is the uncontrollable CPU used by exempt tasks and the Linux kernel, and n is the power drawn by non-machine equipment. Our goal is to cap c_i so that $p < l$ for a power limit l . Preventing overload ($p > l$) is the top priority, while keeping p close to l when $p < l$ is also desirable for efficiency.

We use a *randomized unthrottling/multiplicative decrease* (RUMD) algorithm. If $p(t) > l$, then we apply a cap for the CPU usage of each controllable task. The cap is equal to the task’s previous usage multiplied by a *multiplier*, m , in the

range of (0, 1). Then the power draw at the next time step is

$$\begin{aligned} p(t+1) &= \sum_{i=1}^N f_i(c_i(t+1) + u_i(t+1)) + n(t+1) \\ &\leq \sum_{i=1}^N f_i(mc_i(t) + u_i(t+1)) + n(t+1) \end{aligned} \quad (2)$$

This cap is updated every second, and c_i decreases exponentially with time, until $p < l$. Note that, because of the u_i and n terms, there is no guarantee that $p(t+1) < p(t)$. Nevertheless, as explained in [Section 4.1.1](#), in practice we ensure with high confidence that non-sheddable power is less than the power limit, that is,

$$\sum_{i=1}^N f_i(u_i(t)) + n(t) < l, \forall t \quad (3)$$

Therefore power will eventually be reduced below the limit.

The system works on a time scale of seconds: power measurements are read once per second, and throttling parameters are updated every second. This is because the typical end-to-end response time is 1–2 seconds from a high power draw to power being sufficiently reduced by throttling. This is mostly attributed to metering delays. We conservatively budget 5 seconds to account for occasionally longer metering delays and network tail latency.

Throttling stops when p decreases to be below l . To avoid fast power surges, throttling should stop in a progressive manner. We do this by removing the CPU cap on a random portion of machines every second. For instance, if it is configured to completely unthrottle all machines in 5 seconds, then a random non-overlapping set of 20% of machines will be unthrottled every second. Alternatively, one may progressively lift the cap in an additive manner for each machine at the same time, leading to an *additive increase/multiplicative decrease* (AIMD) algorithm [5]. We choose a randomized unthrottling scheme instead of AIMD because it is simpler (no need for an additive increase parameter), and AIMD’s “fairness” property (machines converging to having the same CPU utilization) is not required for our system, as long as randomization avoids any machine from being disproportionately impacted.

Similar to AIMD, our RUMD algorithm also has the desirable partial distributedness property. The central policy controller requires no detailed system states, such as the CPU usage and task distribution of each machine, other than the total power. The distributed node controllers can make independent decisions based solely on a few parameters that the policy controller sends to all node controllers.

The result of the RUMD algorithm is a power curve oscillating around the capping limit in a sawtooth-like pattern, as can be seen in [Section 6.2](#).

Implementation details. Here we give some details about our implementation of the RUMD algorithm. In particular,

we explain how we balance two competing properties, responsiveness for power safety and efficiency for minimizing performance impact, by maintaining two capping thresholds, one high and one low. The *high threshold*, placed close to the protected power limit, is associated with a *hard multiplier* close to 0 in order to quickly reduce power for safety. The *low threshold*, placed with a larger margin from the protected limit, is associated with a *soft multiplier* for gentle throttling.

We start by explaining the high threshold for power safety. Our end-to-end response time budget is 5 seconds. In 5 seconds, we have observed that power in a nearly full cluster will increase by no more than 2% of the protected equipment limit. Therefore we place the high threshold at 98% of the limit. The hard multiplier associated with this threshold is set to be close to 0 for a quick reduction of a large amount of power. This is because the only strong power guarantee is non-sheddable power being less than the limit ([Equation 3](#)), and thus sheddable power has to be reduced to nearly zero quickly to guarantee responsiveness and safety.

It is worth noting that most circuit breakers do not immediately trip when their rated power limit is reached. They may tolerate a few seconds to tens of minutes of power overload [9]. In theory we may make use of this time buffer and set the capping threshold at the power limit. However, how long a breaker can sustain a power overload depends on many factors, such as the design of the breaker, the magnitude of the overload, and ambient temperature [9], and is thus hard to predict. Power overload also decreases the equipment’s lifetime. Therefore we choose to place the high threshold 2% below the power limit to avoid tapping into the overload region.

We do not reduce the CPU cap of a task below a minimum value (0.01) because the quota value in CPU bandwidth control has to be greater than zero. This has a production implication: when continuous throttling is applied long enough, affected tasks will eventually converge to the minimum CPU share. In this case, while all affected tasks cannot make meaningful progress and power will be low, some tasks can still respond to health checks and survive. Because of this, task failures due to continuous throttling are expected to be fewer than failures caused by completely suspending tasks, as can be seen in [Section 6.2](#).

The hard multiplier close to zero, while being responsive and safe, is not efficient for utilizing the power budget because it leads to power oscillation with a large amplitude. Therefore we introduce the low threshold associated with the soft multiplier. The soft multiplier is close to 1 to improve efficiency at the cost of responsiveness, and the low threshold is placed below the high threshold to allow the longer response time.

We further optimize our design by not activating the low threshold until throttling is triggered, and deactivating it after throttling has not been active for a while. This way power is allowed to reach the range between the two thresholds without throttling.

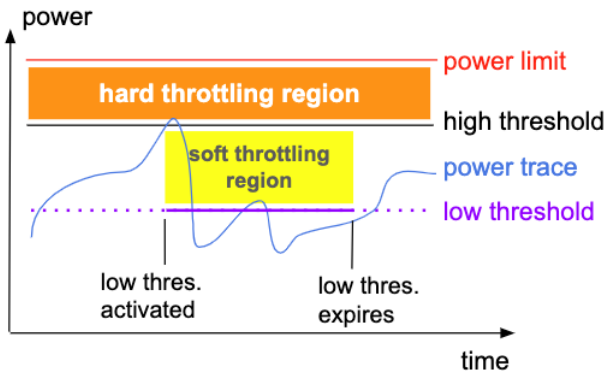

Figure 2: Load shaping power control.

Table 2: Load shaping parameters used in production.

Load shaping parameter	Value
High threshold	98% of protected limit
Low threshold	96% of protected limit
Hard multiplier	0.01
Soft multiplier	0.75
Low threshold expiration	5 minutes
Throttling timeout	1–20 seconds

Randomized unthrottling is implemented by assigning to each machine a random throttling timeout in a range. A random timeout is included in the throttling RPCs and sent to each machine every second to refresh its timeout. When power is below the capping threshold, the machines will stop receiving the RPCs and will unthrottle after the last received timeout has passed. We choose a repeatedly-refreshed timeout instead of a stop-throttling RPC because stop-throttling RPCs may be dropped or even never reach some machines if the network becomes partitioned.

Figure 2 illustrates the power trace in a typical throttling scenario. Table 2 lists the parameters we use in production.

4.2 Failover subsystem: proactive capping

The feedback control of reactive capping relies on power meters. However, power meters and the facility network connecting the meters to the production network are not always available. On average, individual meters and facility network have about 99.9% availability in our data centers, and it varies by location. Transient network issues can cause seconds to minutes of power signal interruption, while meter downtime can be days before the meter gets repaired.

Without power signals, it is not straightforward to use CPU bandwidth control for an open-loop control. We have built models to map machine power utilization to CPU utilization,

so we may distribute the power domain’s total power budget to individual machines and translate a machine’s power budget to a CPU budget. However, it would require a sophisticated algorithm to allocate the machine’s CPU budget among individual tasks while respecting the tasks’ QoS difference. Instead of introducing a complex algorithm, we implement a simple mechanism, CPU jailing, that specifies a total CPU budget for a machine and leverages the Linux CFS scheduler to provide task QoS differentiation (although the differentiation is relaxed compared to when meter is available, which is explained further below). In a nutshell, CPU jailing is coarser-grained than CPU bandwidth control, but much easier to reason about when power signals are unavailable.

DVFS or RAPL, where supported, may also be used for proactive capping because we only need machine-level control. However, we favor the platform-independent CPU jailing for the same reasons as we favor the platform independence of CPU bandwidth control.

We have also considered collecting power signals from secondary sources, such as the machines’ power supply units, or from power models. However, we found that the data quality of the sensors and the accuracy of the models for some hardware do not meet our production requirements.

4.2.1 Node-level mechanism: CPU jailing

CPU jailing masks out (“jails”) a certain number of logical CPUs from tasks’ runnable CPU affinity [15] to cap total machine power. We refer to the portion of jailed CPUs as *jailing fraction*, denoted by J . CFS will maintain proportional fairness among tasks on the remaining available logical CPUs. Each jailing request comes with a timeout that can be renewed. Once jailing expires, previously masked CPUs will immediately become available to all tasks.

CPU jailing immediately caps peak power draw as it effectively limits maximum CPU utilization to $(1 - J)$ on every single machine. It sets an upper bound for power draw, allowing safe operation for an extended time without power signals. Because of increased idleness, jailed CPUs have a higher chance of entering deep sleep to further reduce machine power.

The jailing fraction is uniformly applied to individual machines, regardless of their CPU utilization. Consequently, machines with low utilization are less impacted than highly utilized machines. As an extreme example, CPU jailing might not affect tasks at all on machines with utilization well below $(1 - J)$.

Certain privileged processes, such as critical system daemons, are explicitly exempt (i.e., they can still run on jailed CPUs). The rationale is that their CPU usage is very low compared to regular tasks but the consequences of them being CPU starved can be devastating (e.g., machine cannot function correctly). A side effect of exemption is that it puts some sporadic usage on the jailed CPUs and occasionally prevents

them from entering deep sleep state.

A main disadvantage of CPU jailing is the relaxed QoS differentiation. For example, the latency of a serving task can be severely affected when too many cores are jailed. Although this effect is attenuated by the fact that latency-sensitive tasks run at higher priorities and can preempt lower-priority throughput-oriented tasks during CPU resource contention, CPU jailing is less favorable than CPU bandwidth control and is only employed where load shaping is not applicable.

Technically, one may achieve strict QoS differentiation by applying CPU jailing to only throughput-oriented tasks while exempting latency-sensitive ones. However, doing so without power signals is intangible in practice. If latency-sensitive tasks are exempt from CPU jailing, the only strong guarantee we have about power is that non-sheddable power does not exceed power limit (Equation 3). In this situation, guaranteeing power safety would require not running throughput-oriented tasks at all, which we cannot afford.

Determining jailing fraction J . A proper jailing fraction J can be determined from two factors: the relation between CPU utilization and power utilization, and power oversubscription ratio.

For power safety, we need to ensure power is reduced to a safe level after a certain fraction of CPUs are jailed. This value of J can be calculated from the power oversubscription ratio and the CPU utilization-power utilization relation of the given collection of hardware in the power domain, as follows:

$$J = 1 - U_{cpu} = 1 - g_{power \rightarrow cpu} \left(\frac{1}{1+r} \right) \quad (4)$$

In the formula, U_{cpu} is the highest allowed CPU utilization (normalized to the total CPU capacity), $g_{power \rightarrow cpu}$ is a function to convert power utilization (normalized to the theoretical total peak power) to CPU utilization, and r is the oversubscription ratio defined by the extra oversubscribed power capacity as a fraction of the nominal capacity. $1/(1+r)$ gives the maximum safe power utilization, which can be converted to U_{cpu} given that the CPU utilization-power utilization relation is monotonic. A greater r leads to smaller allowed power utilization and smaller U_{cpu} , which in turn leads to greater J .

In production, we set J to 20%–50% depending on a cluster’s workloads and risk profiles. This is a deliberate trade-off between performance SLO and power oversubscription opportunity.

4.2.2 Control policy: risk assessment of power signal unavailability

As a fallback approach, CPU jailing is triggered when we lose power measurements from the meters and the risk of power overloading is high. The risk is determined by two factors, predicted power draw and meter unavailability duration. Higher predicted power draw and longer meter unavailability

Figure 3: CPU power response to bandwidth control, DVFS, and RAPL.

means higher risk. The end-to-end delay from risk assessment to power reduction is typically 1–2 seconds, similar to load shaping. In our implementation, we use a simple and conservative probabilistic model to estimate the probability of power reaching the protected equipment limit during certain meter downtime given the power draw of the recent past. CPU jailing is triggered if the probability is high due to high recent power draw and long enough downtime. Our conservative model favors low false negatives (i.e., CPU jailing is triggered when overload would have happened without it) at the cost of relatively high false positives (i.e., CPU jailing is triggered even when it does not have to). This is appropriate because power safety is our top priority and power reading unavailability is infrequent. The probabilistic model is not the focus of this paper, but one can freely use any model that estimates the risk from any available data and plug it in here.

5 Evaluation Results at the Node Level

Before discussing data center-level aggregated data, we show two examples of node-level data from experiments performed on an Intel Skylake CPU.

CPU power and set point. To quantify the effectiveness of CPU bandwidth control, DVFS, and RAPL to control power, we measure total CPU power under various set points of the three knobs. We ran Intel’s “power virus” workload [7] that stresses the CPU and the memory to maximize power draw. We then separately used CPU bandwidth control, DVFS, and RAPL to limit CPU power and compared the results, which are shown in Figure 3. CPU power is normalized to the highest power observed when none of the power management mechanisms are enabled.

Figure 3(a) shows that, with CPU bandwidth control, we are able to reduce CPU power to 0.34 due to significant deep sleep state residency from bandwidth control.

In comparison, Figure 3(b) shows that with DVFS, power draw is still relatively high at 0.57 when the lowest frequency limit is applied. The frequency limit is normalized to the base frequency of the processor.

Figure 4: Throughput of a video transcoding task as a function of CPU power under bandwidth control and DVFS.

Figure 3(c) shows RAPL has the widest power reduction range among the three. It is able to reduce power to 0.22. However, we noticed system management tasks were sluggish to respond when RAPL approached the lowest power limits, which suggests higher machine timeout risks if these limits were actually used in practice. By contrast, CPU bandwidth control used in our system only throttles throughput-oriented tasks and the system management tasks are not affected. Thanks to its built-in feedback loop, RAPL is fairly accurate in achieving the provided power budget [26]. RAPL’s predictability is an advantage over DVFS or CPU bandwidth control.

CPU power and throughput. In this experiment, we run a throughput-oriented video transcoding task under various set points of CPU bandwidth control and DVFS, and measure CPU power and task throughput. This gives us information about the throughput impact of the two mechanisms under a power budget. Throughput is calculated as the reciprocal of the wall clock time of completing the task, normalized to the throughput where no power throttling is applied. CPU power is normalized to the highest power observed when power virus is run and no power throttling is applied (matching Figure 3).

Results are shown in Figure 4. Throughput is only mildly affected when power is greater than 0.85 for both bandwidth control and DVFS. Possibly memory bandwidth, rather than CPU bandwidth, is the bottleneck in this region. Throughput drops notably as power drops below 0.85 for both mechanisms, but DVFS has higher throughput than bandwidth control under the same power. Therefore, DVFS is more power efficient than bandwidth control. However, in terms of power control dynamic range, DVFS can only reduce power by 40% when the lowest frequency limit is applied, whereas bandwidth control is capable of nearly 60% power reduction. This is consistent with the power virus result in Figure 3. Load shaping events happen infrequently in our data centers, thus power efficiency is not a major factor for our use case.

6 Evaluation Results at Data Center Scale

To characterize the system at scale, we performed experiments in clusters comprising tens of thousands of machines running

Figure 5: Typical load shaping patterns. (a1) and (a2) show the normalized power and CPU utilization of a load-shaped power domain, with 0.01 hard multiplier and 0.5 soft multiplier. (b1) and (b2) show similar data for the same power domain but with 0.01 hard multiplier and 0.95 soft multiplier. The blue horizontal dashed lines are low power thresholds associated with the soft multipliers. The red vertical lines mark the start of load shaping. (The power and CPU readings are not exactly time-aligned due to sampling delays.)

diverse production workloads in our data centers. Throttling was manually triggered with various combinations of parameters. Power data is collected from data center power meters, which is the same data that Thunderbolt also uses. Power measurement data is normalized to the power domain’s equipment limit.

Other metrics are sampled from individual machines and aggregated at the same power domain level corresponding to the power readings. Machine metrics such as CPU usage are normalized to the total capacity of all machines in the power domain unless specified otherwise. Task failures are normalized to the total number of affected tasks.

Latency data are collected from low-level storage services that read and write Linux files and support Google’s distributed file system. They are critical services widely deployed in our data centers, running at high priorities and thus exempt from load shaping. They are not exempt from CPU jailing but have high priority to access the remaining CPUs.

6.1 Load shaping in typical scenarios

In this experiment, we picked a production cluster that is dominated by throughput-oriented workloads to test the typical behavior of load shaping. Load shaping was triggered by manually lowering the high power threshold to be just below the ongoing power draw of a power domain.

Power and CPU usage patterns. Figure 5(a1) shows a typi-

Table 3: Load shaping duration, task failure fraction, and 99%-ile read latency of storage services under different scenarios.

	Duration	Failure fraction	Latency
Baseline	25 min.	0.00002	79 ms
0.95 soft mult.	5 min.	0.00000	79 ms
0.75 soft mult.	10 min.	0.00003	80 ms
0.5 soft mult.	5 min.	0.00007	78 ms

cal load shaping pattern of power oscillating around the low threshold. Seconds after throttling is triggered, power is reduced by a large margin because of the hard multiplier. Meanwhile the low threshold is activated. Throttling is gradually lifted as power drops below the low threshold, and power goes back up until it reaches the low threshold. Then power is reduced again, but by a smaller margin because of the soft multiplier. The process continues as throttling is turned on and off repeatedly, resulting in power oscillating around the low threshold. Figure 5(b1), as compared to (a1), shows a soft multiplier closer to 1.0 leads to oscillations of a smaller amplitude, as expected. The response time from load shaping triggering to significant power reduction is about 2 seconds.

Figure 5(a2) and (b2) show the CPU utilization corresponding to (a1) and (b1) respectively. At the shown CPU utilization level, about 0.1 reduction of CPU utilization is needed to reduce 0.02 of power.

Task failures. While tasks are slowed down, we want to ensure that most of them do not fail because of CPU starvation or unexpected side effects. Table 3 shows task failure fractions (the number of failed tasks normalized to the total number of affected tasks) of the same power domain under load shaping with various soft multipliers. “Baseline” indicates no throttling and serves as the baseline for comparison. All load shaping events have a hard multiplier of 0.01 (not shown in the table) while the soft multiplier varies from 0.5 to 0.95. Clearly load shaping does not cause noticeably more failures. The failure fraction remains low compared to the baseline.

Latencies. To assess load shaping’s effect on the latencies of latency-sensitive tasks, we inspect the tail 99%-ile read latency of latency-sensitive storage services, shown in Table 3. As expected, the latency is not affected by load shaping because the tasks are exempt from the mechanism.

Differentiation of QoS. To test Thunderbolt’s ability to differentiate QoS, we classified tasks into two groups based on their priority, and load-shaped the low-priority group while exempting the high-priority group. Figure 6 shows the total power draw and CPU usage of the two groups of tasks, during the event. The CPU usage of the shaped and the exempt group is reduced by about 0.1 and 0.03, respectively. The exempt group is indirectly affected because the tasks in the

Figure 6: Power and CPU utilization during a load shaping event with multiplier 0.1 that directly affects a subset of tasks. The red vertical line marks the start of the event. The CPU reduction of the load-shaped tasks are more prominent than that of the exempt tasks. The exempt tasks are indirectly affected because of their interaction with the shaped tasks. (The power and CPU readings are not exactly time-aligned due to sampling delays.)

two groups are production tasks with complex interactions. One of such interactions is that a high-priority controller task in the exempt group coordinates low-priority workers in the shaped group, and the controller task has less work to do and consumes less CPU when the workers are throttled. Nevertheless, the ability of load shaping to differentiate tasks is evident.

6.2 Load shaping pushed to the limit

In typical scenarios, as demonstrated in Section 6.1, load shaping reduces power to a safe level just below the threshold and allows power to oscillate around it. However, in extreme cases where power stays above the threshold, the system will need to continuously reduce tasks’ CPU usage, eventually to the preset minimum value. The affected tasks will essentially be stopped and make no forward progress. For example, power may remain high after throttling is triggered because new compute-intense tasks are continuously scheduled, or many high-priority tasks exempt from the mechanism spike in their CPU usage. In such cases it is the right trade-off to stop the low-priority tasks in order to prevent power overloading.

To test the behavior of load shaping in such extreme scenarios, we picked a cluster with some low-priority, non-production, throughput-oriented workloads and applied a multiplier continuously to those tasks. (Most of the tasks in that cluster are high-priority, which we exempt from this test thanks to load shaping’s ability to differentiate tasks.) We com-

Figure 7: Power responsiveness of continuous throttling and of SIGSTOP. (a) and (b) are throttling with a multiplier of 0.95 and 0.01, respectively. (c) is SIGSTOP. The red vertical lines mark the start of throttling and SIGSTOP.

pared continuous throttling to explicitly stopping the tasks by sending them a SIGSTOP signal followed by a SIGCONT signal after 60–75 seconds.

Power responsiveness and range of control. Figure 7 shows the power responsiveness of continuous throttling and of SIGSTOP. Here power is reduced noticeably in 2 seconds. This is true for all the tested multipliers as well as for SIGSTOP. In 4 seconds, about 3% of power is shed by throttling with a 0.01 multiplier and by SIGSTOP, and 0.5% by throttling with a 0.95 multiplier, respectively.

If throttling is applied continuously, we expect tasks to eventually have close-to-zero CPU shares and we achieve similar power reduction as SIGSTOP. This is indeed true. Figure 8 compares the power reduction by continuous throttling with two multipliers, and compares them to SIGSTOP. It plots the same data as Figure 7 but on a larger time scale to show the power reduction. (Note that the x axes of the sub-figures are scaled differently because the power reduction happens at different time scales.) Power is reduced at a slower pace with a multiplier closer to 1, but given enough time it is eventually reduced by an amount similar to SIGSTOP (about 0.015) regardless of multiplier. This is expected, because the cumulative effect of applying any multiplier between 0 and 1 should eventually converge to CPU shares that are close to zero. This also implies that the selection of the multiplier does not affect the effectiveness of power reduction in terms of sheddable power. The selection of the multiplier does affect responsiveness, however, which is important when power spikes need to be throttled quickly.

Task failures. Table 4 lists the task failure fractions during the test periods of continuous throttling and SIGSTOP. “Baseline”

Figure 8: Power reduction by continuous throttling and by SIGSTOP. (a) and (b) are throttling with a multiplier of 0.95 and 0.01, respectively. (c) is SIGSTOP. The red vertical lines mark the start of throttling and SIGSTOP. The x axes of the sub-figures are scaled differently because the power reduction happens at different time scales.

Table 4: Power shedding duration, task failure fraction, and 99%-ile read latency of storage services under different scenarios.

	Duration	Failure fraction	Latency
Baseline	15 min.	0.0007	126 ms
0.95 mult.	20 min.	0.0007	122 ms
0.01 mult.	2 min.	0.003	125 ms
SIGSTOP	2 min.	0.06	135 ms

indicates no throttling or SIGSTOP and serves as baseline for comparison. Throttling with a 0.95 multiplier has mild effect on failure fraction and can be continuously applied to tasks for longer time (20 minutes here). Both throttling with a 0.01 multiplier and SIGSTOP were only performed for a short period of time (2 minutes), but they caused skyrocketed failure fraction by one to two orders of magnitude. The failures are mostly attributed to tasks being terminated because they fail to respond to health checks. The increased failure fraction of continuous throttling with a 0.01 multiplier is contrasted with the low failure fractions of load shaping in Table 3. Those load shaping events in Table 3 had a 0.01 hard multiplier in effect only for a few seconds, because the hard multiplier was progressively lifted in seconds after power drops below the high power threshold. The failure fraction of continuous throttling with a 0.01 multiplier is one order of magnitude lower than that of SIGSTOP because the throttled tasks still have a minimum CPU share, and some of them can respond

Figure 9: Responsiveness and power reduction of CPU jailing with 20% jailing fraction. Power is reduced by 0.02 in 5 seconds when the power domain’s CPU utilization is about 60% (not shown in the figure).

Table 5: Effect of 20% CPU jailing on machine CPU utilization.

	Duration	Machine CPU utilization		
		50%ile	95%ile	99%ile
Baseline	60 min.	0.58	0.80	0.94
CPU jailing	55 min.	0.55	0.69	0.75

to health checks and survive.

Latencies. Table 4 shows the tail 99%-ile read latency of latency-sensitive storage services. As expected, the latency is not notably affected by either load shaping or SIGSTOP, both of which are not applied to those services.

6.3 CPU jailing

For this experiment of CPU jailing, we picked the same production cluster as in Section 6.1, which is dominated by throughput-oriented workloads. We manually performed CPU jailing with a 0.2 jailing fraction, denoted by “20% CPU jailing”, and collected data for power, CPU usage, CPU cores in deep sleep states, task failures, and latencies. The same types of data were collected during a period before the CPU jailing event; those data will serve as the baseline for comparison.

Power responsiveness. For the purpose of a failover mechanism, response time is not a concern in most cases, except for the corner case where meter signals are lost while load shaping is, or very close to being, active. Nevertheless, Figure 9 shows that power utilization is reduced by 0.02 (from 0.72 to 0.70) in 5 seconds under 20% CPU jailing. The power reduction is relatively small, because most machines had lower than 80% CPU utilization even before 20% jailing was applied to them. This can be seen in Table 5, discussed further below.

CPU usage. CPU jailing affects machines with high CPU utilization more than those with low CPU utilization. This is evident from Table 5. The median machine CPU utilization

Table 6: Task failure fraction and 99%-ile read latency of storage services under 20% CPU jailing.

	Duration	Failure fraction	Latency
Baseline	60 min.	0.00003	79 ms
CPU jailing	55 min.	0.00002	86 ms

without CPU jailing is 0.58, and it is only mildly affected by 20% CPU jailing that limits available machine CPU capacity to 80%. In contrast, the 99%-ile and 95%-ile machine CPU utilizations, which are close to or higher than 80%, are reduced significantly during CPU jailing.

While CPU jailing is a pure software mechanism, it can get extra benefits with hardware support that puts idle cores in power-saving states. In our experiment with 20% CPU jailing, 5% of affected CPU cores entered deep sleep states (C6/C7 states) as compared to 1% of cores without jailing. Noticeably, although 20% of cores are jailed, the portion of deep-sleep cores is always less than 20% due to processes exempt or unaffected by the mechanism.

Task failures and latencies. Table 6 shows the task failure fraction and the 99%-ile read latency of storage services of a power domain in a 20% CPU jailing event. There is no notable difference in failure fraction and latency compared to the baseline. Both latencies are far below our SLO. However, in a separate experiment of 80% CPU jailing we observed an order of magnitude higher latency (not shown in the table), which is not surprising because severe CPU contention is expected with such heavy jailing.

7 Deployment at Scale and Benefits

Thunderbolt has been deployed at scale in our logs processing clusters and has enabled 9%–25% power oversubscription relative to the nominal capacity, depending on the power delivery architecture. The oversubscription is determined by an SLO with the clusters’ stakeholders about the expected occurrence frequency of throttling events under realistic worst conditions. Other throughput-oriented clusters, such as web indexing, are also in scope of more aggressive power oversubscription with Thunderbolt.

Logs processing workloads are mostly throughput-oriented and continuously running. Resources are provisioned to accommodate worst-case daily throughput demands, and any disruptive power capping actuation on the worst day is a waste of the resources and cancels the benefits of aggressive power oversubscription. Thunderbolt, by gently throttling computation, distributes the actual work throughout the day, gracefully allowing throughput to be conserved. Despite that most workloads are throughput-oriented, there are still critical latency-sensitive workloads such as low-level storage services, and

therefore QoS differentiation is important.

The reactive capping mechanism has been activated three times by exceptionally high power draw in three production clusters in the first 130 days of year 2020. The proactive capping mechanism has been activated two times by power telemetry unavailability in two high-power production clusters in the same period of time. Such incidents could have resulted in tripping data center breakers without the protection from the power capping system. The activation events went unnoticed by stakeholders, with negligible adverse effect on production.

8 Challenges and Future Work

Thunderbolt, implemented as described in this paper, is suitable for our production clusters running a mix of throughput-oriented and latency-sensitive workloads. Those clusters have a sizable portion of power drawn by throughput-oriented tasks, and a stable usage pattern of latency-sensitive workloads. Therefore, we are able to set an appropriate oversubscription level with high confidence that non-sheddable power will not pose a risk, and that CPU jailing will not starve latency-sensitive tasks. Nevertheless, the Thunderbolt framework is flexible enough for extension and optimization to accommodate clusters of different workload patterns. Here we discuss some directions and challenges.

Our implementation exempts all high-priority latency-sensitive workloads from load shaping but this is not always required. In clusters where latency-sensitive workloads may use too much power, one could further break them down into multiple priority buckets and throttle them as appropriate under their SLOs. Doing so in practice is a challenge as latency-sensitive tasks are generally not amenable to CPU throttling. It will likely require a co-design of throttling policy, SLO, and software infrastructure. For example, one could have an SLO that permits affecting the latencies for a small fraction of time, and design the workload and software infrastructure to respond to high latency properly. For cloud data centers where the infrastructure owner has limited control over the workloads, cloud providers may carefully design service-level agreements (SLAs) to allow throttling “abusive” behaviors, and possibly use price incentives to encourage “good” behaviors.

Thunderbolt sheds power by controlling CPU usage. This may not be effective if the majority of power is used by non-CPU components, such as hardware accelerators. While hardware support is needed to effectively throttle such components, the Thunderbolt software architecture and control policies of load shaping and proactive capping can be adapted to control additional hardware throttling knobs. QoS differentiation will depend on the control granularity of the hardware. For example, if an accelerator supports per-chip throttling and a chip is used by one task at a time, then task-level QoS differentiation is possible.

While proactive capping addresses the availability bottleneck of power telemetry unavailability, it may become a limiting factor for power oversubscription. We have to set the jailing fraction conservatively (i.e., it may be set greater than necessary) for the open-loop control to be safe. For clusters with a high portion of latency-sensitive tasks, only a small jailing fraction may be feasible, leading to a small oversubscription. To increase oversubscription for those clusters, it may be worth investing in building a reliable secondary source of power signals, either from rack- or machine-level power sensors or from machine learning models that map resource usage to power, so that closed-loop control is still functional when the primary source, data center power meters, is unavailable. Proactive capping may be used as the last resort when both the primary and the secondary sources are unavailable.

Thunderbolt is a *reactive* system (not to be confused with “reactive capping” defined in this paper), in the sense that it reacts to riskily high data center power that is present (in the case of reactive capping) or expected (in the case of proactive capping). A more *proactive* approach, such as power-aware job scheduling and admission control, may actively balance load to avoid riskily high data center power via scheduling rather than throttling. Job scheduling and admission control are largely orthogonal and complementary to Thunderbolt and are valuable candidates for future work.

9 Related Work

This work has a similar architecture as Google’s power capping for medium-voltage power planes (MVPPs) [18]. It shares many advantages of the MVPP power capping, such as fast response, priority- and QoS-awareness, platform-independence, and scalability, while making a critical improvement of not interrupting throughput-oriented workloads. This is to be contrasted with the MVPP power capping design that uses Linux SIGSTOP and SIGKILL signals. This work also introduces the proactive capping sub-system to improve system availability, which the MVPP capping system does not have.

Our primary, reactive capping subsystem uses node-level CPU bandwidth control provided by the Linux kernel’s CFS scheduler. To our knowledge this is the first time this node-level mechanism, applicable on a per-task basis, is used for data center power management. There is literature [2] that discusses using CPU bandwidth control for power management of mobile devices, but not for data centers. Other node-level mechanisms used for power management include DVFS [6, 16, 24], RAPL [25], Intel node manager [14], power gating [16], and thread packing [6, 17].

Reactive capping also uses load shaping, a data center-level closed-loop control, as the power control policy. Load shaping is implemented at one level of the power delivery “choke point” that constrains the overall power capacity. It is

simpler than multi-level controls in other large-scale implementations [14, 24, 25].

Our failover, proactive capping subsystem to mitigate the risk of power signal unavailability, uses node-level CPU affinity control. It is the same low-level mechanism as “thread packing” [6, 17], but in this work we use it only as a failover mechanism when power signals are unavailable because of its limitations compared to CPU bandwidth control.

Other studies also use power-aware job scheduling and admission control to limit power draw [4, 12, 23]. Compared to node-level and hardware-level power throttling mechanisms such as ours, these scheduler-level techniques can improve availability and performance of running jobs. It is a valuable direction for future work, as discussed in Section 8.

10 Summary

In this paper we present Thunderbolt, a throughput-optimized and QoS-aware power capping system that is robust and scalable. We elaborate important design choices and present production evaluation of its policy decisions. Thunderbolt has been deployed in warehouse-sized data centers and saved us millions of dollars on capital expenses by enabling otherwise nonexistent additional power capacity in our data centers.

Acknowledgments

This work is the result of multi-year efforts contributed by many engineers, managers, and supporting staff. We would like to thank Strata Chalup, Greg Imwalle, Tom Kennedy, Dave Landhuis, Mian Luo, Matthew Nuckolls, Pablo Perez, Etienne Perot, Brad Strand, Jeff Swenson, Jikai Tang, Steve Webster, Quincy Ye, Henry Zhao, and Steven Zhao for their contributions and support for the Thunderbolt program. We are also grateful to David Culler, Gernot Heiser, Jeff Mogul, and the anonymous reviewers for their constructive feedback.
