2021 USENIX Annual Technical Conference

July 14–16, 2021

Message from the USENIX ATC '21 Program Co-Chairs x

Wednesday, July 14

Peeking over the Fence: RDMA

Naos: Serialization-free RDMA networking in Java 1
Konstantin Taranov, *ETH Zurich*; Rodrigo Bruno, *INESC-ID / Técnico, ULisboa*; Gustavo Alonso and Torsten Hoefler, *ETH Zurich*

One-sided RDMA-Conscious Extendible Hashing for Disaggregated Memory 15
Pengfei Zuo, Jiazhao Sun, Liu Yang, and Shuangwu Zhang, *Huawei Cloud*; Yu Hua, *Huazhong University of Science and Technology*

Characterizing and Optimizing Remote Persistent Memory with RDMA and NVM 31
Xingda Wei, Xiating Xie, Rong Chen, Haibo Chen, and Binyu Zang, *Shanghai Jiao Tong University; Shanghai AI Laboratory; Engineering Research Center for Domain-specific Operating Systems*

MigrOS: Transparent Live-Migration Support for Containerised RDMA Applications 47
Maksym Planeta and Jan Bierbaum, *TU Dresden*; Leo Sahaya Daphne Antony, *AMOLF*; Torsten Hoefler, *ETH Zürich*; Hermann Härtig, *TU Dresden*

Dogs Never Get Tired: Power and Edge Computing

Prediction-Based Power Oversubscription in Cloud Platforms 65
Alok Gautam Kumbhare, Reza Azimi, Ioannis Manousakis, Anand Bonde, Felipe Frujeri, Nithish Mahalingam, Pulkit A. Misra, Seyyed Ahmad Javadi, Bianca Schroeder, Marcus Fontoura, and Ricardo Bianchini, *Microsoft Research and Microsoft Azure*

Proactive Energy-Aware Adaptive Video Streaming on Mobile Devices 81
Jiayi Meng, Qiang Xu, and Y. Charlie Hu, *Purdue University*

Video Analytics with Zero-streaming Cameras 99
Mengwei Xu, *Peking University/Beijing University of Posts and Telecommunications*; Tiantu Xu, *Purdue ECE*; Yunxin Liu, *Institute for AI Industry Research (AIR), Tsinghua University*; Felix Xiaozhu Lin, *University of Virginia*

ASAP: Fast Mobile Application Switch via Adaptive Prepaging 117
Sam Son, Seung Yul Lee, Yunho Jin, and Jonghyun Bae, *Seoul National University*; Jinkyu Jeong, *Sungkyunkwan University*; Tae Jun Ham and Jae W. Lee, *Seoul National University*; Hongil Yoon, *Google*

Barking up the Wrong Tree: Correctness and Debugging

PyLIVE: On-the-Fly Code Change for Python-based Online Services 131
Haochen Huang, Chengcheng Xiang, Li Zhong, and Yuanyuan Zhou, *University of California, San Diego*

RIFF: Reduced Instruction Footprint for Coverage-Guided Fuzzing 147
Mingzhe Wang, Jie Liang, Chijin Zhou, and Yu Jiang, *Tsinghua University*; Rui Wang, *Capital Normal University*; Chengnian Sun, *Waterloo University*; Jiaguang Sun, *Tsinghua University*

TCP-Fuzz: Detecting Memory and Semantic Bugs in TCP Stacks with Fuzzing 161
Yong-Hao Zou and Jia-Ju Bai, *Tsinghua University*; Jielong Zhou, Jianfeng Tan, and Chenggang Qin, *Ant Group*; Shi-Min Hu, *Tsinghua University*

MLEE: Effective Detection of Memory Leaks on Early-Exit Paths in OS Kernels 177
Wenwen Wang, *University of Georgia*

Argus: Debugging Performance Issues in Modern Desktop Applications with Annotated Causal Tracing 193
Lingmei Weng, *Columbia University*; Peng Huang, *Johns Hopkins University*; Jason Nieh and Junfeng Yang, *Columbia University*

Searching for Tracks: Graphs

- aDFS: An Almost Depth-First-Search Distributed Graph-Querying System** 209
Vasileios Trigonakis and Jean-Pierre Lozi, *Oracle Labs*; Tomáš Faltín, *Oracle Labs and Charles University*; Nicholas P. Roth, *KUNGFU.AI*; Iraklis Psaroudakis, Arnaud Delamare, Vlad Haprian, Călin Iorgulescu, Petr Koupy, Jinsoo Lee, Sungpack Hong, and Hassan Chafi, *Oracle Labs*
- GLIST: Towards In-Storage Graph Learning**..... 225
Cangyuan Li, Ying Wang, Cheng Liu, and Shengwen Liang, *SKLCA, Institute of Computing Technology, Chinese Academy of Sciences, Beijing, China; University of Chinese Academy of Sciences, Beijing, China*; Huawei Li, *SKLCA, Institute of Computing Technology, Chinese Academy of Sciences, Beijing, China; University of Chinese Academy of Sciences, Beijing, China*; Peng Cheng Laboratory, *Shenzhen, China*; Xiaowei Li, *SKLCA, Institute of Computing Technology, Chinese Academy of Sciences, Beijing, China; University of Chinese Academy of Sciences, Beijing, China*
- DART: A Scalable and Adaptive Edge Stream Processing Engine** 239
Pinchao Liu, *Florida International University*; Dilma Da Silva, *Texas A&M University*; Liting Hu, *Virginia Tech*
- CrystalPerf: Learning to Characterize the Performance of Dataflow Computation through Code Analysis** 253
Huangshi Tian, *HKUST*; Minchen Yu, *HKUST and Huawei Technologies Ltd.*; Wei Wang, *HKUST*
- Controlling Memory Footprint of Stateful Streaming Graph Processing** 269
Pourya Vaziri and Keval Vora, *Simon Fraser University*

Please Don't Chain Me Up: Blockchain and Security

- Avocado: A Secure In-Memory Distributed Storage System** 285
Maurice Bailleu, Dimitra Giantsidi, and Vasilis Gavrielatos, *University of Edinburgh*; Do Le Quoc, *Huawei Research*; Vijay Nagarajan, *University of Edinburgh*; Pramod Bhatotia, *University of Edinburgh and TU Munich*
- Accelerating Encrypted Deduplication via SGX** 303
Yanjing Ren and Jingwei Li, *University of Electronic Science and Technology of China*; Zuoru Yang and Patrick P. C. Lee, *The Chinese University of Hong Kong*; Xiaosong Zhang, *University of Electronic Science and Technology of China*
- ICARUS: Attacking low Earth orbit satellite networks** 317
Giacomo Giuliani, Tommaso Ciussani, Adrian Perrig, and Ankit Singla, *ETH Zurich*
- RainBlock: Faster Transaction Processing in Public Blockchains** 333
Soujanya Ponnappalli, Aashaka Shah, and Souvik Banerjee, *University of Texas at Austin*; Dahlia Malkhi, *Diem Association and Novi Financial*; Amy Tai, *VMware Research*; Vijay Chidambaram, *University of Texas at Austin and VMware Research*; Michael Wei, *VMware Research*
- An Off-The-Chain Execution Environment for Scalable Testing and Profiling of Smart Contracts** 349
Yeonsoo Kim and Seongho Jeong, *Yonsei University*; Kamil Jezek, *The University of Sydney*; Bernd Burgstaller, *Yonsei University*; Bernhard Scholz, *The University of Sydney*

I'm Old But I Learned a New Trick: Machine Learning

- Octo: INT8 Training with Loss-aware Compensation and Backward Quantization for Tiny On-device Learning** . 365
Qihua Zhou and Song Guo, *Hong Kong Polytechnic University*; Zhihao Qu, *Hohai University*; Jingcai Guo, Zhenda Xu, Jiewei Zhang, Tao Guo, and Boyuan Luo, *Hong Kong Polytechnic University*; Jingren Zhou, *Alibaba Group*
- Fine-tuning giant neural networks on commodity hardware with automatic pipeline model parallelism** 381
Saar Eliad, Ido Hakimi, and Alon De Jagger, *Department of Computer Science, Technion - Israel Institute of Technology*; Mark Silberstein, *Department of Computer Science and Department of Electrical Engineering, Technion - Israel Institute of Technology*; Assaf Schuster, *Department of Computer Science, Technion - Israel Institute of Technology*
- INFaaS: Automated Model-less Inference Serving** 397
Francisco Romero, Qian Li, Neeraja J. Yadwadkar, and Christos Kozyrakis, *Stanford University*
- Jump-Starting Multivariate Time Series Anomaly Detection for Online Service Systems** 413
Minghua Ma, *Tsinghua University, BNRist*; Shenglin Zhang, *Nankai University*; Junjie Chen, *Tianjin University*; Jim Xu, *Georgia Tech*; Haozhe Li and Yongliang Lin, *Nankai University*; Xiaohui Nie, *Tsinghua University, BNRist*; Bo Zhou and Yong Wang, *CNCERT/CC*; Dan Pei, *Tsinghua University, BNRist*
- Palleon: A Runtime System for Efficient Video Processing toward Dynamic Class Skew** 427
Boyuan Feng, Yuke Wang, Gushu Li, Yuan Xie, and Yufei Ding, *University of California, Santa Barbara*

Thursday, July 15

Can I Come In? It's Raining!: Cloud Computing

- FAASNET: Scalable and Fast Provisioning of Custom Serverless Container Runtimes at Alibaba Cloud Function Compute** 443
Ao Wang, *George Mason University*; Shuai Chang, *Alibaba Group*; Huangshi Tian, *Hong Kong University of Science and Technology*; Hongqi Wang, Haoran Yang, Huiba Li, and Rui Du, *Alibaba Group*; Yue Cheng, *George Mason University*
- Experiences in Managing the Performance and Reliability of a Large-Scale Genomics Cloud Platform** 459
Michael Hao Tong, Robert L. Grossman, and Haryadi S. Gunawi, *University of Chicago*
- Scaling Large Production Clusters with Partitioned Synchronization** 473
Yihui Feng, *Alibaba Group*; Zhi Liu, Yunjian Zhao, Tatiana Jin, and Yidi Wu, *The Chinese University of Hong Kong*; Yang Zhang, *Alibaba Group*; James Cheng, *The Chinese University of Hong Kong*; Chao Li and Tao Guan, *Alibaba Group*
- Fighting the Fog of War: Automated Incident Detection for Cloud Systems** 489
Liquan Li and Xu Zhang, *Microsoft Research*; Xin Zhao, *University of Chinese Academy of Sciences*; Hongyu Zhang, *The University of Newcastle*; Yu Kang, Pu Zhao, Bo Qiao, and Shilin He, *Microsoft Research*; Pochian Lee, Jeffrey Sun, Feng Gao, and Li Yang, *Microsoft Azure*; Qingwei Lin, *Microsoft Research*; Saravanakumar Rajmohan, *Microsoft 365*; Zhangwei Xu, *Microsoft Azure*; Dongmei Zhang, *Microsoft Research*

SIT, Fido!: Training Machine Learning Algorithms

- Habitat: A Runtime-Based Computational Performance Predictor for Deep Neural Network Training** 503
Geoffrey X. Yu, *University of Toronto/Vector Institute*; Yubo Gao, *University of Toronto*; Pavel Golikov and Gennady Pekhimenko, *University of Toronto/Vector Institute*
- Zico: Efficient GPU Memory Sharing for Concurrent DNN Training** 523
Gangmuk Lim, *UNIST*; Jeongseob Ahn, *Ajou University*; Wencong Xiao, *Alibaba Group*; Youngjin Kwon, *KAIST*; Myeongjae Jeon, *UNIST*
- Refurbish Your Training Data: Reusing Partially Augmented Samples for Faster Deep Neural Network Training** ... 537
Gyewon Lee, *Seoul National University and FriendliAI*; Irene Lee, *Georgia Institute of Technology*; Hyeonmin Ha, Kyungeun Lee, and Hwarim Hyun, *Seoul National University*; Ahnjae Shin and Byung-Gon Chun, *Seoul National University and FriendliAI*
- ZeRO-Offload: Democratizing Billion-Scale Model Training** 551
Jie Ren, *UC Merced*; Samyam Rajbhandari, Reza Yazdani Aminabadi, and Olatunji Ruwase, *Microsoft*; Shuangyan Yang, *UC Merced*; Minjia Zhang, *Microsoft*; Dong Li, *UC Merced*; Yuxiong He, *Microsoft*

I Can Smell That Fluffy Was Here: Networks

- Hashing Linearity Enables Relative Path Control in Data Centers** 565
Zhehui Zhang, *University of California, Los Angeles*; Haiyang Zheng, Jiayao Hu, Xiangning Yu, Chenchen Qi, Xuemei Shi, and Guohui Wang, *Alibaba Group*
- Live in the Express Lane** 581
Patrick Jahnke, *TU Darmstadt and SAP*; Vincent Riesop, *SAP*; Pierre-Louis Roman and Pavel Chuprikov, *Università della Svizzera italiana*; Patrick Eugster, *Università della Svizzera italiana, TU Darmstadt, and Purdue University*
- Understanding Precision Time Protocol in Today's Wi-Fi Networks: A Measurement Study** 597
Paizhuo Chen and Zhice Yang, *ShanghaiTech University*
- AUTO: Adaptive Congestion Control Based on Multi-Objective Reinforcement Learning for the Satellite-Ground Integrated Network** 611
Xu Li, Feilong Tang, and Jiacheng Liu, *Shanghai Jiao Tong University*; Laurence T. Yang, *St. Francis Xavier University*; Luoyi Fu and Long Chen, *Shanghai Jiao Tong University*
- Hey, Lumi! Using Natural Language for Intent-Based Network Management** 625
Arthur S. Jacobs, Ricardo J. Pfitscher, and Rafael H. Ribeiro, *Federal University of Rio Grande do Sul (UFRGS)*; Ronaldo A. Ferreira, *UFMS*; Lisandro Z. Granville, *Federal University of Rio Grande do Sul (UFRGS)*; Walter Willinger, *NIKSUN, Inc.*; Sanjay G. Rao, *Purdue University*

I Buried That Bone Here Somewhere: Storage

- Boosting Full-Node Repair in Erasure-Coded Storage.** 641
Shiyao Lin, Guowen Gong, and Zhirong Shen, *Xiamen University*; Patrick P. C. Lee, *The Chinese University of Hong Kong*; Jiwu Shu, *Xiamen University and Tsinghua University*
- KVIMR: Key-Value Store Aware Data Management Middleware for Interlaced Magnetic Recording Based Hard Disk Drive** 657
Yuhong Liang, Tsun-Yu Yang, and Ming-Chang Yang, *The Chinese University of Hong Kong*
- Differentiated Key-Value Storage Management for Balanced I/O Performance** 673
Yongkun Li and Zhen Liu, *University of Science and Technology of China*; Patrick P. C. Lee, *The Chinese University of Hong Kong*; Jiayu Wu and Yinlong Xu, *Anhui Province Key Laboratory of High Performance Computing, University of Science and Technology of China*; Yi Wu, Liu Tang, Qi Liu, and Qiu Cui, *PingCAP*
- ZNS: Avoiding the Block Interface Tax for Flash-based SSDs** 689
Matias Björling, *Western Digital*; Abutalib Aghayev, *The Pennsylvania State University*; Hans Holmberg, Aravind Ramesh, and Damien Le Moal, *Western Digital*; Gregory R. Ganger and George Amvrosiadis, *Carnegie Mellon University*
- MapperX: Adaptive Metadata Maintenance for Fast Crash Recovery of DM-Cache Based Hybrid Storage Devices.** ..705
Lujia Yin, *NUDT*; Li Wang, *Didi Chuxing*; Yiming Zhang, *NiceX Lab, NUDT*; Yuxing Peng, *NUDT*

Friday, July 16

My Tail Never Has Any Latency: OS & Hardware

- Exploring the Design Space of Page Management for Multi-Tiered Memory Systems.** 715
Jonghyeon Kim, Wonkyo Choe, and Jeongseob Ahn, *Ajou University*
- A Fast and Flexible Hardware-based Virtualization Mechanism for Computational Storage Devices.** 729
Dongup Kwon, Dongryeong Kim, Junehyuk Boo, Wonsik Lee, and Jangwoo Kim, *Seoul National University*
- Fair Scheduling for AVX2 and AVX-512 Workloads** 745
Mathias Gottschlag, Philipp Machauer, Yussuf Khalil, and Frank Bellosa, *Karlsruhe Institute of Technology*
- SKQ: Event Scheduling for Optimizing Tail Latency in a Traditional OS Kernel** 759
Siyao Zhao, Haoyu Gu, and Ali José Mashtizadeh, *University of Waterloo*
- A Linux Kernel Implementation of the Homa Transport Protocol.** 773
John Ousterhout, *Stanford University*

Friends Fur-Ever: Persistent Memory and In-Memory Computing

- Ayudante: A Deep Reinforcement Learning Approach to Assist Persistent Memory Programming** 789
Hanxian Huang, Zixuan Wang, Juno Kim, Steven Swanson, and Jishen Zhao, *University of California, San Diego*
- Tips: Making Volatile Index Structures Persistent with DRAM-NVMM Tiering.** 805
R. Madhava Krishnan, Wook-Hee Kim, Xinwei Fu, and Sumit Kumar Monga, *Virginia Tech*; Hee Won Lee, *Samsung Electronics*; Minsung Jang, *Peraton Labs*; Ajit Mathew and Changwoo Min, *Virginia Tech*
- Improving Performance of Flash Based Key-Value Stores Using Storage Class Memory as a Volatile Memory Extension** 821
Hiwot Tadese Kassa, *University of Michigan*; Jason Akers, Mrinmoy Ghosh, and Zhichao Cao, *Facebook Inc.*; Vaibhav Gogte and Ronald Dreslinski, *University of Michigan*
- First Responder: Persistent Memory Simultaneously as High Performance Buffer Cache and Storage** 839
Hyunsub Song, Shean Kim, J. Hyun Kim, Ethan JH Park, and Sam H. Noh, *UNIST*
- A Case Study of Processing-in-Memory in off-the-Shelf Systems** 855
Joel Nider, Craig Mustard, Andrada Zoltan, John Ramsden, Larry Liu, Jacob Grossbard, and Mohammad Dashti, *University of British Columbia*; Romaric Jodin, Alexandre Ghiti, and Jordi Chauzi, *UPMEM SAS*; Alexandra Fedorova, *University of British Columbia*

Time to File the Claws: Files

XFUSE: An Infrastructure for Running Filesystem Services in User Space 863
Qianbo Huai, Windsor Hsu, Jiwei Lu, Hao Liang, Haobo Xu, and Wei Chen, *Alibaba Group*

MAX: A Multicore-Accelerated File System for Flash Storage 877
Xiaojian Liao, Youyou Lu, Erci Xu, and Jiwu Shu, *Department of Computer Science and Technology, Tsinghua University, and Beijing National Research Center for Information Science and Technology (BNRist)*

Z-Journal: Scalable Per-Core Journaling 893
Jongseok Kim and Cassiano Campes, *Sungkyunkwan University*; Joo-Young Hwang, *Samsung Electronics Co., Ltd.*;
Jinkyu Jeong and Euseong Seo, *Sungkyunkwan University*

LODIC: Logical Distributed Counting for Scalable File Access 907
Jeoungahn Park, *KAIST*; Taeho Hwang, *Hanyang University*; Jongmoo Choi, *Dankook University*; Changwoo Min, *Virginia Tech*; Youjip Won, *KAIST*

But You Played with Me Yesterday: Serverless Computing and Consistency

UNISTORE: A fault-tolerant marriage of causal and strong consistency 923
Manuel Bravo, Alexey Gotsman, and Borja de Régil, *IMDEA Software Institute*; Hengfeng Wei, *Nanjing University*

Optimistic Concurrency Control for Real-world Go Programs 939
Zhizhou Zhang, *University of California, Santa Barbara*; Milind Chabbi and Adam Welc, *Uber Technologies*; Timothy Sherwood, *University of California, Santa Barbara*

Faastlane: Accelerating Function-as-a-Service Workflows 957
Swaroop Kotni, Ajay Nayak, Vinod Ganapathy, and Arkaprava Basu, *Indian Institute of Science*

SONIC: Application-aware Data Passing for Chained Serverless Applications 973
Ashraf Mahgoub, *Purdue University*; Karthick Shankar, *Carnegie Mellon University*; Subrata Mitra, *Adobe Research*;
Ana Klimovic, *ETH Zurich*; Somali Chaterji and Saurabh Bagchi, *Purdue University*

Message from the USENIX ATC '21 Program Co-Chairs

1. Introduction

Welcome to the 2021 USENIX Annual Technical Conference (ATC).

Running a conference of any size is a significant challenge, one that comes with many opportunities to build upon and perhaps improve what has gone before—and the challenge is all the greater for a conference of the scale and caliber of ATC.

We are fortunate that ATC is sponsored by USENIX, an organization with extensive experience in conference planning. Working with USENIX means joining a well-oiled machine that magically takes care of an almost endless list of tasks that must be completed for a conference to be successful. We are humbled and honored by their trust in asking us to take the helm of USENIX ATC '21 and we are grateful for their invaluable guidance and support throughout the process.

We hope that everyone is as thrilled as we are with the ensuing program. In the rest of this document, we describe the process for USENIX ATC '21, with an emphasis on how we created and managed the program committee.

For USENIX ATC '21, we had to deal with two unusual challenges: first, the ongoing pandemic, and second, the collocation with OSDI '21. The former turned out to be more of a nuisance than a challenge, thanks to the help we received from the USENIX ATC '20 co-chairs, Erez Zadok and Ada Gavrilovska. Ada and Erez had been forced to adapt to the pandemic as it unspooled, switching both their program committee meeting and the conference itself from in-person to virtual. They extensively documented their experience in their own conference message, which we referred to repeatedly, and also offered additional answers to specific questions we had. As a result, we were able to plan a smooth PC meeting (which managed to finish on time!) and are confident that the conference itself will be equally successful.

2. Running a Combined Conference

Navigating the decision to collocate OSDI and ATC was more difficult. In response to requests from the systems research community, USENIX concluded that OSDI needs to be held more often, changing from strict alternation with SOSP to an annual conference. However, for a number of years both SOSP and OSDI have taken place in October; USENIX felt that it would be inappropriate to hold OSDI close to the time when SOSP was scheduled. Instead, after carefully considering the options, the USENIX board decided to experiment with holding OSDI and ATC together.

That presented its own dilemma: since OSDI and ATC are both systems conferences, would they find themselves in competition? How would the the conferences themselves be run? Would either conference experience a significant drop—or a rise—in submissions? Fortunately for us, we had an ace in the hole: the OSDI '21 co-chairs, Angela Demke Brown and Jay Lorch, are two of the nicest and most generous people in systems research. From the beginning, we were able to work closely to ensure a smooth experience.

The first question we had to address, almost immediately after the co-chairs for both conferences were chosen, was submission deadlines. Should the deadlines be the same for both conferences? If not, which conference should “get” to go first? We concluded that OSDI should have an earlier deadline, almost exactly a month before our own. That would allow authors who were unable to make the OSDI deadline to have a significant period of time for completing their papers before they submitted to ATC. It also reduced the burden on the USENIX staff by preventing two simultaneous crunch times.

We then turned to the challenge of selecting program committees for both conferences. OSDI '20 received 400 submissions; USENIX ATC '20 received 350. If those levels continued, we would need a record number of PC members across both conferences. That raised the risk that we would find ourselves competing for PC candidates.

To avoid that possibility, the four co-chairs of the two conferences met several times to discuss PC invitations and create a comprehensive list of candidates. Working from a shared spreadsheet, we created one list for each conference, balancing both lists on a number of axes to ensure that we would have diverse committees that covered a range of viewpoints, areas of expertise, and levels of experience. We gave special attention to including less established researchers, both to advance their careers and to develop new possibilities for future program committees.

Our cooperation in identifying PC members was successful; both conferences were able to assemble strong committees. In the end we wound up with a PC of 120 members: 69 heavy (16-20 reviews expected), 39 light (8-10 reviews), and 12 extended (3-5 reviews).

After considering previous submission levels and growth, we decided not to assume that either conference would experience a drop in submissions; instead we built a program committee that would be able to handle an increase. That proved to be a wise decision.

3. Program Committee

The most important task that we did as USENIX ATC '21 program chairs was selecting and inviting the program committee. The PC had 120 members, with expertise in a wide range of topics. The areas with the highest expertise among the PC members were Distributed Systems, Storage, Cloud, Architecture, OS, Analytics and Machine Learning. Those fields allowed us to cover most of the submissions well, but we could have used more expertise in Quantum Computing. We also were surprised to discover that we had multiple submissions in the area of Low-Earth-Orbit Satellite Networks; we had to seek additional help on that topic.

In addition to covering a wide range of research topics, we also wanted to ensure diverse representation in the PC across several dimensions:

- Junior vs. Senior members of the community. We believe it is important to invite new community members to take part in the review process. Our PC had 34% junior members.
- Academia vs. Industry. USENIX ATC has broad industry impact, so we wanted to have this duality reflected in our PC membership as well. Industry and Industrial Research Labs members constituted 34% of the PC.
- Women and Under-represented Minorities. The PC representation was 22%.
- Geography. 63% of the PC members are located in North America, 24% in Europe, 8% in Asia, and the remaining 5% in other areas.

The PC was split into three categories, depending on the number of reviews the PC members were able to provide, as well as whether they could attend the PC meeting or not: heavy (up to 17 reviews), light (up to 9 reviews), and extended (up to 5 reviews). The heavy PC consisted of 68 members, the light PC 39 members, and the extended PC 12 members.

We found it important for each PC member to provide us information before the reviewing process started. In particular, it simplified the conflict verification process if each PC member updated their own lists of collaborators and other conflicts. Doing this before the submission deadline is ideal, as it provides the authors the opportunity to double-check the identified conflicts through HotCRP. In addition, the PC members rank their topics of interest from the conference topics. While this step is optional for PC members who spent the time to go through the submissions after the deadline and submit their paper preferences, we asked the PC members who did not to make sure they at least had their topics preference filled in. It would have been impossible for us to assign papers to PC members who had expressed neither a paper nor a topic preference. In retrospect, the PC members who actually took the time to bid on (a larger number of) papers also got a better assignment. In addition, it was easier for us to assign papers when extra reviews were needed.

3.1. Submissions Chairs

Following the prior two editions of USENIX ATC, we adopted the practice of having two submissions chairs. Alex Conway (VMware Research) and Chris Stone (Harvey Mudd College) provided invaluable support during the USENIX ATC evaluation period. In particular, the submissions chairs helped with the pre-review checks, verified the authors' reported conflicts, helped with checking the quality of the reviews and took notes during the PC meeting. We would not have been able to put the conference together without their able and tireless assistance.

4. Review Process

Perhaps the most important part of putting a conference program together is the lengthy period of peer review. As is common for most large conferences, we divided the review into several steps.

4.1. Pre-Review Quick Checks

After the deadline passed, we had a total of 341 completed submissions, excluding spurious ones. We divided the papers into four equal groups assigned to the co-chairs and submissions co-chairs for a quick validity check. Each person scanned their pile for several flaws:

- Anonymity violations, both obvious (authors on the title page) and more subtle (self-citation, mention of authors' institutions, etc.).

- Formatting problems not caught by the automated format checker (e.g. unreadable figures).
- Violations of the Call for Papers, such as appendices following the bibliography.
- Other random submission errors, such as accidentally submitting a version of the paper as supplemental material.

During the quick checks, we also identified an oversight in the Call for Papers. A number of authors had included links to online copies of their source code in their papers. Such links had not been prohibited by the CFP, but they created the risk of anonymity violations. In addition, since online resources can be modified at any time, there was no way to ensure that they were representative of work done before the deadline. For those reasons, we decided to ask authors to remove those links.

In the end, we rejected one submission immediately because it was too flawed to be rescued and because it violated the anonymity requirement by including the authors' names. We gave the authors of 67 (!) others a brief window in which to correct the problems; all accepted the offer. Although the CFP clearly stated that format violations would result in instant rejection, we chose to be gentle because the violations appeared to be unintentional mistakes rather than an attempt to evade the rules.

Finally, we also reviewed the papers for undeclared conflicts with PC members. That task was eased because the submission form had included a request for DBLP links for all co-authors. Nevertheless, that task was a major one, and we hugely appreciate Alex and Chris for carrying it out. We added a number of new conflicts into HotCRP, and notified the authors so that they would be more careful in the future.

4.2. Review Timeline

The review process was scheduled over two rounds, with ample discussion time after each round. The discussions were very useful not only because PC members had time to read each other's reviews and reach a common decision, but also because it gave us time to supplement reviews where necessary by asking other PC members or external reviewers. For example, it was necessary to supplement reviews when a paper had lower reviewer expertise, or when the reviews were late or missing. We advise future co-chairs to allow for these buffer periods as well, while still enforcing the round deadlines.

4.3. Review Sequence

Once we had 340 conforming submissions, we assigned reviews to the members of the program committee. In the first round, heavy PC members were assigned 10-12 papers, with proportionally fewer going to light and extended members. Each paper received three first-round reviews. An unexpected issue arose when one member was forced to withdraw from the PC due to serious health issues. We are hugely grateful to Reto Achermann, David Cock, Dave Dice, and Scott Stoller, who were willing to accept an additional assignment on insufficient notice to help out.

After the round-1 reviews arrived, we held brief online discussions to decide which papers would advance to round 2. We took a cautious approach, leaning toward advancement for papers that had received at least one weak accept and papers where no reviewer had rated themselves as having high expertise in the area. At the same time, though, we were cognizant of the fact that we were planning to send round-1 reject notices right away (rather than waiting until after the PC meeting), since rejected authors generally prefer to receive the news early so that they can begin work on a revision. In the end, 178 papers advanced to the second round.¹

Papers rejected in round 1 did not have the option to provide an author response, due to the early notification. We found that a small number of the authors of the papers rejected in round 1 would have preferred to take the option of a later notification, so that they could have the chance to submit a response to the reviews. Thus, future chairs might consider incorporating an option to choose between early notification and response at submission time, or adding a response period to round-1 rejected papers.

For the papers that advanced, we solicited brief (500-word) responses to the reviews from the authors. Unfortunately HotCRP does not enforce the word limit, and some authors went far over. Nevertheless, the program committee found the responses useful in a number of cases, and some papers were accepted at least partly based on the clarifications given in the responses.

Each round-2 paper received at least two additional reviews, so that in the end every paper had at least five². After those reviews were in, we again held online discussions to divide the papers into three categories: clear accepts, clear rejects, and those that needed in-person discussion at the online PC meeting. In several cases we asked for additional reviews from experts in the area, either on the PC or external.

¹ A few were advanced despite low ratings because some reviews were still missing at the deadline.

² The papers that would have been rejected in R1 but for their late reviews were an exception, having only 3 or 4 total reviews.

4.4. PC Meeting

In the end, we wound up with 52 papers that needed discussion by the program committee. We had planned from the first to hold the PC meeting online over a period of two days. Inspired by USENIX’s conference-scheduling practices, we decided to limit the meeting to five-hour slots, running from 7:00 am to noon Pacific Time; those times are acceptable on the West Coast of the U.S., pleasant on the East Coast, and not horrible in Europe. Unfortunately they work less well in some other locales (e.g., 7:30 pm to past midnight in India, midnight to 5:00 am in Korea, and 1:00 am–6:00 am in Eastern Australia).

To deal with the time-zone problem, we polled the PC members to ask where they would be on the days of the meeting. We then hand-scheduled the papers for discussion on a rolling basis, beginning with those that had reviewers with the most challenging time zones so that those people could leave the meeting as soon as possible. The approach worked effectively, but only because of the heroic efforts of our distant PC members to stay up far beyond what most of us would consider a reasonable time.

In past face-to-face PC meetings, a significant amount of time was lost moving conflicted members in and out of the meeting room; HotCRP offers an option to automatically generate a schedule that minimizes such motion. We discarded that option in favor of accommodating time zones; we created a single Zoom breakout room named “Hallway” and used it for conflicts. That worked well; we were usually able to move people into and out of the room in 10–30 seconds so little time was lost.

Given necessary overheads such as introductions and breaks, we wound up with about 10 minutes to discuss each paper. As is common in PC meetings, discussions of the early papers often ran over, but the committee gradually developed a sense of timing so that we finished the first day’s work on schedule. As is also common, the reviewers of a few papers came to an accept/reject decision overnight, and in the end we were able to finish slightly early.

5. Statistics

It has become traditional to offer a number of statistics about the submissions and the review process. Some of the numbers are impressive:

- 341 submitted papers (25 short)
- 64 accepted (1 short), 277 rejected (23.1% acceptance rate)
- 119 PC members wrote 1357 reviews
- 750,218 total words in reviews

As has been common in recent years (and not just in ATC), short papers faced something of an uphill battle, with only a 4% acceptance rate. We encourage future chairs to consider whether the short-paper category is a good idea.

6. Conference Plans

Although we are writing this message well in advance of the conference, we are looking forward to a few changes that we hope will make it run smoothly and improve the virtual conference experience for attendees:

- Before the pandemic, several conferences had run successful experiments with “preview sessions” aimed at new attendees. The goal of these sessions was to provide enough background for the uninitiated to understand a group of papers being presented during the conference. This year, we have asked some PC members to create similar previews that will be posted in advance of the conference itself. The preview session will cover common topics from both USENIX ATC and OSDI.
- One of the most important things that was lost in the shift to virtual conferences was the so-called “hallway track”—the break times during which attendees mingled, met new people, and discussed research ideas. There have been several attempts to find substitutes, including extended Zoom sessions, Zoom breakout rooms, and Slack channels; however, none of these options have been entirely satisfactory. At USENIX ATC and OSDI, we will be experimenting with a new option, ohay.co, which we hope will provide an attractive and fun alternative where small groups can interact with each other in a productive fashion. We want to provide a more interactive environment for attendees to replicate the informal discussions that would normally happen at the conference, as well as provide additional time for authors to answer questions and discuss their work in a smaller group setting.
- Several editions of OSDI have implemented a successful mentoring program—matching students with senior researchers and facilitating 1-1 discussions outside the conference program. A few USENIX ATC ’21 PC members are collaborating with OSDI ’21 PC members to create a common mentoring program for both conferences.

7. Final Thoughts

Co-chairing USENIX ATC '21 has been a challenging, instructive, and rewarding experience. In the end, we are pleased to have been able to create a strong program featuring many new insights and creative ideas. We are grateful to everyone who contributed to creating the program and to all who are still working behind the scenes to ensure that USENIX ATC '21 runs smoothly and provides value to all attendees; to the authors who worked hard on their submissions and final papers; to the program committee and external reviewers, who spent countless hours reading, discussing and selecting the best papers; to the shepherds, who ensured that each paper appears in the program in its best shape; and to the volunteers who are organizing mentoring, networking, and preview sessions jointly with OSDI '21. At last, but most importantly, we are grateful to our submissions chairs, who jumped in at a moment's notice to help out with all the tasks where we felt overwhelmed, and to the wonderful USENIX staff, who directed us and cleared any roadblocks.

We thank everyone for their hard work and dedication. We are humbled by your willingness to go above and beyond to make USENIX ATC '21 a success!

We hope that you enjoy the conference!

USENIX ATC '21 Program Co-Chairs

Naos: Serialization-free RDMA networking in Java

Konstantin Taranov¹, Rodrigo Bruno^{2†}, Gustavo Alonso¹, and Torsten Hoeffler¹
¹Department of Computer Science, ETH Zurich ²INESC-ID / Técnico, ULisboa

Abstract

Managed languages such as Java and Scala do not allow developers to directly access heap objects. As a result, to send on-heap data over the network, it has to be explicitly converted to byte streams before sending and converted back to objects after receiving. The technique, also known as object serialization/deserialization, is an expensive procedure limiting the performance of JVM-based distributed systems as it induces additional memory copies and requires data transformation resulting in high CPU and memory bandwidth consumption. This paper presents Naos, a JVM-based technique bypassing heap serialization boundaries that allows objects to be directly sent from a local heap to a remote one with minimal CPU involvement and over RDMA networks. As Naos eliminates the need to copy and transform objects, and enables asynchronous communication, it offers significant speedups compared to state-of-the-art serialization libraries. Naos exposes a simple high level API hiding the complexity of the RDMA protocol that transparently allows JVM-based systems to take advantage of offloaded RDMA networking.

1 Introduction

Managed programming languages, such as Java and Scala, are a common vehicle for developing distributed platforms such as Spark [36], Flink [6], or Zookeeper [11]. However, the high level abstractions available in managed languages often cause significant performance overheads. In particular, to exchange data over the network, Java applications are currently forced to transform structured data via serialization, causing a high CPU overhead and requiring copying the data multiple times. While less of an issue in single-node applications, the overhead is substantial in distributed settings, especially in big data applications. Serialization already accounts for 6% of total CPU cycles at Google datacenters [15].

Data transfer with object serialization/deserialization (OSD) is a complex process involving five steps: **graph**

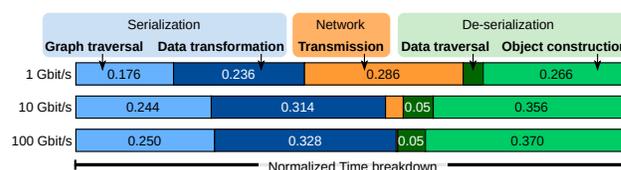

Figure 1: Impact of network bandwidth on OSD time.

traversal to identify all objects that should be serialized; **data transformation** to convert the objects into a byte stream (network-friendly format); **transmission** to send the serialized data over the network; **data traversal** at the receiver to decode the received data; and **object construction** that involves allocating memory and object re-initialization.

To illustrate the CPU overhead caused by OSD, we benchmarked the Kryo [26] serializer and measured its CPU utilization while sending objects over different networks. Figure 1 shows the fraction of time spent on each OSD step for the transfer of an array of 1.28M objects, all of the same exact type. Each object has two fields, each encapsulating a primitive type. Results show that the time spent in OSD increases as networks get faster. For a 10 Gbit/s network, it takes less than 3% of the time to send data over the network, but it takes more than 31%/35% of the time in data transformation/object construction. This discrepancy is even more evident in 100 Gbit/s networks in which the network time drops to less than 0.01% and the time spent on the CPU performing OSD accounts for almost 100% of the transfer time. While networks are getting faster, the pressure is moving away from the network and into the CPU (and memory bandwidth), further aggravating the already well-known CPU-bottleneck problems encountered in distributed applications [22, 32]. Furthermore, existing distributed platforms that heavily rely on OSD are not able to take advantage of faster networks such as RDMA.

With the widespread use of Java in large scale data processing and the increased availability of RDMA, it is time to rethink current OSD techniques so that part of the load of object shifts from the CPU back to the network. In this paper, we aim to develop native runtime support for *serialization-free*

[†]This author was at ETH Zurich during this project.

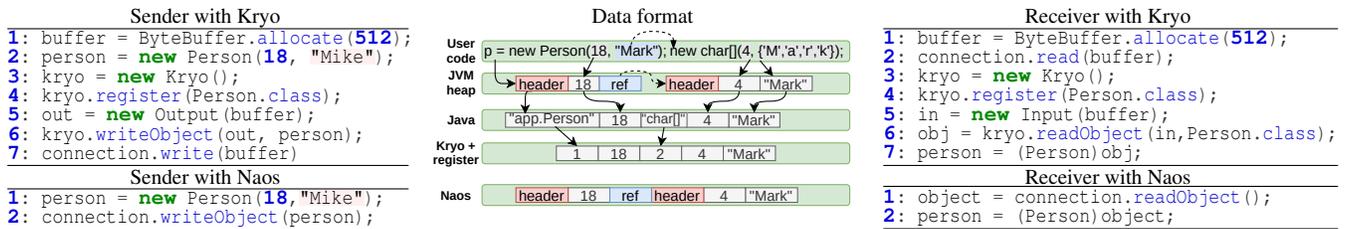

Figure 2: Serialization, Data format, Deserialization for Kryo and Naos

networking that avoids superfluous memory copies and data transformation by sending objects directly from the source heap into the remote heap. Sending and receiving data without data marshalling enables the use of zero-copy RDMA networking, bypassing not only serialization but the need to copy data. Such a design significantly reduces the pressure on the CPU at the cost of higher data volumes to be transferred, since objects are sent in their uncompressed memory format.

To test and evaluate these ideas, we have developed Naos (Naos stands for Not Another Object Serializer), a library and runtime plugin for OpenJDK 11 HotSpot JVM that allows objects in the source heap to be directly written into a remote heap, avoiding data transformations and excessive data copies. Naos is designed to accelerate object transfers in distributed applications by taking advantage of RDMA communication (although it also supports conventional TCP sockets).

Naos allows applications to directly send objects without employing serialization libraries. Its API requires no type registration nor serialization snippets, guaranteeing developers a close to zero effort when building systems using Naos. Finally, Naos is the first (to the best of our knowledge) library integrating RDMA into JVM allowing the user to communicate on-heap objects transparently, thereby easing the adoption of RDMA networking by JVM-based distributed applications. Our evaluation shows that Naos provides a 2x throughput speedup over serialization approaches for transferring contiguous objects and for moderately sparse object graphs. Naos improves latency-sensitive applications such as RPCs by providing a 2.2x reduction in latency.

Contributions. Naos is the first *serialization-free* communication library for JVM that allows applications to send objects directly through RDMA or TCP connections. Naos unlocks efficient asynchronous RDMA networking to JVM users hiding all the burden of low-level RDMA programming from the users, thereby facilitating the adoption of RDMA. For that, Naos solves several complex design issues such as sending unmodified memory segments across Java heaps without employing intermediate buffers, and interacting with concurrent garbage collection without compromising JVM’s memory safety. For the first issue, Naos proposes a novel algorithm that writes objects directly to the remote heap and makes them valid on the receiver’s address space (§3.3). For the second one, Naos proposes techniques preventing a concurrent JVM garbage collector from moving unsent objects

that may be accessed by RNIC and from accessing unrecovered received objects (§3.2). Finally, Naos enables pipelining communication and serialization, which was previously impossible with the OSD approach (§3.4).

2 Object Serialization

Overview. Many third-party libraries [12, 16, 26] have been developed to perform OSD in Java. Some of them provide Java bindings for popular cross-language OSD approaches (e.g., Protobuf [12]), allowing serializing arbitrary data structures into well-defined messages that can then be exchanged using any network protocol. While remaining independent of programming languages or operating systems, such libraries suffer from low performance [21]. Therefore, JVM-based big-data applications (e.g., Spark, Flink) rely on specialized libraries such as Kryo [26], designed specifically for JVMs.

Figure 2 presents a serialization example of a Java object and its data formats: memory layout (JVM heap), and serialization formats (Java, Kryo). All Java objects start with a JVM-specific header (red) followed by a number of primitive (gray) or reference fields (blue). The object of type `Person` has one primitive `int` field followed by a reference field to a character array (`char[]`). The character array starts with the length of the array followed by all characters.

Serializing an object involves traversing the object graph starting from that object and, upon visiting each reachable object, copying all primitive fields into the pre-allocated byte buffer. During native Java serialization, headers are replaced by class descriptors in textual format (`app.Person`) and field references are replaced by the contents of the pointed object. Deserialization follows a similar logic; upon visiting a serialized object, a new object must be allocated, and all primitive fields are copied out of the buffer into the allocated object.

Kryo. Kryo [26], one of the most widely used OSD libraries, addresses some limitations of native Java serialization by requiring manual registration of classes to achieve a more compact representation of the serialized data. Figure 2 shows a serialized data format in Kryo with class registration (Kryo+register). Kryo can represent all primitive types and classes using integer identifiers, thereby reducing the amount of space needed for storing type names. Although the class registration is trivial in this example, this task is cumbersome

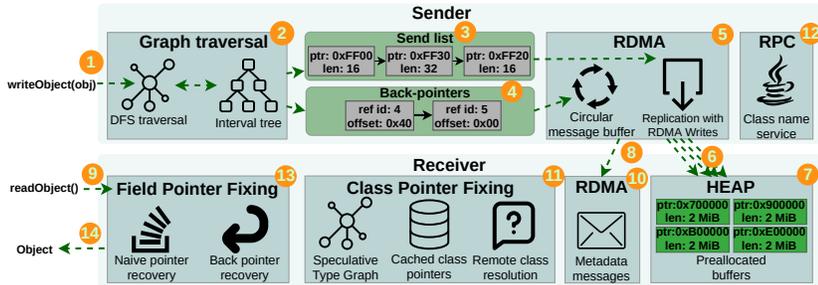

Figure 3: Naos' workflow for sending and receiving a Java object.

for applications with hundreds of data types. Compared to Kryo, Naos provides a cleaner interface (see Figure 2) with no need for developer involvement. To send a Java object, one can directly write it (`writeObject`) to the network. The receiver can directly read the object with `readObject`.

Accelerated OSD. To address the overhead of having to transform the data, Cereal [13] and Optimus Prime [24] resort to dedicated hardware accelerators for OSD. These accelerators are co-designed with the serialization format to parallelize the OSD process. Even though their data formats are not portable across different JVMs, their simulation results promise 15x speedup in serialization throughput on average over Kryo at the expense of requiring specialized hardware.

Zero-transformation OSD. The trade-off portability vs. performance is also exploited by the serialization library Skyway [21]. By dropping portability, Skyway manages to partially avoid data transformations and object construction by serializing Java objects in their JVM formats, i.e., the objects are written to communication buffers in the same binary format they are stored in the heap. Like Skyway, Naos sends objects in the JVM heap format, assuming that communicating parties run on the same JVM software. Unlike Naos, however, Skyway is a *serialization library* requiring to copy objects to and from communication buffers. Naos, on the other hand, completely removes the need to explicitly serialize and deserialize objects to send objects between Java heaps even with RDMA. What is more, Skyway's memory management prevents the use of RDMA networking (§4).

Naos integration and applicability. *Naos is not a serialization library.* Naos only covers end-to-end transfers (see Table 1) and cannot replace OSD in systems that do not use it for communication (e.g., for writing objects to disks). Naos has been primarily designed for future systems that want to take advantage of serialization-free zero-copy RDMA networking.

In several existing Java frameworks the main obstacle to using Naos is that some of these systems do not consider the possibility to send objects without serialization. For example, Spark and Hadoop completely decouple serialization from communication: their serialization modules are designed to serialize objects only to files, and their shuffle modules are designed to communicate only files. Such file-centric design

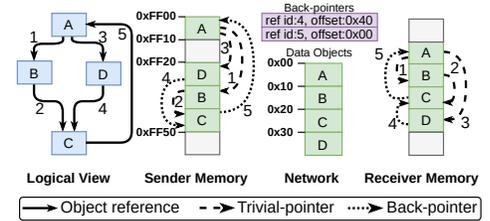

Figure 4: Object views of Naos' graph traversal and pointer recovery.

simplifies inter-node communication, as processes can share file descriptors instead of sending data, and helps to reduce memory usage by dumping data to disks. However, it makes integrating Naos very difficult. For such use-cases, conventional OSD libraries are a better fit than Naos if a redesign for true zero-copy is infeasible.

Table 1: APIs of Naos RDMA.

API	Description
<code>void writeObject(Object)</code>	Blocking send of a single object
<code>Object readObject()</code>	Blocking read of an object from heap
<code>boolean isReadable()</code>	Check whether an object can be read
<code>long writeObjectAsync(Object)</code>	Nonblocking send of a single object
<code>int waitHandle(long)</code>	Wait for a send request to complete
<code>int testHandle(long)</code>	Tests completion of a send request

3 System Overview

Naos allows Java applications to send/receive objects directly through RDMA or TCP connections. Naos uses a collection of algorithms and data structures to efficiently transmit large complex data structures. Figure 3 presents a graphical overview of Naos' workflow, including the main algorithms and data structures. An object transfer starts with a `writeObject` (1) triggering a DFS graph traversal (2) (§3.1). During the traversal, pointers to already visited objects are detected using an interval tree. After the traversal, both the objects (3) and metadata (4) are sent over the network using RDMA (5) (§3.2). Naos uses a circular message buffer to send metadata (8) and writes objects directly to the remote heap (6). Upon reception of the data and metadata, the receiver starts recovering (§3.3) the object graph by fixing class pointers (11) and field pointers (13). Once pointers are fixed, the head of the object graph is returned (14) to the caller of `readObject` (9).

The `writeObject` call in Naos is blocking, that is, the call returns once the object transmission is completed. It ensures that the object is received by the destination. In contrast to the classical TCP/IP semantics, all RDMA operations are executed asynchronously by design, allowing overlapping computation with communication. Naos also provides a nonblocking `writeObjectAsync` call enabling asynchronous communication for RDMA connections (§3.2). The nonblocking call initiates the send operation but does not fully complete it.

Instead, it returns a request handle, that is used by a user to wait for the completion using `waitHandle` call or to verify whether the request is completed using `testHandle` call.

Structure	The length of the send list				Traversal time (us)			
	(1-0-0)	(1-1-0)	(1-2-0)	(1-1-1)	(1-0-0)	(1-1-0)	(1-2-0)	(1-1-1)
BFS	1	2048	3072	3072	42	194	315	271
DFS	1	2	2	1	42	57	74	76

Table 2: Graph traversal of the object *array*.

3.1 Object Graph Traversal

Java objects can contain reference fields pointing to other Java objects and therefore, when an object is passed as an argument to `writeObject` ①, all objects reachable from it need to be sent. To find all objects reachable from a particular object, Naos traverses the object graph ② in Depth-First-Search (DFS) order. Figure 4 illustrates a simple example of an object graph’s (*Logical View*), sender memory layout, format sent over the network, and receiver memory layout. The *sender memory* starts at address `0xFF00` and all objects occupy 16 bytes. Edges are numbered according to DFS order.

When an object is visited for the first time, it is included in the *Send list* ③: a list of memory blocks that will be sent over the network. Each memory block has two elements: the starting virtual address, and the length. The send list contains objects ordered according to DFS order, and the objects are sent in this order over the network. Naos also merges the memory blocks that are adjacent in the send list to reduce its length. For that, during traversal Naos checks whether a new visited memory block is a continuation of the last block of the send list: if yes, then Naos increases the length of the last block, otherwise, Naos adds a new block to the list. The resulting send list is presented in ⑤, which contains three elements: for object *A*, for objects *B* and *C* as they are adjacent in memory and in DFS order, and for object *D*.

DFS vs BFS traversal. Even though Skyway [21] uses BFS traversal for serialization, Naos exploits DFS due to the fact that Java objects are constructed in DFS order (i.e., a JVM first allocates memory for an object and then recursively for all its fields). Thus, DFS traversal has better memory locality that can be illustrated by traversing an object *array* from the following code snippet. Let us consider a class *Person* that has different graph structures denoted as (L0-L1-L2), where *Li* is the number of objects on the level *i* of the object graph (e.g., the object in Figure 4 has structure (1-2-1)).

```

1: Person[] array = new Person[1024];
2: for(int i=0; i<1024; i++)
3:   array[i] = new Person();

```

Table 2 reports the length of the send list after BFS and DFS traversals and corresponding traversal time for several object graphs. The data shows that for complex graph structures DFS provides much shorter send lists and faster traversal time.

Back-pointers. Naos sends objects directly from one heap to another. As a result, objects are sent containing pointers

Algorithm 1 Was object *o* already visited?

```

1: if o.addr = curr.addr + curr.len ∧ o.addr ≠ next.addr then
2:   curr.len ← curr.len + o.size ▷ hot-path
3:   return false
4: if o.addr > curr.addr ∧ o.addr < next.addr then
5:   curr ← tree.insert_before(next, o) ▷ warm-path
6:   return false
7: node, success ← tree.insert(o) ▷ cold-path
8: if success then
9:   curr ← node
10:  next ← curr.next()
11:  return false
12: return true ▷ is a back-pointer

```

that are valid only in the sender address space, but not in the receiver’s. Naos addresses this problem by sending extra metadata along with data objects, which is used by the receiver to efficiently recover the pointers (§3.3).

Naos is designed to send as little metadata as possible. The metadata contains a 24-byte header with object and metadata sizes and, if present, pointers to already visited objects ④. These pointers are redundant edges after building a spanning tree over the object graph using DFS. We call them *back-pointers* since they always point to already visited objects in the send list (see Figure 4). For each back-pointer, a reference identifier representing the order by which the reference was visited in DFS order, and an offset within the send list where this reference should point to are sent to the receiver as metadata. In our example in Figure 4, only references 4 (*D* → *C*) and 5 (*C* → *A*) are sent.

All edges of the spanning tree (we call them *trivial-pointers* for simplicity) can be automatically inferred during a DFS traversal in the receiver (§3.3). This allows Naos to send no information about *trivial-pointers* resulting in a massive reduction of metadata sent over the network. Note the graphs without cycles do not contain back-pointers, which covers the vast majority of the most popular Java data structures.

Back-pointer/Cycle detection. To detect pointers to already visited objects (i.e., back-pointers), Naos uses a *memory interval tree* that keeps tracks of all visited memory intervals during DFS traversal. The interval tree is implemented using a red-black tree, which is selected over a hashtable (as Java and Kryo do) for two reasons. First, for large data structures, the hashtable grows (one entry per visited object) to large sizes and will lead to expensive lookups due to hash collision. Second, references to already visited objects are very rare and references pointing to objects in nearby memory positions are common in most Java popular data structures. Therefore, an interval tree, in most cases, contains a few large memory intervals, thereby ensuring fast lookups. We further optimize our interval tree by providing different fast paths.

Algorithm 1 presents how Naos decides whether a particular object *o* has been already visited. Two helper variables are used: *curr* points to the last node inserted into the tree; *next* points to the tree node that follows *curr* in the tree. All

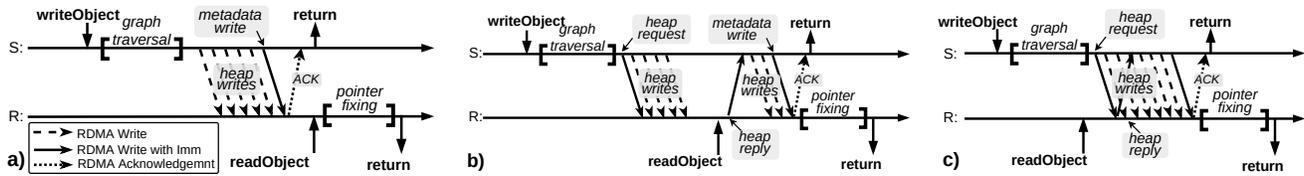

Figure 5: Blocking communication mechanism for three scenarios: (a) the sender can fit data to the pre-allocated receiver heap; (b,c) the sender needs to request extra heap memory. The receiver was not ready to receive data in (b), and it was ready in (c).

tree nodes keep an initial address `addr` and its length `length`. If the object's address is adjacent to the last memory interval inserted into the tree, the insertion is performed in $O(1)$ time (*hot-path*). If the memory pointer is higher than the current tree node and lower than the *next* tree node, then insertion is performed in $O(1)$ (*warm-path*), unless the tree needs to be re-balanced, taking $O(\log(n))$ time. Otherwise, the memory pointer is inserted in the tree in $O(\log(n))$ time (*cold-path*).

As a comparison, Skyway does not use complex structures for cycle detection and simply extends the JVM header of Java objects by 8 bytes. Even though it ensures that the newness of an object can be checked in $O(1)$, it results in a 15.4% increase in memory usage [21].

3.2 Network exchange of on-Heap Objects

Naos adds native RDMA communication to JVM without compromising JVM's memory safety. Naos' interface does not expose explicit RDMA access to the remote or local heap memory. Instead, its API allows only sending and receiving Java objects, hiding all the burden of low-level RDMA programming from the user. Internally, though, Naos fully relies on efficient one-sided RDMA communication to completely avoid redundant data copies. Naos also supports TCP for sending objects directly from its heap, but the use of RDMA requires overcoming peculiarities of managed languages such as concurrent garbage collection.

Blocking RDMA protocol. This section describes the *blocking* RDMA protocol for a single connection. All connections are handled independently and do not share resources. The core idea of Naos RDMA is that the receiver pre-registers buffers of fixed size in its heap and registers them for RDMA Write access. The sender uses RDMA Writes 6 to write the objects from its local heap directly to the known reserved buffers in the remote heap 7. The metadata is sent separately using a circular buffer 8 for RDMA messaging [8, 23].

The protocol allows the sender to start writing memory to the remote heap even if the receiver did not call `readObject`, as illustrated in Figure 5(a). The sender can continue writing the data while it has enough free remote memory. Once the sender completes writing all objects to the remote heap using RDMA, it sends a separate completion message with metadata via the circular message buffer 8. The remote circular buffer is filled using *RDMA Write with immediate data*, which

generates a completion event on the receiver after the write completes. The sender can unblock from sending once it receives an acknowledgment from the network indicating that all data has been written to the receiver. The acknowledgment is generated by the network and does not require the receiver's interaction. The receiver fetches the received object when it calls `readObject`, after all pointers are recovered (§3.3).

Sender's heap management. Naos utilizes *object pinning* to prevent a JVM garbage collector (GC) from moving objects until they are fully transmitted by the RNIC. Object pinning is already offered by some garbage collectors, such as Shenandoah [9]. Shenandoah is a high-performance GC that is supported by upstream OpenJDK. Besides object pinning, Naos also utilizes Shenandoah's memory allocator, that maintains the heap as the collection of fixed size Shenandoah regions. To pin and unpin objects efficiently, Naos pins whole Shenandoah regions containing the affected objects instead of pinning individual objects. During a send request, Naos pins and remembers all affected Shenandoah memory regions. Once the request completes, Naos unpins the regions associated with the request. Shenandoah allows pinning a region multiple times, and each region needs to be unpinned as many times as it has been pinned, thereby successfully preventing Naos from accidentally unlocking the GC for unsent objects.

RNICs cannot simply send data from any buffer and communication buffers must be registered at the RNIC*. Thus, the sender must register the memory addresses of all objects it needs to send. However, RDMA memory registration is an expensive process that may take hundreds of microseconds for a single buffer [14, 20, 30]. Therefore, naive registration of all objects from the send list may completely cancel all performance advantages of RDMA. Naos addresses this issue by registering large fixed-size memory regions (i.e., Shenandoah regions) where the objects are allocated. It enables reusing a single memory registration for all objects stored in it, exploiting spatial locality. Naos also caches memory registrations to reuse them later for future sends, exploiting temporal locality.

Receiver's heap management. When the sender runs out of the remote buffers for writing, it sends a request to the receiver to register more on-heap memory, as illustrated in Figure 5(b,c). Thus, the sender can block until the receiver

*Modern RNICs support implicit on-demand paging (ODP) [17] that removes the need to register buffers. In our preliminary experiments, however, ODP performed worse than conventional explicit memory registration.

replies with new heap buffers, as in Figure 5(b). However, when the receiver is ready to receive data it can immediately reply to the heap request and do not obstruct the sender as in Figure 5(c). The receiver can reply to heap requests when it calls `readObject` or `isReadable`. During these calls, Naos checks for received requests by polling completion events from the RNIC. The process of handling requests is invisible to the caller, which hides the complexity of the underlying protocol from the user.

Upon receiving a heap request, the receiver allocates a new Java byte array buffer of fixed size inside the Java heap and *registers its payload* for RDMA Write access and replies with the RDMA address of the registered buffer. To prevent the GC from moving the reserved on-heap buffers, Naos utilizes *object pinning* offered by Shenandoah [9]. Importantly, the sender writes data to the *payload* of the pre-allocated byte array as it prevents the GC from reading invalid data. The main reason for that is that the unrecovered received objects have invalid class and object pointers (§3.3). Thanks to this enclosure, the GC observes only the array and skips reading objects stored in the payload.

The sender fills the remote buffers in the order it received them from the receiver, constituting a queue of remote heap buffers. Since pre-registered RDMA heap buffers are of fixed size, the sender is not always capable of fully utilizing them. To address this issue, the sender informs the receiver about how many bytes were unused in each *finalized* heap buffer by sending *heap truncate request*. A buffer becomes finalized when the sender jumps to the next buffer in the queue. After receiving the data, the receiver revokes RDMA access to finalized buffers and then unpins them to enable the GC for received objects. It also deallocates unused memory of the finalized buffer and removes the array header to make all received objects visible to the GC.

Nonblocking object sending. The main difference between the blocking `writeObject` and the nonblocking `writeObjectAsync` is that the latter returns right after the dispatching *metadata write* request to the device. The nonblocking call submits all communication requests to the RNIC but does not wait for a network acknowledgment. Instead, Naos returns a request handle that can be used by an application to confirm the delivery of the object using `testHandle` call. Compared to the blocking call, Naos prevents the GC from moving affected objects even after the call returns. Naos *pins* the affected objects before exiting the JVM, and unpins them later once the corresponding acknowledgment is received.

Naos TCP. Naos supports sending objects directly from the heap using TCP as well. Unlike RDMA connections, a traditional TCP socket connection has a single datapath. Thus, to send the objects to the remote heap, the TCP sender first writes the metadata to the socket and then all elements of the send list. The receiver first reads metadata to a temporal buffer from its socket, then, to avoid redundant data copies, it directly reads the data from the socket to the heap. For

that, it allocates a byte array buffer of the required size inside the Java heap, and then reads the data from the socket to the payload of the allocated buffer.

Network buffering. Naos is designed to send data directly from the heap without intermediate buffering. However, the size of a JVM object can be as small as 24 bytes. Thus, a highly sparse object graph can result in a lot of small writes to the network, which can significantly reduce the network performance. To address this issue, Naos may buffer small objects before sending them to the remote heap. Large objects are still sent directly from the heap. Naos sends buffered objects once it batches enough bytes to utilize the network, or when a large object needs to be flushed to preserve DFS object order (§3.1).

An alternative approach is to use scatter-gather capability of RNICs [18] for RDMA networking and scatter-gather I/O for TCP sockets. The scatter-gather networking enables building a network message from multiple buffers without intermediate buffering. The current version of Naos does not implement it, but it is an interesting direction for future research.

Memory safety of Naos. Naos uses reliable transport to ensure the delivery of transmitted data. Naos materializes only fully received objects, which prevents returning partially received objects from a faulty sender. Faulty sends can be detected during graph recovery from the network errors provided by the reliable transport. If an error is detected, the receiver revokes RDMA access to pre-allocated buffers and deallocates the unused memory.

Naos' implementation follows all security advice related to RDMA networking [25, 31], therefore, we believe that Naos does not open security breaches. In particular, the pre-allocated heap buffers are not shared between connections preventing remote JVMs to access buffers of each other. In addition, each sender registers its heap only for local read access preventing other remote JVMs to access it. Finally, remote read access is always disabled, and Naos only temporarily enables write access to pre-allocated in-heap buffers, which are private for each sender. Once the in-heap buffer is full, the write access is revoked.

For compatibility between communicating applications, Naos requires that communicating JVMs have the same memory layout of in-heap objects. This can be achieved by running the same JVM with the same settings including GC.

3.3 Object Graph Recovery

Naos sends unmodified memory segments from one heap to another. As a result, objects are sent containing pointers that are valid only on the sender address space, but not on the receiver's. Naos' graph recovery algorithm overwrites these pointers making them valid on the receiver's address space. Java objects have two types of pointers: **class pointers** and **object pointers**. Class pointers point to JVM-internal data structures that describe Java types. Object pointers are

Algorithm 2 Object Graph Recovery

```
1: buffer                                ▷ the buffer with received objects
2: refid ← 0                              ▷ the number of traversed references
3: offset ← 0                             ▷ current offset in the receive buffer
4: stack.push(new_field(), new_hint())    ▷ push dummy field and hint
5: while stack.is_not_empty() do
6:   field, hint ← stack.pop()
7:   FIX_FIELD_POINTER(field, hint)
8:   refid ← refid + 1
```

Phase 1 – Fix Field Reference

```
9: procedure FIX_FIELD_POINTER(field, hint)
10: if refid = cur_back_pointer.id then                                ▷ a back-pointer
11:   field.ptr ← buffer + cur_back_pointer.offset
12:   cur_back_pointer ← get_next_back_pointer()
13: else                                                                    ▷ a trivial-pointer
14:   obj ← (obj)(buffer + offset)
15:   field.ptr ← obj
16:   FIX_CLASS_POINTER(obj, hint)
17:   ITERATE_FIELDS(obj, hint)
18:   offset ← offset + obj.size
```

Phase 2 – Fix Class

```
19: procedure FIX_CLASS_POINTER(obj, hint)
20: if hint.rem_class = obj.class then
21:   // hint is correct, do nothing                                       ▷ hot-path
22: else
23:   if class_cache.contains(obj.class) then
24:     new_hint ← class_cache.get(obj.class)                                ▷ warm-path
25:     hint.update(new_hint)
26:   else
27:     new_hint ← class_service(obj.class)                                ▷ cold-path
28:     class_cache.put(obj.class, new_hint)
29:     hint.update(new_hint)
30:   obj.class ← hint.loc_class
```

Phase 3 – Iterate Fields

```
31: procedure ITERATE_FIELDS(obj, hint)
32:   for field, field_hint in hint.fields do
33:     stack.push({obj + field.offset, field_hint})
```

reference fields that point to other on-heap Java objects.

Naos uses a recovery approach different from the one used in Skyway [21]. Since Skyway copies objects to communication buffers, it can afford modifying data before sending. Thus, Skyway simply replaces class pointers with integers (as Kryo does) and object pointers with their relative offsets within the communication buffer. Such design allows the receiver to simply replace class integers with corresponding class pointers and relative object offsets with corresponding absolute addresses. Unlike Skyway, Naos sends objects directly from the heap using RDMA requiring more sophisticated algorithm for pointer fixing in return for not requiring data copying.

Algorithm 2 describes the Naos’ graph recovery approach that starts with a DFS traversal of the object fields (lines 5-8). The traversal is initialized by pushing a *dummy* field pointing to the first received object. The graph recovery terminates when the DFS *stack* is empty. At that point, all pointers are valid in the receiver’s heap and the first object can be safely returned to the user.

Fixing Field References. For every object field, the algo-

rithm applies *FIX_FIELD_POINTER* procedure, which investigates whether the tested reference is a *back-pointer* or a *trivial-pointer* by checking whether the received metadata contains the current reference ID (line 10). For *back-pointers*, the *offset* associated with the current pointer is used to fix the reference. If the reference is a *trivial-pointer*, the new memory address can be determined by just using the current *offset* in the *receive* buffer (line 14). For a trivial-pointer, the next step is to fix the class field of the pointed unvisited object (line 16). Note that Naos sends no metadata for trivial pointers, since the sender and the receiver traverse the graph in the same DFS order, providing a significant reduction in metadata size.

Fixing Class References. Updating class pointers is a particularly expensive operation if not designed carefully, since the class pointer needs to be fixed for every object. To achieve high performance, Naos proposes a 3-way approach:

Class Service (cold-path) is an RPC service [12] that is started upon creation of a Naos connection. Once a receiver needs to determine the class of a particular sender’s class pointer, it issues an RPC request to the sender to translate the pointer to the full class name. The full class name can be used locally to query local JVM internal data structures.

Class Map (warm-path) is a per-connection table that caches all class translations. However, accessing a table for every object reference still produces a large overhead, especially in large graphs. To overcome this limitation, Naos proposes the use of Speculative Type Graphs (STG), a type of polymorphic cache inspired by [10].

STG (hot-path) is a data structure that dynamically captures type relations in the object graph, providing a translation *hint* for each class pointer. Each STG hint caches: i) a translation between a local and remote class pointer; ii) class description including object fields; iii) pointers to other hints for each field allowing to build hints recursively (lines 32-33). Using STG, Naos can speculate on the type of a particular object using a hint. If the hint is correct the class translation and retrieval of a class descriptor takes $O(1)$ time (line 20). Speculation might fail due to type polymorphism in Java (line 22) and, in that case, the cache is used for resolving the class pointer and the STG is updated (line 25) with the new translation hint. In practice, however, most data structures have very regular type graphs allowing the STG to guess correctly most of the times.

After the class pointer of an object is fixed, Naos iterates all its reference fields (line 17). Naos utilizes object’s class pointer translation hint to create translation hints for its reference fields (lines 32-33), which are then pushed into the *stack* together with the corresponding object reference.

3.4 Overlapping network and graph traversal

An important disadvantage of conventional serialization approach is that it does not support overlapping serialization and communication: an object must be fully serialized before sending it over a network. Similarly, the receiver cannot start

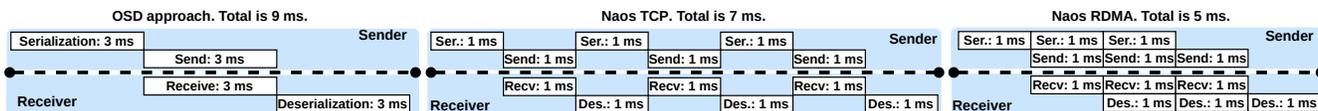

Figure 6: The communication benefits of Naos’ pipelining compared to the conventional OSD approach.

deserialization unless it receives all the data (see Figure 6). As a result, applications can suffer from high end-to-end latency for large object graphs.

Naos supports pipelining graph traversal with communication on the sender and pointer fixing with object receiving on the receiver. Both Naos TCP and Naos RDMA benefit from pipelining as it allows the receiver to start pointer fixing of *partially received object graphs*, thereby reducing end-to-end latency. Using offloaded RDMA communication, Naos RDMA can continue traversing the graph after submitting write requests to the RNIC, thereby overlapping communication and graph traversal on both the sender and the receiver.

Pipelining in Naos is implemented by pausing the object traversal and sending partial graphs to the remote heap. A partial graph contains only objects and back-pointers found at a given traversal stage. The receiver can read the partial graph and start pointer fixing. Once all received objects are traversed, the receiver reads the next fragment of the graph.

Figure 6 illustrates how Naos with pipelining improves communication latency of large object graphs compared to the OSD approach. The OSD approach cannot break serialization of a single graph, which results in 9 ms latency. Naos TCP can send partially traversed graphs reducing the latency by 2 ms, but cannot overlap computation with communication. Naos RDMA enables overlapping communication and graph traversal, which reduces the latency by another 2 ms.

4 Evaluation

We evaluate the performance of Naos[†] and compare it with Java, Kryo, and Skyway[‡] serialization engines using four different classes of workloads. First, the performance of Naos is studied by transferring data structures that are commonly used in distributed applications. The goal is to measure the performance benefits of the different techniques proposed in Naos and the trade-offs involved depending on the shape of object graph. In addition, it also shows the impact of using RDMA instead of TCP. Second, we study the role of data streaming and pipelining in OSD performance. Then, we show results for integrating the Naos library into Apache Dubbo [2], a high-performance RPC framework developed in Java, to show the impact of Naos on RPC workloads. Lastly,

[†]The source code is available at <https://github.com/spcl/naos/>.

[‡]We could not compare with the original Skyway as it is not open-source. Therefore, we re-implemented Skyway following the instruction provided in the paper [21]. Note that we did not extend object headers by 8 bytes for cycle detection and simply evaluated Skyway without cycle detection.

we use a map-reduce implementation of PageRank to measure the performance of Naos for data processing workloads.

Experimental setup. All experiments were performed on a cluster of 4 nodes interconnected by 100 Gbit/s Mellanox ConnectX-5 NICs. Each node is equipped with an Intel(R) Xeon(R) CPU 6154 @ 3.00 GHz and 384 GB of RAM.

Implementation details. Naos is implemented and tested for OpenJDK HotSpot 11.0.6 [1], a widely-used production JVM. Naos does not require changes to the internals of the JVM and is implemented as a JNI plugin and a Java-level library that allows users to write objects directly to TCP and RDMA connections. Naos TCP provides constructors to create a Naos connection from TCP connections of various network libraries (e.g., `java.net.Socket`). Naos RDMA does not rely on existing JVM RDMA libraries and fully implements a specialized RDMA network library including an API to create and connect RDMA endpoints. Our plugin is implemented in Java and C++ and depends on: *libibverbs*, an implementation of the RDMA verbs, and *librdmacm*, an implementation of the RDMA connection manager.

RDMA communicators for Java and Kryo serializers have been implemented using Disni [27] RDMA library, a high-performance Java RDMA library that encapsulates native C RDMA verbs API. The Disni library is used by Java applications such as Spark [19], Crail [29], and DaRPC [28]. Note that Skyway cannot be used with existing RDMA libraries, including Disni, as these libraries can only work with specialized off-heap memory residing outside of the Java heap memory, whereas Skyway requires the memory buffers reside inside the heap memory to deserialize objects. These limitation stems from the fact that garbage collection can move on-heap buffers while they are being accessed by the RNIC.

In all experiments, the JVM was configured with default parameters and enabled Shenandoah garbage collector as it is the only collector that is currently supported by Naos. Shenandoah was configured with 32 MiB memory regions. Naos was configured with 20 MiB receive buffers. If not stated differently, Naos and all serialization algorithms were deployed without graph cycle detection and with no pipelining (§3.4).

4.1 Serializing Java Data Structures

The performance of OSD approaches is measured using three data structures that are among the most common serialized data structures in real-world workloads deployed in platforms such as Spark, Hadoop, and Flink: a) an array of `float` primitive types, which is common for machine learning workloads;

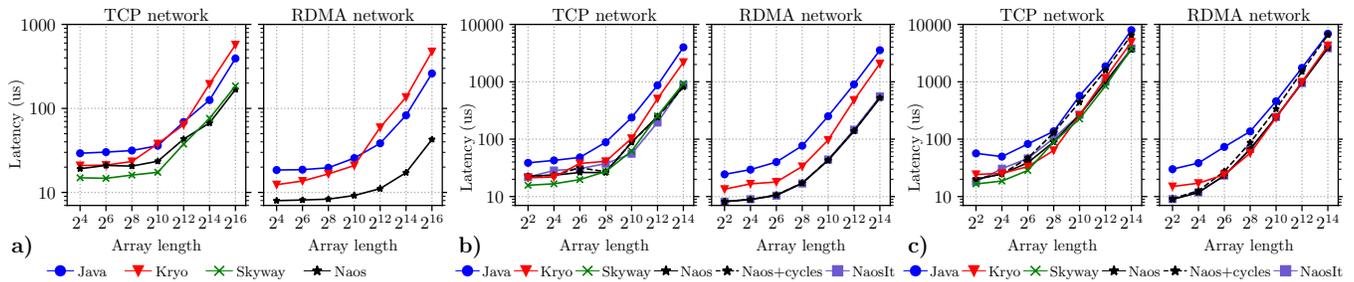

Figure 7: Latency in us for **a)** an array of floats **b)** an array of Points **c)** an array of Pairs. The y-axis is in log scale.

b) an array of `class Point` containing only two primitive types, which represents a 2D Euclidean point; **c)** an array of `class Pair` containing an integer and a char array, which represents a key-value pair, in many algorithms such as Word Count. In our experiments the char array had length 5, the average word length in the English language.

Benchmarks are carefully designed to guarantee the optimal configuration of all serializers. In particular, for Java, Kryo, and Skyway, all buffers are pre-allocated with the correct size to avoid re-allocation and memory copies during the serialization process. Besides, all types were pre-registered in Kryo to guarantee maximum data format compression. Measurements are taken after a JVM warmup (of at least 100 ms) until convergence of the JIT compiler to achieve maximum performance. All experiments run in complete isolation for several seconds and the aggregated statistics are reported.

Latency. Figure 7 shows the average latency of transferring the aforementioned data types with increasing their size.

Naos performs excellently for contiguous data structures such as the array of float, as it can send them from the heap without making extra copies and using fewer RDMA requests. For comparison, Kryo, Java, and Skyway must first serialize objects to a dedicated send buffer. RDMA-Naos' latency can be as small as 8 us, which is at least a 2x and a 2.4x improvements over Kryo and Java serializers, respectively, for small arrays, and at least a 4.5x for large arrays. For example, Naos RDMA needs only 42 us to send 2^{16} floats, whereas serialization approaches need at least 190 us.

Naos RDMA has lower latency than Skyway, however, Skyway performs better than TCP-Naos for small arrays because of two reasons. First, Naos buffers small objects (less than 256B) to better utilize the network (§3.2). Second, Naos TCP allocates on-heap memory after data arrives, whereas Skyway has all buffers preallocated in our experiments. Both reasons give an advantage to Skyway over Naos TCP for small arrays. For large arrays, Naos TCP provides a 9.1% reduction in latency over Skyway as it incurs fewer data copies.

An array of float is the simplest object graph for graph traversal as it contains a single contiguous object. An array of Point, however, is non-contiguous in memory as this array contains references to objects of class Point, which are 32 bytes each. Nonetheless, Naos provides a 2x and a 4x improve-

ments on average over Java and Kryo for RDMA networks, even with cycle detection enabled (+cycles). *Naos+cycles* benefits from our hot-paths of Algorithm 1 as the JVM tends to collocate objects in memory even for the potentially sparse object graphs. The experiment shows that moderately sparse graphs with small objects are not an issue for Naos.

An array of Pair is even sparser graph than the array of Point, as the class Pair has more references than the class Point. Naos RDMA still achieves the lowest latencies for all sizes. However, with cycle detection, Naos' traversal is slower for long arrays is slower compared to Kryo. The main problem is that Naos sends more data than conventional serializers since it needs to send a JVM header of 16 bytes for each Java object. We conclude that Naos does not always provide lower latency compared to conventional OSD approaches and that its performance depends on sparsity and the number of traversed objects.

A shortcoming of Skyway's and Naos' data format is that they do not compress arrays with references and are forced to send long arrays with (invalid) references, whereas Kryo can encode this information in few bytes. To address this issue, we designed a specialized send call for Naos, namely *NaosIt*, that sends only objects stored in an array. The receiver of such compressed message creates a new array and then fills it with received objects. *NaosIt* reduces the size of communicated data, but requires extra memory allocation on the receiver. Overall, NaosIt provides a small improvement over Naos, as the experiments are performed on 100 Gb/s network. Such compression would be more beneficial for slower networks.

CPU and network costs. To show the key differences between Naos networking and the traditional OSD approaches, Table 3 shows the time breakdown of transferring various data structures and their network cost. Naos as a serialization-free approach always has zero cost for serialization and deserialization. Naos' graph traversal time is included in the send time. The OSD approaches with RDMA has zero receive cost as the data delivered directly to pre-allocated receive buffers by the RNIC. Naos, on the other hand, has non-zero cost as the receive time includes the graph recovery.

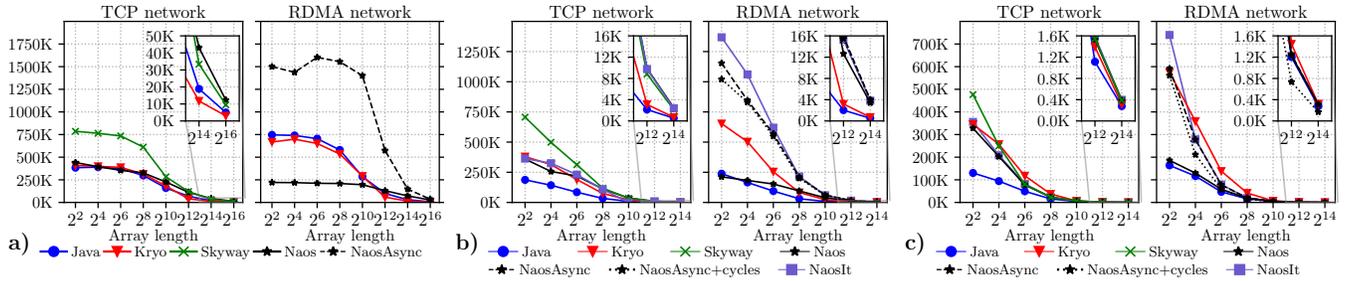

Figure 8: Throughput in objects/sec for a) an array of floats b) an array of Points c) an array of Pairs.

Test	TCP				RDMA				Size (B)
	Ser.	Send	Receive	Deser.	Ser.	Send	Receive	Deser.

	CPU sender		CPU receiver		CPU sender		CPU receiver		Network

Table 3: CPU time breakdown (in us) and Network cost for transferring arrays. Percentiles 5 and 95 are reported.

Object serialization in TCP experiments takes longer than for RDMA. The difference comes from the fact that in TCP experiments the data is serialized to on-heap buffers, which can be affected by the GC, whereas RDMA requires data to be serialized to off-heap buffers, that are invisible to the GC.

Java and Kryo for RDMA have the same send cost which is the cost of submitting offloaded RDMA request to RNIC. Blocking Naos RDMA has higher cost to send as it needs to wait for a network acknowledgment to finish sending.

For all data types, Naos RDMA shows at least a 2x reduction in CPU time for receiver over Kryo and Java. The main reason is that conventional serialization libraries need to allocate and initialize memory for each received object. Naos does not construct objects and only fixes pointers in the received data. For senders, however, Naos is better at reducing CPU cost for simple graphs such as arrays of floats and points. Note that Naos TCP has a longer receive time as it needs to allocate receive memory, whereas Skyway worked with pre-allocated buffers in our experiments.

The network cost of Naos and Skyway increases with the number of transmitted Java objects. For an array of floats, therefore, the size of the transmitted data is approximately the same for all approaches. On the other hand, for an array of Points or Pairs, the network cost of Naos is about 2x higher in comparison with Java and about 3.5x over Kryo. Kryo has the

lowest network costs as it replaces the class descriptors with integer identifiers significantly compressing object graphs. Naos and Skyway have the same network cost as they have the same data format, but our NaosIt provides a reduction in the network size for array containers.

Throughput. In this experiment, senders continuously send objects to the receiver. For RDMA approaches with serializers, we provide at the sender and the receiver a large number of send and receive buffers to enable asynchronous communication so that the sender can start serializing and sending the next object without the need to wait for the completion of the previous requests.

Figure 8(a) shows that Naos TCP was not able to significantly outperform Skyway for small arrays, as the throughput of Naos was mostly limited by the receive buffer allocation, whereas Skyway, with pre-allocated memory, achieved 750K req/sec. For arrays larger than 2^{12} elements, however, Naos TCP outperforms Skyway as the cost of data copies at the sender overwhelms the cost of memory allocation at the receiver, showing the advantage of our zero-copy design.

The performance of blocking Naos RDMA is bound by the network latency, which prevented the application to send requests at a higher rate. The NaosAsync RDMA, which avoids waiting for an acknowledgment, achieves the highest performance showing the importance of asynchronous communication. For the array of 512 floats, Naos achieves 1600 Kreq/sec, which is a 2x speedup over existing serialization approaches.

Figures 8(b,c) show that the throughput of Naos RDMA was limited by the network bandwidth since NaosIt, that communicates less data, outperforms NaosAsync RDMA. This observation indicates the benefit of our data compression.

The cycle detection decreases the throughput of Naos by less than 3% for moderately sparse graphs. For sparser graphs such as an array of Pairs the slowdown increases to 19%, which is explained by the growth of the Naos' interval tree for cycle detection. Therefore, Naos has lower performance than Kryo, but still outperforms the Java serializer. We think that, in real systems, Naos can be used together with traditional OSD libraries depending on the sparsity of the object graph.

Streaming data transfers. Data processing frameworks such as Spark and Flink rely on data streaming to enable processing of continuous streams of data. The continuous data stream is generated by sending small chunks of data to the

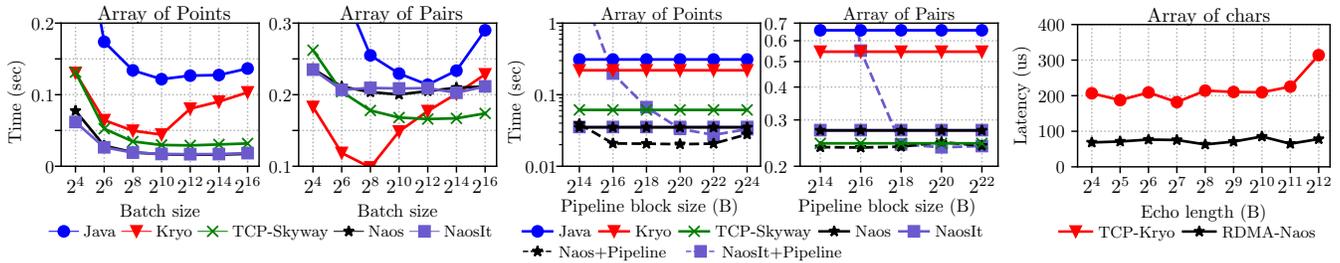

Figure 9: Streaming an array of 2^{20} elements. Figure 10: Pipelining an array of 2^{20} elements. Figure 11: Dubbo RPC latency.

processing nodes. To represent this use-case we implemented the streaming of long data arrays over RDMA networks. Figure 9 shows the streaming time of an array of Points and Pairs with increasing the chunk size.

For the array of Points, Naos RDMA outperforms all serializers for all chunk sizes, and decreases the streaming time of Kryo by 2.1x. For the array of Pairs, Kryo has the highest performance, by sending 256 objects at a time, due to its ability to compress the objects efficiently. For larger chunks, Naos and Skyway take less time than Kryo, since Kryo starts suffering from longer object construction for larger chunks, whereas Skyway and Naos do not need to construct objects.

Even though Skyway and Naos have the same data format, Skyway streamed the array of Pairs faster than Naos. The difference comes from the complexity of Naos’ communication algorithm, leading to the higher CPU cost at the sender (see Table 3). Skyway’s serialization code only copies traversed objects to send buffers, whereas Naos as a communication library needs to take more factors into account: building send lists, RDMA memory registration, and triggering multiple RDMA requests. Naos could employ various modern RDMA techniques for optimized memory accesses [18], which are interesting directions for future research.

Pipelining data transfers. Naos supports pipelining graph traversal with communication on the sender, and pointer fixing with communication on the receiver. Unlike Naos, conventional OSD approaches require an object to be fully serialized before sending it over the network. In this experiment, we show the effect of pipelining for large object graphs by measuring the time of transferring arrays with 2^{20} elements.

The latencies of Java, Kryo, Skyway, and Naos with no pipelining are depicted as straight lines in Figure 10 as they are independent of the pipeline size. Naos with pipelining provides a 20% reduction in latency in comparison with a non-pipelined variant, since the receiver can start pointer recovery earlier. Note that in the previous experiments with streaming large sparse object graphs, Kryo outperformed Naos as it could split the graph into chunks. For inseparable large graphs, however, Naos takes less time even for highly sparse graphs.

Workload	(50:50)	(95:5)	(100:0)
TCP-Kryo	14-24 Kreq/sec	16-24 Kreq/sec	23-25 Kreq/sec
RDMA-Naos	194-266 Kreq/sec	196-266 Kreq/sec	219-281 Kreq/sec

Table 4: Throughput under YCSB workloads with various (read:write) ratios. Percentiles 5 and 95 are reported.

4.2 Accelerating applications with Naos

Naos provides a simple programming interface (see Table 1) hiding all the burden of low-level RDMA communication. In particular, RDMA benchmarks from the previous experiments take only 10 lines for Naos and over 300 lines for the Disni RDMA library. Thus, we believe that it is simple to build systems using Naos. As proof, we have extended Apache Dubbo with Naos communicator, and implemented a Naos-enabled map-reduce framework.

Zero-copy RPC messages with Dubbo. To show that Naos is easy to use, we extended an RPC library Apache Dubbo with the Naos communicator. For that we added a new Naos-enabled communication module that has no serialization module.

In the first experiment we measure the latency of an RPC function that echoes back a Java String. Naos’ performance was compared with the default TCP network library, Mina [3], with Kryo serializer. Naos was deployed with cycle detection. Note that Dubbo besides an RPC arguments also sends an RPC metadata resulting in sending several Java objects. Figure 11 shows that employing Naos RDMA decreases the latency by at least 55% for all tested sizes.

To understand the performance of Naos under a realistic throughput workload, we built a key-value store (KVS) using a Java concurrent hashtable and Dubbo library for communication. We populated the KVS with one million entries of 1 KiB each. We benchmark it under different YCSB [7] workloads. Table 4 shows that Naos RDMA achieves an average speedup of 11x over TCP-Kryo. The speedup comes from the fact that TCP-Kryo was bottlenecked by the CPU, whereas Naos consumes less CPU time to send a KVS request. The experiment shows that Naos can be utilized for KVS workloads as KVS requests and responses have low sparsity.

In comparison with microbenchmarks (§4.1), the performance difference between Naos and Kryo is much higher for the current workload than for the microbenchmarks, where Kryo’s performance was measured after JIT compilation that

Test	LiveJournal [4] (2 nodes)				Orkut [35] (3 nodes)			
	TCP		RDMA		TCP		RDMA

[†] PageRank with sparsity-aware implementation.

Table 5: Total and per stage processing times in seconds for 100 iterations of PageRank algorithm. Percentiles 5 and 95 are reported for PageRank iterations.

significantly improved its performance for repetitive sending of the same object. Since Naos does not depend on Java runtime optimizations, it can achieve much higher performance than Kryo for dynamic workloads.

Improving Data Processing Applications. We could not integrate Naos into Spark as its shuffle module is designed to communicate files with serialized objects. Integration of Naos would require a substantial redesign of Spark’s code base. Therefore, we implemented our own map-reduce framework that takes advantage of Naos. Our framework supports all discussed serializers including Skyway and also offers RDMA networking with Disni. It was designed to resemble Spark but perform shuffle completely in-memory.

We evaluate the OSD approaches by running PageRank on real-world graphs as input: LiveJournal [4] and Orkut [35]. The LiveJournal dataset was processed with two shuffle workers and Orkut with three shuffle workers. Naos was deployed with 256 KiB pipelining and without cycle detection. We report total runtime including data loading and 5 and 95 percentiles for processing a single Pagerank iteration. We also provide two implementations of PageRank: the first one follows conventional design where each score update is a class of 32 bytes; the second implementation was designed to communicate dense contiguous score updates, thereby reducing sparsity of communicated shuffle blocks.

Table 5 shows the lowest runtime was achieved by Naos and Skyway for the first implementation. A side effect of Naos and Skyway is that, after receiving, objects are always contiguous in memory, thereby improving data locality. As a result, an application can process such contiguous objects faster as fewer memory pages need to be fetched. Overall, Naos TCP performs approximately as Skyway, but NaosIt RDMA provides 2.1% and 4.8% improvement over Skyway for LiveJournal and Orkut, respectively. The experiment shows that zero-transformation approaches for OSD can reduce processing time for data-processing workloads.

The sparsity-aware implementation provides an additional 4% reduction in runtimes, showing that applications need to take Naos’ limitations into consideration to achieve the highest performance. Thus, Naos could be used in combination with works on data sparsity reduction for JVMs [5, 33, 34].

5 Discussion and Future work

The role of RDMA. RDMA helps Naos to remove potential copies induced by the TCP stack. Application-wise, Naos is zero-copy for both TCP and RDMA networks, unlike Skyway. On the other hand, for trivial graphs, Skyway and Naos TCP use almost identical algorithms for the receiver, as they both receive objects with zero-copy and only fix the class reference. However, since Naos TCP does not pre-allocate memory for receiving, its performance could be bound by memory allocation. It is possible to modify Naos TCP to pre-allocated buffers as Skyway and RDMA Naos do, removing the bottleneck. In this work, however, we focus on the RDMA implementation of Naos.

SmartNICs. In Naos, a sender cannot modify its on-heap memory before sending. Therefore, a receiver has to employ a complex pointer recovery algorithm, whereas Skyway can pre-process buffers before sending them to help the receiver to recover objects faster. We believe that such a feature is better implemented at the SmartNIC level that would fix the pointers on the fly before writing the data to DRAM. For example, since a Naos’ RDMA sender already knows the destination addresses of the objects, either the SmartNIC at the sender or at the receiver could fix the object pointers. The class pointers could be fixed by storing class translation tables in the SmartNIC.

6 Conclusions

We have presented Naos, a JVM communication library that enables transferring objects directly from one heap to another over the network with minimal CPU involvement and zero-copy. We demonstrated that existing OSD techniques are bound to CPU and that, as networks get faster, they will become the bottleneck of distributed systems. Naos completely avoids the need to serialize and deserialize objects for data transfers, with the corresponding performance advantages. Naos provides a simple API that simplifies the use of RDMA from JVM-based applications. Our evaluation shows that Naos outperforms all existing OSD approaches for moderately sparse object graphs.

One-sided RDMA-Conscious Extendible Hashing for Disaggregated Memory

Abstract

Memory disaggregation is a promising technique in datacenters with the benefit of improving resource utilization, failure isolation, and elasticity. Hashing indexes have been widely used to provide fast lookup services in distributed memory systems. However, traditional hashing indexes become inefficient for disaggregated memory since the computing power in the memory pool is too weak to execute complex index requests. To provide efficient indexing services in disaggregated memory scenarios, this paper proposes RACE hashing, a one-sided **RDMA-Conscious Extendible** hashing index with lock-free remote concurrency control and efficient remote resizing. RACE hashing enables all index operations to be efficiently executed by using only one-sided RDMA verbs without involving any compute resource in the memory pool. To support remote concurrent access with high performance, RACE hashing leverages a lock-free remote concurrency control scheme to enable different clients to concurrently operate the same hashing index in the memory pool in a lock-free manner. To resize the hash table with low overheads, RACE hashing leverages an extendible remote resizing scheme to reduce extra RDMA accesses caused by extendible resizing and allow concurrent request execution during resizing. Extensive experimental results demonstrate that RACE hashing outperforms state-of-the-art distributed in-memory hashing indexes by 1.4 – 13.7× in YCSB hybrid workloads.

1 Introduction

Memory disaggregation, which has attracted extensive attentions from both industry, e.g., HP’s The Machine [20] and Intel RSD [21], and academia [6, 16, 18, 28, 29, 38], decouples the traditional monolithic compute and memory resources in datacenters and forms independent compute and memory resource pools. Due to resource pooling and independent hardware deployments, disaggregated memory enjoys the benefits of improvements on resource utilization, failure isolation, and elasticity [5, 42]. In the disaggregated memory architecture, compute blades run applications with only a small amount of memory as cache. In contrast, the memory pool stores application data with weak computing power. Due to not involving the compute resources in the memory pool, fast one-sided

RDMA networks generally serve for data accesses from the compute blades to the memory pool.

Distributed in-memory hashing indexes have become one of the fundamental building blocks in many datacenter applications, such as databases [23, 27, 45] and key-value stores [2, 3, 25]. With the increasing popularity of RDMA in modern datacenters, RDMA-search-friendly (RSF) hashing indexes have been intensively studied, e.g., FaRM hopscotch hashing [13], Pilaf cuckoo hashing [31], and DrTM cluster hashing [44]. These RSF indexes execute search requests by using one-sided RDMA `READS` to fetch data from remote memory without involving remote CPUs. In contrast, insertion, deletion, and update (IDU) requests are sent to the remote CPUs, which locally execute them. However, this mechanism fails to work in the new disaggregated memory architecture, since the computing power in the memory pool is too weak to execute the aforesaid complex IDU requests. In fact, in these RSF hashing indexes, IDU requests can be executed in the compute blades by using one-sided RDMA `WRITE` and `ATOMIC` verbs to operate on remote data. However, we observe that executing IDU requests using one-sided RDMA verbs in existing RSF hashing indexes incurs significant performance degradation, due to a large number of network round-trips and concurrent access conflicts. In a nutshell, it is non-trivial to design an efficient hashing index for disaggregated memory due to the following challenges:

- *Many remote reads&writes for handling hash collisions.*

In order to handle hash collisions, existing hashing schemes incur significant data movement overheads to make room for newly inserted items, e.g., hopscotch hashing [19] and cuckoo hashing [36]. These data movements are executed by many remote reads and writes in the disaggregated memory, which significantly decrease the performance of hashing indexes, since each remote read or write produces one RDMA network round-trip.

- *Concurrency control for remote access.* To handle conflicts of concurrent accesses, lock-based techniques have been widely used in hashing indexes [15, 26]. Locks have low overhead for local hashing indexes, due to nanosecond-level latency for local execution. However, when using locks for hashing indexes in disaggregated memory scenarios, remote locking has to be implemented using RDMA `ATOMIC` verbs

with microsecond-level latency, thus incurring high overheads and increasing the waiting delay when lock contention occurs. Especially for the hashing indexes with excessive data movement, multiple locks are acquired before moving data, which exacerbates the lock contention.

- *Tricky remote resizing of hash tables.* When a hash table is full, resizing is inevitable for increasing its size. Conventional full-table resizing needs to move all key-value items from an old hash table to a new one. Extendible resizing [14,33] reduces the number of moved items during resizing, at the cost of one extra RDMA READ due to the need of first accessing the directory of the hash table. Moreover, during resizing, it is challenging to concurrently access the hash table.

To address the above challenges, we propose RACE hashing, to the best of our knowledge, the first hashing index designed for disaggregated memory which fully relies on one-sided RDMA verbs to efficiently execute all index requests. To reduce the performance influence of resizing, RACE hashing leverages the extendible resizing, and hence a RACE hash table consists of multiple subtables and a directory which is used to index subtables. The subtable structure is designed to be one-sided RDMA-conscious (RAC), achieving that all index requests (including search, insertion, deletion, and update) can be executed using only one-sided RDMA verbs while having a constant-scale time complexity in the worst case, and therefore delivering high performance. To improve the performance of remote concurrency, RACE hashing leverages a lock-free remote concurrency control scheme for the RAC hash subtable, which achieves that all index requests except failed insertions are concurrently executed in a lock-free manner. Moreover, to reduce the performance penalty from extendible resizing, RACE hashing caches the directory at the client side (a client is a CPU blade), and therefore eliminates the RDMA access to the directory. Nevertheless, since the directory in the client cache becomes stale when the hash table is resized, accessing the hash table via a stale directory cache may obtain incorrect or inconsistent results. RACE hashing presents a simple yet efficient stale-read scheme to guarantee the correctness of accessed data and allow current request execution during resizing.

Specifically, this paper makes the following contributions:

- *One-sided RDMA-conscious table structure.* We present a RAC subtable structure that is both RDMA-search-friendly and RDMA-IDU-friendly. All index requests are executed by using only one-sided RDMA verbs with constant worst-case time complexity. IDU requests do not cause any extra data movement.

- *Lock-free remote concurrency control.* We design lock-free remote concurrent algorithms for RACE hashing to enable all requests except failed insertions to be concurrently executed without locking.

- *Extendible remote resizing.* We present a stale-read client directory cache scheme to reduce one extra RDMA READ for remote directory lookups and guarantee request execution

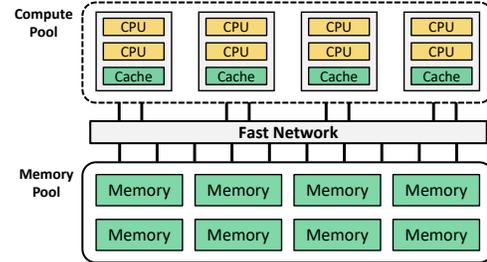

Figure 1: Architecture for disaggregated memory.

correctness when using the stale directory cache. We also achieve concurrent access to the subtable that is being resized.

- *Implementation and evaluation.* We have implemented the RACE hashing and evaluated its performance. Extensive experimental results demonstrate that RACE hashing outperforms state-of-the-art distributed in-memory hashing indexes by up to 13.7× in YCSB [11] hybrid workloads.

2 Background and Motivation

2.1 Disaggregated Memory

In a general disaggregated memory architecture in datacenters [6, 18, 28, 29, 42], different types of resources are separated into pools, e.g., a compute pool and a memory pool, as shown in Figure 1. Each pool is managed and scaled independently as well as failure-isolated. The compute pool consists of many CPU blades, each of which retains a small amount of memory as the local cache for the memory pool. The memory pool includes many memory blades that can be DRAM or persistent memory DIMMs, RNICs, and controllers (the RNIC and controller can be the same entity). The RNIC and controller have low-power processing units used only for interconnection. The communication between compute and memory pools leverages fast remote-access interconnect techniques, such as one-sided RDMA, Omni-path [8], or Gen-Z [1]. The interfaces that the memory pool provides for the compute pool include READ, WRITE, ALLOC, and FREE for variable-size memory blocks, as well as ATOMIC operations, e.g., compare-and-swap (CAS) and fetch-and-add (FAA). We assume ALLOC and FREE interfaces are implemented in the RNICs or controllers of the memory pool [1, 42]. Without loss of generality, the rest of this paper considers using one-sided RDMA for the interconnect in the disaggregated memory architecture, i.e., compute blades access the memory pool using RDMA READ, WRITE, and ATOMIC verbs.

2.2 RDMA-search-friendly Hashing Index

In this subsection, we first present existing RDMA-search-friendly (RSF) hashing indexes and then analyze their performance on disaggregated memory.

2.2.1 Existing Hashing Schemes

With the wide use of RDMA in modern datacenters, RSF hashing indexes have been intensively studied [13, 31, 44]. All

these RSF hashing indexes are designed for the datacenter architecture with monolithic servers. Clients execute search requests by using RDMA READs to fetch data from remote memory without involving remote CPUs. In contrast, IDU requests are sent to the remote servers and executed using the remote CPUs. We review each of these hashing indexes in detail as follows.

Pilaf Cuckoo Hashing: Pilaf [31] proposes a 3-way cuckoo hashing that uses 3 orthogonal hash functions to compute 3 different hash buckets for each key. When executing a key Search, the client first reads one of its 3 corresponding hash buckets using an RDMA READ. If the key does not exist in the first bucket, the client then reads the second hash bucket. Upon not finding the key in the second bucket, the client reads the third hash bucket. For Insertion requests, the client sends them to the server and the server CPUs handle them locally. An insertion may iteratively evict existing key-value items in the cuckoo hash table to their alternate locations. This mechanism incurs an inconsistency problem in which a search request executed by the client may miss the key when the server is handling its eviction. To address this problem, the server first calculates all affected buckets (called a cuckoo path [26]) before moving keys. The server then moves each key to its alternate location starting from the last affected bucket in the cuckoo path.

FaRM Hopscotch Hashing: FaRM [13] proposes a chained associative hopscotch hashing in which each bucket has a neighborhood that includes the bucket itself and its following bucket. Each bucket has multiple slots and each key is stored in the neighborhood of the bucket that the key is hashed to. For an Insertion that is also handled at the server side, the hopscotch hashing tries to find an empty slot in the neighborhood of the key's hash bucket. If found, the empty slot stores the item. Otherwise, the hopscotch hashing continues to find an empty slot forward by executing a *linear probe*. If finding an empty slot, the hopscotch hashing tries to iteratively displace items to *move* the empty slot towards the neighborhood. If there is no empty slot or the movement fails, the hopscotch hashing stores the item in the bucket list linked to the key's hash bucket. When executing a Search, the client reads the neighborhood of the key's hash bucket, i.e., two adjacent buckets, using an RDMA READ. Upon not finding the key, the client further traverses the linked buckets. Note that traversing each bucket needs an RDMA READ.

DrTM Cluster Hashing: Cluster hashing proposed in DrTM [44] is a chained hashing with associativity, in which reading and writing key-value items use RDMA READs and WRITEs and insertions and deletions to the hash table are shipped to the server for local execution. To insert a new key, the cluster hashing tries to find an empty slot in the key's hash bucket and the bucket list linked to the key's hash bucket. If there is no empty slot, the cluster hashing adds a new bucket in the bucket list to store the inserted key-value item. For a Search request, the client reads the key's hash bucket using

an RDMA READ. Upon not finding the key, the client further traverses the linked buckets one by one.

2.2.2 Performance on Disaggregated Memory

To the best of our knowledge, there is no existing hashing index specifically designed for disaggregated memory. As a first step, we analyze the performance of using the above RSF hashing indexes in disaggregated memory. Due to the absence of computing power in the memory pool to execute their IDU requests, we consider implementing the IDU requests with one-sided RDMA verbs.

For *Pilaf cuckoo hashing* [31], to insert a key-value item, the client needs to execute eviction operations when the hash table is in a high load factor. Specifically, based on the state-of-the-art concurrent cuckoo hashing algorithm [26], the client first calculates a cuckoo path and locks all buckets in the path using RDMA CASEs. The client then uses RDMA WRITEs to iteratively evict key-value items in the cuckoo path. A cuckoo path may include tens or hundreds of buckets [15]. Thus an insertion is executed by using a large number of RDMA CASEs and WRITEs, delivering poor insertion performance and also decreasing the performance of other search requests due to the use of a large number of locks.

For *FaRM hopscotch hashing* [13], to insert a key-value item, the client needs to linearly probe buckets in the hash table using RDMA READs until finding an empty slot. When the hash table is in a high load factor, inserting a key may need to read the entire hash table to the client until finding an empty slot. After finding an empty slot, moving the empty slot toward the neighborhood of the inserted key is also complex and expensive, due to locking multiple buckets in the movement path and using multiple RDMA WRITEs to move items. Moreover, if there is no empty slot or the movement fails, the operation of adding linked buckets is also expensive.

For *DrTM cluster hashing* [44], to insert a key-value item, the client needs to traverse buckets in its corresponding bucket list one by one until finding an empty slot. Traversing each bucket needs an RDMA READ. If there is an empty slot in these buckets, the client inserts the item using an RDMA WRITE. Otherwise, the client adds a new overflow bucket to the bucket list. Before modifying the bucket list, the client needs to lock the bucket list to prevent other clients from inserting duplicate keys or freeing buckets. Thus an insertion executes operations including traversing the bucket list, locking/unlocking, allocating memory for a new bucket and the new item, linking the new bucket, and writing the new item, resulting in many RDMA READs, WRITEs, and CASEs. The operations of allocating overflow buckets in the cluster hashing are more frequent than in FaRM hopscotch hashing, since the cluster hashing has a weaker ability to deal with hash collisions in the main hash table. Moreover, the deletion requests are also complex in the structure of linked bucket lists, due to the need of moving items from buckets at the list tail towards ones at the list head to fill empty slots and recycling

tail buckets for higher performance and space utilization [13].

In summary, these RDMA-search-friendly hashing indexes become RDMA-IDU-unfriendly for disaggregated memory since IDU requests incur a large number of RDMA operations to deal with hash collisions and concurrency control. Our paper proposes RACE hashing which is *both RDMA-search-friendly and RDMA-IDU-friendly* while efficiently dealing with hash collisions and concurrency control as presented in Section 3. The performance is also verified in Section 4.

2.3 Resizing Hash Tables

When a hash table is full, i.e., an insertion failure occurs or its load factor reaches a threshold, the hash table needs to be resized by expanding its capacity. In general, there are two kinds of resizing mechanisms including full-table resizing and extendible resizing [14, 33].

To expand a hash table, the *full-table resizing* mechanism allocates a new hash table whose size is larger than the old one, e.g., double the size, and then iteratively moves each key-value item from the old hash table to the new one. The full-table resizing is expensive due to moving all items.

In the *extendible resizing*, a resizing operation only needs to move partial items. Specifically, the hash table using extendible resizing includes multiple subtables and there is a directory to index these subtables as shown in Figure 2a. For a 64-bit hash value, M bits are used by the directory to locate a subtable (we use the last M bits as an example, i.e., suffix) and the remaining $(64 - M)$ bits are used to locate target buckets within the subtable. The number of suffix bits currently used by the directory is called *global depth (GD)* ($GD \leq M$). Thus the directory has 2^{GD} entries that correspond to at most 2^{GD} subtables. Each subtable has a *local depth (LD)* ($LD \leq GD$) that indicates the number of suffix bits used by the subtable.

When a subtable is full, we split the subtable into two by adding a new subtable. As shown in Figures 2a and 2b, when the subtable with the suffix “1” is full, it is split into Subtables “01” and “11”. The resizing mechanism moves the key with suffix “11” from Subtable “01” to Subtable “11” and changes their *LDs* to 2. When a subtable is full and its *LD* is equal to the *GD*, we grow the directory by doubling its size, as shown in Figures 2b and 2c. The full subtable is split into two ones. Except for the directory entry that the added new subtable corresponds to, other new directory entries point to their corresponding original subtables. After resizing the directory, search requests use the new *GD* to locate their corresponding subtables. In summary, by performing extendible resizing, when a subtable is full, we only need to resize this single subtable without affecting key-value items in other subtables. Therefore, RACE hashing uses the extendible resizing.

Nevertheless, there are two challenges when using extendible resizing in disaggregated memory. First, compared with the full-table resizing, the extendible resizing incurs one extra memory access for each search request, due to the need of first querying the directory to obtain the address of the tar-

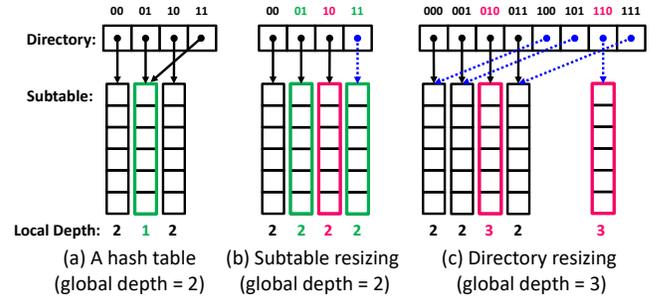

Figure 2: A hash table with extendible resizing.

get subtable before accessing the subtable. One extra memory access has little impact on the performance of a local hash table, due to fast local memory access. However, in the disaggregated memory, the one extra memory access *produces one more RDMA round-trip*, significantly decreasing the search performance. Second, as there is no powerful compute resource in the disaggregated memory to execute the complex resizing, the resizing has to be triggered and executed by a remote client, i.e., a CPU blade, which is different from the traditional resizing mechanism that is always executed by local CPUs. When a client is performing the resizing, other clients do not know about its occurrence. Therefore, we have to *deal with concurrent access to the hash table during resizing*.

3 RACE Hashing

3.1 Overview

Figure 3 shows the overall architecture of RACE hashing for disaggregated memory. The RACE hash table is stored in the memory pool. Clients in the compute pool operate the hash table using one-sided RDMA verbs. To alleviate the performance influence of resizing, RACE hashing leverages the extendible resizing and hence the hash table consists of multiple subtables and a directory. In order to reduce the extra RDMA *READ* for accessing the remote directory, RACE hashing leverages a directory cache¹ in the client. Each client maintains a local cache to store only the directory of the RACE hash table. Thus a client can access the directory using a local memory access rather than a remote RDMA *READ*, and use RDMA verbs to access only the subtable. We present the design of an *RDMA-conscious (RAC) hash subtable structure* in Section 3.2, i.e., the RAC hash subtable, in which all index requests are executed by using only one-sided RDMA verbs while having constant worst-case time complexity. We then present a *lock-free remote concurrency control scheme* in Section 3.3 for the RAC hash subtable, achieving that index requests including search, insertion, deletion, and update are concurrently executed in a lock-free way. Moreover, caching the directory in clients causes data inconsistency issues between the directories in the memory pool and client caches.

¹The memory overhead of the cache is small since the directory generally has at most hundreds of entries and each entry has only several bytes.

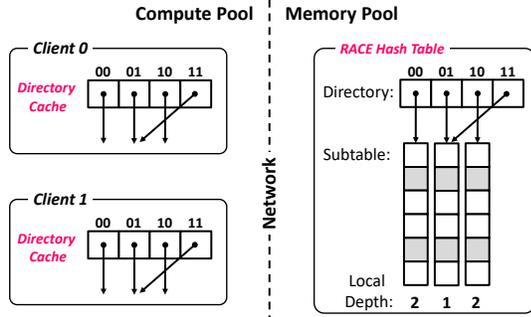

Figure 3: The overall architecture of RACE hashing in disaggregated memory. (The entire RACE hash table is stored in the memory pool. Clients in the compute pool store the directory of the hash table in their local caches and access subtables only using one-sided RDMA verbs.)

Therefore, we finally present a client directory cache with stale reads scheme in Section 3.4 to address the inconsistency issue at low overhead.

3.2 The RAC Hash Subtable Structure

In disaggregated memory scenarios, the challenge of designing a RAC hash subtable structure stems from minimizing the number of remote RDMA operations for IDU requests while keeping high memory efficiency and Search performance. To achieve this goal, we design the RAC hash subtable that does not allow any movement operations, evictions, or bucket chaining to handle hash collisions, since these operations incur a large number of remote writes as presented in Section 2.2. Instead, the RAC hash subtable uses three major design choices, including associativity, two choices, and overflow colocation, for addressing hash collisions and thus achieves a constant worst-case time complexity for all index requests.

1) Associativity. With associativity, each bucket has multiple slots, being capable of storing multiple key-value items. K -way associativity means that each bucket has K slots. Associativity is friendly for one-sided RDMA operations since multiple items within one bucket can be read together in one RDMA READ. Figure 4 shows a RAC hash subtable with 4-way associativity.

2) Two Choices. Based on the theory of “the power of two choices” [32], enabling each key to have two choices for its storage location can achieve a good load balance among buckets, effectively handling hash collisions. Hence, the RAC subtable uses two independent hash functions, $h_1()$ and $h_2()$, to compute two hash locations for each key, as shown in Figure 4. By efficiently combining associativity with two choices, the RAC subtable inserts a new item into the less-loaded bucket between its two hash locations. Note that, according to Mitzenmacher’s observations [32], two choices achieve exponential improvements over one choice for the efficiency of load balancing, while three choices only have a constant factor improvement than two choices. In disaggregated memory, three choices incur one more bucket access (i.e., one more

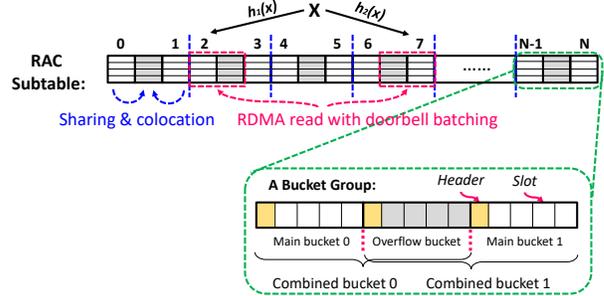

Figure 4: The RAC hash subtable structure (4-way associativity as an example).

RDMA READ) than two choices. Therefore, unlike Pilaf [31], which uses three choices, we use two choices in our design.

3) Overflow Colocation. The overflow sharing technique [46] enables an overflow bucket (or called standby bucket) to be shared by the other two main buckets to store conflicting items for better load balancing. However, overflow buckets are discrete from their main buckets [46], incurring extra bucket accesses, which performs worse for disaggregated memory, due to extra RDMA READs. To address this problem, we propose an overflow colocation scheme to store the overflow buckets adjoining with their main buckets. As shown in Figure 4, three continuous buckets are considered as a group, in which the first and last buckets are main buckets that can be addressable by the hash functions. The middle bucket is an overflow bucket that cannot be addressable by the hash functions and is shared by the first and last buckets to store their conflicting items. By doing so, one RDMA READ can fetch one main bucket and its overflow bucket together, thus reducing the number of RDMA READs.

Putting it all together, the structure of a RAC hash table is shown in Figure 4. A RAC hash subtable is a one-dimensional bucket array stored in a continuous memory space. Each bucket is K -way associative and a bucket group includes three continuous buckets, i.e., two main buckets and a shared overflow bucket. The combination of a main bucket and its overflow bucket is called a combined bucket. For each key, we compute two hash locations that are respectively in two different bucket groups. The structure of the RAC hash subtable is simple yet efficient for disaggregated memory, having the following strengths:

- **RDMA-IDU friendly:** As each key only involves two combined buckets, IDU requests only need to operate within the two combined buckets without moving/evicting items from/to other buckets or linking new buckets, having constant worst-case time complexity while being RDMA-friendly.
- **RDMA-search friendly:** A search request only issues two RDMA READs, each of which fetches one combined bucket. More importantly, the two RDMA READs can be issued in parallel to reduce the request latency, unlike cluster hashing [44] in which issuing the next RDMA READ has to wait for the return of the previous one to traverse the linked buckets.

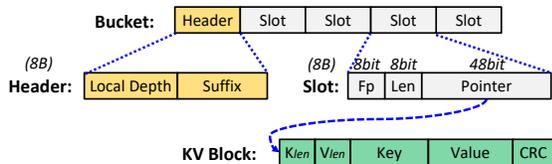

Figure 5: The structure of a bucket.

Moreover, by using doorbell batching [22] that is an RDMA-optimized technique to read multiple disjoint memory regions within one RDMA round-trip time (RTT), we package the two RDMA READ operations into one. Therefore, the search latency in the RAC subtable is one RTT rather than two ones.

- *High memory efficiency:* By combining associativity, two choices, and overflow colocation, the RAC hash subtable enables items to be more evenly distributed among buckets and thus efficiently handles hash collisions to achieve a good load balance. It hence achieves a high load factor of up to 90% (with 7-way associativity) as evaluated in Section 4.2.1.

3.3 Lock-free Remote Concurrency Control

Lock-based techniques have been widely used in existing hashing indexes within a single machine for concurrency control [15, 26]. Nevertheless, for disaggregated memory, all requests are executed by using one-sided RDMA verbs, which results in non-trivial challenges for handling concurrent access conflicts. This is because remote locking implemented by using microsecond-level-latency RDMA CAS incurs much higher overheads, compared with nanosecond-level-latency local locking, and each locking or unlocking operation requires an RDMA round-trip. In order to deliver high concurrent performance, we propose a *lock-free remote concurrency control scheme* for RACE hashing which achieves that all index requests, except failed insertions, become lock-free. A failed insertion triggers a subtable resizing and needs to acquire the resizing lock as presented in Section 3.4.2.

Bucket Structure. In RACE hashing, to support variable-length keys and values, full key-value items are stored outside the hash table like existing hashing indexes [10, 31, 44]. The pointers to full key-value items are stored inside the hash table. The structure of each bucket in the RAC hash subtable is shown in Figure 5. A bucket consists of a header and multiple slots. The header is used for hash table resizing and will be introduced in Section 3.4.1. Each slot corresponds to a key-value item. To support lock-free remote concurrent access, a slot is 8B, i.e., the maximum size of an RDMA CAS, and composed of a fingerprint (8 bits), a key-value length (8 bits), and a pointer (48 bits). A fingerprint (Fp) is the 8-bit hash of a key. Based on the analysis of existing work [15], an 8-bit fingerprint is enough to achieve a very low false positive (a false positive means that different keys in a bucket have the same fingerprint). Moreover, before reading a full key-value item using an RDMA READ, we need to know the size of the item. Therefore, we store the length (Len) of the key-

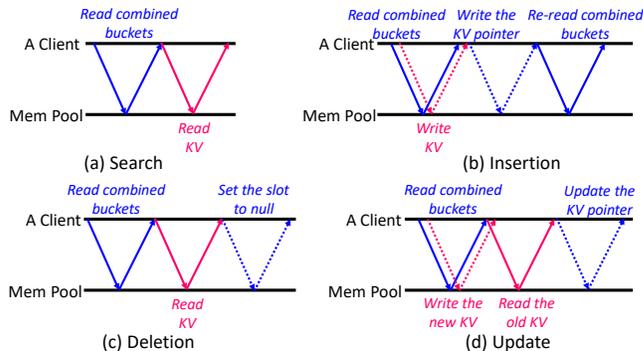

Figure 6: The main workflows of lock-free search, insertion, deletion and update. (The blue lines mean accessing the hash table and the red lines mean accessing the key-value blocks. The solid lines mean RDMA READ round-trips and the dotted lines mean RDMA WRITE/ATOMIC round-trips.)

value block in the slot. The length is 8-bit and the length unit is 64B². Thus the length of a key-value block is always multiple of 64B and the maximum length of a key-value block is $2^8 * 64B = 16KB$, which covers most application scenarios for current key-value stores since small key-values dominate in them [7]. When a key-value item is larger than 16KB, which in fact rarely occurs, we store the remaining item content beyond 16KB in the second key-value block and link the second block to the first one. The respective lengths of the key and value (i.e., K_{len} and V_{len}) are stored in the head of the key-value block. The pointer in a slot consumes 48 bits like the x86_64 system [10, 34, 43]. A null pointer means the slot is empty. Based on the bucket structure, we present lock-free search/insertion/deletion/update operations below.

Lock-free Insertion. To insert a key-value item, the client uses doorbell batching to read two combined buckets that the key corresponds to. At the same time, the client writes the key-value block³ in the memory pool. Therefore, reading buckets and writing the key-value block are executed in parallel, as shown in Figure 6b. Once receiving the combined buckets, the client looks for an empty slot in the order of main buckets first and overflow buckets second, as presented in Section 3.2. If an empty slot is found, the client uses an RDMA CAS to write the pointer of the key-value block into it. Otherwise, the hash table resizing is triggered, as presented in Section 3.4.

In rare cases, clients may concurrently insert duplicate keys into the hash table, since RDMA ATOMIC verbs only ensure the 8B atomicity. For example, Client 1 and Client 2 try to insert the same key K . As each key corresponds to two combined buckets in RACE hashing, it may occur that Client 1 selects one empty slot in Combined Bucket 0 to insert K and Client 2 selects one empty slot in Combined Bucket 1 to insert K . In this case, two duplicate keys K exist in the hash table. To address the issue of duplicate keys, after writing the pointer in

²The length unit can be changed as needed.

³The memory of the key-value block can be pre-allocated to reduce the latency of memory allocation in the critical path of insertion.

a bucket for an insertion, the client re-reads the two combined buckets to check duplicate keys, as shown in Figure 6b. On finding duplicate keys, the client only keeps one *valid* key and removes the remaining duplicate keys. Different clients have to determine the same key-value item as the valid key when finding duplicate keys in order to guarantee the consistency of a concurrent access. To guarantee this, we hence make an agreement in the algorithm to determine the only valid key for different clients. For example, within the two combined buckets, the agreement considers the key stored in the slot with the minimal bucket number and the minimal slot number to be the only valid one.

Lock-free Deletion. To delete a key-value item, the client first executes a search to find the target key. If the target key is found, the client sets its corresponding slot to be null by using an RDMA CAS, as shown in Figure 6c. Once the RDMA CAS is done successfully, the deletion request is returned. The client then sets the key-value block to full-zero and frees the key-value block in background. The zero-setting operation can be avoided if the RNIC can automatically set the freed memory to full-zero for data security, i.e., avoiding the old data to be observed by other clients.

Lock-free Update. To update a key-value item, the client searches the target key. At the same time, the client writes the new key-value item into the memory pool, as shown in Figure 6d. Once finding the target key exists, the client uses an RDMA CAS to change the content of the slot to point to the new key-value item. If the RDMA CAS is executed successfully, the update request is returned. The client finally frees the old key-value block in background.

Lock-free Search. As shown in Figure 6a, to search a key, the client reads its corresponding two combined buckets. If the fingerprint matches one of the slots, the client reads the key-value block that the slot points to. The client then compares the full key. If the full key matches, the value is returned.

Since all modifications on buckets are atomic and update requests do not modify the old key-value item in place, the only inconsistency case for a search is that the key-value block is freed or re-allocated before a search request reads the key-value block (after obtaining the pointer of the key-value). However, this inconsistency case can be easily observed by comparing the length and content of the key stored in the block with those of the search key. This is because once the key-value block is freed/re-allocated, its content is full-zero/changed, rendering the comparison mismatched. Nevertheless, there still exists a special case that another client re-allocates the key-value block and issues an RDMA WRITE to write the same key, key length, and value length as those of the old key-value block. As an RDMA WRITE is not atomic, it may write the key and key length completely but be writing the value. At this time, if reading the key-value block, a client can find the key is matched. But the value is broken, which cannot be observed by the client. To address this problem, we add a 64-bit checksum in each key-value block to enhance the

self-verification and check the integrity of a key-value block like Pilaf [31], as shown in Figure 5. Pilaf also shows that a 64-bit checksum is sufficient for verification.

Moreover, for insertion, deletion, and update requests, the operation of CASing a slot may fail, which means the slot is changed by another client before the CAS. In this case, RACE hashing re-searches the target key and then re-executes the failed insertion, deletion, or update request.

3.4 Extendible Remote Resizing

Using extendible resizing for disaggregated memory incurs two challenges, i.e., one extra remote access to read the directory for each index request and concurrent access during resizing, as presented in Section 2.3. In this subsection, we present a stale-read client directory cache scheme and a concurrent access scheme during resizing to address the two challenges respectively.

3.4.1 Client Directory Cache with Stale Reads

In order to reduce the extra RDMA READ for accessing the directory, we use a client directory cache for RACE hashing. However, caching the directory in clients incurs the data inconsistency issue between the directories in the memory pool and client caches. For example, when a client triggers a subtable resizing or directory resizing, the content of the directory in the memory pool is modified and thus the directories in the caches of other clients become stale. If other clients still query the hash table using their stale directories, they may locate an incorrect subtable and obtain incorrect data.

To address the inconsistency problem between client caches and the memory pool, in a *baseline solution* [17], and upon a client triggers a resizing operation, the client broadcasts a notification message to all other clients to invalidate their respective directory caches and does not start modifying the directory in the memory pool until receiving acks of all other clients. Obviously, the baseline solution incurs high performance overhead for resizing due to broadcasting messages and waiting for all acks. *The second solution* proposed by Pilaf [31] is to close the RDMA connections of all other clients to prevent these clients from performing RDMA READS once a resizing is triggered. Clients then re-connects the memory server to obtain the new table root after the resizing is completed. Pilaf addresses the problem of incorrect access but incurs high performance penalty due to blocking RDMA READS of clients. Therefore, both the solutions incur significant performance overheads.

In order to efficiently address this inconsistency problem, we propose a *stale-read client directory (SRCD) cache scheme* that does not need to broadcast messages or close the connections of other clients to the memory pool when triggering a resizing. Instead, by using the SRCD cache scheme, clients query the hash table still using the stale directories in their caches, but can verify whether the obtained data is correct. To achieve this, we add a header in each bucket of the RAC

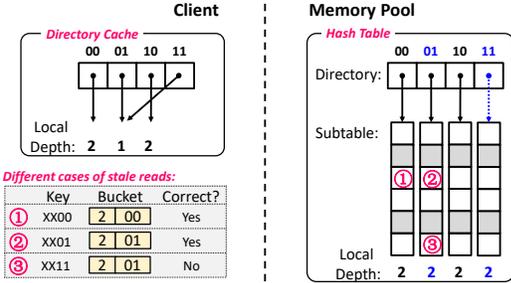

Figure 7: The stale-read client directory scheme. (Three cases when comparing the key with the fetched bucket header.)

hash subtable, as shown in Figure 5. The bucket header stores the local depth (LD) and suffix bits (Suffix) of the subtable that the bucket belongs to. The bucket header is not modified in IDU requests and is modified only when the subtable is created and resized. The local depth and suffix bits in the bucket header are used to verify whether the bucket is correct when executing search/insertion/deletion/update.

Figure 7 shows an illustration of using the SRCD cache scheme to verify the correctness of buckets. The client currently caches the directory of the hash table shown in Figure 2a, in which the directory entries “01” and “11” point to the same subtable. In the memory pool, the hash table is resized to be a new hash table shown in Figure 2b, in which a new subtable is created and the directory entries “01” and “11” point to different subtables. To search a key, the client first locates a subtable using the SRCD cache with stale reads and then fetches the buckets in this subtable via RDMA READs. After receiving a bucket, the client respectively compares the local depth and suffix bits stored in the bucket header with the local depth of the directory entry in the SRCD cache and the suffix bits of the key. The client can observe three cases as follows.

1) Both local depth and suffix bits match. If the local depth and suffix bits in the bucket header are respectively the same as the local depth of the directory entry in the cache and suffix bits of the key, the client can verify that the subtable is not resized and the fetched bucket is correct. For example, the key is “XX00” that corresponds to the directory entry “00”, i.e., Case ① in Figure 7.

2) Local depth mismatches and suffix bits matches. If the local depth in the bucket header is the same as that of the directory entry in the cache, the client knows the accessed subtable was resized in the memory pool. The client further computes the suffix bits of the key using the local depth stored in the bucket header and finds that the suffix bits of the key and those stored in the bucket header are matched. In this case, the client can verify the bucket is also correct although the subtable was resized. For example, the key is “XX01” but Subtable “01” was resized in the memory pool, i.e., Case ② in Figure 7. During the resizing, the keys with “11” are moved out Subtable “01” while the keys with “01” still remain in Subtable “01”. Therefore, when locating Subtable “01” to

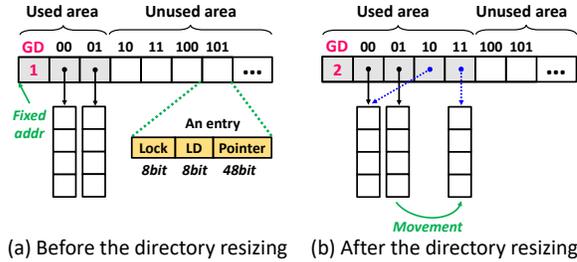

Figure 8: The resizing of the directory. (The global depth (GD) increases. The used area is not changed and new directory entries are written into the unused area.)

search the key with “01”, the client can obtain the correct key-value item.

3) Both local depth and suffix bits mismatch. If the local depth and suffix bits in the bucket header mismatch, the client can verify the subtable is resized and the searched key should be stored in the new subtable. For example, the key is “XX11” that corresponds to the directory entry “01” in the cache but Subtable “01” is resized in the memory pool and the key “XX11” is moved to the new Subtable “11”, i.e., Case ③ in Figure 7. In this case, the client fetches the new directory entries from the memory pool and re-executes the search.

In summary, only in Case “3) Both local depth and suffix bits mismatch”, the client needs to fetch new directory entries and update the local directory cache. In other cases, the client can locate correct buckets via stale reads.

3.4.2 Concurrent Access during Resizing

When an insertion failure occurs, a subtable resizing is triggered. During a resizing, we need to move slots from the resized subtable to the new one. Due to the slot movement, it is challenging to guarantee the correct execution of concurrent search, insertion, deletion, and update requests upon the subtable that is being resized. To address this challenge, we design the workflow of concurrent resizing as below.

To support concurrent access during resizing, the starting address of the directory in the memory pool cannot be changed. Otherwise, clients fail to find the new hash table after resizing. Therefore, we reserve a large enough contiguous memory space⁴ used for the future resizing of the directory. As shown in Figure 8, the directory includes a used area and an unused area. Clients only cache the used area. To resize the directory, e.g., increasing the GD from 1 to 2, the used area is not changed and the new directory entries are written into the unused area.

To resize a subtable, the client first locks the directory entry of the subtable in the memory pool. The lock only prevents other clients from resizing the same subtable but does not prevent other clients from executing search and IDU requests in the subtable. The client creates a new subtable and initializes the header of each bucket in the new subtable.

⁴For example, if we use at most 16 suffix bits for the directory, the memory space of 2^{16} directory entries is reserved.

The client further writes the pointer of the new subtable to the directory and locks the directory entry at the same time. The client then starts to move items. Figure 8b shows an example. The client moves items with Suffix “11” from Subtable “01” to Subtable “11”. The movement includes three steps for each bucket in Subtable “01”: ❶ updating the suffix bits in the bucket header from “1” to “2” (one RDMA CAS); ❷ inserting all items with Suffix “11” in this bucket into Subtable “11” (one or multiple RDMA CASes); ❸ deleting all items with Suffix “11” in this bucket (one or multiple RDMA CASes). By guaranteeing the order of executing the three steps, we support concurrent access to the subtable that is being resized. In the following, we discuss how to deal with the corner cases caused by the concurrent resizing below.

- *Concurrent search:* When executing a search, if finding that both local depth and suffix bits mismatch, the client can perceive the occurrence of the resizing in Subtable “01”. In this case, the movement may be before Step ❸ or after Step ❸. If the target key is found in the read bucket, it means the movement is before Step ❸. Otherwise, the movement is after Step ❸ or the key does not exist. The client further reads the bucket in Subtable “11” to lookup the target key.

- *Concurrent insertion:* During an insertion, the client re-reads the buckets to check duplicate keys, as shown in Figure 6b. To support concurrent insertion during resizing, we also check the bucket header after re-reading the bucket that the key is inserted to. If the bucket header is not changed, the insertion is successful. Otherwise, the client knows that a resizing occurs in the bucket. The client then compares suffix bits in the new bucket header with those of the inserted key. If the suffix bits match, the insertion is also successful. Otherwise, the client removes the pointer from Subtable “01” and re-inserts the key into Subtable “11”. Moreover, during a subtable resizing, an insertion may fail, i.e., not finding an empty slot in the subtable. In this case, the failed insertion triggers the next resizing. The next resizing will be blocked until the previous resizing releases the directory entry lock.

- *Concurrent deletion/update:* When executing a deletion/update, if finding that both local depth and suffix bits mismatch, the client waits for the completion of the movement and then deletes/updates the key from the new subtable. If the suffix bits match and Step ❶ occurs before the RDMA CAS operation of the deletion/update, there are two corner cases. First, if the RDMA CAS of the deletion/update fails, it means the item has been moved into the new subtable. The client will redo the deletion/update request in the new subtable. Second, the RDMA CAS of the deletion/update succeeds. But the client performing resizing operation fails to delete one item in Step ❸, which means that another client deleted/updated the item. The client performing resizing further cleans the pointer of the item in the new subtable and re-executes the item movement.

In summary, during a subtable resizing, all search/update/deletion and most insertion requests to the subtable are concur-

rently executed in a lock-free way. Only the failed insertions to the subtable are blocked due to triggering the next resizing.

4 Performance Evaluation

4.1 Experimental Setup

Testbed. We run all experiments on 5 machines, each with two 26-core Intel Xeon Gold 6278C CPUs, 384 GiB DRAM, and one 100Gbps Mellanox ConnectX-5 IB RNIC. Each RNIC is connected to a 100Gbps Mellanox IB switch. One machine is used for emulating the memory pool. To emulate the weak compute power, CPUs in the memory pool are only used for registering memory to RNICs during the initialization stage and do not involve in any requests of hashing indexes. The memory is registered with huge pages to reduce the page translation cache misses of RNICs [13]. The other machine is used for building the compute pool in which each CPU core serves as a client. Since current RNIC hardware does not support remote memory allocation in real time, we enable clients to pre-allocate all memory that future insertion and update requests require, which can also reduce the memory allocation latency in the critical path of request execution.

Workloads. We use YCSB [11] to evaluate the performance of different hashing indexes. We use the default Zipfian request distribution ($\theta = 0.99$) for all YCSB workloads. For most experiments, we use 16-byte keys and 32-byte values that are representative in real workloads of key-value stores [7, 15, 35]. We also evaluate the impact of different key-value sizes on the performance.

Comparisons. We compare RACE hashing with three state-of-the-art RDMA-search-friendly hashing indexes, i.e., Pilaf cuckoo hashing [31], FaRM hopscotch hashing [13], and DrTM cluster hashing [44]. Based on the optimal configurations presented in their papers, we use 3-way hashing and one slot per bucket in Pilaf cuckoo hashing, 4 slots per main bucket, 2 neighborhood, and 2 slots per overflow bucket in FaRM hopscotch hashing, and 8 slots per main or overflow bucket in DrTM cluster hashing. Moreover, since the disaggregated memory pool without CPUs cannot execute two-sided RDMA verbs, we implement these hashing indexes using only one-sided RDMA verbs as presented in Section 2.3 to facilitate a fair comparison. All key-value items are stored outside of the hash table to support variable-length keys and values. Each hash table is sized to store 100 million items.

4.2 Experimental Results and Analysis

4.2.1 Maximum Load Factor

The maximum load factor is defined as the ratio of the maximum number of stored items to the total number of slots in a hash table (including slots in main and overflow buckets), which is an important metric that affects the memory efficiency of a hash table. We insert unique keys into RACE, Pilaf cuckoo, FaRM hopscotch, DrTM cluster hash tables until an insertion failure occurs to evaluate their maximum load factors. Specifically, Pilaf cuckoo hashing reaches the maximum

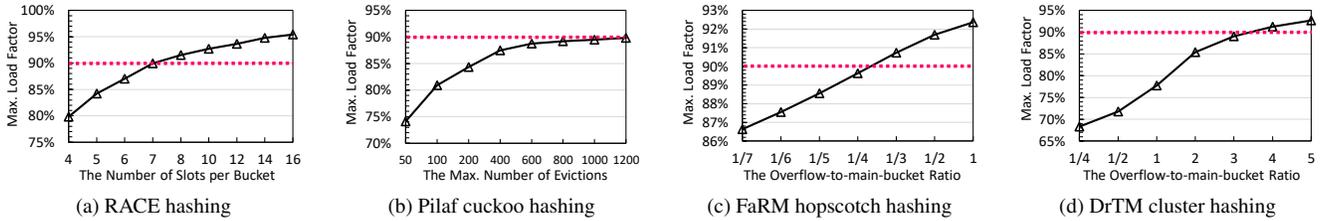

Figure 9: Maximum load factors of different hash tables. (In FaRM hopscotch hashing and DrTM cluster hashing, overflow buckets indicate the buckets linked in conflicting lists. The load factor indicates the ratio of the number of occupied slots to that of all slots in both overflow and main buckets. The overflow-to-main-bucket ratio means the ratio of the number of overflow buckets to that of main buckets.)

load factor when an insertion fails to lookup an empty slot after X cuckoo evictions. X means the maximum number of cuckoo evictions for an insertion and we evaluate maximum load factors of Pilaf cuckoo hashing under different X values. FaRM hopscotch hashing and DrTM cluster hashing reach their maximum load factors when running out of overflow buckets. As the ratio of the number of overflow buckets to that of main buckets (called overflow-to-main-bucket ratio) affects their maximum load factors, we evaluate their maximum load factors under different overflow-to-main-bucket ratios. For RACE hashing, since associativity (i.e., the number of slots per bucket) affects its maximum load factor, we evaluate its maximum load factors under different associativity.

As shown in Figure 9, the maximum load factor of RACE hashing increases with the increase of associativity. The maximum load factor of Pilaf cuckoo hashing increases with the increase of X . The maximum load factors of FaRM hopscotch hashing and DrTM cluster hashing increase with the increase of their overflow-to-main-bucket ratios.

To facilitate a fair comparison, we configure these hash tables to approach the same maximum load factor of 90% for the following experiments. RACE hashing reaches 90% when the associativity is 7. With 7 slots and one header, each bucket in RACE hashing is a cache-line size, i.e., 64B. Pilaf cuckoo hashing approaches 90% when $X = 1000$. FaRM hopscotch hashing and DrTM cluster hashing approach 90% when their overflow-to-main-bucket ratios are 1/4 and 3 respectively.

4.2.2 Execution Latency

To investigate request latencies of different hashing indexes, we respectively execute 1 million search, update, deletion, and insertion requests using one thread when these hash tables are in different load factors and evaluate average latencies of different requests, as shown in Figure 10. The items for search, update, and deletion are recently inserted [11].

Figure 10a shows the average insertion latencies of different hash tables. With the increase of load factors, the insertion latency of Pilaf cuckoo hashing exponentially increases due to causing more and more eviction operations and thus producing a large number of RDMA WRITES and locks; the insertion latency of FaRM hopscotch hashing dramatically increases due to linearly probing more buckets to find empty slots and

linking overflow buckets; the insertion latency of DrTM cluster hashing increases due to traversing longer bucket lists and linking new overflow buckets. The insertion latency of RACE hashing does not increase with the increase of load factors due to not causing any extra RDMA operations in which an insertion has 3 round-trip times (RTTs). When the hash tables are at the load factor of 90%, RACE hashing reduces the insertion latency by 1.9 \times , 8.8 \times , and 57.4 \times compared with DrTM cluster hashing, FaRM hopscotch hashing, and Pilaf cuckoo hashing respectively.

Figure 10b shows the average search latencies of different hash tables and all search requests are lock-free. A search in Pilaf cuckoo hashing needs 1.6 RTTs on average to serially read buckets and 1 RTT to read key-value block. A search in FaRM hopscotch hashing needs only 2 RTTs (one reads the neighborhood and the other reads the key-value block) at a low load factor and its latency increases in a high load factor due to traversing linked buckets. The search latency of DrTM cluster hashing sharply increases with the increase of the load factor since the bucket list becomes longer. When the hash tables are at the load factor of 90%, RACE hashing reduces the search latency by 2.3 \times , 1.2 \times , and 1.4 \times compared with DrTM cluster hashing, FaRM hopscotch hashing, and Pilaf cuckoo hashing respectively.

Figures 10c and 10d show the average deletion and update latencies of different hash tables, which deliver similar characteristics to those of search latencies. But deletion and update latencies of DrTM cluster hashing, FaRM hopscotch hashing, and Pilaf cuckoo hashing are much higher than their search latencies due to the needs of locking, unlocking, modifying slots, and unlinking buckets. The deletion and update latencies of RACE hashing are only higher than its search latency by 1-RTT latency. When the hash tables are at the load factor of 90%, RACE hashing reduces the deletion and update latencies by 1.8 – 2.3 \times and 1.6 – 2.2 \times respectively.

4.2.3 Concurrent Throughput

To investigate the concurrent request throughput of different hashing indexes, we first load 100 million items into a hash table and then successively execute 10 million searches, updates, deletions, and insertions to evaluate the concurrent throughput of different requests. We also vary the numbers of

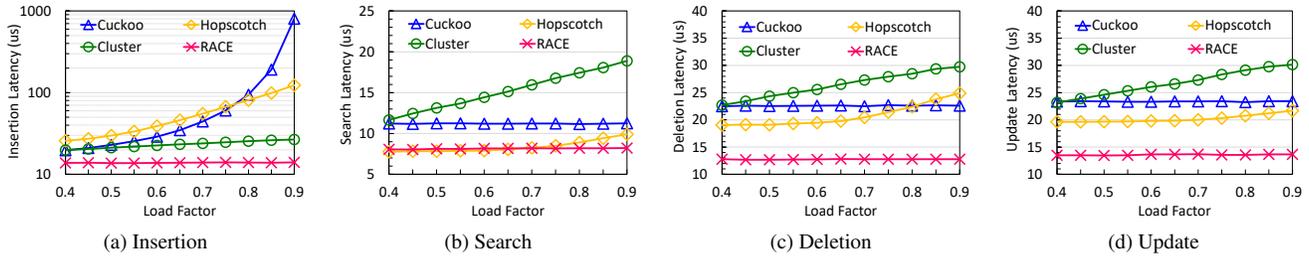

Figure 10: Average latencies of different requests when hash tables are in different load factors.

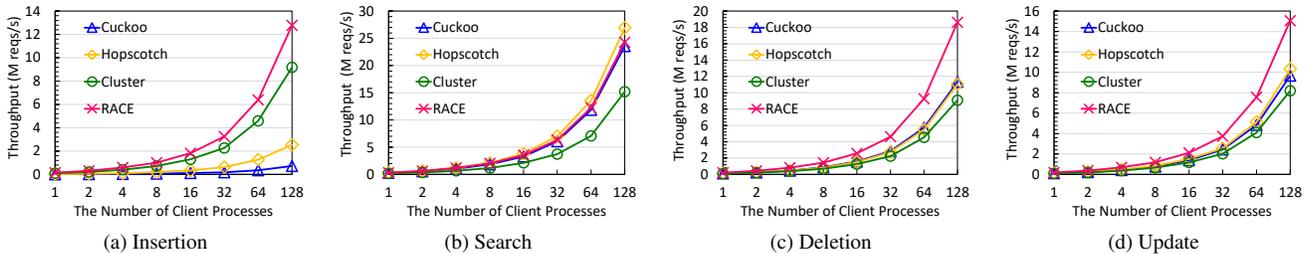

Figure 11: Concurrent throughput of different requests when using different numbers of client processes.

client processes to investigate the change of the throughput with the increase of clients, as shown in Figure 11. When the number of clients is not larger than 32, they are run in one client machine. When the number of clients is 64 and 128, they are run in 2 and 4 client machines respectively.

Figure 11a shows the concurrent throughput of insertion requests. The insertion throughputs of Pilaf cuckoo hashing and FaRM hopscotch hashing are much less than that of RACE hashing, of which reasons are the same as those of their high execution latencies. The insertion throughput of RACE hashing is 16.9 \times , 5.3 \times , and 1.4 \times on average higher than those of Pilaf cuckoo hashing, FaRM hopscotch hashing, and DrTM cluster hashing respectively.

Figure 11b shows the concurrent throughput of search requests. Pilaf cuckoo hashing, FaRM hopscotch hashing, and RACE hashing have a similar search throughput which is higher than that of DrTM cluster hashing. This is because DrTM cluster hashing needs to traverse linked bucket lists. The search throughput of RACE hashing is 1.7 \times on average higher than that of DrTM cluster hashing.

Figures 11c and 11d show the concurrent throughput of deletion and update requests respectively. The deletion and update throughput of RACE hashing is 1.7 – 2.1 \times and 1.5 – 1.9 \times higher than other hashing schemes due to the benefits of locking-free concurrency and RAC index structure.

4.2.4 YCSB Hybrid Workloads

To evaluate the throughput of different hashing indexes under YCSB hybrid workloads, we first load 90 million items into a hash table and then respectively run hybrid search/insertion workloads with different ratios. All tests use 128 client processes. The experimental results are shown in Figure 12. We observe that the throughput of all hashing indexes increases with the increase of search/insertion ratios, and RACE hashing

performs the best for all search/insertion ratios due to having both high search and insertion performance. Compared with DrTM cluster hashing, FaRM hopscotch hashing, and Pilaf cuckoo hashing, RACE hashing improves the performance of hybrid workloads by 1.4 \times , 4.9 \times , and 13.7 \times respectively when the search/insertion ratio is 10%/90%.

4.2.5 Variable-length Values

We increase the size of the key-value (KV) block from 64B to 8KB to evaluate the impact of variable-length KV sizes on the performance of RACE hashing, as shown in Figure 13. With the increase of the KV size, the latencies of insertion, deletion, update, and search requests increase due to reading and writing larger data. When the KV size is no larger than 512B, the increase of latencies is slight.

4.2.6 Extendible Remote Resizing

To support extendible remote resizing, we propose two techniques, i.e., the SRCD cache and concurrent access during resizing as presented in Section 3.4. We investigate the impact of the two techniques on the performance of RACE hashing.

Figure 14 shows the performance of RACE hashing with and without the SRCD cache. We observe that using the SRCD cache reduces 23%, 32%, 24%, and 23% of insertion, search, deletion, and update latencies respectively. This is because using the SRCD cache reduces one extra RDMA READ for accessing the directory.

To investigate concurrent access during resizing, we run two clients of which one executes insertions to trigger multiple resizings (the GD increases from 2 to 5) and the other executes random searches at the same time. We evaluate the average search latencies of RACE hashing with and without concurrent access during resizing as shown in Figure 15.

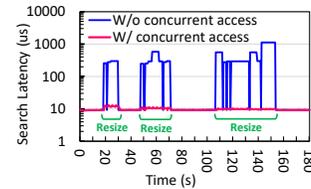

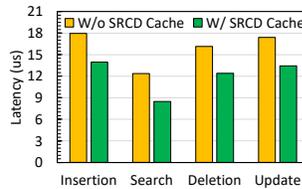

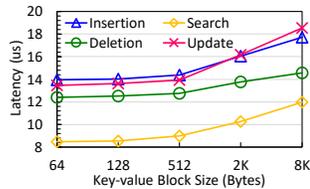

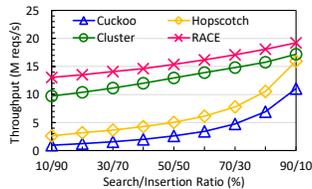

Figure 12: Hybrid workloads. Figure 13: Variable KV sizes.

Figure 14: The SRCD cache. Figure 15: Concurrent access.

Without the concurrent access, the average search latency during the resizing significantly increases since the searches stall until a resizing is completed. With the concurrent access, the average search latency during the resizing does not significantly increase and thus is about two orders lower than that without concurrent access.

5 Discussion

Concurrency Correctness. RACE hashing follows the concurrency correctness condition of *no lost keys* [30]: “a $get(K)$ operation must return a correct value for K , regardless of concurrent writers”. Specifically, when a search and an update run concurrently, the search can return either the new or the old value, while both of them should be unbroken and atomic. When a search and a deletion run concurrently, the search can return no key or the value that will be deleted.

Resizing Execution. In our current implementation, the client triggering the resizing itself performs the resizing. To improve the implementation, the client can create a background client/thread to perform the resizing.

Hardware Failure. Handling hardware failures including network failure, memory failure, and client CPU failure in the disaggregated memory architecture is complicated and tough. For example, after locking a directory entry, the client fails. To handle this failure, we need to enable other clients to perceive the failed client and release the lock directory entry or use the lease-based lock [44]. Our paper mainly focuses on the design of hashing index for disaggregated memory and plan to extend RACE hashing to support the handle of hardware failures in the future work.

6 Related Work

Memory Disaggregation. Memory disaggregation has recently received widespread attentions due to providing significant benefits for datacenters on resource utilization and scaling. Existing work studies various components in datacenters to support memory disaggregation including operating systems [38], hardware architectures [28, 29], memory managements [4, 37, 40–42], networks [1, 9, 12, 39], and new requirements [5, 18]. RACE hashing focuses on the design of index structures in the disaggregated memory which is orthogonal to these works.

Hashing Indexes on RDMA. With the wide use of RDMA in modern datacenters, RDMA-search-friendly hashing indexes have been intensively studied [13, 31, 44]. These hashing indexes are designed for traditional monolithic servers,

which however fails to efficiently work on the new disaggregated memory architecture, due to producing a large number of RDMA operations when executing IDU requests. RACE hashing is the first hashing index designed for disaggregated memory, in which all index requests can be efficiently executed by using only one-sided RDMA operations. Moreover, KV-direct [24] leverages programmable NICs with FPGA to offload hashing index operations, which is orthogonal to our paper that does not rely on FPGA.

Concurrent Hashing Indexes. Different concurrent hashing indexes are proposed to deliver high access throughput. MemC3 [15] uses a global lock to multi-reader and single-writer concurrency for concurrent cuckoo hashing. Libcukoo [26] leverages fine-grained locking to achieve multi-reader and multi-writer concurrent cuckoo hashing. Existing work [10, 33, 46] also proposes concurrent hashing indexes for persistent memory. However, all these existing schemes focus on concurrent access to local memory. Unlike them, our RACE hashing addresses the challenge of concurrent access to remote memory in hash indexes and enables all index requests to be executed in a lock-free manner.

7 Conclusion

This paper proposes RACE hashing, a one-sided RDMA-conscious extendible hashing index for disaggregated memory with lock-free remote concurrency control and efficient remote resizing. The hash table structure is designed to be one-sided RDMA-conscious, achieving that all index requests can be executed using only one-sided RDMA verbs while delivering high performance with constant-scale worst-case time complexity. Moreover, RACE hashing leverages a lock-free remote concurrency control scheme to enable index requests to be concurrently executed in a lock-free manner, and a stale-read client directory cache scheme to reduce one extra RDMA read for accessing the directory while guaranteeing the correctness of stale cache reads. We also achieve concurrent access to the subtable that is being resized. Experimental results show that RACE hashing outperforms state-of-the-art distributed in-memory hashing indexes by up to $13.7\times$ in YCSB hybrid workloads.

Abstract

The appealing properties of NVM including high performance, persistence, and byte-addressability, and a recent active thread of building remote memory systems with RDMA, have produced considerable interest in combining them for fast and persistent remote memory systems. However, many prior systems are either based on emulated NVM or have failed to fully exploit NVM characteristics, leading to sub-optimal performance.

This paper conducts a systematic study to summarize optimization hints that the system designer can use to exploit NVM with RDMA better. Specifically, we demonstrate how system configurations, NVM access patterns, and RDMA-aware optimizations affect the efficacy of RDMA-NVM systems. Based on the summarized hints, we empirically study the design of two existing RDMA-NVM systems, namely a distributed database (DrTM+H) and a distributed file system (Octopus). Both systems are designed when no production NVM is available, and neither of them achieves good performance on it. Our optimized systems achieve up to 2.4X (from 1.2X) better performance.

1 Introduction

People have been studying systems with emerging hardware technologies like Remote Direct Memory Access (RDMA) and Non-Volatile Memory (NVM) for many years, including but not limited to databases [8, 11, 25, 37, 39, 53], file systems [31, 32, 58], key-value stores [2, 10], and distributed shared memory systems [33, 38, 61]. These RDMA-NVM systems can either leverage NVM to persistently store the data or use it as DRAM to extend DRAM capacity.

Unfortunately, few systematic studies examined how to best leverage NVM with RDMA, since production NVM is only publicly available via Intel Optane DC persistent memory [36] (Optane PM¹) until recently. Except for a few systems [22, 33], prior work either uses emulated NVM [58, 61]

¹Since we exclusively study Optane PM in this paper, we use the terms NVM and Optane PM interchangeably throughout the paper.

or simply treats DRAM as NVM [8, 11, 32, 53]. Without such a study, system developers are unclear whether existing RDMA-NVM designs are efficient for Optane PM due to the following three reasons. First, emulating NVM with RDMA is particularly challenging because, to the best of our knowledge, most NVM emulators use CPU for the emulation [49]. However, RDMA may access NVM in a CPU-bypassing manner. Second, a recent study revealed that even the emulator could not faithfully simulate many Optane PM features [59]. Finally, a few systems evaluated with Optane PM do not consider its unique performance characteristics [33].

Our initial experiments further demonstrate that RDMA-NVM systems suffer from inferior performance when they treat NVM as DRAM. For example, the performance of *remote write* is far from the limits of NVM (§3) after switching the memory used in a *remote write* benchmark from DRAM to NVM: 16B one-sided RDMA WRITE only achieves 29% of NVM’s ideal write throughput. Hence, it is imperative to conduct a thorough study of the inferior performance and provide optimizations to mitigate the inefficiency.

There have been valuable studies on how to efficiently use NVM [59] with CPU and how CPU cache may affect the efficiency of RDMA with NVM [22]. Yang *et al.* [59] provide optimizations for the CPU to best utilize Optane PM. We study their findings on RDMA-NVM systems and confirm the importance of their optimizations. Nevertheless, we found some of the optimizations are suboptimal when considering RDMA. We further present optimizations that are best suited for RDMA on NVM. Kalia *et al.* [22] is the most relevant work: we share the same goal of improving RDMA’s performance with NVM. Specifically, they identify how CPU cache could hinder RDMA from fully utilizing NVM write bandwidth. We made a similar observation during our study. Besides, we also study other RDMA-NVM related factors, including inappropriate system configurations (§4.1) and application access patterns (§4.2).

Finally, existing systems use two network roundtrips to implement persistent write atop RDMA and NVM [20] because existing RDMA hardware is unaware of NVM. We ar-

gue that RDMA-NVM systems should consider broadly explored RDMA-aware optimizations [23, 24] to improve the persistent write performance with RDMA. With the help of known RDMA-aware optimizations, RDMA only needs one roundtrip for remote persistent write on the current hardware platforms (§4.3).

In this paper, we conduct a thorough systematic study on how to best utilize NVM with RDMA. Note that our focus is on *remote write*, i.e., the client issues write to the server NVM, either using one-sided or two-sided RDMA. The remote NVM read performance is close to that of DRAM (§3). To summarize, the contributions of this paper are:

A summary of optimization hints (H1–H9) to best utilize NVM with RDMA (§4). We study and collect various RDMA-NVM related optimizations—scattered from different sources—into one systematic study. We also propose new optimizations (H6–H8) that address the limitations of the existing study. The summarized hints are categorized into system configuration advice (§4.1), access pattern advice (§4.2) and RDMA-aware advice (§4.3). We empirically demonstrate how these hints help to fully utilize NVM for different RDMA primitives, i.e., RDMA can attain close to NVM write bandwidth and processing power.

An end-to-end study of improved RDMA-NVM system designs (§6). We use the summarized hints to analyze and improve the design of existing RDMA-NVM systems, namely a distributed database (DrTM+H [53]) and a distributed file system (Octopus [32]). We find that there is still significant room for improvement because both of them are designed when no production NVM is available. Our study helps to improve the throughput of DrTM+H by 1.5X and 2.2X for TPC-C [46] new-order transaction and Small-Bank [45], respectively. It also improves the I/O throughput of file data operations in Octopus by up to 2.4X (from 1.2X). These results strongly suggest we need further revisiting the design and implementations of existing RDMA-NVM systems, especially those not designed for Optane PM.

Our tools and benchmarks are available at <https://github.com/SJTU-IPADS/librdpma>.

2 Background

Figure 1 presents typical hardware components of a node with NVM in an RDMA-capable cluster. RDMA-capable NIC (RNIC) and NVM are attached to the processor, and they communicate with each other via the PCI Express (PCIe) bus.

2.1 Optane PM (NVM)

Intel Optane DC persistent memory [36] (Optane PM) is the first commercially available NVM. Besides a huge

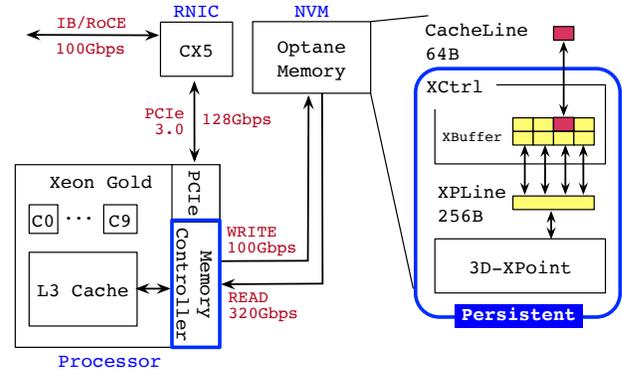

Figure 1. Hardware components of a node with NVM in an RDMA-capable cluster.

performance gain compared to traditional persistent storage (e.g., SSD), Optane PM also provides a DRAM-like memory interface. Thus, CPU can use load and store/non-temporal store² (ntstore) to read and write it, and RNIC can access it through PCIe read/write transactions.

Our study relies on an in-depth look at how Optane PM handles reads/writes. The right half of Figure 1 presents an overview of its components. Data is stored in NVM DIMMs (3D XPoint), while XController (XCtrl) transforms the read/write requests from the processor/PCIe into read/write requests to 3D XPoint. XCtrl has two important features. First, it receives requests in cacheline (CLine) granularity (64B), while 3D XPoint stores data in XPLine granularity (256B). Such a difference in granularity may incur read/write amplification. Second, in order to reduce write amplification, XCtrl has a small write-combining buffer (XBuffer) that merges adjacent cacheline writes into one XPLine write. Note that read requests also compete for XBuffer with write requests [59].

Persistent domain. Data is persistent once it reaches the node’s persistent domain. On the current hardware platform, the persistent domain comprises the Optane PM and the processor’s memory controller, as shown in Figure 1. Future hardware will further extend the persistent domain to the processor cache [4]. Nevertheless, the scope of the persistent domain is orthogonal to the results of this paper. We describe its impact in §5 in more detail.

Asymmetric performance feature. Optane PM is known for two asymmetric performance features. First, its read is much faster than write (320Gbps vs. 100Gbps). Second, sequential write has a higher bandwidth than random write due to the involvement of XBuffer.

Optane PM counters. Optane PM provides various useful counters³ that we use to analyze its behavior: NReadReq and

²non-temporal store has the same semantic as store except that it bypasses the CPU cache.
³Measured via ipmctl [5].

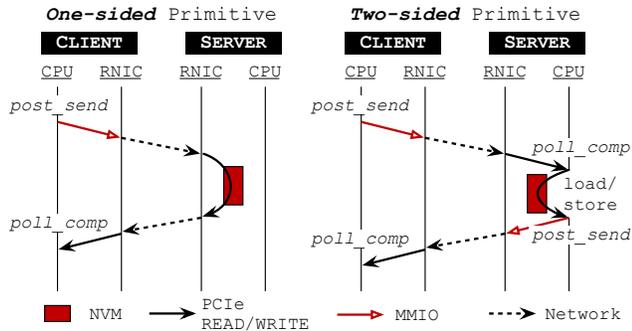

Figure 2. An overview of the interaction between RDMA and NVM.

`NWriteReq` record how many 64B read and write requests are received by XCtrl, while `NMediaRead` and `NMediaWrite` record how many bytes are read/written by 3D-XPoint Media. Based on these counters, we calculate the counter rates and use the counter rates to compute the read/write amplification of NVM: e.g., $\text{NMediaWrite rate} / (\text{NWriteReq rate} \times 64)$ measures the write amplification of Optane PM.

2.2 Remote direct memory access (RDMA)

RDMA is a fast networking feature with high throughput (e.g., 100Gbps bandwidth), low latency (e.g., $2\mu\text{s}$), and low CPU overhead. Representative implementations of RDMA include InfiniBand (IB) and RDMA over Converged Ethernet (RoCE). RDMA is well-known for its one-sided primitives (READ/WRITE⁴): RDMA-capable NIC (RNIC) can directly read/write the server memory bypassing the server CPU. RDMA also provides two-sided primitives (SEND/RECV) that are similar to message passing.

QP and the programming model of RDMA. RDMA hosts use queue pair (QP) to issue RDMA requests. The QP contains one *send queue* and one *completion queue*. To issue an RDMA request (e.g., one-sided RDMA READ), the host calls `post_send`, which uses memory-mapped IO (MMIO) to post the request to the *send queue*. If the host marks the request as *signaled*, then it can further obtain the completion event of the sent request, e.g., whether the payload of the READ has been fetched to the host, by polling the *completion queue* via `poll_comp`.

2.3 RDMA with NVM

Figure 2 shows how various RDMA primitives interact with Optane PM. One-sided RDMA primitives communicate with Optane PM through PCIe read/write transactions, while two-sided RDMA uses server CPU to read/write Optane PM⁵.

⁴We may use READ/WRITE as one-sided RDMA READ/WRITE.

⁵Although two-sided RDMA can use PCIe read/write transactions to write messages to Optane PM, we omit the discussion of such a case because its mechanism is the same as one-sided RDMA WRITE.

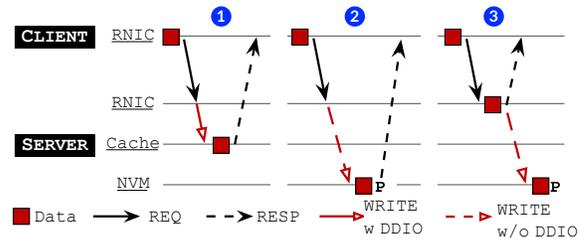

Figure 3. Three execution flows of using one-sided RDMA to write the server NVM. Note that without proper configurations (see §2.3), all three request flows are possible. The client uses the MMIO to post the WRITE request (REQ), and the client RNIC generates the response (RESP) via DMA. When DDIO (§2.3) is enabled, RNIC writes to the server’s last level cache (LLC). Otherwise, RNIC directly writes to Optane PM. **P** denotes the persistent point of the data, i.e., when the client can ensure the WRITE is persistent.

When different RDMA primitives access NVM, several factors may impact their efficacy:

Access granularity. RNIC, CPU and NVM (including XController and 3D XPoint) have different access granularities. Requests that do not match the device granularity cause extra read/write requests to the NVM. Hence, systems should carefully tune their NVM access patterns for different RDMA primitives (§4.2). Table 1 summarizes the access granularities of different devices.

Table 1: Access granularities of different hardware components.

	CPU	PCIe	XController	3D XPoint
Granularity	CLine	CLine	CLine	XPLine
Payload	64B	64B	64B	256B

DDIO. Data Direct I/O (DDIO) [16] aims to improve the server cache locality of the DMA-ed data, which allows the last level cache (i.e., L3 Cache) as the primary destination of the RNIC’s DMA-ed data (e.g., one-sided RDMA WRITE and two-sided RDMA). However, it is not friendly to Optane PM (§4.1).

Persistence. Two-sided primitives can use extended CPU instructions (e.g., `c1wb`) to ensure that the write to NVM is persistent. However, one-sided RDMA has no such instruction. Thus, one-sided RDMA-NVM WRITE is not persistent.

Figure 3 depicts three possible execution flows of one-sided RDMA-NVM WRITE on the current hardware platforms, only in the second case that the data is persistent (②). In the first case (①), the data is not persistent because it still resides in the volatile processor cache when the client receives the response. In the third case (③), the data is cached at the RNIC’s internal buffer when the client believes the write has finished. RNIC is not in the persistent domain (see Figure 1).

Table 2: *The configurations of machines in our testbed.*

Name	#	Hardware
Server	1	2x Intel Xeon Gold 5215M (10 cores), 384GB DRAM 2x ConnectX-5 IB RNIC (100Gbps) 1x 1.5T NVM (12x Optane DIMM)
Client	5	2x Intel Xeon E5-2650 v4 (12 cores), 128GB DRAM 2x ConnectX-4 IB RNIC (100Gbps)

Implementing persistent one-sided RDMA WRITE over current hardware (i.e., guarantee to achieve ② in Figure 3) requires specific configurations and extra one-sided requests: we should first disable DDIO to bypass the processor cache and then send an extra one-sided RDMA READ to the same QP issued the WRITE [19] to flush the previously cached WRITES. These two steps guarantee the WRITE is executed as the second case in Figure 3. However, a strawman implementation of this strategy uses two network roundtrips for a single write [20]. We describe optimizations for persistent WRITE in §4.3.

3 Testbed and Methodology

Testbed. Table 2 lists the hardware descriptions of our testbed. The server machine that equips Optane PM has two 10-core Intel Xeon Gold 5215M processors, 384GB DRAM and two ConnectX-5 MT27800 100Gbps Infiniband NIC. We attach six NVM DIMMs to each server’s processor, allowing them to achieve the maximum (ideal) bandwidth of Optane PM (320Gbps for read and 100Gbps for write). Each client machine has two 12-core Intel Xeon E5-2650 v4 processors, 128GB of DRAM, and two ConnectX-4 MCX455A 100Gbps Infiniband NIC. All machines are connected to a Mellanox SB7890 100Gbps InfiniBand Switch.

Target systems and evaluation methodology. The focus of this paper is on *remote write*, i.e., the client issues write requests to the server NVM using either one-sided or two-sided RDMA. For *remote read*, we find it has close performance to that of DRAM due to the asymmetric read/write performance feature (§2.1) of NVM.

To empirically analyze the read/write features of RDMA with NVM, we conduct a microbenchmark to evaluate the performance of *remote read* and *remote write* implemented by different RDMA primitives. In this benchmark, each client sends read/write requests with different payloads to the server’s NVM via RDMA, similar to prior work [10, 23, 40, 53]. The request addresses are chosen randomly. For one-sided RDMA, the client directly uses its primitives to implement *remote read* and *remote write*. For two-sided RDMA, the client sends messages to the server, and the server reads/writes NVM with `memcpy` after receiving the messages. We implement the benchmark on a state-of-the-art distributed execution framework designed for RDMA [53]. Unless other-

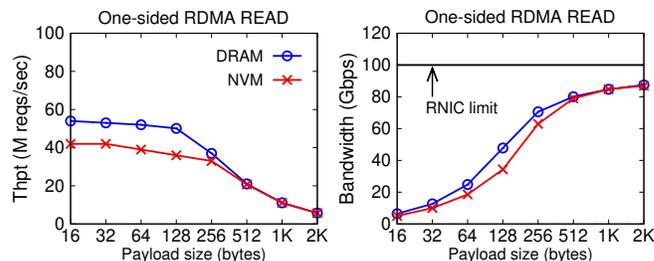

Figure 4. A comparison of one-sided RDMA READ performance on DRAM and NVM, (a) throughput and (b) aggregated bandwidth.

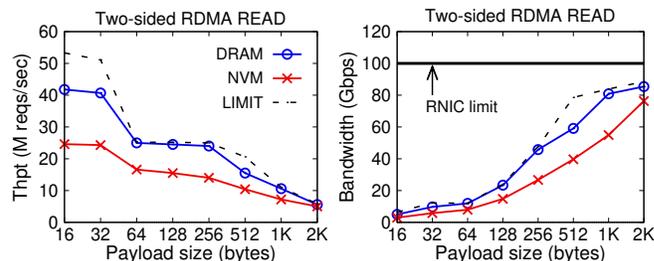

Figure 5. A comparison of two-sided RDMA READ performance on DRAM and NVM, (a) throughput and (b) aggregated bandwidth. LIMIT is measured when the server directly returns to the client without reading the payload.

wise mentioned, we report the per-socket peak throughput or bandwidth of reading/writing NVM through RDMA.

Figure 4 and Figure 5 present the performance of *remote read* on DRAM and NVM for one-sided and two-sided RDMA, respectively. For large payloads (e.g., 2,048B), the read performance of NVM is close to that of DRAM for both one-sided and two-sided primitives (99% and 90%). Reading NVM can hardly become a bottleneck in RDMA-NVM systems since NVM has a much higher read bandwidth than RNIC (320Gbps vs. 100Gbps). Note that for small reads (e.g., 16B), two-sided RDMA READ still suffers from obvious throughput degradation: it only achieves 59% of the DRAM read throughput. This is because CPU has much a higher read latency when reading NVM compared to DRAM (271ns vs. 82ns)⁶. In contrast, increased NVM read latency has negligible impact on one-sided RDMA READ since the PCIe latency is the dominant factor (~1000ns [35]).

Unlike *remote read*, the performance of *remote write* is much slower than that of DRAM, as shown in Figure 6 and Figure 7. More importantly, these results are not optimal because the measured performance is far from the theoretical limit of NVM or RDMA. For example, one-sided RDMA WRITE can achieve only 29% of the NVM peak write throughput (15M vs. 52M reqs/sec⁷) for small 16B writes.

⁶Measured by Intel Memory Latency Checker (MLC) [17].

⁷We estimate the NVM peak write throughput by dividing its peak write

Table 3: A summary of design advice, optimization hints, and whether the hints can apply to a specific RDMA primitive. ✓ indicates a positive optimization effect, and “-” means the hint does not target the case.

Design advice	Optimization hints	One-sided	Two-sided
A1. Configuration (§4.1)	H1. Avoid cross-socket NVM accesses	✓	✓
	H2. Limit concurrent access to a single NVM DIMM for two-sided RDMA	-	✓
	H3. Disable DDIO; if DDIO must be enabled, use two-sided RDMA	✓	-
A2. Access pattern (§4.2)	H4. Use <code>ntstore</code> instead of <code>store</code> for large writes	-	✓
	H5. Use XPLine granularity for writes	✓	✓
	H6. Use PCIe DW granularity (64B) for small writes (i.e., less than XPLine)	✓	-
	H7. Use cacheline granularity (64B) with <code>ntstore</code> for small writes (i.e., less than XPLine)	-	✓
	H8. Use less atomic operations on NVM	✓	✓
A3. RDMA-aware (§4.3)	H9. Enable outstanding request with doorbell batching for one-sided persistent WRITE	✓	-

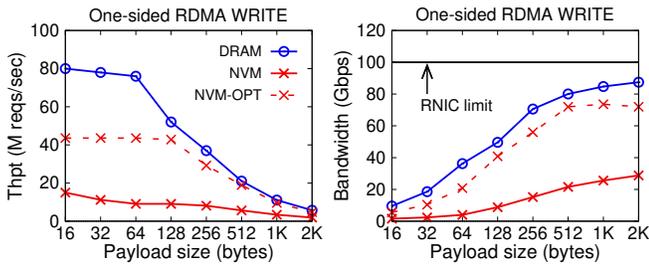

Figure 6. A comparison of one-sided RDMA WRITE performance on DRAM and NVM, (a) throughput and (b) aggregated bandwidth. NVM-OPT applies the optimizations from §4.

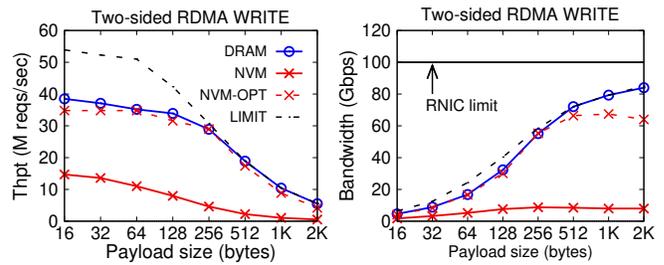

Figure 7. A comparison of two-sided RDMA WRITE performance on DRAM and NVM, (a) throughput and (b) aggregated bandwidth. LIMIT is measured when the server directly returns to the client without writing the payload. NVM-OPT applies the optimizations from §4.

Further, one-sided and two-sided RDMA saturate only 38% and 12.5% of the NVM’s peak write bandwidth for large 2,048B writes, respectively. Therefore, there is significant room for improvement.

Our approach. To understand why *remote write* has inferior performance, we conduct a systematic study to summarize various performance-relevant factors for RDMA to write NVM. Inspired by a recent CPU-specific NVM study [59], we mainly follow two directions. First, we investigate what system configurations can affect RDMA’s efficiency with NVM (§4.1). Second, we study which access patterns from RDMA are friendly to NVM (§4.2). For each direction, we empirically study whether known NVM optimizations are necessary or optimal for RDMA. The results show that some setups are not necessary, while some optimizations are sub-optimal for RDMA. To this end, we present new optimizations by fully considering NVM characteristics with RDMA. Finally, we use existing RDMA optimizations to improve the persistent write of one-sided RDMA atop of NVM (§4.3).

bandwidth (100Gbps) with the size of XPLine (256B).

A preview of the optimization results. Figure 6 and Figure 7 present our optimized version of one-sided and two-sided RDMA NVM write (*NVM-opt*). After applying all the optimizations, they have significantly better performance and achieve close to the NVM limit. For example, one-sided 16B RDMA NVM WRITE achieves 45M reqs/sec, 87% of the ideal peak throughput of NVM write.

4 Design Advice

This section summarizes design advice and optimization hints for high-performance RDMA-NVM systems, as shown in Table 3. We present both new optimizations (e.g., Hint 6, **H6**) and brief descriptions of known optimizations. Further, we show that some known optimizations that only consider CPU accessing NVM are sub-optimal for RDMA (e.g., **H5**). Among these optimizations, **H1–H8** applies to systems that use Optane PM as volatile storage and persistent storage, while **H9** only targets systems that use Optane PM as per-

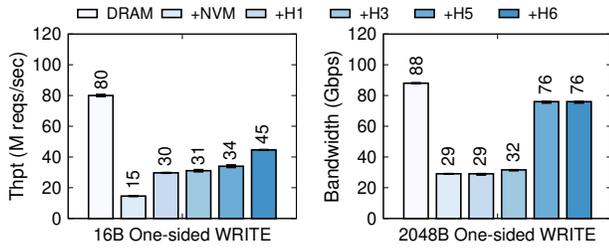

Figure 8. Factor analysis of the optimizations used to improve NVM write performance atop of one-sided RDMA WRITE under (a) small payload (16B) and (b) large payload (2,048B). We do not include **H8** as it does not target remote write. Note that the error bars are small.

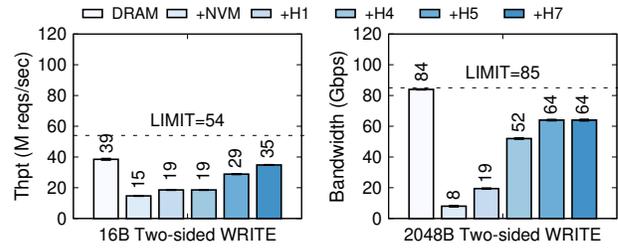

Figure 9. Factor analysis of the optimizations used to improve NVM write performance atop of two-sided RDMA for (a) small payload (16B) and (b) large payload (2,048B). LIMIT is measured as the server directly returns to the client without writing the payload. We do not include **H8** as it does not target remote write. Note that the error bars are small.

sistent storage.

We make two assumptions about the hardware components. First, the RNIC is a PCIe-based device, which holds for most existing RNICs [24]. Second, the NVM is Optane PM [36], the first (and only) commercially available NVM device. Unless otherwise stated, we use the same *remote write* microbenchmark in §3 for the study.

4.1 Configuration advice

A prior CPU-specific NVM study [59] has provided valuable configuration setups (e.g., NUMA setup) for the CPU to better utilize NVM. We summarize these setups in **H1** and **H2**. A natural question to answer is: do RDMA-NVM systems require the same setups? Our study reveals that first, RDMA-NVM systems should also consider **H1**. Meanwhile, one-sided RDMA does not necessarily require **H2** as the CPU. Finally, RDMA introduces a new configuration option, **H3**. Succinctly, the configuration advice for RDMA-NVM systems is the following three optimization hints:

- H1.** Avoid cross-socket NVM accesses;
- H2.** Limit concurrent access to a single NVM DIMM for two-sided RDMA;
- H3.** Disable DDIO; If DDIO must be enabled, use two-sided RDMA for large NVM writes;

Hint H1. Yang *et al.* [59] found that the NVM write bandwidth of a socket could be halved from other sockets. Since an RNIC leverages its attached socket to access NVM from another socket (see Figure 1), slow cross-socket NVM accesses also impact RDMA-NVM systems. Figure 9 and Figure 8 illustrate this: removing cross-socket access improves the baseline two-sided and one-sided RDMA write performance by up to 2.4X (8Gbps vs. 19Gbps) and 2X (15M vs. 30M reqs/sec), respectively. Thus, RDMA-NVM systems should also avoid cross-socket NVM accesses.

Apply H1. Readers may wonder whether **H1** is feasible in real systems. One strategy to apply **H1** is first attaching one RNIC for each socket, and then treating each socket as a logical node in a cluster. Such a setup is common in RDMA-capable systems [11, 29, 51, 54, 62], and it naturally avoids cross-socket NVM access. Furthermore, even if there are insufficient RNICs for each socket to have a dedicated RNIC, one can adopt the techniques in IOctopus [42] to apply **H1**. Using IOctopus, one RNIC can simultaneously communicate with multiple sockets. Hence, RDMA can directly access the NVM bypassing the attached socket.

Hint H2. Another observation from Yang *et al.* [59] is that the CPU fails to scale up when writing to a single NVM DIMM. This phenomenon also affects two-sided RDMA because it uses CPU to write to the NVM. As shown in Figure 10(a), compared to using four threads at the server to handle writes, two-sided RDMA-NVM write bandwidth drops 37% when using 20 threads. Note that to avoid interference from other factors, we have enabled all other optimizations hints in this experiment. Therefore, system designers should also reduce concurrent access to a single NVM DIMM for two-sided RDMA. In practice, designers can control which DIMM to access by selecting the appropriate NVM addresses [59]. For example, assuming the starting address of the NVM is 4KB-aligned, and the NVM is interleaved on 6 DIMMS, the first and seventh 4KB is on the first DIMM, and the second 4KB is on the second DIMM, etc.

Does one-sided RDMA suffer from the same issue? To quantify this, we further conduct an experiment to measure the concurrent write performance of one-sided RDMA-NVM WRITE. In this benchmark, we increase the number of clients that send concurrent one-sided RDMA WRITE to a single NVM DIMM, and measure their aggregated bandwidth. Figure 10(b) presents the results: one-sided RDMA WRITE scales well with the increased number of concurrent requests. This implies that one-sided RDMA is more robust when concurrently accessing a single NVM DIMM.

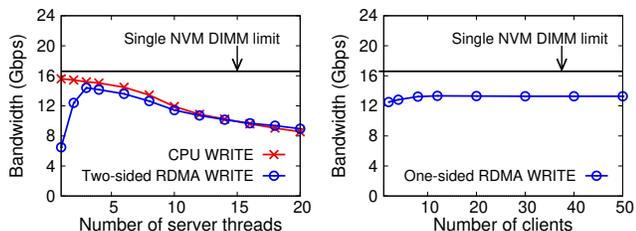

Figure 10. Effects of concurrent accesses to a single NVM DIMM for (a) two-sided RDMA and (b) one-sided RDMA WRITE using a 2048B payload. The write bandwidth limit of a single NVM DIMM is about 16Gbps (one-sixth of the evaluating Optane PM). Note that we have enabled all other optimizations for both RDMA primitives in this experiment.

To the best of our knowledge, it remains unknown why the CPU cannot scale up when accessing a single NVM DIMM. Yang *et al.* [59] suspected that the high NVM access latency may cause head-of-line blocking effects at the processor. Similarly, we suspect that the RNIC can scale well for one-sided RDMA because the increased latency of NVM access is not that significant compared to PCIe latency.

Hint H3. One important RDMA-specific configuration is whether to enable DDIO, which controls the destination of one-sided RDMA WRITE (§2.3). A prior study has revealed that DDIO has a huge performance impact on one-sided RDMA-NVM WRITE for large payloads [22]; we also made a similar observation during our study. Consequently, **H3** is an important configuration setup for RDMA-NVM systems.

Impact of DDIO. Figure 11(a) shows the effects of DDIO on one-sided RDMA-NVM WRITE. Since large RDMA-NVM WRITE is more sensitive to DDIO, we use a bulk write benchmark where a single client issues a sufficient large payload to measure the peak bandwidth of WRITE. With DDIO enabled, we observe that WRITE can only reach half of the NVM peak bandwidth (42Gbps vs. 100Gbps). On the other hand, the WRITE can achieve close to NVM peak bandwidth with DDIO disabled.

Ideally, the client should saturate the RNIC(NVM) bandwidth in this benchmark. However, it fails because DDIO changes the sequential writes from RNIC to random writes to NVM. Figure 12(a) illustrates this: the RNIC first sequentially writes the data into the cache, after that the cache randomly evicts the data to the NVM. Random writes cannot saturate NVM bandwidth because NVM has less chance to merge adjacent writes to avoid write amplification (see §2.1).

Measuring the write amplification of DDIO. To quantify the effect of DDIO, Figure 11(b) analyzes the write amplification of NVM⁸ with different configurations. We can see that

⁸We measure the write amplification of DDIO via NVM counters. §2.1 describes the measurements in more detail.

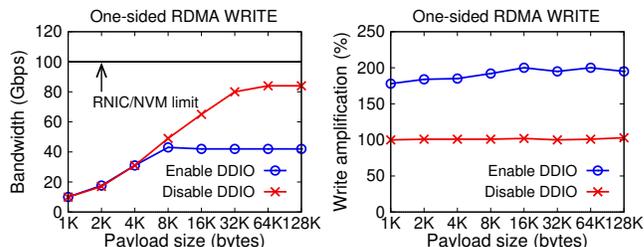

Figure 11. (a) Effects of DDIO to bulk one-sided RDMA-NVM WRITE, (b) write amplification analysis of one-sided RDMA-NVM WRITE. Note that we have enabled all other optimizations in this experiment.

enabling DDIO incurs a roughly 2X write amplification to NVM WRITE, which explains why the bandwidth is halved for a large payload (e.g., more than 64KB).

Implications for RDMA-NVM systems. If the systems must use one-sided RDMA WRITE to saturate the NVM bandwidth, we recommend considering **H3** to turn off the DDIO first. The system can statically enable/disable DDIO via the BIOS setups [58] or dynamically adjust the bits in Integrated I/O (IIO) Configuration Registers [1, 13, 18] at runtime. We follow prior work [13] to use configuration registers to configure DDIO at runtime.

Limitations of disabling DDIO. On the current hardware platform, the DDIO configuration affects all the devices on a processor. Thus, server CPU will have a poorer cache locality for DMA-ed data (e.g., messages in two-sided primitives) with DDIO disabled, resulting in degraded two-sided RDMA performance. For example, we measured a 57% peak throughput drop (54M vs. 23M reqs/sec) of two-sided RDMA primitives after disabling DDIO. Therefore, the current RDMA-NVM systems will make a trade-off between the bandwidth of one-sided RDMA NVM WRITE and the performance of two-sided RDMA. Considering the limitations of disabling DDIO, we extend **H3** as follows:

H3 (extended). If DDIO must be enabled, use two-sided RDMA for large NVM writes;

Two-sided RDMA can leverage the CPU at the server to fully utilize NVM [59]. Hence, RDMA-NVM systems can adopt a hybrid approach for implementing NVM write based on the request payload size.

4.2 Access pattern advice

Tuning systems NVM access pattern according to the Optane PM's features is critical to NVM-aware systems. Known optimizations for CPU include choosing the appropriate CPU instructions and using the proper access granularity [59]. We summarize these hints in **H4–H5**:

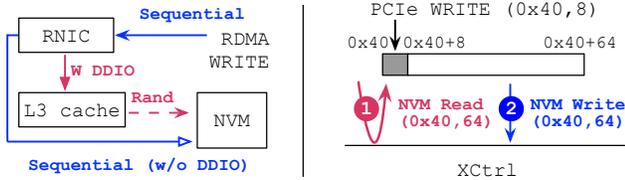

Figure 12. (a) DDIO changes the sequential accesses of RNIC into random accesses. (b) An example of PCIe partial write: PCIe sends two NVM requests when writing 8B at address 0x40.

H4. Use `ntstore` instead of `store` for large writes;

H5. Use XPLine granularity for writes;

Both hints can also benefit RDMA-NVM systems. However, we found **H5** is not optimal when considering RDMA, especially for small writes, because it incurs huge network amplification. For example, applying **H5** only improves the performance of 16B one-sided RDMA NVM WRITE by 1.1X (31M vs. 34M reqs/sec), which remains far from NVM’s ideal processing rate (52M reqs/sec). In this case, **H5** will incur 16X (256B vs. 16B) network amplification to one-sided RDMA WRITE. Since moving 256B data to DRAM over RDMA is even slower than NVM ideal processing rate (37M vs. 52M reqs/sec, as shown in Figure 6), the network would first become the bottleneck for small writes.

To this end, we found the key for small writes to fully utilize NVM is to *avoid sending unnecessary read requests to the NVM*. As we have mentioned in §2.1, NVM read requests compete for XCtrl processing power with NVM write requests. Hence, unnecessary read requests would drastically reduce the NVM write throughput. This fact allows using a smaller access granularity to saturate NVM’s processing rate with RDMA.

CPU and RNIC generate an extra read request to NVM if the payload of the write request does not fit their access granularities (i.e., cacheline and PCIe DW). They execute such a write request in a read-modify-write pattern to avoid overwriting the original content. Thus, using the CPU/RNIC access granularity is sufficient to prevent sending unnecessary reads from the device to NVM. Based on this observation, we first propose **H6–H7** to complement **H5** for small writes. Further, since the read-modify-write pattern is not friendly to NVM, we also propose **H8** to suggest systems use fewer such operations. Specifically, we propose the following hints to complement **H4–H5**:

H6. For one-sided RDMA, use PCIe data word (64B) granularity when the payload is smaller than XPLine;

H7. For two-sided RDMA, use cacheline granularity (64B) with `ntstore` when the payload is smaller than XPLine;

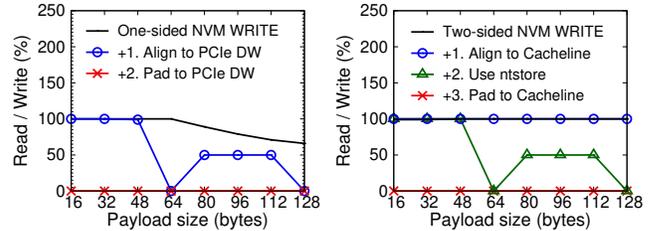

Figure 13. The ratio of extra NVM read per write of (a) one-sided RDMA WRITE and (b) two-sided RDMA on the remote write benchmark. Aligning and padding the write payload to device access granularity (e.g., PCIe DW) is sufficient to avoid unnecessary NVM reads for one-sided RDMA WRITE. On the other hand, two-sided RDMA further needs to use `ntstore`.

H8. Use less atomic operations on NVM;

Hint H6. PCIe issues write in a read-modify-write pattern with PCIe partial-write. Figure 12(b) shows a concrete example where the RNIC uses PCIe to write 8B at 0x40. It will first send a read request to the NVM to read the data word at 0x40 (1). Then, it overwrites the entire data word according to the write request (2).

Figure 8(a) presents the optimized performance of **H6** to one-sided RDMA WRITE: it improves the performance of 16B WRITE to 87% of the NVM’s peak write throughput (45M vs. 52M reqs/sec). The result is 1.3X faster than applying **H5** thanks to the reduced network amplification. Figure 13(a) further examines how eliminating PCIe partial write helps to prevent sending read requests to the NVM. We apply **H6** by first aligning the written address to PCIe DW (+1. Align to PCIe DW), and then padding the payload size (+2. Pad to PCIe DW) to a multiple of PCIe DW. As we can see, after applying both steps, one-sided RDMA WRITE does not issue a read request to the NVM. Consequently, small WRITES (e.g., no larger than 64B) can reach close to the NVM processing limit.

We should mention that reducing the PCIe partial write may also benefit one-sided RDMA-DRAM WRITE. However, our experiments show that it may even have a negative effect on DRAM WRITE. For example, the 16B DRAM WRITE has a 25% performance degradation on our testbed after applying **H6**.

Hint H7. Similar with **H6**, **H7** suggests how to prevent read-modify-write for two-sided RDMA. As shown in Figure 8, it improves the 16B two-sided RDMA-NVM WRITE performance by 1.8X (19M vs. 35M reqs/sec). To apply **H7**, two-sided RDMA should use `ntstore` together with use cacheline granularity (+1. Align to Cacheline and +3. Pad to Cacheline, as shown in Figure 13(b)). This is because, the CPU would pre-fetch the cacheline using NVM read with

store. As shown in Figure 13(b), two-sided RDMA-NVM WRITE always achieves a 100% read/write ratio even after using the proper access granularity.

Hint H8. A lesson learned from H7–H8 is that the read-modify-write access pattern is not friendly to NVM. Atomic operations (e.g., one-sided RDMA ATOMIC compare and swap) naturally follow a read-modify-write pattern. Worse, the designer cannot apply prior hints to optimize atomic operations. For instance, one-sided RDMA ATOMICs cannot apply H6 since they use a fixed 8B granularity. Consequently, we suggest using fewer atomics on NVM for RDMA. Note that we are not suggesting disabling atomics, but *moving the data for atomic operations (e.g., spinlock) from NVM to DRAM whenever possible*.

Discussion of H6–H8. Although applying H6 and H7 may waste NVM storage for storing the padding, while adopting H8 could change the persistent semantic of atomic data, we believe H6–H8 is actionable in real systems. This is because there are many scenarios in RDMA-NVM systems that can use H6–H8 without wasting storage or changing the application semantics. For instance, existing RDMA-NVM enabled databases [10, 11, 25, 53, 54] do not require the lock to be persistent. Thus, we can safely move their lock metadata from NVM to DRAM. Furthermore, distributed logging [10, 11] naturally uses padding to accommodate future logs. Thus, applying H6 to logging does not introduce additional storage overhead. Finally, as we will present in §6, H6–H8 can have huge performance improvements for existing systems. For example, H6–H8 can improve the performance of DrTM+H on the SmallBank [45] benchmark by 1.79X (3.9M vs. 7.0M txns/sec, see Figure 16).

4.3 RDMA-aware advice

Finally, we discuss how known RDMA-aware optimizations can mitigate the inefficiency of implementing persistent write atop of existing hardware platforms. As we have mentioned in the introduction, a strawman approach to implementing persistent write using one-sided RDMA requires two network roundtrips: the first WRITE attempts to store the data to NVM, while the second READ ensures that the written data is flushed to the persistent domain (e.g., Optane PM). Fortunately, it is possible to leverage well-known RDMA-aware optimizations to avoid the additional network roundtrip of READ. H9 summarizes this fact:

H9. Enable outstanding request with doorbell batching for one-sided persistent RDMA WRITE.

Specifically, outstanding request [23] allows us using the completion of READ as the completion of the WRITE, as long as the two requests are sent to the same QP. Since

the READ to persist the WRITE must be post to the same QP as the WRITE (§2.3), we no longer need to wait for the first WRITE to complete. Thus, this optimization reduces the wait time of the first network roundtrip. Applying outstanding request to persistent WRITE is correct because first, later READ flushes previously WRITE [19], and RNIC processes requests from the same QP in a FIFO order [6].

Based on outstanding request, doorbell batching [24] further allows us to send the READ and WRITE in one request using the more CPU and bandwidth efficient DMA, reducing the latency of posting RDMA requests.

On our testbed, a single one-sided RDMA request takes $2\mu\text{s}$. Thus, a strawman implementation of *remote persistent write* uses $4\mu\text{s}$. After applying H9, one-sided *remote persistent write* takes $3\mu\text{s}$ latency to finish.

5 Discussion of Future Trends

Generality of the study. Our study focuses on specific RNIC (Mellanox ConnectX-5) and NVM (Intel Optane DC Persistent Memory), while other hardware devices may yield different results. Nevertheless, we believe ConnectX-5 is a representative RNIC, as recent generations of Mellanox RNICs (e.g., Connect-IB, ConnectX-4) all share the same architecture. Moreover, Optane PM is the only commercially available NVM. Finally, we also provide open-source tools that the developers can use to examine their design choices under different hardware configurations.

Next-generation NVM. The next-generation of NVM not only has a better performance but also provides a larger scope of persistent domain. First, it will have a 25% higher bandwidth [21]. Second, it will include the processor cache in its persistent domain [4]. This feature is desirable for one-sided RDMA since one-sided RDMA no longer depends on DDIO for WRITE to be persistent (§2.3). Consequently, the designer does not need to make a trade-off between one-sided persistence and two-sided RDMA performance (§4.1).

On the other hand, the new features of next-generation NVM are unlikely to change the advice of our study. First, the primary focus of our study is *how to avoid NVM write becoming the bottleneck* in RDMA-NVM systems (§3), even when NVM write has a comparable performance with RDMA (see Figure 1). Thus, the 25% bandwidth improvement of the next-generation NVM is insufficient to twist the performance comparisons between RDMA and NVM, since future generations of RDMA will have much higher bandwidth. For example, RNIC with 200Gbps bandwidth has already been commercially available [3], which is 2X higher than our evaluated RNIC. Besides performance, the enhanced functionality of next-generation NVM, i.e., putting cache in the persistent domain, is also unlikely to address the current performance issue caused by the cache. This is because the random cache eviction is still not suitable for

NVM. Meanwhile, an extra one-sided RDMA READ is still required to ensure persistence as long as the RNIC is not redesigned.

Suggestions to hardware designers. There are proposals to extend RDMA to cooperate with NVM, e.g., Talpey *et al.* [44] proposed to add a *one-sided commit* primitive to support one-side persistent RDMA WRITE. Nevertheless, our study reveals that existing proposals are insufficient: *the hardware designers not only need to consider hardware extensions to support more functionality, but also should consider extensions for better performance.* For instance, adding an RDMA-version of *ntstore*, e.g., one-sided *non-temporal* RDMA WRITE that allows the WRITE to bypass the cache—can greatly improve the flexibility in configuring DDIO for RDMA-NVM systems (§4.1).

6 Improved System Designs

Existing or future RDMA-NVM systems can benefit from the summarized optimization hints in our study (§4). In this section, we present how we use these hints to improve the performance of two open-source RDMA-NVM systems, a distributed database (DrTM+H [53]), and a distributed file system (Octopus [32]). Both systems are designed when no production NVM is available.

6.1 Distributed database

DrTM+H [53] is a distributed transactional system designed for RDMA and NVM. It fully leverages the power of one-sided and two-sided RDMA to boost transaction execution. We choose it for optimization for two reasons. First, its concurrency control and replication protocol use RDMA and NVM heavily. Therefore, there may exist a huge space for improvements. Second, most existing RDMA-NVM distributed databases adopt a similar protocol [8, 10, 11, 25, 37] as DrTM+H. Thus, our improved DrTM+H design can potentially benefit these systems.

Overview. DrTM+H uses optimistic concurrency control [28] (OCC) to ensure strict serializability and primary-backup replication to achieve high availability [8, 11]. It organizes NVM as a distributed shared memory pool similar to prior work [10, 32, 54], which stores the database records and transaction logs. DrTM+H uses four phases to execute a transaction, each interacts with NVM using RDMA as follows: *Execution* uses one-sided RDMA READ to read records stored in NVM; *Validation* uses one-sided RDMA Compare and swap (CAS) to acquire the lock co-located with the record; *Logging* uses one-sided RDMA WRITE to replicate the transaction updates to backups; *Commit* uses two-sided RDMA to update and unlock the records.

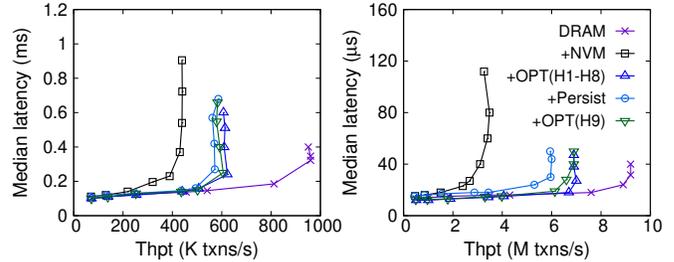

Figure 14. The performance of DrTM+H on (a) TPC-C/no and (b) SmallBank.

6.1.1 Optimizations

The original DrTM+H neither considers the performance features of NVM (§2.1), nor the persistence issue of one-sided RDMA WRITE (§2.3). In this section, we first apply optimizations that are beneficial to DrTM+H both when using NVM to extend DRAM capacity and to support durability (i.e., **H1–H8**):

- Separate the memory pool from different sockets to avoid cross-socket NVM access (**H1**).
- Configure DrTM+H with DDIO disabled (**H3**).
- Use *ntstore* to optimize the *commit phase* (**H4**).
- Align and pad logs/records larger than 256B to XPLine granularity (**H5**).
- Align and pad logs/records smaller than 256B to 64B granularity (**H6 + H7**).
- Implement a DRAM-based lock service for the *validation phase* (**H8**). Note that it is safe not persisting the locks in NVM because DrTM+H does not require the locks to be persistent even when durability is enabled.

Second, we use **H9** to optimize DrTM+H when use NVM to support durability. When following existing approach [20] to support durable transactions, DrTM+H has to use two network roundtrips to persist a single transaction log at the logging phase. With the help of **H9**, the logging phase only use one roundtrip:

- Implement remote persistent log with **H9** in one roundtrip.

6.1.2 Evaluation

Setup. By default, DrTM+H executes transactions in a symmetric setting [10]: each machine both stores database partition and executes transactions. Nevertheless, we evaluate it in an asymmetric setting due to the lack of NVM-capable machines (Table 2): the NVM server stores the

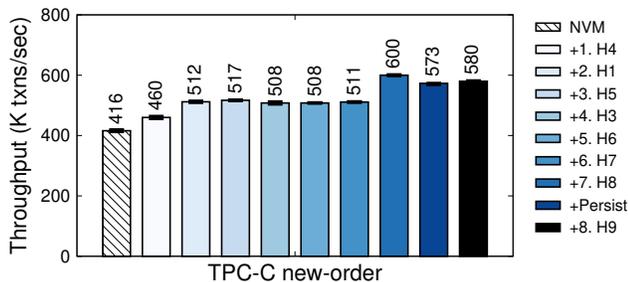

Figure 15. The contribution of optimizations to the throughput of DrTM+H for TPC-C/no. Note that the error bars are small.

database while other machines execute transactions. We use two representative OLTP benchmarks to evaluate its performance:

TPC-C/no [46] simulates the workload of an ordering system that contains complex read/write workloads. We configure the NVM server to store ten warehouses and other machines to execute the *new-order* (no) transaction, the dominant transaction of TPC-C [46].

SmallBank [45] models a simple banking application where each transaction issues one or two read/write requests. We store 20,000,000 bank accounts at the NVM server and run the standard-mix transactions at clients.

Comparing targets. In Figure 14, **DRAM** is the vanilla DrTM+H running on DRAM. **+NVM** runs DrTM+H on Optane PM, and **+OPT(H1-H8)** further applies optimizations (§6.1.1). **+Persist** adopts an existing approach [20] to support durability atop of **+OPT(H1-H8)**. Finally, **+OPT(H9)** optimizes **+Persist** with **H9**.

Performance without Persistence. Figure 14 presents the throughput-latency results of both workloads. We plot the graph by increasing the number of clients until the throughput is saturated. **+OPT(H1-H8)** improves the DrTM+H’s performance under TPC-C/no and SmallBank by 1.45X and 2.20X, respectively.

To analyze the contributions of each optimization, Figure 15 and Figure 16 further present factor analyses of evaluation results on TPC-C/no and SmallBank, respectively. First, we can see that several hints are beneficial to both workloads. For example, **H8** (use atomic operations less on NVM) speedups TPC-C/no and SmallBank by 1.17X and 1.19X, respectively. On the other hand, some hints have negative effects for certain workloads: SmallBank drops 15% throughput when adding **H3**, this is because **H3** is only beneficial when the application is bottlenecked by NVM’s bandwidth. Finally, some hints have more contributions to SmallBank than TPC-C/no. For example, **H7** has a 1.4X speedup on SmallBank but does not affect TPC-C/no. **H7** only improves transaction utilizations of NVM write throughput, while

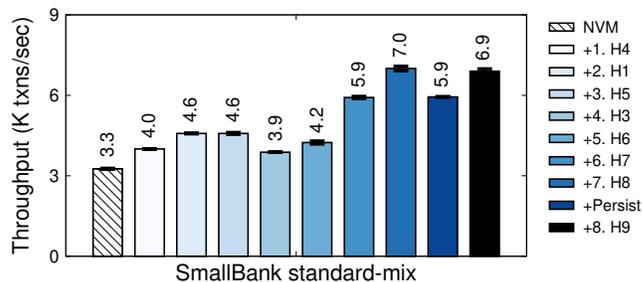

Figure 16. The contribution of optimizations to the throughput of DrTM+H for SmallBank. Note that the error bars are small.

SmallBank is more sensitive to the NVM write throughput utilization due to its simpler workloads.

Performance with persistence. As shown in Figure 14, supporting persistent transaction (**+Persist**) adds 5% and 15% performance overhead to **+OPT(H1-H8)** on TPC-C/no and SmallBank, respectively. The overhead is from the additional one-sided RDMA READ at the logging phase. Hence, reducing this network roundtrip with **H9** improves TPC-C/no and SmallBank’s performance by 1.01X and 1.17X, respectively.

6.2 Distributed file system

Octopus [32] is a distributed file system designed for RDMA and NVM. Due to space limitations, we only give a brief overview of it and our applied optimizations.

Overview. Octopus uses a distributed NVM pool to store the file system metadata and its file data blocks. It achieves high throughput and bandwidth for reading/write file data through *Client-Active Data I/O*: the client directly read/write a file’s data block using one-sided RDMA READ/WRITE. Besides *Client-Active Data I/O*, Octopus also leverages RDMA-enabled distributed transactions to update the filesystem metadata. Similar to DrTM+H (§6.1), its transactional protocol uses one-sided RDMA ATOMICs to coordinate conflicting metadata operations.

Optimizations. We focus on improving Octopus’s *Client-Active Data I/O* because the distributed transaction is not supported in its current public available codebase⁹. Nevertheless, we believe our findings can also improve distributed transaction performance in Octopus, e.g., using **H8** to improve its lock performance.

6.2.1 Evaluation

We use the same Data I/O benchmark in the Octopus paper [32] for the evaluation. In this benchmark, each client writes a fixed payload to a random location in a randomly chosen file. The client first uses two-sided RDMA to query

⁹<https://github.com/thustorage/octopus>

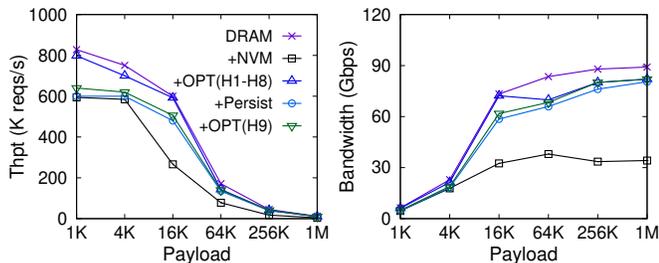

Figure 17. Data I/O (a) throughput and (b) bandwidth of Octopus (Multiple Clients).

the file metadata (e.g., data block addresses). Then, it writes the data payload with one-sided RDMA WRITE.

Comparing targets. In Figure 17, **DRAM** is the vanilla Octopus using DRAM to emulate the NVM pool. **+NVM** uses Optane PM as NVM pool, and **+OPT(H1-H8)** applies our optimizations to **+NVM**. **+Persist** further adopts an existing approach [20] to support synchronous durable file write atop pf **+OPT(H1-H8)**. Finally, **+OPT(H9)** leverages **H9** to reduce network roundtrips for persistence of **+Persist**.

Performance. As shown in Figure 17, **+OPT(H1-H8)** improve **+NVM** by up to 2.4X (from 1.2X), mainly due to applying **H3**. Without **H3**, Octopus’s client-active I/O cannot fully saturate NVM’s write bandwidth because it uses one-sided RDMA WRITE with DDIO enabled to write to the NVM. Further, **+OPT(H9)** outperforms **+Persist** by 1.06X (from 1.02X), thanks to the reduced RDMA roundtrips for persistent write.

7 Related Work

RDMA-NVM systems. We continue the line of research of using RDMA and NVM to improve the performance and reliability of distributed systems [8, 11, 32, 33, 38, 39, 43, 58, 61]. Kashyap *et al.* [27] explores the trade-offs of using different methods to ensure NVM write persistence with RDMA. They conduct their experiments on emulated NVM. Our study instead focuses on Optane PM. Orion [58] is a distributed file system designed for RDMA and NVM. It does not consider RDMA-aware optimizations (i.e., **H9**) and chooses two-sided RDMA for the persistent write. Our study provides another design decision for them. Hotpot [38] uses RDMA and NVM to build a distributed persistent shared memory. AsymNVM [33] proposes an asymmetric architecture to use NVM with RDMA. Though AsymNVM is evaluated with Optane PM, it does not consider the performance features of Optane PM. Hence, we believe our study can further improve its performance on Optane PM.

RDMA-aware optimizations. Our work is built upon broadly explored RDMA-aware optimizations [7, 10, 24, 25, 47, 52, 53]. The evaluating execution framework [53] has integrated most of these optimizations. FaRM [10] proposes

various techniques to utilize RNIC’s cache better, e.g., using huge pages. Kalia *et al.* [24] present the importance of understanding the low-level factors of how RNIC works. Based on this, they propose various RDMA-aware optimizations such as doorbell batching. FaSST [25] presents an efficient and scalable RPC framework atop two-sided RDMA datagram primitive. LITE [47] uses kernel indirection to improve the scalability of one-sided RDMA. Wukong [40, 56, 60] leverages RDMA to improve the performance of distributed graph store and further considers the interaction between RDMA and GPU [51].

NVM-aware systems. Except for RDMA-NVM systems, researchers are building NVM-aware systems for decades, including but not limited to file systems [9, 12, 57], NVM-aware data structures [48, 63], key-value stores [26], NVM-aware JVM [41, 55], and transactions on NVM [14, 15, 30, 34, 50]. Like RDMA-NVM systems, most of them use emulated NVM since there is no commercially available NVM at that time. We hope our study can further inspire future research on revisiting previous NVM-aware systems on Optane PM.

8 Conclusion

Designing high-performance RDMA-NVM systems requires a clear understanding of the interaction between RDMA and NVM. This paper provides a systematic study on how to best utilize NVM with RDMA, which summarizes nine optimization hints. By examining existing RDMA-NVM systems with these hints, we found room for improvements, especially for those not targeting production NVM: our optimized DrTM+H is up to 2.2X faster on Optane PM, while our optimized Octopus file system is up to 2.4X faster. We believe our summarized hints as well as experiences in applying them to existing systems can benefit future systems developers when designing systems with RDMA and NVM.

Abstract

RDMA networks offload packet processing onto specialised circuitry of the network interface controllers (NICs) and bypass the OS to improve network latency and bandwidth. As a consequence, the OS forfeits control over active RDMA connections and loses the possibility to migrate RDMA applications transparently. This paper presents MigrOS, an OS-level architecture for transparent live migration of containerised RDMA applications. MigrOS shows that a set of minimal changes to the RDMA communication protocol reenables live migration without interposing the critical path operations. Our approach requires no changes to the user applications and maintains backwards compatibility at all levels of the network stack. Overall, MigrOS can achieve up to 33% lower network latency in comparison to software-only techniques.

1 Introduction

Major cloud providers increasingly offer RDMA network connectivity [1, 55] and high-performance network stacks [8, 18, 37, 53, 69, 85, 89] to the end-users. RDMA networks lower communication latency and increase network bandwidth by offloading packet processing to the RDMA NICs and by removing the OS from the communication critical path. To remove the OS, user applications employ specialised RDMA APIs, which access RDMA NICs directly, when sending and receiving messages [54]. These performance benefits made RDMA networks ubiquitous both in the HPC [15, 30, 43, 50, 77] and in the cloud settings [22, 59, 72].

At the same time, containers have become a popular tool for lightweight virtualisation. Containerised applications, being independent of the host’s user space (libraries, applications, configuration files), greatly simplify distributed application deployment and administration. However, RDMA networks and containers follow contradicting architectural principles: Containerisation enforces stricter isolation between applications and the host, whereas RDMA networks try to bring applications and underlying hardware “closer” to each other.

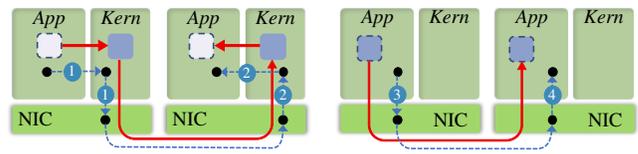

Figure 1: Traditional (left) and RDMA (right) network stacks. In traditional networks, the user application triggers the NIC via kernel (1). After receiving a packet, the NIC notifies the application back through the kernel (2). In RDMA networks the application communicates directly to the NICs (3) and vice-versa (4) without kernel intervention. Traditional networks require copy between application buffers (□) and NIC accessible kernel buffers (■). RDMA NICs (right) access message buffers in the application memory directly (■).

Container orchestration systems, like Kubernetes, stop containers and restart them on other hosts for the purpose of load balancing, resiliency, and administration. To maintain efficiency, containerised applications are expected to restart quickly [9]. Unfortunately, fast application restart requires in-application support and can be very costly, as RDMA applications tend to have large state. In contrast, *live migration* moves application state transparently and imposes no additional requirements for the application.

In the context of live migration, much of the container state resides in the host OS kernel. It can be extracted and recovered elsewhere later on. This recoverable state includes open TCP connections, shell sessions, file locks [13, 40]. However, as we elaborate in Section 3, *the state of RDMA communication channels is not recoverable by existing systems, and hence RDMA applications cannot be checkpointed or migrated.*

To outline the conceptual difficulties involved in saving the state of RDMA communication channels, we compare a traditional TCP/IP-based network stack and the IB verbs API¹ (see Figure 1). First, with a traditional network stack, the kernel fully controls when the communication happens:

¹ IB verbs is the most common low-level API for RDMA networks.

applications need to perform system calls to send or receive messages. In IB verbs, because of the direct communication between the NIC and the application, the OS cannot alter the connection state, except for tearing the connection down. Although the OS can stop a process from sending further messages, the NIC may still silently change the application state. Second, part of the connection state resides at the NIC and is inaccessible for the OS. Creating a consistent checkpoint transparently is impossible in this situation.

The contribution of our paper is a way to overcome the described limitations of current RDMA networks and the supporting operating systems with a novel architecture. The root of the problem to be solved is the impossibility for the OS to intercept packets to manipulate and repair disrupted connections, as it happens in transparent live application migration. The core point of the architecture is a small change in the RDMA protocol, that is usually implemented in RDMA NICs: we propose to add two new states and two new message types to RoCEv2, a popular RDMA communication protocol, while paying careful attention to backwards compatibility.

To make the proposed changes credible, we show that they are 1. *sufficient* for migrations, as an example for disrupted connections, and 2. indeed *small*. To prove the first point, we design and implement a transparent end-to-end live migration architecture for containerised RDMA applications. To prove the second point, and to enable the software architecture, we implement the new protocol by modifying SoftRoCE [48], a software implementation of the RoCEv2 protocol.

Providing a credible evaluation is hard for us, since we cannot modify the state machine of an RDMA NIC. Instead, we substantiate our claims by comparing the latency and bandwidth of the original and our modified protocol using SoftRoCE implementations and show that outside of the migration phase network performance is not affected. To justify the proposed protocol changes and the container-based software architecture, we evaluate software-level support for transparent live migration [2, 44]. We show that these approaches add significant overhead to the *normal* operation.

2 Background

This section gives a short introduction to containerisation and RDMA networking. We further outline live migration and how RDMA networking obstructs this process.

2.1 Containers

In Linux, processes can be logically separated from the rest of the system using *namespaces*. This way processes can have an isolated view on the file system, network devices, users, etc. Container runtimes leverage namespaces and other low-level kernel mechanisms [17, 47] to create a complete system view inside a *container* with one or multiple processes. Migration of a container moves all processes running inside

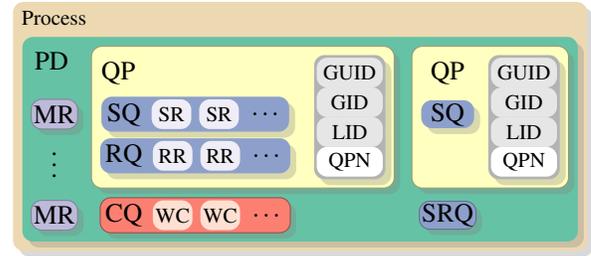

Figure 2: Primitives of the IB verbs library. Each QP comprises a send and a receive queue and has multiple IDs; node-global IDs (grey) are shared by all QPs on the same node.

a given container. A distributed application may comprise multiple containers across a network: a Spark application, for example, can isolate each *worker* in a container and an MPI [21] application can containerise each *rank*.

2.2 Infiniband verbs

The IB verbs API is a de-facto standard for high-performance RDMA communication today. RDMA applications achieve high throughput and low latency by accessing the NIC directly (*OS-bypass*), reducing memory movement (*zero-copy*), and delegating packet processing to the NIC (*offloading*).

Figure 2 shows the following IB verbs objects involved in communication. *Memory regions* (MRs) represent pinned memory shared between the application and the NIC. *Queue pairs* (QPs), comprising a send queue (SQ) and a receive queue (RQ), represent connections. To reduce the memory footprint, the individual RQs of multiple QPs can be replaced with a single *shared receive queue* (SRQ). *Completion queues* (CQs) inform the application about completed communication requests. A *protection domain* (PD) groups all these objects together and represents the process address space to the NIC.

To establish a connection, the IB verbs specification [54] requires the applications to exchange the following addressing information: *Memory protection keys* to enable access to remote MRs, the global vendor-assigned address (*GUID*), the routable address (*GID*), the non-routable address (*LID*), and the node-specific QP number (*QPN*). One way to perform this exchange is over an out-of-band network, e.g. Ethernet. During the connection setup, each QP is configured for a specific *type of service*. MigrOS supports only Reliable Connections (RC), which provide reliable in-order message delivery between two communication partners. Another popular type of service is Unreliable Datagram (UD), which does not provide these guarantees.

The application sends or receives messages by posting *send requests* (SR) or *receive requests* (RR) to a QP as *work queue entries* (WQE). These requests describe the message and refer to the memory buffers within previously created MRs. The application checks for the completion of outstanding work

requests by polling the CQ for *work completions* (WC).

There are various implementations of the IB verbs API for different hardware, including Infiniband [37], iWarp [23], and RoCE [35, 36]. InfiniBand is generally the fastest among these networks but requires specialised NICs and switches. RoCE and iWarp are easier to deploy, because they provide RDMA capabilities in Ethernet networks. They still require hardware support in the NIC, but do not depend on specialised switches. This work focuses on RoCEv2, an increasingly more popular version of the RoCE protocol [15, 60, 88]. At the same time, we change only parts of RoCEv2 that are defined in the same way for Infiniband [37] and RoCEv1 [35], hence MigrOS is also compatible with other RDMA protocols.

To enable RDMA-application migration, it is important to consider the following challenges:

1. User applications have to use physical network addresses (QPN, LID, GID, GUID) but the IB verbs API does not specify a way for virtualising these.
2. The NIC can write to any memory it shares with the application without the OS noticing.
3. The OS cannot instruct the NIC to pause communication, except for abruptly terminating it.
4. User applications do not handle changes in a connection destination address and will go into an erroneous state. As a result, the application will terminate abruptly.
5. Although the OS resides on the control path and is therefore aware of all IB verbs objects created by the application, the OS does not control the whole state of these objects, as the state partially resides on the NIC.

We address all of these challenges in [Section 3](#).

2.3 CRIU

CRIU is a software framework for transparent checkpointing and restoring of Linux processes [13]. It enables live migration, snapshots, or accelerated start-up of processes and containers. To extract the user-space application state, CRIU uses conventional debugging mechanisms, like ptrace [73, 74]. However, to extract the state of process-specific kernel objects, CRIU depends on special Linux kernel interfaces.

During recovery, CRIU runs inside the target process and recreates all OS objects on behalf of the target. This way, CRIU utilises the available OS mechanisms to run most of the recovery without the need for significant kernel modifications. Finally, CRIU removes any traces of itself from the process.

CRIU can also restore the state of TCP connections, a crucial feature for live migration of distributed applications [40]. The Linux kernel introduced a new TCP connection state, `TCP_REPAIR`, for that purpose. In this state, a user-level process can modify the send and receive message queues, get and set the message sequence numbers and timestamps, or open and close a connection without notifying the other side.

As of now, CRIU does not support saving and restoring IB verbs objects. Discarding IB verbs objects during migra-

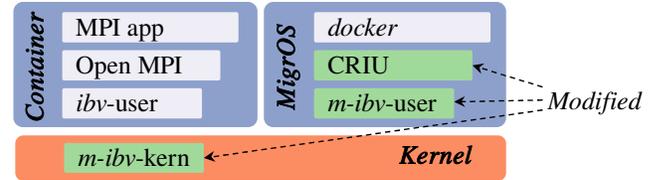

Figure 3: MigrOS architecture. Software inside the container, including the user-level driver (*ibv-user*, grey), is unmodified. The host runs CRIU, kernel- (*m-ibv-kern*) and user-level (*m-ibv-user*, green) drivers modified for migratability.

tion in the naive hope that the application will be able to recover is failure-prone: once an application runs into an erroneous IB verbs object, in most cases, the application will hang or crash. Thus, MigrOS provides explicit support for IB verbs objects in CRIU (see [Section 3](#)).

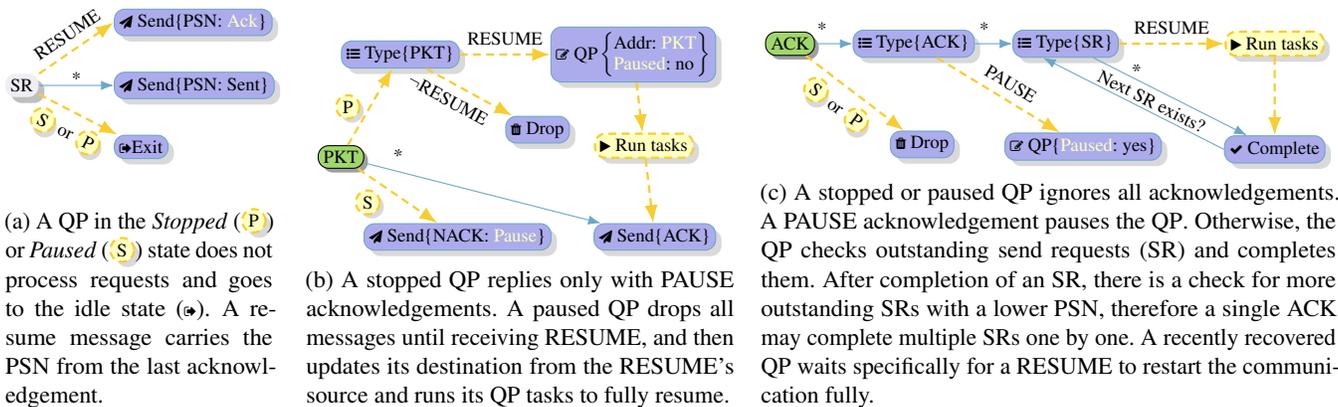

3 Design

MigrOS is based on modern container runtimes and reuses much of the existing infrastructure with minimal changes (see [Section 3.1](#)). Most importantly, we require no modification of the software running inside the container. Instead, MigrOS includes the following changes concerning RoCEv2: two new QP states to enable the creation of consistent checkpoints (see [Section 3.2](#)), a connection migration protocol ([Section 3.3](#)), and modifications to the packet-level RoCEv2 protocol ([Section 3.4](#)). Finally, [Section 3.5](#) describes our modifications to the IB verbs API and how CRIU uses them. It is sufficient to only extend CRIU with IB verbs support, existing container runtimes use CRIU for their checkpoint/restore functionality [17, 47, 71, 76].

3.1 Software Stack

Typically, access to the RDMA network is hidden deep inside the software stack. [Figure 3](#) gives an example of a containerised RDMA application. The container image comes with all library dependencies, like the `libc`, but not the kernel-level drivers. In this example, the application uses a stack of communication libraries, comprising Open MPI [21], Open UCX [77] (not shown), and IB verbs. Normally, to migrate, a container runtime would require the application inside the container to terminate and later recover all IB verbs objects. This removes transparency from live migration.

MigrOS runs alongside the container comprising a container runtime (e.g., Docker [17]), CRIU, and the IB verbs library. We modified CRIU to make it aware of IB verbs, so it can save IB verbs objects when traversing the kernel objects that belong to the container. We extend the IB verbs library (*m-ibv-user* and *m-ibv-kern*) to enable serialisation and deserialisation of the IB verbs objects. Importantly, the

(a) A QP in the *Stopped* (P) or *Paused* (S) state does not process requests and goes to the idle state (⊙). A resume message carries the PSN from the last acknowledgement.

(b) A stopped QP replies only with PAUSE acknowledgements. A paused QP drops all messages until receiving RESUME, and then updates its destination from the RESUME's source and runs its QP tasks to fully resume.

(c) A stopped or paused QP ignores all acknowledgements. A PAUSE acknowledgement pauses the QP. Otherwise, the QP checks outstanding send requests (SR) and completes them. After completion of an SR, there is a check for more outstanding SRs with a lower PSN, therefore a single ACK may complete multiple SRs one by one. A recently recovered QP waits specifically for a RESUME to restart the communication fully.

Figure 6: MigrOS changes processing of incoming packets (PKT and ACK) and outgoing request (SR) by introducing new QP states (P and S), new messages (PAUSE and RESUME), new operations (⊙ and ▶), and new transitions (-▶). Solid arrows (→) represent previously existing transitions, “*” represents the “else” branch, ≡ Type checks the SR or packet type.

run in hardware. We proceed from the fact that a typical RDMA NIC does all packet-level work, including transmitting packets and acknowledgements by itself. As a consequence, the OS cannot itself compose and process arbitrary packets, including the packets that MigrOS introduces.

Therefore, for migration to work, we need to modify RDMA NICs. The NIC adds different packet headers, depending on the service (RC, UD, etc.) and message (read, send, etc.) type. Our changes touch only two headers: Base Transport Header (BTH) and ACK Extended Transport Header (AETH). BTH is the first RDMA-specific header, immediately following IP and UDP headers. Additionally, the NIC needs to maintain two new flags per QP for pause and resume states. The NIC must be able to transfer a QP into the *Stopped* or *Paused* state, process a send request with a resume message issued by the OS, and handle pause/resume packets.

Our changes (see Figure 6) cover three existing workflows in the underlying RoCEv2 protocol: 1. Processing a send request WQE (Figure 6a), 2. receiving a packet (Figure 6b), and 3. receiving an acknowledgement (Figure 6c). The NIC must consider the two new states of the QP in all these workflows. This change of logic is small and does not change the packet layout, as it is only part of the internal state of the QP.

The NIC must compose the new resume message or let the OS do so. In contrast to a normal message, resume takes the packet sequence number (PSN) from the last acknowledged message instead of the last sent message. A receiver recognises the resume message by a new *opcode* in the BTH header. Creating a new message type does not require changes in the message layout due to an abundance of unused opcodes.

Similarly, pause, sent as a new negative acknowledgement type, employs an unused value of the *syndrome* field in the AETH header. Therefore, the new pause NACK also requires no change to the existing packet layout.

The workflows in the Figure 6 run when the user triggers

the NIC through a doorbell register, when a message arrives, or by a timeout. Unless a QP is paused or stopped, the NIC will try to send or complete multiple messages at once (Figure 6a and Figure 6c). As part of resume (▶), the NIC also triggers these workflows.

Figure 6 does not include, for example, additional timeout reaction logic for the sake of brevity. Overall, the changes in logic are simple and mostly reuse existing functionality. Because we change only the AETH and BTH headers, our changes are equally applicable to other RDMA protocols (e.g. Infiniband or RoCEv1) that use these headers in the same way. We believe neither new logic nor new states incur prohibitive design or implementation cost.

A real RDMA NIC would need hardware support for the new QP states and follow the corresponding protocol. Full migration support would also require the NIC to extract the state of Infiniband objects and handle the new message types. We believe all of this can be implemented in the NIC's firmware². Section 4 presents a proof-of-concept software implementation of the proposed changes.

3.5 Checkpoint/Restore API

To enable checkpoint/restore for processes and containers, we extend the IB verbs API with two new calls (see Listing 1): `ibv_dump_context` and `ibv_restore_object`. CRIU relies on the normal IB verbs API supplemented by the two new calls to save and restore the IB verbs state of applications.

The `ibv_dump_context` call returns a dump of all IB verbs objects within a specific IB verbs *context*, an object representing the connection between a process and an RDMA NIC. The creation of a dump runs almost entirely inside the kernel for two reasons: First, some links between the objects are

²The hardware/firmware-boundary will differ for FPGA and ASIC.

```

int ibv_dump_context(struct ibv_context *ctx,
                    int *count, void *dump, size_t length);
int ibv_restore_object(struct ibv_context *ctx,
                      void **object, int object_type, int cmd,
                      void *args, size_t length);

```

Listing 1: Checkpoint/Restore extension for the IB verbs API. `ibv_dump_context` creates an image of the IB verbs context `ctx` with `count` objects and stores it in the caller-provided memory region `dump` of size `length`. `ibv_restore_object` executes the restore command `cmd` for an individual object (QP, CQ, etc.) of type `object_type`. The call expects a list of arguments specific to the object type and recovery command. `args` is an opaque pointer to the argument buffer of size `length`. A pointer to the restored object is returned via `object`.

only visible at the kernel level. Second, to get a consistent checkpoint it is crucial to ensure the dump is atomic.

Although the existing IB verbs API allows to create new objects, it is not expressive enough for *restoring* them. For example, when restoring a completion queue (CQ), the current API does not allow to specify the address of the shared memory region for this queue, instead this address is assigned by the kernel. It is also not possible to recreate a queue pair (QP) directly in its original state, like Ready-to-Send (RTS). Instead, the QP has to traverse all intermediate states to reach the desired state.

We introduce the fine-grained `ibv_restore_object` call to restore IB verbs objects one by one, for situations when the existing API is not sufficient. During recovery, CRIU reads the object dump and applies a specific recovery procedure for each object type. For example, to recover a QP, CRIU calls `ibv_restore_object` with the command `CREATE` and transitions the QP through the `Init`, `RTR`, and `RTS` states using `ibv_modify_qp`. The memory regions or QP buffers are recovered using the standard file and memory operations. Finally, when a QP reaches the `RTS` state (representing an active connection), the new host executes the `REFILL` command using the `ibv_restore_object` call. This command restores the driver-specific internal QP state and sends a *resume* message to the partner QP.

4 Implementation

To provide transparent live migration, MigrOS makes changes to CRIU, the IB verbs library, the RDMA-device driver (SoftRoCE), and the packet-level RoCEv2-protocol. To migrate an application, the container runtime invokes CRIU which checkpoints the target container. CRIU stops active RDMA connections and saves the state of IB verbs objects (see [Section 4.1](#)). SoftRoCE then pauses communication using our extensions to the packet-level protocol. After transferring the checkpoint to the destination node, the container runtime at that node invokes CRIU to recover the IB verbs objects and

restores the application. SoftRoCE then resumes all paused communication to complete the migration process.

SoftRoCE is a Linux kernel-level software implementation (not an emulation [48]) of the RoCEv2 protocol [36]. RoCEv2 runs RDMA communication by tunnelling Infiniband packets through a well-known UDP port. In contrast to other RDMA-device drivers, SoftRoCE allows the OS to inspect, modify, and control the state of IB verbs objects completely.

As a performance-critical component of RDMA communication, RoCEv2 usually runs inside the hardware and firmware of a NIC. We focus on minimising these protocol changes. The key part of MigrOS is the addition of connection migration capabilities to the existing RoCEv2 protocol (see [Section 4.2](#)).

4.1 State Extraction and Recovery

State extraction begins when CRIU discovers that its target process has opened an IB verbs device. We modified CRIU to use the API presented in [Section 3.5](#) to extract the state of all available IB verbs objects. CRIU stores this state together with other process data in an image. Later, CRIU recovers the image on another node using the new API.

When CRIU recovers MRs and QPs of the migrated application, the recovered objects must maintain their original unique identifiers. These identifiers are system-global and assigned by the NIC (in our case the SoftRoCE driver) in a sequential manner. We augmented the SoftRoCE driver to expose the IDs of the last assigned MR and QP to MigrOS in userspace. These IDs are *memory region number* (MRN) and *queue pair number* (QPN) correspondingly. Before recreating an MR or QP, CRIU configures the last ID appropriately. If no other MR or QP occupies this ID, the newly created object will maintain its original ID. This approach is analogous to the way CRIU maintains the process ID of a restored process using the `ns_last_pid` mechanism of Linux, which exposes the last process ID assigned by the kernel.

It is possible for some other process to occupy an MRN or QPN, which CRIU wants to restore. Two processes cannot use the same MRN or QPN on the same node, resulting in a conflict. In the current scheme, we avoid these conflicts by partitioning QP and MR addresses globally among all nodes in the system before application startup. CRIU faces the very same problem with process ID collisions. This problem has only been solved with the introduction of process ID namespaces. To remedy the collision problem for IB verbs objects, a similar namespace-based mechanism, together with a virtual RDMA network [29], would be required. We leave this issue for future work.

Additionally, recovered MRs have to maintain their original memory protection keys. The protection keys are pseudo-random numbers [75] provided by the NIC and are used by a remote communication partner when sending a packet. An RDMA operation succeeds only if the provided key matches

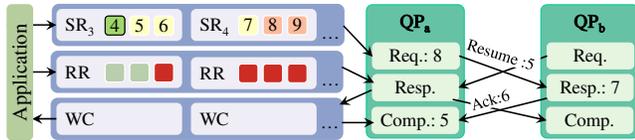

Figure 7: Resuming a connection in SoftRoCE. The figure depicts a snapshot of an immediate state, whereas the arrows indicate the flow of data over time. A send queue comprises multiple SRs, each expected to send multiple packets. Packets 8 and 9 (●) are to be processed by the requester. Packets 5–7 (●) are yet to be acknowledged. Packet 4 (●) is already acknowledged. A receive queue contains RRs with received (●) and not yet received (●) packets. QP_b expects the next packet to be 7. A resume packet has the PSN of the first unacknowledged packet (●). QP_b replies with an acknowledgement of the last received packet.

the expected key of a given MR. Other than that, the key's value does not carry any additional semantics. Thus, no collision problems exist for protection keys.

CRIU sets all protection keys to their original values before communication restarts by making an `ibv_restore_object` call with the `IBV_RESTORE_MR_KEYS` command.

4.2 Resuming Connections

The connection migration protocol ensures that connections are terminated gracefully and recovered to a consistent state. The implementation of this protocol is device- and driver-specific. In this work, we modify the SoftRoCE driver to make it compliant with the connection migration protocol (Section 3.3) by providing an implementation of the checkpoint/restore API (Section 3.5).

Figure 7 outlines the basic operation of the SoftRoCE driver, which creates three concurrent *tasks* for each QP: *requester*, *responder*, and *completer*. When an application posts send (SR) and receive (RR) work requests to a QP, they are processed by requester and responder correspondingly. A work request may be split into multiple packets, depending on the MTU size. When the whole work request is complete, responder or completer notify the application by posting a work completion to the completion queue.

The tasks process all requests packet by packet. Each task maintains the packet sequence number (PSN) of the next packet. A requester sends packets for processing at the responder of its partner QP. The responder replies with an acknowledgement sent to the completer. The completer generates a work completion (WC) after receiving an acknowledgement for the last packet in an SR. Similarly, the responder generates a WC after receiving all packets of an RR.

After migration, when the recovered QP_a is ready to communicate again, it sends a resume message to QP_b with the new address. Upon receiving the resume message, the re-

sponder of QP_b learns the new location of QP_a. Then, the responder replies with an acknowledgement of the last successfully received packet. If some packets were lost during the migration, the next PSN at the responder of QP_b is smaller than the next PSN at the requester of QP_a. The difference corresponds to the lost packets. Simultaneously, the requester of QP_b can already start sending messages. At this point, the connection between QP_a and QP_b is fully recovered.

The presented protocol ensures that both QPs recover the connection without losing packets irrecoverably. If packets were lost during migration, the QPs can determine which packets were lost and retransmit them, as part of the normal RoCEv2 protocol. The whole connection migration protocol runs transparently for the user applications.

5 Evaluation

We evaluate MigrOS from three main aspects. First, we analyse the implementation effort, with a specific focus on the magnitude of changes to the RoCEv2 protocol. Second, we study the overhead of adding migration capability, outside the migration phase. Third, we estimate the fine-grained cost of migration for individual IB verbs objects, as well as the full latency of migration in realistic RDMA applications.

For most experiments, we use a system with two machines: Each machine is equipped with an Intel i7-4790 CPU, 16 GiB RAM, an on-board Intel 1 Gb Ethernet adapter, a Mellanox ConnectX-3 VPI adapter, and a Mellanox Connect-IB 56 Gb adapter. The Mellanox VPI adapters are set to 40 Gb Ethernet mode. The SoftRoCE driver communicates over this adapter. The machines run Debian 11 with a custom Linux 5.7-based kernel. We refer to this setup as *local*. When comparing against DMTCP and FreeFlow, we use Ubuntu 14.04.

We conduct further measurements on a cluster comprising two-socket Intel E5-2680 v3 CPUs nodes with Connect-IB 56 Gb NICs deployed by Bull. We refer to this setup as *cluster*. Two nodes similar to those in the cluster were used in a local setup and equipped with Mellanox ConnectX-3 VPI NICs configured to 56 Gb InfiniBand mode.

5.1 Size of Changes

To quantify the changes MigrOS requires, we count the newly added or modified source lines of code (SLOC) in different components of the software stack. Out of around 4 kSLOC only around 10% apply to the kernel-level SoftRoCE driver. These changes mostly focus on saving and restoring the state of IB verbs objects. We separately counted changes to the requester, responder, and completer QP tasks responsible for the active phase of communication (see Figure 7). These tasks would be implemented in the NICs, for hardware-based RDMA implementations. Therefore, we keep the changes to QP tasks simple and small, as these changes must be reflected

Object	Features required	State (bytes)
PD	None	12
MR	Set memory keys and MRN	48
CQ	Restore ring buffer metadata	64
SRQ	Restore ring buffer metadata	68
QP	+ QP tasks state, set QPN	271
QP w/ SRQ	+ Current WQE state	823

Table 1: Additional features implemented in the kernel-level SoftRoCE driver to enable recovery of IB verbs objects. We provide the size that each object occupies in the dump.

in firmware or hardware. In our implementation, changes to QP tasks accounted only for around 6% of overall changes.

Using `gconv` [20], we verified that most of the changes to the QP tasks do not affect the critical path of communication. During the active phase of communication, 1213 lines were touched out of 4808 lines of the SoftRoCE driver identified by `gconv` as executable. Among the touched lines only 28 lines correspond to code we added for migration, with 3 lines corresponding to variable assignments and the rest being jumps related to checking for the *Paused* or *Stopped* state. The remaining code changes to the QP tasks run only during the connection migration phase.

Besides additional logic in the QP tasks, saving and restoring IB verbs objects requires the manipulation of implementation-specific attributes. Some of these attributes cannot be set through the original IB verbs API. For example, recovering an MR requires the additional ability to restore the original values of memory keys and the MRN. Some other attributes are not visible in the original IB verbs API at all. The queues (CQ, SRQ, QP) implemented in SoftRoCE require the ability to save and restore metadata of ring buffers backing up the queues. If a QP uses a shared receive queue (SRQ), the dump of the QP additionally includes the full state of the current *work queue entry* (WQE). We identified all required attributes for SoftRoCE, calculated their memory footprint (see Table 1), and implemented all features required by these attributes.

The changes to RoCEv2 implemented in SoftRoCE are small and affect the critical path of communication only marginally outside of the migration phase. We believe that for RDMA NICs the same changes to RoCEv2 will remain equally small.

5.2 Overhead of Migratability

Just adding the capability for transparent container migration already may incur overhead even when no migration occurs. For example, DMTCP (see Section 6) intercepts all IB verbs library calls and rewrites both work requests and completions before forwarding them to the NIC. Both with DMTCP and FreeFlow, this interception happens persistently, even if

Size, B	Latency, μ s			Bandwidth, Gb/s		
	Unmod.	FF	DMTCP	Unmod.	FF	DMTCP
2^0	0.8*	1.2*	1.4*	0.09	0.02	0.01
2^4	0.8*	1.2*	1.4*	1.41	0.24	0.20
2^8	1.1*	1.6*	1.8*	22.31	3.95	3.25

2^{20}	230.8	231.2	231.4	36.59	36.59	36.59

Table 2: Performance of CX3/40. Comparing execution without modifications against DMTCP and FreeFlow. The variation over 30 runs was small, except, * when $0.05 < \sigma/\mu < 0.1$.

Size, B	Latency, $\mu \pm \sigma \mu$ s		
	Plain	Migratable	DMTCP
2^0	25.3 ± 0.2	25.0 ± 0.2	26.2 ± 0.6
2^4	25.3 ± 0.3	24.9 ± 0.4	25.5 ± 0.5
2^8	26.9 ± 0.6	25.7 ± 0.7	28.0 ± 0.5
2^{12}	35.7 ± 0.4	36.8 ± 0.7	35.5 ± 0.5
2^{16}	93.2 ± 1.9	93.8 ± 1.9	94.4 ± 1.9
2^{20}	793.9 ± 12.8	802.0 ± 11.3	802.1 ± 13.5

Table 3: Communication latency with SoftRoCE. Comparison of migratable and plain (non-migratable) SoftRoCE against DMTCP using plain SoftRoCE.

the process never migrates. In contrast to this, MigrOS does not intercept communication operations on the critical path, thereby introducing no measurable overhead. This subsection explores the overhead added for normal communication operations without migrations.

DMTCP [2] and FreeFlow [44] do not offer live migration. Nevertheless, they could be extended to provide it. Therefore, we start by estimating the cost of adding migration capability at the user level. We use the latency and bandwidth benchmarks from the `perftest` benchmark suite [68]. We ran each experiment 30 times with 10000 iterations each at the *local* setup, with CX3/40 NICs.

Both frameworks do additional processing for each IB verbs work request, which results into near-constant overhead to latency (see Table 2). Each work request corresponds to a single message, not a single packet, therefore the overhead diminishes for larger message sizes. Table 2 demonstrates that bandwidth is directly affected by the increased latency and thus is lower only for small messages. We expect such bandwidth reduction to be a minor disadvantage for realistic applications, whereas a near 50% increase in latency may be critical for many latency-sensitive applications [30, 78].

It is possible, that despite our best effort to minimise the changes to the NIC, changes proposed by MigrOS introduce measurable overhead. Therefore, we need to show that Mi-

Short	Full name	Location
SR	SoftRoCE	local

grOS adds no additional cycles during message transmission. For that, we compare the performance of migratable and non-migratable versions of the SoftRoCE driver³ against DMTCP running with the non-migratable version of SoftRoCE. Running `ib_send_lat` [68] benchmarks in three different configurations shows (see Table 3) that migratability adds no visible overhead. Simultaneously, the latency increase for DMTCP is also minute, making it hard to distinguish all three configurations. The reason for such small difference between different configurations is the large communication overhead introduced by SoftRoCE. As a result, our experiment only shows that migratability does not add a large overhead, but does not allow to make a confident judgement regarding a potential microsecond-scale overhead. This situation is an unfortunate limitation of SoftRoCE. Considering how tiny we expect the overhead to be, even an FPGA-implementation may not be a precise reflection of a commercial RDMA NIC, because of the significant differences between an FPGA and an actual hardware implementation. We are convinced, due to the arguments given in Section 3, that MigrOS does not introduce even microsecond-scale overhead.

5.3 Migration Costs

With added support for migrating IB verbs objects, the container migration time will increase proportionally to the time required to recreate these objects. Our goal is to estimate the additional latency for migrating RDMA-enabled applications. This subsection shows the cost for migrating connections created by SoftRoCE, as well as the cost for connection creation with hardware-based IB verbs implementations.

Several IB verbs objects are required before a reliable connection (RC) can be established, see Section 2.2. Usually, an application creates a single PD, one or two CQs, multiple memory regions, and one QP per communication partner.

To measure the cost of creating individual IB verbs objects, we modified `ib_send_bw` [68] to create additional MR objects. We created one CQ, one PD, 64 QPs, and 64 1 MiB-sized MRs per run. Figure 8 shows the average time required to create

³Both versions are modified by us, because the original version (*vanilla kernel*) of the SoftRoCE driver is extremely unstable. It contained a multitude of concurrency bugs and could not be used in migration experiments. Unfortunately, fixing the race conditions required significant restructuring and resulted in a performance loss of around 20%.

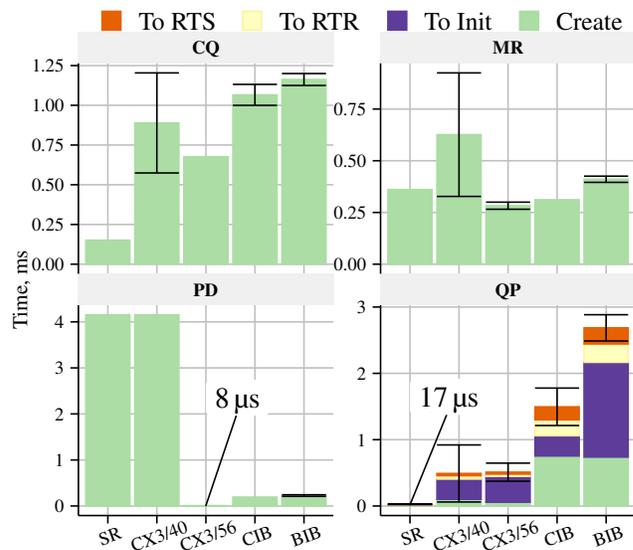

Figure 8: Object creation time for different RDMA devices (see Table 4). To send a message, a QP needs to be in the state RTS, which requires the traversal of three intermediate states (Reset, Init, RTR). Error bars show the interval of the standard deviation (σ) around the mean (μ), if $\sigma/\mu \geq 0.05$.

each object across 50 runs. Each tested NIC is represented by a bar. We draw two conclusions from this experiment. First, there is substantial variation for all operations across different NICs. Second, the time required for most operations is in the range of milliseconds.

The exact time required for migrating RDMA connections depends on two factors: the number of QPs and the total amount of memory assigned to MRs [56]. Both of these factors are application-specific and can vary greatly. Therefore, next, we show how the migration time is influenced by the application’s usage of MRs and QPs.

Figure 9 shows the MR registration time, depending on the region’s size. MR registration costs are split between the OS and the NIC: The OS pins the memory and the NIC learns about the virtual memory mapping of the registered region. SoftRoCE does not incur the “NIC-part” of the cost, so MR registration with SoftRoCE is faster than for RDMA-enabled NICs. For this experiment, we do not consider the cost of transferring the contents of the MRs during migration.

The number of QPs is the second variable influencing the migration time. Figure 10 shows the time for migrating a container running the `ib_send_bw` benchmark. This benchmark consists of two single-process containers running on two different nodes. Three seconds after communication starts, the container runtime migrates one of the containers to another node. The migration time is measured as the maximum message latency as seen by the container that did not move. The checkpoint is transferred over the same network link used by

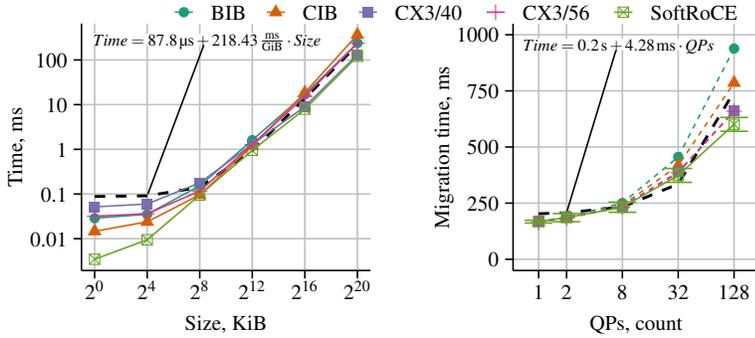

Figure 9: MR registration time depending on the region size.

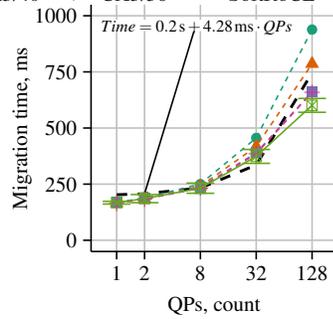

Figure 10: Migration speed with different numbers of QPs.

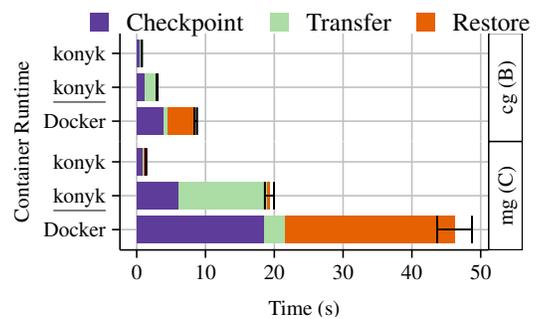

Figure 11: Migration speed of Docker and konyk with optimisations (konyk) and without (konyk)

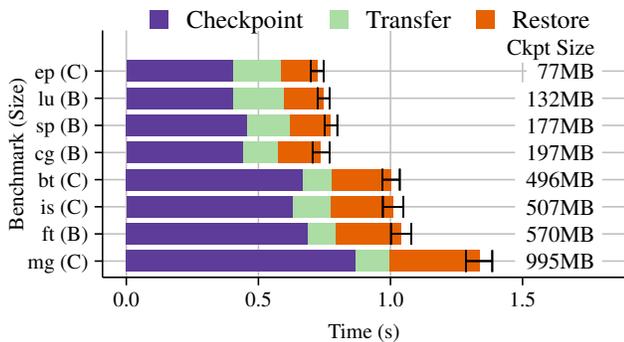

Figure 12: MPI application migration.

the benchmarks for communication. With a growing number of QPs, the benchmark consumes more memory, ranging from 8 MiB to 20 MiB. To put things into perspective, we estimated the migration time for real devices by calculating the time to recreate IB verbs object for RDMA-enabled NICs. We subtracted the time to create IB verbs objects with SoftRoCE from the measured migration time and added the time needed to create IB verbs objects with RDMA NICs (from Figure 8). We show our estimations with the dashed lines.

5.4 MPI Application Migration

For evaluating transparent live-migration of real-world applications, we chose to migrate NPB 3.4.1 [3], an MPI benchmark suite. The MPI applications run on top of Open MPI 4.0 [21], which in turn uses Open UCX 1.6.1 [77] for point-to-point communication. We configured UCX to use IB verbs communication over reliable connections (RC).

This setup corresponds to Figure 3. We containerised the applications using our self-developed runtime *konyk*, based on libcontainer [76]. Unlike Docker, our runtime facilitates faster live migration by sending the image directly to the destination node, instead of the local storage, during the checkpoint process. Additionally, *konyk* stores checkpoints in RAM, reducing migration latency even more. As any other container

runtime, *konyk* internally uses CRIU for checkpointing and restoring containers. Further description of our container runtime is out of scope of this paper.

To measure the application migration latency, we start each MPI application with four processes (*ranks*). Approximately in the middle of the application progress, one of the ranks migrates to another node. Each benchmark has a *size* (A to F) parameter. We chose the size such that all benchmarks run between 10 and 300 seconds. We excluded the “dt” benchmark, because it runs only for around a second. Figure 12 shows container migration latency and standard deviation around the mean, averaged over 20 runs of each benchmark.

We break down the migration latency into three parts: *checkpoint*, *transfer*, and *restore*. MigrOS first stops the target container and prepares the checkpoint. Almost immediately, and in parallel with checkpointing, MigrOS starts to transfer checkpoint data to the destination node. The transfer happens over the network link used by the benchmarks for communication. This overlap of checkpointing and data transfer minimises the time of exclusive data transfer. After the transfer is complete, MigrOS recovers the container at the destination node. Overall, the benchmarks experience a runtime delay proportional to the migration latency, which is proportional to the checkpoint size.

MPI applications (Figure 12) migrate slower than microbenchmarks (Figure 10), even after accounting for the checkpoint size, because of the difference in measurement methodology. For the microbenchmark, we calculate the migration time based on the maximum message latency observed by the non-migrating process. For the MPI benchmarks, we calculate the migration time from the increase in total execution time of the whole benchmark. This discrepancy indicates that the migration of parallel applications may cause a larger disruption to the application performance than the simple state transfer time can explain.

To show the interoperability of MigrOS with other container runtimes, we measured the migration costs when using Docker 19.03 (see Figure 11). We had to provide the end-to-

Table 5: Selected checkpoint/restore systems handle either VMs, processes (P), containers (C), or application objects (O). Runtime-based systems naturally introduce no additional communication overhead for migration support.

end migration flow ourselves, because Docker features only checkpoint and restore. To our disappointment, Docker does not employ some important optimisations and requires much time to complete migration. To understand the performance difference better, we disabled some optimisations in konyk: saving checkpoints to main memory (instead of hard disk), sending checkpoints during dumping, and using an optimised way to transfer the checkpoint. All of this was not enough to match the performance of Docker. Further investigation revealed Docker unnecessarily moving checkpoint images across the file system, proving the importance of explicit live migration support within a container runtime. Nevertheless, we demonstrate the principle possibility of containerised RDMA-application migration using Docker.

6 Related Work

VMs Live migration of virtual machines (VMs) has a long usage history in cloud computing [11, 16, 31, 63, 67]. We expect live migration to become even more popular with the growth of new computing paradigms, like disaggregated and fog computing [12, 25, 65, 86]. Nevertheless, past techniques for live VM migration with RDMA NICs relied on migration-aware, paravirtualised drivers inside the VMs [32, 70]

Checkpoint/Restore Techniques Transparent live migration of processes [4, 57, 81], containers [51, 58, 62], or virtual machines [11, 16, 31, 63, 67] has long been a topic of active research. The key challenge of this technique lies in the checkpoint/restore operation. For processes and containers, this operation can be implemented at three levels: application runtime, user-level system, or kernel-level system. Table 5 compares a selection of existing checkpoint/restore systems.

Runtime-based systems expect the user application to access all external resources through the API of the runtime. This restriction resolves two important issues with resource

migratability: First, the runtime system controls exactly when the underlying resource is used and can easily stop the application from doing so to serialise the state of the resource. Second, the runtime can maintain enough information about the state of the resource to facilitate resource serialisation and deserialisation. Such interception is cheap because it happens within the application’s address space.

Almost all attempts to provide transparent live migration together with RDMA networks rely on modifications of the runtime system [2, 24, 26, 32, 41, 70]. Some runtimes operate on application-defined objects (tasks, agents, lightweight threads) for even more efficient state serialisation and deserialisation [7, 43, 87]. All runtime-based approaches bind the application to a particular runtime system.

Kernel OS-level checkpoint/restore systems [6, 28, 38, 42, 66] either do interposition at the kernel level or extract application state from the kernel’s internal data structures. Although these systems support a wider spectrum of user applications, they incur a significantly higher maintenance burden. BLCR [28] has been abandoned eventually. CRIU [13], currently the most successful OS-level tool for checkpoint/restore, keeps necessary Linux kernel modification at a minimum and does not require interposition at the user-kernel API. We describe this tool in more detail in Section 2.3.

Finally, *user OS-level* systems interpose the user-kernel API, providing the same transparency and generality as kernel-based implementations. Such systems use the `LD_PRELOAD` mechanism to intercept system calls from applications and virtualise system resources, like file descriptors, process IDs, and sockets. In version 4, MOSIX has been redesigned to work entirely at the user level [5]. DMTCP [2] is a transparent fault-tolerance tool for distributed applications with support for IB verbs. To be able to extract the state of IB verbs objects, DMTCP maintains *shadow objects*, which act as proxies between a user process and the NIC [10]. In Section 5.2, we show that maintaining these shadow objects has non-negligible runtime overhead for RDMA networks.

Furthermore, live migration may employ RDMA networks to improve the speed of the checkpoint transfer [33, 39]. These techniques allow to reduce the downtime from migration and could be combined with our technique to improve the migration time of RDMA applications.

Network Virtualisation TCP/IP network virtualisation is an essential tool for isolating distributed applications from the underlying physical network topology. Even though network virtualisation enables live migration, it introduces overhead due to additional encapsulation of network packets [64, 89]. Several new approaches try to address these performance problems [8, 64, 69, 89]. However, these approaches do not consider RDMA networks.

RDMA-network virtualisation approaches focus on implementing connection control policies in software, but do not support live container migration [29, 44, 84]. As an exception, Nomad [32] uses InfiniBand address virtualisation for VM

migration, but implements the connection migration protocol inside an application-level runtime.

MigrOS uses traditional network virtualisation for TCP/IP networks, which is not on the performance-critical path for RDMA applications. However, MigrOS avoids unnecessary interception of RDMA communication. Instead, MigrOS silently replaces addressing information during migration.

RDMA Implementations SoftRoCE [48] and SoftiWarp [83] are open-source software implementations of RoCEv2 [36] and iWarp [23] respectively. Both provide no performance advantage over socket-based communication but are compatible with their hardware counterparts and facilitate the development and testing of RDMA-based applications. We chose to base our work on SoftRoCE because RoCEv2 found wider adoption than iWarp.

There are also open-source FPGA-based implementations of network stacks. NetFPGA [90] does not support RDMA communication. StRoM [79] provides a proof-of-concept RoCEv2 implementation. However, we found it unfit to run real-world applications (for example, MPI) without further significant implementation efforts.

7 Discussion and Conclusion

MigrOS is an OS-level architecture enabling transparent live container migration without sacrificing RDMA network performance. We are convinced the architecture of MigrOS can be useful for dynamic load balancing, efficient prepared fail-over, and live software updates in cloud or HPC settings.

Hardware Modifications and Software Implementation

We believe that limited hardware changes are worthy of consideration and have already been proven feasible [14, 27, 45, 45, 61], even for RDMA protocols [34, 46, 49]. Nevertheless, propositions to modify hardware often meet criticism because they are hard to validate and evaluate for an OS designer. To overcome this difficulty, we have modified SoftRoCE. It turned out that adding only few states to the state machine and two new message types were necessary. As result, we enabled transparent live migration of containerised RDMA applications without affecting the critical path of the communication. Lesokhin et al. [46] have demonstrated that RDMA protocol changes can be achieved just through firmware updates, barring the need to replace NICs. Furthermore, our design maintains full backwards-compatibility with the existing RDMA network infrastructure at every level and can be adopted by other RDMA protocols (e.g. Infiniband and RoCEv1) verbatim.

Unreliable Datagram Communication MigrOS provides live migration for reliable communication (RC), but not for unreliable datagram (UD), because, first, every message received over UD exposes the address of its sender. When this sender migrates, its address will change and, currently, MigrOS cannot conceal the change from the receiver. Second, a

UD QP does not know where to send resume messages after migration, because it can receive messages from anywhere. Consequently, to support UD, a NIC would need to maintain an additional simple table to translate between user-visible and actual addresses. We leave this issue for future work.

Security As of today, lack of authentication and integrity control is a general problem in RDMA networks [52, 75, 80, 82]. Therefore, modern RDMA networks rely on trusted NICs and hosts. In the context of this paper, we require the host OS to ensure that pause and resume messages may only be sent by authorised hosts. If either NICs or hosts cannot be trusted, additional protocols must prevent the sending of unauthorised (e.g. by spoofing) pause and resume messages. In this regard, we do not degrade security of the RDMA network.

White-box migration Previous live migration techniques require cooperation on the application's behalf, because they see RDMA NICs as *black boxes*. To our knowledge, our work is first to consider an RDMA NIC as a *white box* for the purpose of live migration. We categorise the device state as 1. *public state*, observable through the IB verbs API, 2. *device-driver-visible state*, visible by kernel- and user-level drivers, 3. *internal state*, invisible outside the device. The device must expose its internal state to the OS at the time of migration. We hope, these findings can be useful, when implementing live migration for other devices, e.g. GPUs.

Beyond migration We believe that the pause/resume protocol can find other uses, like efficient fail-over, congestion control, or load balancing. As an example, consider MasQ [29], a virtual RDMA network with firewall capabilities. MasQ can shut down RDMA connections, but unlike TCP/IP firewalls, cannot block them temporarily. Our protocol could return control over RDMA connections to the OS and replicate TCP/IP-like behaviour to RDMA firewalls as well.

Prediction-Based Power Oversubscription in Cloud Platforms

Microsoft Research and Microsoft Azure

Abstract

Prior work has used power capping to shave rare power peaks and add more servers to a datacenter, thereby oversubscribing its resources and lowering capital costs. This works well when the workloads and their server placements are known. Unfortunately, these factors are unknown in public clouds, forcing providers to limit the oversubscription and thus the potential performance loss from power capping. In this paper, we argue that providers can use predictions of workload performance criticality and virtual machine (VM) resource utilization to increase oversubscription. This poses many challenges, such as identifying the performance-critical workloads from opaque VMs, creating support for criticality-aware power management, and increasing oversubscription while limiting the impact of capping. We address these challenges for the hardware and software of Microsoft Azure. The results show that we enable a $2\times$ increase in oversubscription with minimum impact to critical workloads. We describe lessons from deploying our work in production.

1 Introduction

Motivation. Large Internet companies continue building datacenters to meet the increasing demand for their services. Each datacenter costs hundreds of millions of dollars to build. Power plays a key role in datacenter design, build out, IT capacity deployment, and physical infrastructure cost.

The power delivery infrastructure forms a hierarchy of devices that supply power to different subsets of the deployed IT capacity at the bottom level. Each device includes a circuit breaker to prevent damage to the IT infrastructure in the event of a power overdraw. When a breaker trips, the hardware downstream loses power, causing a partial blackout.

To avoid tripping breakers, designers conservatively provision power for each server based on either its maximum nameplate power or its peak draw while running a power-hungry benchmark, such as SPEC Power [25]. The maximum number of servers is then the available power (or breaker limit) divided by the per-server provisioned value. This provisioning leads to massive power under-utilization. As the IT demand increases, it also requires building new datacenters even when there are available resources (space, cooling, networking) in existing ones, thus incurring huge unnecessary capital costs.

To improve efficiency and avoid these costs, prior work has proposed combining power capping and oversubscription [12, 43]. The idea is to leverage actual server utilization

and statistical multiplexing across workloads to oversubscribe the delivery infrastructure by *adding more servers to the datacenter*, while ensuring that the power draw remains below the breakers' limits. This is achieved by continuously monitoring the power draw at each level and using power capping (via CPU voltage/frequency and memory bandwidth throttling), when necessary. As throttling impacts performance, these approaches carefully define which workloads can be throttled and by how much. For example, Facebook's Dynamo relies on predefined workload priority groups, and throttles each server based on the priority of the workload it runs [43].

This oversubscription approach works well when workloads and their server placements are known. However, *public cloud platforms violate these assumptions*. First, each server runs many VMs, each with its workload, performance, and power characteristics. Hence, throttling the entire server would impact performance-critical (e.g., interactive services) and non-critical (e.g., batch) workloads alike. Second, VMs dynamically arrive and depart from each server, producing varying mixes of characteristics and preventing predefined server groupings or priorities. Third, each VM must be treated as a black box, as customers are often reluctant to accept deep inspection of their VMs. Thus, the platform does not know which VMs are performance-critical and which ones are not. For these reasons, *oversubscription in public clouds has been limited so that performance is never impacted*.

Our work. In this paper, we argue that cloud providers can increase oversubscription substantially by carefully scheduling VMs and managing power, based on predictions of workload performance criticality and VM CPU utilization. Our insight is that there are many non-critical workloads (e.g., batch jobs) that can tolerate a slightly higher rate of capping events and/or deeper throttling; the capping of performance-critical workloads must be controlled more tightly. Using predictions to identify these workloads and place them carefully across the datacenter provides the power slack and criticality-awareness needed to increase oversubscription.

Accurately predicting workload criticality from outside opaque VMs is itself a challenge. Prior work [9] associated a diurnal utilization pattern with user interactivity and the critical need for high performance. Here, we present an accurate and robust pattern-matching algorithm to infer criticality, and a machine learning (ML) model that uses the algorithm's output during training. We also propose a model for predicting the 95th-percentile CPU utilization over a VM's lifetime.

*Azimi, Javadi and Schroeder were at Microsoft Research for this work.

With these predictions, we increase the power slack in the datacenter by balancing the expected power draw and our ability to lower it via throttling when a power budget is exceeded (causing a capping event). We accomplish this with a criticality- and utilization-aware VM placement policy. When events occur, we must cap power intelligently as well. So, we propose a system that protects performance-critical VMs from throttling when capping a server's power draw.

Using the above contributions and the history of power draws, we devise a new strategy for selecting the amount of oversubscription. The strategy limits the impact of capping on the two VM types to predefined acceptable values, thereby enabling significant but controlled increases in oversubscription. *Providers that prefer to treat all external (i.e., third-party) VMs the same can simply assume them all to be critical, and classify only the internal (i.e., first-party) VMs into the two types at the cost of a lower increase in oversubscription.*

We implement our work for the infrastructure of Microsoft Azure. The evaluation shows that our criticality algorithm and ML models are very accurate. We also show that our system and policy lower the performance impact of a capping event, while our policy produces fewer events. Overall, we can increase oversubscription by $2\times$ (from 6 to 12%), compared to the state-of-the-art approach. This increase would save \$75.5M in capital costs from *each* datacenter site (128MW). Assuming that all external VMs are performance-critical would lower the savings to a still significant \$28.1M. We have also started deploying our work in production in Azure and mention some lessons in Section 5.

Related work. The prior work on power capping [16, 19, 26, 27, 29–31, 34, 36, 45] and oversubscription [12, 14, 18, 28, 38, 39, 42, 43] produced major advances in server and datacenter power management. Unfortunately, it falls short for real public clouds. For example, it has capped server power using inputs that are typically not available in the public cloud, such as application-level metrics or operator annotations. Moreover, it has employed reactive and expensive VM migration in clusters, instead of leveraging predictions for capping and capping-aware scheduling. Prior oversubscription works have focused on non-cloud datacenters and full-server capping when workloads and their priorities are known.

Summary. We make the following main contributions:

1. An algorithm and ML model for predicting performance criticality, and a model for predicting VM utilization.
2. A VM placement policy that uses these predictions to minimize the number of capping events and their impact.
3. A per-VM power capping system that uses predictions of criticality to protect certain VMs.
4. A strategy that leverages the contributions above to increase the amount of oversubscription.
5. Implementation and results for Azure's infrastructure, showing large potential cost savings.
6. Lessons from production deployment of our work.

Though we build upon Azure's infrastructure, our concep-

tual contributions (e.g., predicting criticality; using predictions in VM placement, power budget enforcement, and oversubscription) apply directly to any cloud platform. Similarly, although we focus on VMs, our contributions also apply to containers running on bare-metal servers. As providers want to maximize the use of their servers via multi-tenancy, each container typically runs on a lightweight VM for security isolation [3, 32]. We can treat these VMs like any other. For scenarios where isolation between containers is not required, we can treat the whole server as a single workload or adapt our software to treat containers as we treat VMs.

2 Background and context

2.1 Typical power delivery, server deployment

At the top of the power delivery hierarchy, the electrical grid provides power to a sub-station that is backed up by a generator. An Uninterruptible Power Supply (UPS) unit provides battery backup while the generator is starting up. The UPS feeds one power distribution unit (PDU) per row of servers. Each row PDU supplies power to several rack PDUs, each of which feeds a few server chassis. Each chassis contains a few power supplies (PSUs) and dozens of blade servers.¹ A PDU trips its circuit breaker when the power draw exceeds the rated value (budget) for the unit, causing a power outage.

Designers deploy servers so that breakers never trip, leading to wasted resources (chiefly space, cooling, and networking). Combining hierarchical power capping and oversubscription enables more capacity to be deployed and better utilizes resources [12, 43]. For example, if designers find that the historical per-row power draw is consistently lower than the row PDU budget, they can “borrow” power from each row to add more rows (until they run out of row space) under the UPS budget. The extra rows oversubscribe the power at the UPS level. The servers downstream from the oversubscribed PDUs/UPS must be power-capped, whenever they are about to draw power that has already been borrowed.

2.2 Azure's existing capping mechanisms

For clarity and ease of experimentation, in this paper we explore power budget enforcement at the chassis level.

Azure sets power budgets for each chassis, where each blade in the chassis is allocated its even share of the chassis budget; uneven blade budgets are infeasible due to the overhead of dynamically reapportioning and reinstalling budgets. No capping takes place under normal operation, i.e. each blade is free to draw more power than its even share, as long as the total chassis draw is below the budget. The PSUs alert the board management chip (BMC) on blades directly when the chassis budget is about to be exceeded. Upon an alert, the blade power must be brought below its even-share cap. The BMC splits the cap evenly across its sockets and uses Intel's Running Average Power Limit (RAPL) [10] to lower

¹We refer to “blades” and “servers” interchangeably throughout the paper.

the blade power. RAPL throttles the entire socket (slowing down *all cores equally*) and memory using a feedback loop until the cap is respected. Typically, RAPL brings the power below the cap in less than 2 seconds. This reaction time is sufficient for power safety because leaf-level PDUs have a high (e.g., 7x) overload tolerance over 2 seconds, according to their breaker-trip curves [40]. Such overdraws are impractical even with aggressive oversubscription.

2.3 Azure’s existing VM scheduler

A cloud platform first routes an arriving VM to a server cluster. Within each cluster, a VM scheduler is responsible for placing the VM on a server. The scheduler uses heuristics to tightly pack VMs, considering the incoming VM’s multiple resource requirements and each server’s available resources.

Azure’s scheduler [17] implements its heuristics as two sets of rules. It first applies *constraint* rules (e.g., does the server have enough resources for the VM?) to filter invalid servers, and then applies *preference* rules, each of which orders the candidate servers based on a preferred metric (e.g., a packing score derived from available resources). It then weights each candidate based on its order on the preference list for each rule and the rule’s pre-defined weight. Finally, it picks a server with the highest aggregate weight for allocation. No rules currently consider power draws or capping.

2.4 Azure’s existing ML system

To integrate predictions into VM scheduling in practice, we use Resource Central [6], the existing ML and prediction-serving system in Azure. The system provides a REST service for clients (e.g., the VM scheduler) to query for predictions. It can receive input features (e.g., user, VM size, guest OS) that are known at deployment time from the scheduler, execute one of our ML models (criticality or CPU utilization), and respond with the prediction and a confidence score. Model training is done in the background, e.g. once a day.

3 Prediction-based oversubscription

Cloud providers provision servers conservatively, and have full-server capping mechanisms and capping-oblivious VM schedulers. We propose to provision servers more aggressively by making the infrastructure smarter and finer-grained via VM behavior predictions. Key challenges include having to create or adapt certain components (e.g., scheduler, chassis manager) to the predictions, while controlling the tradeoff between oversubscription and performance tightly.

Next, we overview our design and detail its main components. Then, we describe our strategy for provisioning servers to balance cost savings and performance impact.

3.1 Overview

Figure 1 overviews our system and its operation, showing the existing and new/modified components in different colors. We modify the VM scheduler to use predictions of VM performance criticality and resource utilization. We implement

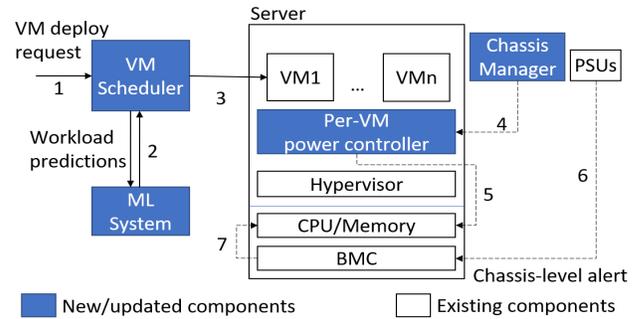

Figure 1: System overview.

our ML models so they can be managed and served by Resource Central. We modify the chassis manager to query the chassis power draw and interact with our new per-VM power controller. The controller manages its server’s power draw during a capping event.

A request to deploy a set of VMs arrives at our VM scheduler (arrow #1). The scheduler then queries the ML system for predictions of workload performance criticality and resource utilization (#2). Using these predictions, it decides on which servers to place the VMs (#3). After selecting each VM’s placement, the scheduler tags the VM with its predicted workload type and instructs the destination server to create it. Each chassis manager polls its local PSUs to determine whether the power draw for the chassis crosses a threshold just below the chassis budget. (This threshold enables the controller to perform per-VM capping and hopefully avoid needing full-server RAPL.) When this is the case, the manager alerts the controller of each server in the chassis (#4).

Upon receiving the alert, our controller at each server manages the server’s (even) share of the chassis budget across the local VMs based on their workload types. It does this by first throttling the CPU cores used by non-performance-critical VMs (#5). Throttling these VMs may be enough to keep the power below the chassis budget, and protect the performance-critical VMs. If it is not enough, the PSUs alert the servers’ BMCs (#6), which will then use RAPL as a last resort to lower the chassis power below the budget (#7).

Limiting impact on non-critical VMs. Though we protect critical VMs from throttling, we also limit the performance impact on non-critical VMs in three ways. First, for long-term server provisioning, our oversubscription strategy carefully selects chassis budgets to limit the number of capping events and their severity to predefined acceptable values (e.g., no more than 1% events for non-critical VMs, each lowering the core frequency to no less than 75% of the maximum). Second, for medium-term management, our scheduler places VMs seeking to minimize the number of events and their severity. Finally, in the shortest term, our per-VM controller increases the core frequency of non-critical VMs as soon as possible, to keep a server’s power close to (but below) the limit during a capping event (Section 3.4).

Treating external VMs as performance-critical. Providers

who prefer to treat all paying customers the same can easily do so by assuming that all external VMs are performance-critical; only internal VMs (e.g., running the provider’s own managed services) would be classified into the two criticality types. We explore this assumption in Section 4.6.

3.2 Predicting VM criticality and utilization

Our approach depends on predicting VM performance criticality and utilization at arrival time, i.e. just before the VMs are deployed. We train supervised ML models to produce these predictions based on historical VM arrival data and telemetry that was collected after those VMs were deployed. Since VMs are black boxes, our telemetry consists of CPU utilization data only, as deep inspection is not an option.

Inferring criticality. Predicting criticality requires a method to determine the VM *labels*, i.e. whether the workload of each VM is performance-critical or not, before we can train a model. As in prior work [9], we consider a workload critical if it is user-facing, i.e. a human is interacting with the workload (e.g., front-end webservers, backend databases), and less critical otherwise (e.g., batch, development and testing workloads). As user-facing workloads exhibit utilization patterns that repeat daily (e.g., high during the day, low at night), the problem reduces to identifying VMs whose time series of CPU utilizations exhibit 24-hour periods [9].

Although some background VMs may exhibit 24-hour periods, this is not a problem as we seek to be conservative (i.e., it is fine to classify a non-user-facing workload as user-facing, but not vice-versa). Moreover, some daily batch jobs have strict deadlines, so classifying them as user-facing correctly reflects their needs. Importantly, focusing on the CPU utilization signal works well even when the CPU is not the dominant resource, as the CPU is always a good proxy for periodicity (e.g., network-bound interactive workloads exhibit more CPU activity during the day than at night). This is true even for workloads that use load-based auto-scaling [2, 33], as auto-scaling impacts VM utilization but does not create or destroy periodicity, e.g. a VM deployment that receives diurnal load will show periodicity whether auto-scaling is enabled or not.

We considered but discarded other approaches for inferring whether a VM’s workload is user-facing. For example, observing whether a VM exchanges messages does not work because many non-user-facing workloads communicate externally (e.g., to bring data in for batch processing).

Identifying periodicity. There are statistical methods for identifying periods in time series, such as FFT or the auto-correlation function (ACF). For example, [9] assumes a workload is user-facing if the FFT indicates a 24-hour period. *We evaluated ACF and FFT methods on 840 workloads.* Surprisingly, we find that both methods lead to frequent misclassifications. We identify three culprits:

1. The diurnal patterns in user-facing workloads often have significant noise and interruptions. For example, we observe user-facing workloads with clear 24-hour periods for many

days, interrupted by a period of constant or random load, causing them to be mis-classified as non-user-facing.

2. The diurnal patterns often exhibit increasing/decreasing trends (e.g., the workload becomes more popular over time), and varying magnitudes of peaks/valleys across days. These effects cause some user-facing workloads to be mis-classified.

3. There are many machine-generated workloads with periods of 1 hour, 4 hours or other divisors of 24 hours, which therefore also have 24-hour periods, leading to machine-generated workloads that are mis-classified as user-facing.

Part of the problem is that ACF and FFT are very general tools with different goals, e.g. decomposing a signal for compact representation and capturing general correlations, not solutions for our specific problem of 24-hour periods.

Criticality algorithm. Thus, we devise a new algorithm that is more robust and targeted at our specific problem. Our idea is to extract from a VM’s utilization time series a *template* for a typical 24-hour period and then check how well this template captures most days in the series. We design the template extraction and comparison to be robust to noise and interruptions to deal with issue #1 above. We pre-process the data using methods from time series analysis to address #2. To deal with #3, we extract templates for shorter periods (8 and 12 hours) and ensure that the 24-hour template is the best fit. These periods subsume the other short periods.

More precisely, the input to our pattern-matching algorithm is the average CPU utilization for each 30-minute interval over 5 weekdays; this duration is long enough to unearth any periodicity in a VM’s CPU utilization signal. (Shorter workloads cannot be classified and should be conservatively assumed user-facing.) For each utilization time series, the algorithm does the following:

1. It de-trends and normalizes the time series, so that all days exhibit utilizations within the same rough range. De-trending scales each utilization based on the mean of the previous 24 hours, whereas normalization divides each utilization by the standard deviation of the whole time series.

2. It extracts the 24-hour template by identifying, for each time of the day (in 30-minute chunks), its “typical” utilization computed as the median of all utilizations in the pre-processed series that were reported at this time of the day.

3. It overlays the template over the pre-processed series for each day and computes the average deviation for each utilization, after excluding the 20% largest deviations.

4. It repeats steps 2 and 3 to compute average deviations for 8-hour and 12-hour templates, and then computes two scores: 24-hour average deviation divided by 8-hour average deviation (called `Compare8`), and 24-hour average deviation divided by 12-hour average deviation (called `Compare12`). If the scores are close to 0, the workload is likely to be user-facing. Ultimately, it classifies a time series as user-facing, if its `Compare8` value is lower than a threshold (Section 4.2).

Criticality prediction. The algorithm above produces labels that we use to train an ML model to classify arriving VMs as

user-facing or non-user-facing. Specifically, we train a Random Forest using the labels and many features (pertaining to the arriving VM and its cloud subscription) available at arrival time: the percentage of user-facing VMs in the subscription, the percentage of VMs that lived at least 7 days in the subscription, the total number of VMs in the subscription, the percentage of VMs in each CPU utilization bucket, the averages of the VMs' average and 95th-percentile CPU utilizations in the subscription, the arriving VM's number of cores and memory size, and the arriving VM's type.

Utilization prediction. For utilization predictions, we train a two-stage model to predict 95th-percentile VM CPU utilization based on labels produced by previous VM executions (actual 95th-percentile utilizations over the VMs' lifetimes) and the same VM features we use in the criticality model. Since predicting utilization exactly is hard, our model predicts it into 4 buckets: 0%-25%, 26%-50%, and so on. The first stage is a Random Forest that predicts whether or not the 95th-percentile utilization is above 50%. In the second stage, we have a Random Forest for buckets 1-2 and another for buckets 3-4. We train these latter forests with just the VMs we can predict with high-confidence ($\geq 60\%$) in the first stage.

We experimented with single-stage models, but they did not produce accurate predictions with enough confidence.

Model training and inference. Resource Central trains our prediction models in the background once a day. It also monitors prediction accuracy; we do not find significant improvements from more frequent training. The models exhibit sub-millisecond prediction latency, which is a small fraction of VM creation times [1].

3.3 Modified VM scheduler

Our ability to increase oversubscription and the efficacy of the per-VM power controller depend on the placement of VMs in each cluster. Better placements have a balanced distribution of power draws across the different chassis to reduce the number of capping events (Goal #1); and a balanced distribution of cap-able power (drawn by non-user-facing VM cores) across servers, so the controller can lower the power during an event without affecting critical VMs (Goal #2). The scheduler must remain effective at packing VMs while minimizing the number of deployment failures (Goal #3).

Given these goals, we modify Azure's VM scheduler to become criticality- and utilization-aware, using predictions at VM arrival time. Our policy is a preference rule that sorts the feasible servers based on a "score". Each server's score considers the predicted 95th-percentile CPU utilization of the VMs already placed in the same chassis (targets Goal #1), and the predicted criticality and 95th-percentile CPU utilization of the VMs already placed on the same server (targets Goal #2). The policy only considers CPU utilization because the CPUs are the dominant source of dynamic power in Azure's servers. Moreover, throttling the CPUs typically reduces the power of other resources (e.g., memory, storage) because of

Algorithm 1 Criticality- & utilization-aware VM placement

```

1: function SORTCANDIDATES( $V, \zeta$ )
    $\triangleright V$ : VM to be placed,  $\zeta$ : list of candidate servers
2:    $\omega \leftarrow V^{PredictedWorkloadType}$ 
3:   for  $c_i$  in  $\zeta$  do
4:      $\kappa_i \leftarrow SCORECHASSIS(c_i.Chassis)$ 
5:      $\eta_i \leftarrow SCORESERVER(\omega, c_i)$ 
6:      $c_i.score \leftarrow \alpha \times \kappa_i + (1 - \alpha) \times \eta_i$ 
7:   return  $\zeta.SORTDESC(c_i.score)$ 
8: function SCORECHASSIS( $C$ )
9:   for  $n_i$  in  $C.Servers$  do
10:    for  $v_j$  in  $n_i^{VMs}$  do
11:       $\rho^{Peak} \leftarrow \rho^{Peak} + v_j^{PredictedP95Util} \times v_j^{cores}$ 
12:       $\rho^{Max} \leftarrow \rho^{Max} + n_i^{cores}$ 
13:    return  $1 - \left[ \frac{\rho^{Peak}}{\rho^{Max}} \right]$ 
14: function SCORESERVER( $\omega, N$ )
15:   for  $v_i$  in  $N^{UF\_VMs}$  do
16:      $\gamma^{UF} \leftarrow \gamma^{UF} + v_i^{PredictedP95Util} \times v_i^{cores}$ 
17:   for  $v_i$  in  $N^{NUF\_VMs}$  do
18:      $\gamma^{NUF} \leftarrow \gamma^{NUF} + v_i^{PredictedP95Util} \times v_i^{cores}$ 
19:   if  $\omega = UF$  then
20:     return  $\frac{1}{2} \times \left( 1 + \frac{\gamma^{NUF} - \gamma^{UF}}{N^{cores}} \right)$ 
21:   else
22:     return  $\frac{1}{2} \times \left( 1 + \frac{\gamma^{UF} - \gamma^{NUF}}{N^{cores}} \right)$ 

```

the reduced number of accesses per second coming from the CPUs. As Section 4.5 shows, our policy does not degrade the packing of VMs onto servers, nor does it increase the percentage of VM deployment failures (achieves Goal #3).

Algorithm 1 shows our rule (*SortCandidates*) and two supporting routines. We show the predictions with the *PredictedWorkloadType* and *PredictedP95Util* superscripts. The rule ultimately computes the score for each candidate server (line #6). The higher the score, the more preferable the server. The score is a function of how preferable the server (line #5) and its chassis (line #4) are for the VM to be placed. Both server and chassis intermediate scores range from 0 to 1. We weight the intermediate scores to give them differentiated importance. We select the best value for the α weight in Section 4.5.

Function *ScoreChassis* computes the chassis score for a candidate server by conservatively estimating its aggregate chassis CPU utilization, i.e. assuming all VMs scheduled to the chassis are at their individual 95th-percentile utilization at the same time. This value is the sum of the predicted 95th-percentile utilizations for the VMs scheduled to the chassis, divided by the maximum core utilization (#cores in chassis $\times 100\%$). This ratio is proportional to utilization. We subtract it from 1, so that chassis with low utilization get higher values and are preferred (line #13).

Function *ScoreServer* scores a candidate server differently depending on the type of VM that is being deployed. First, it sums up the predicted 95th-percentile utilizations of the user-facing VMs (lines #15-16) and non-user-facing VMs (lines #17-18) independently. When a user-facing VM is being deployed, we compute how much more utilized the non-user-

facing VMs on the server are than the user-facing ones. We do the reverse for a non-user-facing VM. The reversal is the key to balancing the cap-able power on servers. Adding 1 and dividing by 2 ensures that the score will be positive between 0 and 1 (lines #20 and #22), while higher values are better.

Each run of the algorithm is for a single cluster with a few thousand homogeneous servers (heterogeneity is across clusters). Overall, the algorithm takes only 7 milliseconds to run, which is negligible as VM creation takes many seconds [1].

3.4 Per-VM power capping controller

To protect performance-critical VMs without losing power safety, we augment Azure’s out-of-band (i.e., independently of software on the server) full-server capping mechanism with an in-band (i.e., software-only) controller to cap only non-user-facing VMs when necessary. In our modified system, the chassis manager polls the PSUs every 200ms and alerts the in-band controller on each server when the chassis power draw is close to the chassis budget. Upon an alert, each controller uses per-core DVFS to power-cap the cores running non-user-facing VMs. To account for (1) high power draws between polls or (2) the inability of the controller to bring power below the budget, we keep the out-of-band mechanism that uses RAPL to throttle all cores equally as a backup.

To manage power per VM, we use the hypervisor’s core-grouping feature (e.g., cpupools in Xen, cpugroups in Hyper-V) to split the cores into high- and low-priority classes. We assign the user-facing VMs and the I/O VM (e.g., Domain0 in Xen, Root VM in Hyper-V) to run on cores in the high-priority class, and the non-user-facing VMs on the low-priority one.

Upon receiving an alert from the chassis manager, the per-VM power controller compares the server’s power draw to its budget. If the current draw is higher than the budget, the controller immediately lowers the frequency of the low-priority cores to the minimum p-state, i.e. half of the maximum frequency; the lowering of the frequency may entail a lower voltage as well. The goal is to quickly bring the server’s power draw below the limit and thereby avoid having to engage RAPL, which throttles all cores and impacts performance of all the VMs on the server. However, this large frequency reduction may overshoot the needed power reduction. To reduce the impact on the non-user-facing VMs, the controller then enters a feedback loop where each iteration involves (1) checking the server power meter and (2) increasing the frequency of N low-priority cores to the next higher p-state (100 MHz step), until the power is close to the budget. It selects the highest frequency that keeps the power below this threshold. $N = 4$ works well in our experiments. The feedback loop also adapts to changes in workload behavior on the VMs, which ends up impacting the server power draw.

It is possible that cutting the frequency of the low-priority cores in half is not enough to bring the power below the server’s budget. For example, a VM placement where there are not enough non-user-facing VMs in the workload mix, non-

user-facing VMs exhibiting lower utilization than predicted, or a controller bug can cause this problem. In this case, the out-of-band mechanism will kick in as backup. More aggressive mechanisms to reduce power, such as core sleep states (c-states) or shutting down the non-user-facing VMs, can also be leveraged before resorting to using RAPL. We will add such capability to our production system (Section 5).

The controller lifts the cap after some time (30 secs by default), allowing all cores to return to maximum performance.

3.5 Oversubscription strategy

We now describe our oversubscription strategy, which uses our per-VM capping system and placement policy, historical VM arrivals, and historical power draws, to increase server density. We considered using the placement policy along with Azure’s existing full-server capping system for oversubscription. However, without per-VM throttling, the only way to protect performance-critical VMs is to avoid capping events on servers/chassis running these VMs. This drawback severely limits the level of oversubscription.

Our strategy uses the algorithm below for computing an aggressive power budget for all the chassis of each hardware generation. Adapting it to find budgets for larger aggregations (e.g., rack, row) is straightforward. We refer to the uncapped, nominal core frequency as the “maximum” frequency.

To configure the algorithm, we need to select the maximum acceptable rate of capping events (e.g., #events per week) for user-facing ($emax_{UF}$) and non-user-facing ($emax_{NUF}$) VMs, and the minimum acceptable core frequency (e.g., half the maximum frequency) for user-facing ($fmin_{UF}$) and non-user-facing ($fmin_{NUF}$) VMs. If we want no performance impact for user-facing VMs, we set $emax_{UF} = 0$ and $fmin_{UF} =$ maximum frequency. As we describe next, our 5-step algorithm finds the lowest chassis power budget that satisfies $emax_{UF}$, $emax_{NUF}$, $fmin_{UF}$, and $fmin_{NUF}$.

Estimate future behaviors based on history:

1. Estimate the historical average ratio of user-facing virtual cores in the allocated cores (β). Estimate the historical average P95 utilization of virtual cores in user-facing ($util_{UF}$) and non-user-facing ($util_{NUF}$) VMs.

Profile the hardware:

2. Estimate how much server power can be reduced by lowering core frequency at $util_{UF}$ and $util_{NUF}$, given $fmin_{UF}$ and $fmin_{NUF}$, respectively. This step produces two curves for power draw (one curve for each average utilization), as a function of frequency.

Compute power budgets based on historical draws:

3. Sort the historical chassis-level power draws (one reading per chassis per unit of time) in descending order.

4. Start from the highest power draw as the first candidate budget and progressively consider lower draws until we find P_{min} . For each candidate power budget, we check that the rate of capping events would not exceed $fmax_{UF}$ or $fmax_{NUF}$ (considering the higher draws already checked), and the at-

tainable power reduction from capping is sufficient (given β and the curves from step 2).

5. To compute the final budget, add a buffer (e.g., 10%) to the budget from step 4 to account for future variability of β or substantial increases in chassis utilization.

We can use the difference between the overall budget computed in step 5 and the provisioned power to add more servers to the datacenter. Because we protect user-facing VMs and use our VM scheduling policy, this difference is substantially larger than in prior approaches, as we show in Section 4.6.

Example. Suppose (1) we are willing to accept rates of 0.1% and 1% capping events for user-facing and non-user-facing VMs, respectively; (2) upon a capping event, we are willing to lower the core frequencies to 75% and 50% of the maximum, respectively; (3) we have 10000 historical chassis power draws (collected from every chassis); and (4) the highest draws have been 2900W, 2850W, and 2850W. We first consider 2900W. If we were to set the chassis budget to just below that value to say 2890W, there would be 1 capping event out of 10000 observations, i.e. a rate of 0.01%, and we would have to shave 10W during the event. Given the acceptable capping rates and minimum frequencies, we can operate with the data from step 1 and the curves from step 2 to determine (a) whether we could reduce power by 10W, and (b) whether there would be an impact on user-facing VMs. If we can achieve the reduction, we count 1 event out of 10000 that would affect non-user-facing VMs. If the user-facing VMs would also have to be throttled, we would count 1 event out of 10000 that would affect those VMs. Since both rates are lower than 0.1% and 1%, we can now check a budget just below 2850W, say 2840W. We repeat the process for this budget, then the next lower budget and so on, until we violate the desired capping rates and minimum frequencies.

4 Evaluation

4.1 Methodology

Data analysis. We evaluate our criticality algorithm and ML models (Section 4.2) using standard metrics, such as precision and recall from predictions. We compute the metrics based on Azure’s *entire VM workload in April 2019*.

Real experiments. We run experiments on the same hardware that Azure uses in production. We use a chassis with 12 servers, each containing 40 cores split into two sockets. At their nominal frequency, each server draws between 112W (idle) and 310W (100% CPU utilization). At half this frequency, each server draws from 111W to 169W.

Our single-server experiments (Section 4.3) explore our per-VM capping controller and resulting VM workload performance for a combination of user-facing and non-user-facing VMs and various power budgets. For comparison, we use the existing full-server capping controller (RAPL) in Azure. Our chassis-level experiments (Section 4.4) explore our system on 12 servers, including PSU alerts. For comparison, we use Azure’s existing chassis-level mechanisms.

Parameter	Value
Cluster configuration	20 racks \times 3 chassis \times 12 blades
Blade configuration	2x20 cores
VM size dist. (cores)	1 (33%), 2 (27%), 4 (21%), 8 (10%), 16 (5%), 24 (3%), ≥ 32 (1%)

Table 1: Simulation parameters.

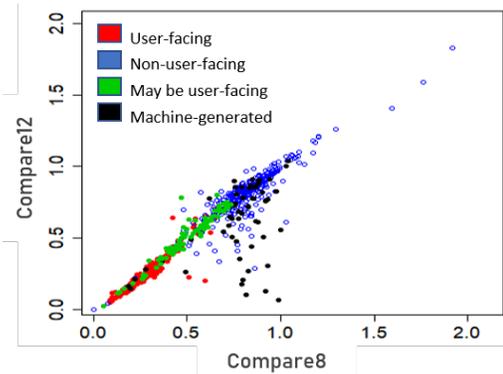

Figure 2: Algorithm compared to manual classification.

For both sets of experiments, we use instances of a latency-critical transaction processing application (similar to TPC-E) for the user-facing workload, and instances of a batch Hadoop computation (Terasort) for the non-user-facing workload. For the user-facing workload, we use real inputs from the team responsible for it, whereas we use synthetic input data for the non-user-facing computation.

Simulation. We evaluate our modified VM scheduler in simulation (Section 4.5), leveraging the same simulator that Azure uses to evaluate changes to the VM scheduler before putting them in production; our only extension is to simulate calls to Resource Central. An event generator drives the simulation with a sequence of VM arrivals. For each arrival, it invokes the production scheduling algorithm (or the scheduling algorithm with the addition of our policy) for server placement decisions. Running the actual scheduler code in the simulator ensures that simulations are faithful to reality.

We simulate a cluster of 60 chassis in 20 racks. The simulator produces VM arrivals based on distributions matching Azure’s load in April 2019. Table 1 lists the main statistics.

4.2 Criticality algorithm and ML models

Criticality algorithm. To evaluate our algorithm (Section 3.2), we first compare its classifications to our own manual labeling of 840 workloads. Figure 2 shows one dot for each workload with coordinates corresponding to its Compare8 and Compare12 values. The colors indicate whether we deem the workload clearly user-facing, possibly user-facing,

Technique	Recall target	Recall achieved	Precision achieved
Pattern-matching	99%	99%	76%
ACF	99%	99%	54%
FFT	99%	99%	48%
Pattern-matching	98%	98%	77%
ACF	98%	98%	56%
FFT	98%	98%	50%

Table 2: Pattern-matching vs ACF vs FFT.

clearly machine-generated, or clearly non-user-facing. The figure shows that Compare8 can separate the first two groups, which the algorithm should conservatively classify as user-facing, from the last two. A vertical bar at Compare8=0.72 gets all important workloads to the left of the bar, and the vast majority of unimportant ones to the right. Compare12 does not separate the classes well.

Thus, the algorithm accurately classifies workloads based on their Compare8 value. For a quantitative assessment, we compare it to two well-known approaches for finding periodicity in a time series, ACFs and FFTs, for the same set of workloads. For both approaches, we do the same pre-processing and disambiguate between user-facing and machine-generated workloads using the same methods as in our algorithm.

As we want to protect user-facing VMs, we must achieve high recall for this class as the recall indicates the probability of correctly identifying these VMs. Table 2 shows the precision and recall, for two high recall targets (0.99 and 0.98) for whether a workload is user-facing. Our algorithm achieves the target recall with much higher precision, i.e. it classifies many more non-user-facing VMs correctly. This reduces performance degradation during capping events, as more of those VMs can be throttled to lower power.

ML models. We now evaluate our models for *Azure’s entire VM workload*. Table 3 lists the percentage of predictions with confidence score higher than 60% (3rd column), and the per-bucket recalls and precisions (4th-7th columns) and the accuracy (rightmost column) for those high-confidence predictions. The VM scheduler disregards predictions with lower confidence and conservatively assumes the VM being deployed will be user-facing and will exhibit 100% 95th-percentile utilization. For comparison, we show results for the equivalent Gradient Boosting (GB) models.

The table shows that our criticality model achieves 99% recall for user-facing VMs (Bucket 2), which is critical for protecting these VMs. The most important features for our model are the percentage of user-facing VMs observed in the cloud subscription, the percentage of VMs that live longer than 7 days in the subscription, and the total number of VMs in the subscription. The GB model achieves similar results.

Our utilization model also does well with good recall and precision (83-93%) for the most popular buckets (1 and 4), and good accuracy (84%) for the 73% of high-confidence predictions. Here, the most important features are the average of the VMs’ 95-percentile CPU utilizations in the subscription, the average of the VMs’ average CPU utilizations in

Prediction	Model	% High Conf.	Bucket 1 R P	Bucket 2 R P	Bucket 3 R P	Bucket 4 R P	Accuracy
Criticality	GB	99%	67% 77%	99% 99%	NA	NA	98%
	RF	99%	69% 78%	99% 99%	NA	NA	98%
P95 util	GB	68%	95% 85%	47% 77%	51% 79%	94% 80%	82%
	RF	73%	93% 87%	61% 76%	65% 81%	92% 83%	84%

Table 3: Random Forest (RF) and Gradient Boosting (GB) models recall (R), precision (P), and accuracy for high-confidence predictions.

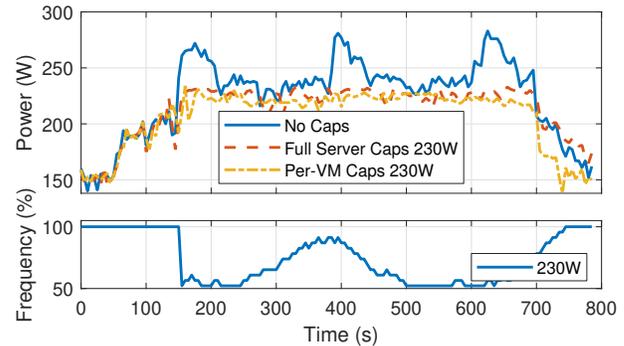

Figure 3: Server power dynamics.

the subscription, and the percentages of VMs in each CPU utilization bucket in the subscription. The GB model achieves similar accuracy, but with fewer high-confidence predictions and lower recall for the two middle (least popular) buckets.

4.3 Per-VM capping controller experiments

We run experiments on a server with our user-facing application running on a VM with 20 virtual cores and our non-user-facing application running simultaneously on another VM with 20 virtual cores. Each execution takes 10 minutes.

Figure 3 plots the dynamic power behaviors and core frequencies of full-server and per-VM capping with caps at 230W. In the bottom graph, we plot the lowest frequency of any non-user-facing core. The experiments have capping enabled throughout their executions. For comparison, we show the power profile of an experiment without any cap.

When unconstrained (no cap), the power significantly exceeds 250W. In contrast, full-server and per-VM capping keep the power draw below 230W. Because of the lower target of our controller (225W for the 230W cap), its draws are slightly below those of full-server capping most of the time. The frequency curve depicts the adjustments that our controller makes to the performance of the non-user-facing VM. The steep drop to the lowest frequency occurs when the controller abruptly lowers the frequency to the minimum value when the power first exceeds the target. After that, its feedback component smoothly increases and decreases the frequency.

Figure 4 shows the impact of capping in these experiments on the 95th-percentile latency of the user-facing application (10 leftmost bars) and the running time of the non-user-facing application (10 rightmost bars). Results are normalized to the unconstrained performance of each application. We also include bars for capping at 250W, 240W, 220W, and 210W.

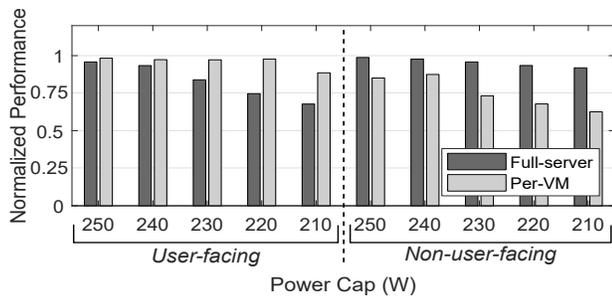

Figure 4: Performance impact of power capping.

The results show that full-server capping imposes a large tail latency degradation, especially for the lower caps. When the cap is 230W, the degradation is already 18%, which is often unacceptable for user-facing applications. For lower caps, full-server capping provides even worse tail latency (35% degradation for 210W). In contrast, our controller keeps tail latency very close to the unconstrained case, until the cap is so low (210W) that it becomes impossible to protect the user-facing application and RAPL needs to engage. This positive result comes at the cost of performance loss for the non-user-facing application. While full-server capping keeps running time fairly close to the unconstrained case, our controller degrades it by 28% for the 230W cap. This is the right tradeoff, as non-user-facing workloads have looser performance needs.

4.4 Chassis-level capping experiments

We now study the power draw at the chassis level, and the impact of different capping granularities (full-server vs per-VM) and VM placements. We experiment with a 12-server chassis running 36 copies of our user-facing application (each on a VM with 4 virtual cores), and 36 copies of our non-user-facing application (each running on a VM with 6 virtual cores). In terms of VM placement, we explore two extremes: (1) *balanced* placement, where we place the user-facing and non-user-facing VMs in round-robin fashion across the servers, i.e. 3 VMs of each type on each server; and (2) *imbalanced*, where we segregate user-facing and non-user-facing VMs on different sets of servers. Each experiment runs for 26 minutes.

Figure 5(left) plots the dynamic behavior of the chassis for an overall budget of 2450W for the two capping approaches. For comparison, we also plot the no-cap case. In these experiments, we use the balanced placement as an example.

As expected, both capping granularities are able to limit the power draw to the chassis budget, whereas the no-cap experiment substantially exceeds this value. We observe the same trends under the imbalanced placement approach. The placement does not matter in terms of the power profiles because the capping enforcement ensures no budget violations.

However, VM placement has a large impact on application performance. Figure 5(right) plots the impact of VM placement and capping granularity on the average 95th-percentile latency of the user-facing applications (4 leftmost bars) and on the average running time of the non-user-facing applications (4 rightmost bars). We normalize to the no-cap results.

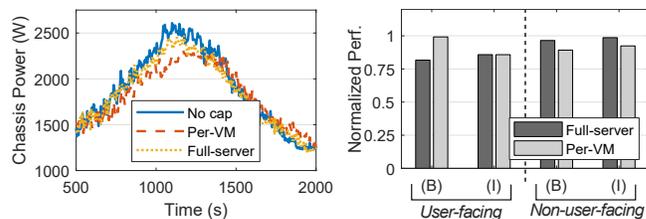

Figure 5: Chassis dynamics and performance vs placement.

Per-VM capping under balanced placement keeps the average tail latency the same as the no-cap experiment, despite the tight 2450W budget. In contrast, per-VM capping degrades performance as much as full-server capping when the placement is imbalanced. These results show that our controller protects user-facing VMs when the placement allows it.

Full-server capping provides slightly better performance than per-VM capping for the non-user-facing applications. More interestingly, the results for balanced placement are slightly worse than for imbalanced placement, regardless of the capping granularity. For per-VM capping, the reason is that servers with only non-user-facing VMs need to reduce the frequency of fewer cores. For full-server capping, the reason is that servers with only non-user-facing VMs tend to have higher utilization, so a smaller reduction in frequency is enough for a large power reduction. Comparing the two rightmost bars, we see that full-server capping hurts performance slightly less than per-VM capping in the imbalanced case, as RAPL lowers frequency more slowly than our controller.

4.5 Cluster VM scheduler simulation

In the previous section, we explored extreme and manually-produced VM placements in controlled experiments. However, in practice, placements are determined by the VM scheduler. Consequently, we implement our placement policy (Algorithm 1) as a preference rule in Azure’s VM scheduler, and simulate a cluster using 30 days of VM arrivals (Section 4.1). The simulator runs the same rules as in production, along with our added preference rule. It reports four main metrics:

- Deployment failure rate: percent of VM deployment requests rejected due to resource unavailability or fragmentation. This rate impacts users, so our policy should not increase it;
- Average empty server ratio: percent of servers without any VMs averaged over time. Empty servers can host the largest VM sizes, so our policy should not decrease this ratio;
- Standard deviation of the average chassis score, i.e. $1 - (\rho^{Peak} / \rho^{Max})$ (Algorithm 1, line 13), for each chassis. This metric reflects how balanced the chassis are with respect to their power loads. Lower values are better and mean better balance and fewer power capping events;
- Standard deviation of the average server score, i.e. $(1/2) \times (1 + (\gamma^{NUF} - \gamma^{UF}) / N^{cores})$ (Algorithm 1, line 20), for each server. This metric reflects how balanced the servers are in terms of UF and NUF core 95th-percentile utilizations. Lower values mean better balance and that we are more likely to only need to cap NUF VMs.

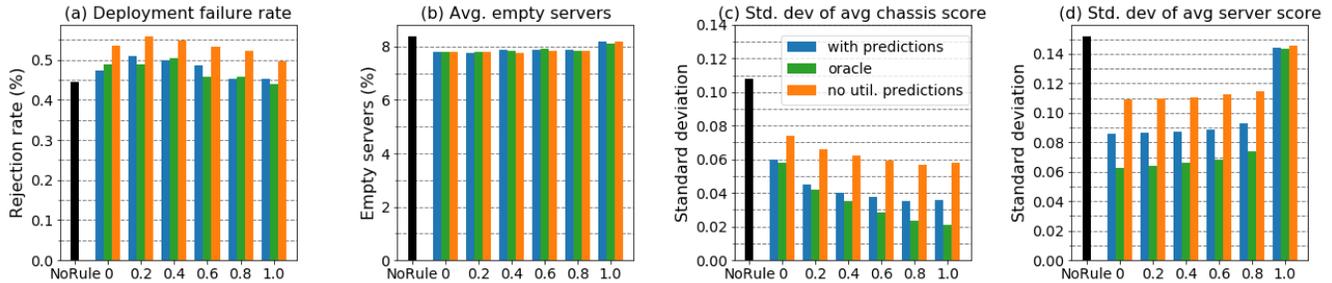

Figure 6: Key scheduler metrics, as a function of α .

Results. Figure 6 shows the results for these metrics, as a function of the α weight in our policy (Algorithm 1, line 6). $\alpha = 1$ means that the server score is irrelevant, whereas $\alpha = 0$ means that the chassis score is irrelevant. From left to right in each graph, the “NoRule” (black) bar represents the existing scheduler; the leftmost (blue) bar in each group represents our modified scheduler using our policy and ML predictions; the next (green) bar shows the modified scheduler using oracle predictions; and the rightmost (orange) the modified scheduler using criticality predictions, but no utilization predictions.

Comparing the black and blue bars illustrates the benefit of our policy and predictions. Figures 6(a) and (b) show that our modified scheduler impacts the failure rate slightly for low values of α (not at all for high values), while slightly decreasing the percentage of empty servers regardless of α . The reason is that our policy may use a few more servers in the interest of better balancing the load. In fact, Figures 6(c) and (d) confirm that the load is more balanced using our policy and predictions. These latter graphs also show that the value of α is important. $\alpha = 0$ produces much worse utilization balancing across chassis than other values. At the same time, $\alpha = 1$ produces as poor server utilization balancing as the existing scheduler, whereas other values produce much better server balancing. These observations confirm that it is key to balance both across chassis and servers, as in our policy. $\alpha = 0.8$ strikes a good compromise between the importance of these types of balancing.

Impact of prediction accuracy. Comparing the blue and green bars illustrates the impact of mispredictions and predictions with low confidence. Figures 6(c) and (d) show that oracle predictions produce only slightly better balancing than our real predictions for certain values of α .

Impact of criticality and utilization predictions. Comparing the orange and blue bars with the black bar illustrates the impact of having criticality only, and both criticality and utilization predictions, respectively. Clearly, it is critical to predict the workload type of each VM, as we want to protect the performance of user-facing VMs during capping events (black vs orange bars). The results demonstrate that having utilization predictions is also important (orange vs blue bars). The lack of such predictions degrades the balancing substantially for most values of α , and thus increases the capping rate and limits the power reduction during an event (thereby

decreasing the potential for oversubscription).

4.6 Oversubscription increases

We now estimate the amount of oversubscription and dollar savings that result from our lower chassis power budgets. To do so, we translate the amount of budget we can reduce in each 60-chassis cluster into the infrastructure cost we would avoid. Oversubscription allows servers to be added to an existing datacenter (assuming space, cooling, and networking are available, as it is often the case), avoiding the cost of building a corresponding fraction of a new datacenter.

We instantiate our 5-step oversubscription strategy (Section 3.5) with power telemetry from 1440 of Azure’s chassis over 3 months in 2018. We also use VM statistics from April 2019. Specifically, the 95th-percentile core utilizations for non-user-facing ($util_{NUF}$) and user-facing ($util_{UF}$) VMs were 44% and 65%, respectively, and the ratio of user-facing cores in the allocated cores (β) was 40%. Although user-facing VMs dominate in absolute count over the month, a majority of such VMs are short-lived – 52% of VMs last for less than 1 hour (Table 1). In contrast, all non-user-facing VMs last for at least 5 weekdays (Section 3.2). Consequently, a snapshot at various points in time in the month indicates an average value of 40% for β . We add a buffer of 10% to the chassis budget (step 5). For the results where providers treat external (i.e., third-party) VMs differently than internal (i.e., first-party) VMs, we adjust these parameters accordingly, while keeping the same amount of buffer.

Table 4 lists results for several types of provisioning:

1. “Traditional” provisioning (no oversubscription);
2. State-of-the-art full-server capping without VM insights.

In this approach, the power capping events need to be rare and the throttling has to be light to prevent performance loss to user-facing VMs. To model this approach with our provisioning strategy, we use $emax_{UF} + emax_{NUF} = 0.1\%$, $fmin_{UF} = fmin_{NUF} = 75\%$;

3. Predictions-based per-VM capping and scheduling, without impact on user-facing VMs. We use $emax_{UF} = 0$, $fmin_{UF} = 100\%$, $emax_{NUF} = 1\%$ and $fmin_{NUF} = 50\%$;

4. Predictions-based per-VM capping and scheduling, with minimal impact on user-facing VMs. To make this approach comparable to the others, we set the overall rate of capping events at 1%. Specifically, we use $emax_{UF} = 0.1\%$, $fmin_{UF} = 75\%$, $emax_{NUF} = 0.9\%$ and $fmin_{NUF} = 50\%$;

Approach	Chassis budget delta (%)	Savings (\$10/W)
Traditional	0	0
State of the art	6.2%	\$79.4M
Predictions for all VMs, no UF impact	11.0%	\$140.8M
Predictions for all VMs, minimal UF impact	12.1%	\$154.9M
Predictions for internal VMs, no UF impact	8.4%	\$107.5M
Predictions for internal VMs, minimal UF impact	10.3%	\$131.8M
Predictions for internal and non-premium external VMs, no UF impact	10.6%	\$135.7M
Predictions for internal and non-premium external VMs, minimal UF impact	12.1%	\$154.9M

Table 4: Comparison between provisioning approaches.

5. Predictions-based per-VM capping and scheduling for internal VMs only (all external VMs considered user-facing), without impact on user-facing VMs;

6. Predictions-based per-VM capping and scheduling for internal VMs only, with minimal impact on user-facing VMs;

7. Predictions-based per-VM capping and scheduling for internal and non-premium external VMs, without impact on user-facing VMs; and

8. Predictions-based per-VM capping and scheduling for internal and non-premium external VMs, with minimal impact on user-facing VMs.

The state-of-the-art approach achieves 6.2% oversubscription. This amount is comparable to that (8%) achieved by Facebook [43], which knows the (single) workload that runs on each server. Public cloud platforms do not have this luxury.

In contrast, our approach (#3 and #4) can *almost double* the oversubscription and savings. We achieve more than 12% oversubscription with minimal impact on user-facing VMs. Assuming a datacenter campus of 128MW and an infrastructure cost of \$10/W [4], 12.1% oversubscription translates into \$154.9M in savings; an increase in savings of \$75.5M over the state of the art. As providers can oversubscribe many campuses, the savings would be much higher in practice.

When providers prefer to treat external and internal VMs differently (approaches #5-#8), they can do so at the cost of a lower increase in oversubscription. For example, when treating all external VMs as user-facing and protecting the performance of user-facing VMs (#5), the increase in savings becomes \$28.1M. At the other extreme, where we treat the premium external VMs as user-facing and allow minimal impact on user-facing VMs (#8), the increase in savings returns to \$75.5M. The reason is that this provisioning approach has enough non-critical VMs, and oversubscription is limited only by the rate of capping events.

As our results show, the amount of oversubscription and savings depends upon the user-facing vs non-user-facing core ratio (β) and the amount of power that can be recovered from

each type through frequency reduction (f_{min}), while satisfying the constraints (e_{max}). Generally, a higher (lower) value of β results in less (more) oversubscription. This analysis for oversubscription has to be done on a per-cluster basis.

5 Lessons from production deployment

We have deployed our per-VM capping controller and ML models on thousands of servers in multiple datacenters. Next, we discuss some of the lessons from these deployments.

Hypervisor support for per-VM power capping. Our prototype controller (Section 3.4) leveraged the hypervisor’s core-grouping feature to manage the frequency of each VM’s physical cores. In production, Azure typically prefers not to restrict a VM to a subset of cores, so we could not rely on this feature. Instead, we had to extend the hypervisor to (1) add the capability to dynamically specify the frequency for a VM, and (2) carry the frequency to whichever cores it schedules the VM on during the context switch (changing the frequency takes tens of microseconds, whereas a scheduling quantum lasts 10 milliseconds). As most VMs are small (Table 1), there was no need to manage frequency on a per-virtual-core basis.

Refresh VM criticality prediction on servers. Misclassification of a VM’s criticality can result in unintended performance degradation (Section 4.2). To address this problem, we added the capability to periodically (e.g., daily) refresh a VM’s criticality tag on a server. We change the tag after Resource Central has observed the VM long enough to classify the criticality of the VM’s workload. As the prediction models already provide good placements (Section 4.5), we do not migrate VMs when their criticality changes.

Expanded workload criticality definition. Some first-party customers were concerned about the impact of per-VM capping on their non-user-facing VMs. To alleviate their concerns, we added a configurable *prioritized* throttling list to our system. Using the list, we first consider all low-priority and internal non-production VMs for throttling and throttle production non-user-facing VMs as a last resort, i.e. when throttling the other types is insufficient. Furthermore, our system has a “do-not-throttle” list of highly-sensitive internal workloads (e.g., gaming, repair) that are always considered critical. Finally, the criticality of VMs can be also be dynamically updated on servers based on changes to the static lists.

Metrics to measure capping impact. Since VMs are black boxes, we cannot use any workload-specific metric in production. Instead, our deployed system measures how long and how hard VMs are being capped. The data shows that our system is successful at protecting production user-facing VMs, while prioritizing the VMs that do get throttled.

Increasing rack density with per-VM capping. While deploying our system, we learned that Azure was installing fewer servers per rack when deploying a new generation of power hungrier servers. Having fewer servers per rack reduces the probability that the rack power draw will hit the provisioned limit and cause capping using RAPL. With our

per-VM capping system in place, Azure can increase the number of servers per rack. *This is another type of power oversubscription that per-VM capping enables.*

Shutting down VMs. Some first-party customers indicated that they would prefer their VMs to be shut down rather than throttled, as their services can handle losing VMs but an unpredictable impact due to throttling is not acceptable. Under extreme power draws, shutting down these customers' VMs can help protect production user-facing VMs and throttle fewer non-user-facing ones. We will soon add this capability to our system.

Server support for per-VM management. Our production experience has highlighted the drawbacks of managing VM power per-component (e.g., core, uncore, memory). We expect that cloud providers would prefer to raise the level of abstraction from individual components to entire VMs, even if VM power would have to be approximated. This would enable advances that have been too complex for production use, such as power-aware VM placement, enforcing per-VM power limits, and making throttling and shutting down decisions based on VM power. We are working with silicon vendors towards this end.

6 Related work

Our paper is *the first to use ML predictions for increasing power oversubscription in public cloud platforms*. Next, we discuss some of the most closely related works.

Leveraging predictions. Some works predict resource demand, resource utilization, or job/task length for provisioning or scheduling purposes, e.g. [7, 9, 13, 20, 23, 37]. In contrast, we introduce a new algorithm and ML models for predicting workload type and high-percentile utilization, seeking to protect critical workloads from capping and place VMs in a criticality- and capping-aware manner.

Server power capping. Most efforts have focused on selecting the DVFS setting required to meet a tight power budget as applications execute, e.g. [16, 19, 21, 22, 26, 29–31, 34, 36, 45]. Both modeling/optimization and feedback techniques have been used. The inputs to the selection have been either application-level metrics (e.g., request latency), low-level performance counters, or operator annotations (e.g., high priority application). Our capping controller uses per-core DVFS and feedback, so it adds to this body of work. However, it also uses predictions about the VMs' performance-criticality as its inputs. Our approach seems to be the best for a cloud platform, since criticality information and application-level metrics are typically not available, and collecting and tracking low-level counters at scale involves undesirable overhead.

Controlling CPU bandwidth (or utilization) to cap server power has also been studied [8, 27]. Reducing CPU bandwidth allows cores to go into sleep states. This approach is complementary and can be used in conjunction with per-core DVFS in our server power capping system.

Cluster-wide workload placement/scheduling. Many

works select workload placements to reduce performance interference or energy usage, e.g. [5, 6, 11, 35, 41, 44]. Unfortunately, they are often impractical for a cloud provider, relying on extensive profiling, application-level metrics, short-term load predictions, and/or aggressive resource reallocation (e.g., via live migration). Live migration is particularly problematic, as it retains contended resources, may produce traffic bursts, and may impact VM availability; it is better to place VMs where they can stay. Our scheduler uses predictions in VM placement. Unlike prior work, it reduces the number and impact of capping events, and increases power oversubscription.

Datacenter oversubscription. Researchers have proposed to use statistical oversubscription, where one profiles the aggregate power draw of multiple services and deploy them to prevent correlated peaks [12, 14, 18, 38, 42]. Our work extends these works by using predictions to place the workload, inform capping, and increase oversubscription. Our oversubscription strategy is also the first to carefully control the extent and impact of capping on important cloud workloads. Also, unlike [38], it does not affect workload availability.

Others have studied hierarchical capping in production datacenters [12, 18, 43]. Our paper focuses on chassis-level power budget enforcement to make our experimentation easier. However, our techniques extrapolate directly. For example, for row-level budget enforcement, we can place VMs across rows trying to balance rows and servers.

Finally, researchers have proposed using energy storage to shave power peaks in oversubscribed datacenters [15, 24]. When peaks last long, this may require large amounts of storage, which our work does not require. Nevertheless, the two approaches are orthogonal and can be combined.

7 Conclusions

We proposed prediction-based techniques for increasing power oversubscription in cloud platforms, while protecting important workloads. Our techniques can increase oversubscription by $2\times$. We discussed lessons from deploying our techniques in production. We conclude that recent advances in ML and prediction-serving systems can unleash further innovations in cloud resource provisioning and management.

Acknowledgements

We thank the reviewers and our shepherd, Avani Wildani, for helping us improve this paper. We also thank Tristan Brown, Jayden Chen, Cheng Chi, Eric Lee, Roberto de Oliveira, Sudharssun Subramanian, and Brijesh Warriar for their suggestions and help in deploying per-VM capping in production.

Abstract

Energy-aware app adaptation enables mobile apps to dynamically adjust data fidelity such as streaming video quality to meet a user-specified goal for battery duration. Traditional energy-aware app adaptation is reactive in nature where the operating system monitors the app energy drain and signals the app to adapt upon detecting energy drain deviation from the pre-specified energy budget which can cause high oscillation and poor quality-of-experience (QoE).

In this paper, we observe that modern power-hungry apps such as video streaming and offloading-based apps already come with sophisticated app adaptation to deal with resource changes such as network dynamics and propose proactive energy-aware adaptation where the user-specified energy budget is integrated with the app adaptation logic. The potential benefit of such an approach is that app energy drain adaptation is no longer an “after-effect”, and hence the approach is likely to reduce the oscillation in app adaptation and improve the app QoE.

In this paper, we study the design, implementation and performance tradeoffs of reactive and proactive energy-aware app adaptation in the context of one of the most power-hungry classes of mobile apps, ABR-based video streaming. Our study shows that proactive energy-aware ABR video streaming is easy to implement by leveraging the built-in adaptation of modern apps and can improve the QoE of reactive approach by 44.8% and 19.2% in streaming 360° videos to Pixel 2 and Moto Z3 phones under low power budget.

1 Introduction

For enriched user experience, modern mobile apps utilize a large number of power-hungry hardware components such as the CPU, GPU, WiFi and 4G, and hardware decoder and as a result draw significant amount of power. As a result, the user experience of such feature-rich apps is often limited by the shortened battery life from increased power draw [7, 8].

Energy-aware app adaptation [31, 88] exploits a key observation that many apps can reduce their power draw by reducing their data fidelity such as the size and quality of a video in video streaming apps or the filtering level of a map in navigation apps, and enables apps to dynamically adjust their data fidelity to meet a user-specified goal for battery duration, *e.g.*, a four-hour plane ride.

There are two components in building an energy-aware app adaptation system: energy accounting and control. First, an energy accounting subsystem is needed to monitor the

energy drain during the app execution and detect any significant deviation, *e.g.*, exceeding a threshold, from the user-specified energy budget. Second, the app needs to implement some adaptation logic to stay within the energy drain budget or correct energy drain deviation.

Traditional energy-aware app adaptation schemes such as PowerScope [31], ECOSystem [88], Cinder [68], and Nemesis [62] have mainly focused on system-level energy accounting and control, treating the app as a “black-box”. In particular, in such systems, the operating system (OS) monitors the app energy drain during app execution, and upon detecting energy drain deviation from the pre-specified budget either throttles the execution of the app process or threads or issues an upcall to the app to trigger app reactive adaptation. The benefit of such a black-box approach is simplified app implementation, as real-time energy accounting is provided as an OS service. The downside of such an approach is that the disintegrated and reactive nature prevents jointly optimizing the app QoE and meeting the energy drain budget. In particular, correcting energy drain deviation as an after-effect can lead to app fidelity oscillation and negatively affect the QoE.

In this paper, we make a key observation that compared to the mobile apps studied two decades ago [31], mobile apps today not only are more power hungry, but also often come with sophisticated adaptation built in to optimize the user-perceived QoE in reaction to network dynamics or other system constraints. For example, fidelity adaptation such as adaptive bitrate (ABR) is now widely adopted in video streaming systems [15, 38, 45–47, 54, 59, 61, 65, 69, 72–74, 76, 83, 85], and adaptive offloading of computation to edge servers has been proposed for deep learning enhanced tasks such as video analytics [21, 37, 51, 57, 66].

We argue that the built-in QoE optimization frameworks in such modern mobile apps naturally lend themselves to *integrated, proactive* energy-aware app adaptation where the energy drain budget is seamlessly integrated into the pre-existing QoE adaptation as a constraint. The key benefit of such an integrated, proactive approach is that app energy drain adaptation is no longer an after-effect and hence likely to reduce the oscillation in app adaptation and improve the app QoE. Compared to the reactive approach, the integrated approach faces two design challenges: (1) the app needs to predict the power consumption for each adaptation candidate beforehand, and (2) the app needs to incorporate the energy budget into its QoE optimization logic.

In this paper, we study the design, implementation, and performance tradeoffs of reactive and proactive energy-aware

app adaptation in the context of one of the most power-hungry classes of mobile apps, ABR-based video streaming [41,79,87,89]. We focus on a state-of-the-art ABR scheme, Robust MPC [85], that employs receding horizon control [19] to maximize the QoE for the next few video chunks based on the predicted network throughput in the moving horizon of video chunk downloading intervals.

We design ENERGY-AWARE ABR, an energy-aware ABR video streaming system to demonstrate how to address the two challenges in designing proactive energy-aware app adaptation. First, proactive energy-aware app adaptation requires a power predictor that can *predict* the average power draw of the streaming app in the next time interval in fetching a chunk of any candidate chunk quality. Traditional mobile device power models [22,23,26,70,87,91] cannot be used as they take component utilization logged as input which are not available *before* app execution. We propose a novel function-level power modeling methodology that accurately predicts the app energy drain in the next interval.

Second, integrating an energy budget into the app adaptation logic, in particular, the model predictive control (MPC)-based QoE optimizer for MPC-based ABR, faces a unique challenge. Unlike other constraints such as network throughput in the QoE optimization problem, *app energy drain is cumulative and hence elastic over time*. At any time interval during a streaming session, the app may have accumulated energy drain surplus or deficit from past time intervals, *e.g.*, from selecting low chunk formats limited by transient low network bandwidth. We explore several design options on how to integrate such energy surplus/deficit with the QoE optimization framework of MPC-based ABR controllers.

Since MPC-based controllers are notoriously hard to analyze [17,34,67], we evaluate the end-to-end performance of reactive and proactive energy-aware ABR video streaming designs using testbed experiments. We have implemented both designs on top of Puffer [11], an open-sourced video streaming platform, and evaluated different design options by streaming 360° videos from a media server to a mobile client, while varying the network condition using network traces from two large datasets, YTrace and FCC [4].

Our evaluation results show that (1) Our function-wise power predictor achieves low mean per-interval (2-second) energy prediction error of 4.87% (Pixel 2) and 5.86% (Moto Z3). (2) Under dummy power budget, *i.e.*, using the average power draw of the energy-oblivious ABR as the power budget, both proactive and reactive ENERGY-AWARE ABR achieve only slightly lower QoE than that of the energy-oblivious ABR, with proactive ENERGY-AWARE ABR achieving slightly higher QoE than reactive ENERGY-AWARE ABR. (3) Under low power budget, proactive ENERGY-AWARE ABR improves the QoE by 44.8% (Pixel 2) and 19.2% (Moto Z3) over reactive ENERGY-AWARE ABR. (4) The majority of the improvement comes from significantly reduced video quality variation component of the QoE, of 85.2% (Pixel 2) and 87.4% (Moto Z3), showing that

proactive ENERGY-AWARE ABR can effectively mitigate the oscillation drawback of reactive energy-aware adaptation.

In summary, this paper makes the following contributions:

- We show prior reactive energy-aware app adaptation can lead to app fidelity oscillation which can negatively affect user-perceived QoE.
- We propose to our knowledge the first proactive energy-aware app adaptation and show that it can be easily implemented by integrating user-specified energy budget with the built-in app adaptation logic of modern apps such as MPC-based ABR systems for video streaming.
- We present a novel function-wise power predictor that can be used for what-if power draw analysis needed in proactive energy-aware app adaptation, *e.g.*, ENERGY-AWARE ABR.
- We experimentally compare the end-to-end performance of reactive and proactive energy-aware adaptive streaming of 360° videos on Pixel 2 and Moto Z3 phones.
- Our results show proactive energy-aware video streaming improves the QoE by 44.8% (Pixel 2) and 19.2% (Moto Z3) over the reactive approach under low power budget.

To further the research on energy-aware app adaptation, we have open-sourced ENERGY-AWARE ABR implementation.¹

2 Motivation

To motivate how energy-aware adaptation can help to reduce app power draw and elongate battery duration, we performed a measurement study of one of the most power-hungry classes of apps, video streaming, with example apps such as Youtube and Netflix consistently ranked among the top 10 battery draining apps [8,12,13].

Experimental Setup. We streamed 6 popular panoramic videos in full screen mode in the Youtube app on a Pixel 2 phone, which was connected to a Monsoon power monitor to measure the total phone power draw during video streaming. The videos were categorized into 3 groups, slow, medium and high, based on the moving speed of the camera. Each video was encoded into different resolutions and frame rates, including (4K, 60FPS), (1440p, 60FPS), (1080p, 60FPS), (720p, 60FPS), (480p, 30FPS) and (360p, 30FPS). Table 1 shows the bitrates of the videos at different quality settings.

We streamed each video in Youtube at different qualities with and without screen on, respectively. When the screen was on, the brightness level was set at 60%. To prevent the app from directly retrieving video frames from the cache rather than through the Internet, we cleared the cache of Youtube app on the phone before each experiment.

To understand the power breakdown of 360° video streaming, we built component-wise power models [22,26,44,75,

¹<https://github.com/meng72/Proactive-Energy-Aware-Adaptive-Video-Streaming>

Table 1: Average bitrate (Mbps) of 6 panoramic videos at different resolutions and frame rates from Youtube.

Videos	4K/60	1440p/60	1080p/60	720p/60	480p/30	360p/30
Slow						
Planets [1]	18.10	6.20	2.06	1.01	0.35	0.19
Solar [6]	22.10	5.38	1.70	0.76	0.22	0.10
Medium						
Orleans [5]	25.70	12.00	3.72	2.13	0.61	0.33
Chicago [9]	25.60	10.60	3.41	1.93	0.58	0.31
High						
Monster [2]	26.20	12.60	4.20	2.49	0.71	0.39
Optical [10]	24.40	12.60	4.16	2.47	0.71	0.39

81, 87] for major hardware components in the Pixel 2 phone, profiled hardware component usage while streaming 360° videos at (4K, 60FPS) in Youtube on Pixel 2, and finally estimated the corresponding power draw for each hardware component using the power models.

Findings. Figure 1 shows the average power consumption of streaming the 6 panoramic videos at different quality settings over the Internet in Youtube. We derived the screen power by subtracting the total power of video streaming when the screen was off from that when the screen was on. We see that (1) 360° video streaming is power-intensive on modern mobile devices. Streaming videos at (4K, 60FPS) consumes the highest total power of 579.73mA.² At this rate, a fully charged Pixel 2 phone (with a 2700 mAh battery) will drop to 15% in 3 hours and 40 minutes when the Battery Saver mode will turn on. (2) Thanks to the OLED technology, the power consumption of the display is relatively small, only 41.66–50.36mA, or 7.0%–12.0% of the total power across different settings. (3) Reducing the data fidelity, *i.e.*, the video resolution and frame rate, can significantly lower the total app power draw. For example, the total power draw decreases by 33.1% from 579.73mA to 387.79mA when the video quality changes from (4K, 60FPS) to (360p, 30FPS).

Figure 2 shows the power breakdown of streaming 360° videos at (4K, 60FPS). We see that (1) the CPU, GPU and screen consume relatively low power, of 82.11mA (14.0%), 74.49mA (12.7%) and 46.92mA (8.0%), respectively; (2) in contrast, the NIC (network interface card) and hardware decoder, two primary hardware components involved in video streaming, dominate the total power draw of streaming, *i.e.*, 220.53mA (37.6%) and 162.47mA (27.7%), respectively. These results suggest that adapting the data fidelity of video chunks to control the power draw of networking and decoding will be effective in controlling the total power draw of the app.

3 Prior Work on Energy-aware App Adaptation

The large body of research on managing the energy drain of applications on mobile systems has mainly focused on

² In this paper, for power measurement we directly report the current drawn in milli-Amperes (mA); the actual power consumed would be the current drawn multiplied by 3.7V, the voltage supply of the battery. The smartphone batteries are rated using these metrics and hence are easy to cross reference.

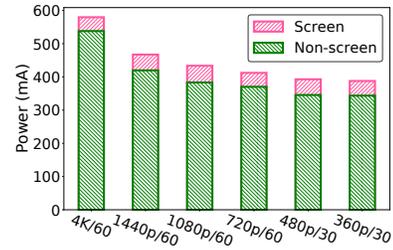

Figure 1: Average power consumption of streaming 360° videos with different qualities in Youtube on Pixel 2.

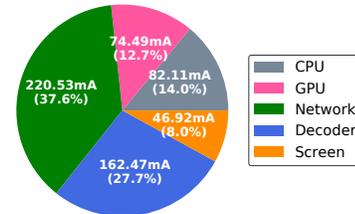

Figure 2: Power breakdown of streaming 360° videos at 4K/60FPS on Pixel 2.

system-level energy accounting and control, treating the app as a “black-box”.

Since managing the energy drain of apps requires accurately monitoring the energy drain during application execution, a large body of work proposed solutions to the resource container-level, process-level, or thread-level energy accounting problem in the OS, such as PowerScope [32], ECOSystem [88], Cinder [68], and Nemesis [62]. In a nutshell, energy accounting in these systems is achieved via either aligning external power measurement with interrupt-triggered program sampling as in early systems such as PowerScope [32] and Quanto [33], or using a pre-trained power model that captures the correlation between utilization of each hardware component in each of its power states and the resulting power draw and feeding the power model with hardware component usage logged during app execution to estimate the app energy drain, *e.g.*, in ECOSystem [88] and Cinder [68].

Upon detecting that an app’s energy drain has exceeded a predetermined budget, the system needs a way to throttle the app’s energy drain. In ECOSystem [88], Currentcy [88], and Cinder [68], the kernel would enforce energy budget by halting or throttling app threads, processes, or resource containers from execution. The Odyssey extension [31] and Nemesis [62] do not throttle applications, but issue upcalls or provide feedbacks to the applications to trigger fidelity adaptation to adjust their energy drain rate.

4 Reactive vs. Proactive Energy-aware App Adaptation

We discuss the drawbacks of prior reactive energy-aware app adaptation and propose proactive energy-aware app

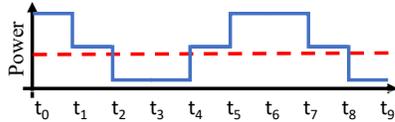

Figure 3: Reactive approach causes power oscillation.

adaptation.

Reactive energy-aware app adaptation. The prior system-level app energy control solutions are *reactive* and *disintegrated*. They are reactive because they treat applications as black-boxes and passively monitor their energy drain, and inform apps of the need to perform adaptation reactively upon detecting any deviation of the app energy drain from the pre-specified budget. They are disintegrated because the two tasks are performed in isolation: the OS monitors the app energy drain while the app performs adaptation.

The benefit of such a reactive approach is simplified app implementation, as real-time energy accounting can be provided as an OS service and the apps can focus on reactive adaptation, although fine-grained model-based energy monitoring relies on collecting fine-grained hardware component usage which can incur high runtime overhead.

The downside of a reactive approach is that the disintegrated and reactive nature deprives the opportunity of jointly optimizing the app QoE and meeting the energy drain budget at each time interval. In particular, the app not only performs adaptation *after* deviating from the energy drain target, but also typically does not have specific guidance on *how much* app fidelity to adapt in the next time interval, which can result in power draw and app fidelity oscillation.

Figure 3 shows an example of how the power draw of a disintegrated, reactive app adaptation scheme can cause oscillation in app power draw. Assume an app has three fidelities, high, medium, and low, drawing correspondingly high, medium, and low power. An energy-aware OS like Odyssey [31] tries to steer the app towards a target power budget specified in the dashed line to ensure a target battery duration. The app starts running in high fidelity, drawing high power. At t_1 , the OS performs an upcall informing the app of an energy drain deficit, and the app lowers the fidelity to medium. At t_2 , the OS informs the app of energy drain deficit again as the average power is still above the budget, and the app lowers the fidelity to low. The trend reverses in the next three intervals, and the oscillation would continue as a result of the reactive correction without concrete guidance on app adaptation due to the disintegrated approach.

Proactive energy-aware app adaptation. Our proposal of proactive energy-aware app adaptation is motivated by the above drawbacks of the reactive approach and an observation about modern mobile apps. Compared to the mobile apps studied two decades ago (e.g., [31]), mobile apps today are more power hungry, but also often come with sophisticated proactive adaptation built in to optimize the user-perceived

QoE under network dynamics or other system constraints. For example, proactive fidelity adaptation such as adaptive bitrate (ABR) (e.g., DASH) is now a standard feature in regular video streaming systems [15, 45, 46, 54, 59, 61, 72, 73, 76, 83, 85] as well as 360^o video streaming systems [38, 47, 65, 69, 74]. Similarly, adaptive offloading of computation to an edge server according to the network dynamics has been proposed in many systems [21, 37, 51, 57, 66]. More recently, adaptive offloading of machine learning inference has been proposed to adaptively offload a subset of DNN layers from the mobile device to the edge server [30, 49, 52, 92].

Motivated by the above two observations, we argue that the built-in QoE optimization frameworks in many modern mobile apps lend themselves to integrated, proactive energy-aware app adaptation that potentially overcomes the oscillation drawback of reactive approaches. In such an approach, at every step of the QoE optimization for selecting the quality of the chunk to be fetched in the next time interval, the power budget is explicitly taken into consideration so that the QoE optimization will directly output the optimal chunk format that maximizes the QoE for the next chunk and satisfies the energy budget in the next interval.

The key benefit of such an integrated, proactive approach is that app energy drain adaptation is no longer an after-effect correction and hence likely to reduce the oscillation in app adaptation. The challenge of such an approach is that each app needs to (1) predict the power consumption for each adaptation candidate beforehand, and (2) incorporate the energy budget in its QoE optimization logic.

In this paper, we investigate the design and performance tradeoffs of reactive and proactive energy-aware app adaptation in the context of one of the most power-hungry classes of mobile apps – ABR-based video streaming.

5 Energy-aware ABR

We briefly review state-of-the-art ABR algorithms and state the energy-aware QoE maximization problem.

Background on ABR. Adaptive bitrate (ABR) algorithms embody a primary technique of streaming videos over the Internet [71], where each video is encoded into multiple "tracks" with different quality bitrates and each track is segmented into "chunks" (e.g., 2-second each). These algorithms aim at optimizing the video QoE by dynamically selecting which chunk to fetch based on network conditions. Earlier ABR schemes were either "buffer-based" [45, 73], or "rate-based" which pivot on estimating available network throughput and finding a matching video bitrate [46, 76]. MPC [85] unifies the QoE objective of chunk k as a weighted sum of three key elements, (1) video quality, (2) video quality variation, and (3) stall time:

$$QoE_k = Q_k - \lambda|Q_k - Q_{k-1}| - \mu T_k \quad (1)$$

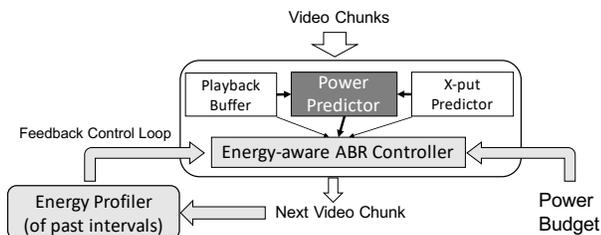

Figure 4: Architecture of energy-aware ABR. Lightly shaded components are new to both reactive and proactive designs, and the dark shaded one is new to the proactive design.

where Q_k represents the quality of video chunk k , T_k represents the stall time experienced by fetching chunk k and λ , and μ are weighting parameters for quality variation and rebuffering, respectively. Some papers (e.g., [85]) quantify Q_k as the bitrate of chunk k , while others (e.g., [83]) use perceptual quality metrics, e.g., SSIM [77]. The ABR problem is then formulated as maximizing the QoE of all the chunks of a video downloaded in a streaming session:

$$\text{maximize } \sum_k QoE_i, \text{ subject to buffer and network dynamics} \quad (2)$$

Since future throughput is unknown, practical algorithms like Robust MPC [85] employ receding horizon control [19] to maximize the QoE for the next few chunks (e.g., 5 future chunks). Such algorithms take estimated network throughput for the next few intervals and client playback buffer occupancy as input and output the quality format for the next video chunk to be downloaded from the server while maximizing the QoE of next few chunks.

Energy-aware QoE maximization problem. We consider the canonical energy-aware app adaptation scenario in previous work [31, 68, 88], where the phone user specifies the total energy budget E_b (e.g., 50% of batter level drop) over a fixed amount of time T_d (e.g., duration of a train ride) and hence an average power target $P_b = E_b/T_d$. The energy-aware ABR problem is then formulated as maximizing the QoE of all the chunks of a video downloaded in a streaming session:

$$\text{maximize } \sum_k QoE_i, \text{ subject to buffer and network dynamics} \\ \text{and total energy constraint} \quad (3)$$

Energy drain is elastic. We note that in the above problem statement, the energy constraint is different from other constraints like network throughput in that *app energy drain is cumulative and elastic over time*. Since the user-specified energy budget is the total energy drain over a streaming duration, the streaming app may accumulate some surplus or deficit based on the energy drain so far during the streaming session. For example, due to network bandwidth fluctuation, there can be intervals during which the network bandwidth is low and the ABR algorithm is forced to pick low video

Algorithm 1: Reactive Energy-Aware ABR – RA

Input : Power budget P_b ; Energy draw E_{actual} over streaming time so far T ; Selected format F_{k-1} for interval $k-1$; Average interval duration t

Output: Format F_k for next interval k

// if energy deficit, downgrade format

if $E_{actual} - P_b T > \gamma P_b t$ **then**

$F_k = \min(F_{k-1} - 1, \text{predicted format by ABR});$

else $F_k = \text{predicted format by ABR};$

quality formats which result in low power draw and hence low energy drain during those intervals. In such intervals, the app effectively accumulates an energy surplus, which can be spent in later intervals, i.e., when the network bandwidth is high and high quality video chunks can be downloaded and played, to improve the total QoE.

6 Reactive Energy-Aware ABR Design

A reactive energy-aware ABR can be easily implemented by adding an energy profiler and adding reactive adjustment to the QoE optimizer output of the ABR controller, as shown in Figure 4. The energy profiler monitors the app energy drain and is decoupled from the ABR controller, either implemented in the OS as in [36, 63, 86] or in an app-agnostic library linked with the app. It sends an upcall to the ABR player either reactively upon detecting significant deviation of the predetermined energy budget or periodically to inform the app of its energy drain so far which is used by the ABR controller to monitor the energy surplus or deficit and to decide when and how to adapt. We assume the later approach which gives the ABR controller more flexibility.

In particular, the ABR controller accumulates a running energy drain balance as the difference between the expected energy drain so far $P_b \cdot T$ and the actual energy drain E_{actual} so far which is monitored by the energy profiler.

The goal of the reactive adjustment is to adjust the chunk format selected by the ABR QoE optimizer to try to correct the energy drain deviation from that according to the pre-specified average power budget. To achieve this, the final chunk quality format is adjusted as no higher than the previous chunk format if there is an energy deficit greater than a threshold, as shown in Algorithm 1. We experimentally found a threshold of 10% of the energy budget to work well.

7 Proactive Energy-aware ABR Design

7.1 Integrated Energy-aware MPC Algorithm

Since an MPC-based ABR algorithm is proactive by nature, i.e., it calculates the video chunk quality to be fetched next based on the predicted network throughput in the next time interval, a proactive energy-aware ABR can be naturally realized by integrating the energy constraint with a practical

MPC algorithm such as Robust MPC [85]. In particular, the new energy-aware MPC algorithm optimizes the worst-case QoE assuming that the throughput in the future can take any value in range $[\hat{C}_t, \hat{C}'_t]$, by solving the following optimization problem at time t_k to derive the quality format for fetching the next chunk $F_k = f_{\text{empc}}(F_{k-1}, B_{k-1}, \hat{C}_t)$:

$$\max_{F_k, \dots, F_{k+N-1}} \min_{\hat{C}_t \in [\hat{C}_t, \hat{C}'_t]} \sum_k^{k+N-1} QoE_i$$

subject to buffer and throughput dynamics and

$$E_k + \dots + E_{k+N-1} < N \cdot P_b \cdot \delta t \quad (4)$$

where \hat{C}_t is the low bound in the predicted throughput range $[\hat{C}_t, \hat{C}'_t]$, B_{k-1} is the buffer occupancy after downloading chunk $k-1$ and δt is the interval duration, e.g., 2 seconds.

We note that since app energy drain is cumulative, converting the total energy constraint into a constant energy constraint per time interval can be conservative. As with MPC [85], we do not claim this energy-constrained MPC is necessarily the optimal control algorithm for the energy-constrained bitrate adaptation problem, but one that is practical and can leverage accurate network throughput prediction and power draw prediction in the near horizon.

7.2 Architecture Overview

Figure 4 (adding the power predictor) shows the architecture of our proposed integrated, proactive ENERGY-AWARE ABR. As with the original ABR, ENERGY-AWARE ABR derives the client-side playback buffer status and estimated network throughput from two generic modules of ABR, the playback buffer module and throughput predictor module, respectively. The energy profiler module estimates the energy drain in past intervals which is used to maintain the energy surplus/deficit.

To select the video format for the next video chunk, ENERGY-AWARE ABR uses a new power predictor to predict the average power draw of the next video chunk of each candidate format. Its controller then filters out the formats whose predicted energy drain exceeds the energy budget adjusted for energy surplus or deficit so far and chooses the one that maximizes the QoE stated in Equation 1.

The proactive ENERGY-AWARE ABR system design faces two challenges: (1) how to predict the power consumption in fetching future video chunks of different candidate formats in the power predictor? (2) how to incorporate the energy constraint into the MPC algorithm in the ENERGY-AWARE ABR controller to facilitate maximizing the QoE for the future chunks? We start with discussing our solution to (2).

7.3 Energy-aware QoE Maximization

The basic design for incorporating the expected energy drain for the N future intervals in Eqn. 4 is straight-forward. To exploit dynamic energy surplus/deficit, the ENERGY-AWARE

Algorithm 2: Design option 3 – LA(N)+LB

Input :Power budget P_b ; Energy draw E_{actual} over streaming time so far T ; Energy surplus/deficit $E_s = P_b T - E_{\text{actual}}$; Current buffer level B_{k-1} ; Predicted power array $P_k[f][N]$ for all the formats from next interval k to interval $k+N-1$; Interval duration δt

Output: Format F_k for next interval k

Call recursiveABR(0, 0, B_{k-1} , 0) to derive F_k ;

Function recursiveABR($n, F_{k+n-1}, B_{k+n-1}, E$):

```

if  $n == N$  then
  if  $E > N \cdot P_b \cdot \delta t + E_s$  then return  $-\infty$ ;
  else return Quality of  $F_{k+n-1}$ ;
end
 $\max\_QoE = -\infty$ ;
for  $i = 0$  to  $f$  do
   $q = \text{QoE between chunk } n \text{ and } n+1$ ;
   $B = \text{Buffer level after downloading chunk } n+1$ ;
   $E' = E + P_k[i][n] \cdot \delta t$ ;
   $Q = q + \text{recursiveABR}(n+1, i, B, E').\text{QoE}$ ;
  if  $Q > \max\_QoE$  then
     $F_{k+n} = i$ ;  $\max\_QoE = Q$ ;
  end
end
return  $\langle \max\_QoE, F_{k+n} \rangle$ 

```

ABR controller accumulates the energy surplus/deficit as in the reactive approach, which is then exploited by the QoE maximization module to maximize the QoE of future video chunks. We explore three design options for incorporating energy surplus/deficit into the QoE maximization.

(1) **Look ahead 1 (LA(1))**. The strawman design is to ignore energy surplus/deficit, and choose among all the candidate chunk formats with which the predicted app power draw in the next interval will not exceed the average power budget P_b , the one that maximizes the total QoE for the horizon (e.g., 5 intervals). Such a design can be conservative in terms of QoE from not exploiting potential energy drain surplus accumulated in the past intervals when the network bandwidth fluctuates up and down.

(2) **Look ahead 1 and look back (LA(1)+LB)**. Design option 2 extends LA(1) by exploiting the amount of energy surplus/deficit during past intervals. In selecting the video format for the new video chunk to fetch, the controller increases the energy budget for the next interval to $P_b \cdot \delta t + E_s$ (energy surplus/deficit). However, such a design may sacrifice video smoothness, as the energy surplus from past intervals may be large and allow some high quality chunk to be fetched in the next interval, followed by video chunks that go back to some low format.

(3) **Look ahead N and look back (LA(N)+LB)**. To overcome the potential smoothness problem of LA(1)+LB, we extend it by allowing the energy surplus/deficit and the N -chunk energy budget to be spread over the next N chunks. Since the basic MPC already looks ahead N chunks in pick-

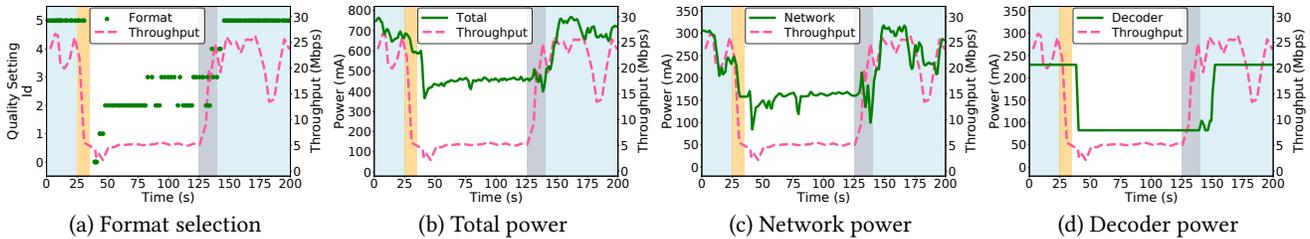

Figure 5: Network throughput, ABR decision, total and individual hardware component power in different network states (**H**: blue; **L**: white; **H-L**: orange; **L-H**: gray). Quality setting: 5: (4K, 60 FPS); 4: (1440p, 60 FPS); 3: (1080p, 60 FPS); 2: (720p, 60 FPS); 1: (480p, 30 FPS); 0: (360p, 30 FPS). The client buffer size is 7s, the same as 4K streaming on Youtube mobile app stated in §9.

ing the next chunk k to optimize the total QoE for them, allowing spreading the energy surplus over the N chunks can be easily incorporated in the modified MPC. In particular, Algorithm 2 adds the total energy $N \cdot P_b \cdot \delta t + E_s$ as the total energy constraint to the dynamic programming which will search among all possible ways to spread the energy surplus among the N intervals to find the one that gives the maximal total QoE for the N intervals. As in the basic MPC, optimizing the total QoE for the next N intervals will take smoothness in the next N chunks into consideration.

7.4 Function-wise Power Prediction

We next describe a practical and accurate function-wise power prediction methodology for use with any proactive energy-aware ABR adaptation such as ENERGY-AWARE ABR.

7.4.1 Why Function-wise Power Prediction?

The obvious choice of using traditional component-wise power models for mobile devices which have been well studied [22, 23, 26, 29, 44, 64, 70, 75, 81, 87, 91] does not work. Such a model derives the correlation between the utilization of each phone component in each of its power states, *e.g.*, utilization and operating frequency, and the resulting power draw using carefully designed microbenchmarks. To use such a model, the hardware component usage is logged *during* app execution and afterwards fed into the power model as input to estimate the component-wise power draw that happened during the app execution. Thus such traditional power models are *postmortem*; they are suitable for post-processing, *e.g.*, monitoring the actual energy drain of a past interval (or calculating the energy surplus/deficit) in reactive or proactive energy-aware app adaptation, but not for predicting the app energy drain in future intervals.

The other design choice is to treat the video streaming app as a black-box and measure and tabulate its average power draw offline when streaming all possible video bitrates under all possible network bandwidth. However, this is not practical as there are potentially infinite number of such combinations. More importantly, such an approach cannot easily model the power draw of *asynchronous component behavior* discussed below where different phone components, *e.g.*, the decoder and the network interface, can be processing different video

chunks (of different bitrates) in a time interval, due to the playback buffer delay effect explained below.

Asynchronous Component Behavior. To illustrate the asynchronous component power behavior in video streaming, we profile the component power draw in an ABR-based 360° video streaming session.

Our experimental setup is the same as in §2 except two differences for enabling power profiling of phone components. First, we build our own ABR server for 360° video streaming with Robust MPC [85] as the default ABR algorithm, and implement our own mobile client using ExoPlayer [3]. Second, we derive the traditional component-wise power model for our experimental phone, Pixel 2, by running microbenchmarks and measuring the phone power draw using an external high-resolution Monsoon power monitor.

Figure 5 shows the profiling result. We see that the network bandwidth went through five stages: high (the H stage), high transitioning to low (the H-L stage), low (the L stage), low transitioning to high (the L-H stage), and finally high again. Figure 5a shows that the network bandwidth change causes the chunk format selected to change almost immediately, *e.g.*, from format 5 during the H stage dropping to format 1 during the H-L stage. However, Figure 5b shows that there is a lag of the total power draw change in following the network bandwidth change, mostly notably at 25-40s and 130-150s. To understand this lag, we zoom into the per-component power draw timeline.

The lag cannot be explained by the CPU and GPU power, both staying almost constant during the session (not shown due to page limit) regardless of the chunk format because of their constant load. The lag also cannot be explained by the network interface (NIC) power which, as shown in Figure 5c, is directly affected by the chunk format and closely follows the format change, *e.g.*, during the H stage and the L stage. In the L-H stage, the NIC power first goes up due to chunk size increase but then goes down as it spends an increasing fraction of the 2-second interval in the idle state as the network bandwidth goes up sharply.

Finally, Figure 5d shows that although in general the hardware decoder power in the H stage is higher than in the L stage because the chunk format and hence decoding load are higher in the H stage, the change of the decoder power

shows a prominent delay behind the network bandwidth change, e.g., when the network bandwidth drops sharply around 24-40s and increases sharply around 130-150s. This explains the lag of the total power draw curve behind the network bandwidth curve. This happens due to the *buffer delay effect* which results in asynchronous power behavior of phone components: while the NIC is downloading the next chunk (e.g., in a low format), the decoder decodes the video chunk at the head of the playback buffer (e.g., in a high format) which was downloaded several intervals ago. The extent of the delay depends on the occupancy of the client buffer as well as network throughput.

7.4.2 Function-wise Power Prediction

The above asynchronous hardware component power behavior suggests that if we cluster the hardware components according to the common video chunk they process at each time interval, the components within each cluster will have synchronous power behavior, i.e., which only depends on the properties of the chunk they process, and such power behavior can be modeled using a power predictor that only uses chunk properties as input. Semantically, each cluster typically corresponds to a high-level app function. We thus propose *function-wise power prediction* that models the power draw of each high-level app function.

In 360° video streaming, there are two primary tasks: (1) *video decoding and displaying* which employs the CPU, GPU, hardware decoder, screen and game rotation vector sensor to process the same chunk in each time interval; (2) *network transmission* for fetching video chunks which involves the CPU and the network interface to process the same chunk (which is different from in task 1) in each interval. In function-wise power prediction, we build the power predictors for these two functions separately.

For the video decoding and displaying function, we make a key observation that the primary hardware components involved are the GPU and hardware decoder, and their power only depend on video properties such as resolution and frame rate but barely depend on video content (based on our measurements). Thus we should be able to develop a power prediction model using these video properties as input. We model the display power separately as a function of the brightness.³ In particular, we measure the total power draw in playing pre-downloaded 360° videos with the same six quality settings as in §2 using the Monsoon power monitor. In offline processing, the video decoding and displaying function power draw is modeled as a piecewise linear function,⁴ $P_{vid} = P(b, res, fps)$, where b , res and fps represent the screen brightness level, video resolution and video frame rate, respectively.

³We did not use possibly more accurate, content-aware OLED power models [25, 28] as OLED display only draws a small amount of energy (§2).

⁴The hardware decoder power draw behaves as a step function of the resolution and FPS.

Algorithm 3: Smoothing in Energy-aware ABR

Input : Selected format FS_{k-1} for interval $k-1$;
 Format F_k for next interval k selected by reactive or proactive energy-aware ABR;
Output : Final format FS_k for next interval k
if $F_k > FS_{k-1}$ **then** $FS_k = FS_{k-1} + 1$;
else $FS_k = F_k$;

For the network transmission function, we develop a linear model that models the power draw as a function of the down-link throughput and chunk size. We experimentally found that running network microbenchmarks does not capture well the share of CPU usage due to downloading when the whole streaming app is running. Instead, we directly stream 360° videos over the Internet, while logging the inputs to both function-wise prediction models, i.e., application events for each 2-second video chunk, including three video properties (resolution, frame rate, and size), start and end time of network transmission, and start and end time of decoding and displaying. We measure the total phone power draw using the power monitor, and then subtract from it the power consumed by the video decoding and displaying function (estimated using its power prediction model built above) as the power for the network transmission function. Finally, the network transmission function power draw is modeled as $P_{net} = P_{\Delta,net} \times \gamma + P_{base,net}$, where γ is the throughput of fetching the video chunk and $P_{\Delta,net}$ and $P_{base,net}$ are derived from linear regression.⁵

8 Adaptation Smoothing

The baseline reactive adaptation Algorithm 1 can result in significant oscillation in selecting the next chunk format, e.g., under high network bandwidth which allows some high format that exceeds the power budget, followed by switching to some low format to compensate for temporary energy deficit (see Figure 3). A proactive adaptation algorithm like Algorithm 2 will not pick arbitrarily high format due to the fixed per-interval energy budget, but exploiting energy surplus from past low-bandwidth intervals can also result in the controller picking some high format transiently since it can only look ahead N chunks. In both cases, the sudden change in format can reduce the smoothness component of the QoE over time (e.g., beyond the N chunk horizon).

To mitigate this potential effect, we propose a smoothing step that can be applied to both reactive and proactive algorithms: it imposes an incremental increase when the chosen format for the next chunk is much higher than the previous one, as shown in Algorithm 3. Note we cannot impose an incremental decrease when newly chosen format is much lower than the previous one, since such a choice is limited by the network bandwidth.

⁵ Network conditions, e.g., signal strength, are reflected in throughput which is one of the model predictors.

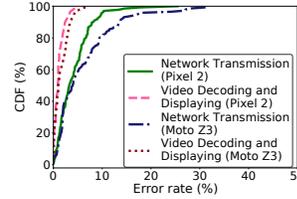

Figure 8: CDF of training accuracy of function-wise power modeling.

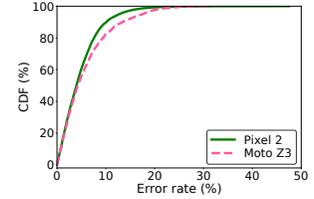

Figure 9: CDF of actual prediction accuracy on Pixel 2 and Moto Z3.

9 Implementation

We implemented the ENERGY-AWARE ABR server on top of Puffer, an open-sourced platform for video streaming [11] in about 1800 lines of C++ code, and built a simple ENERGY-AWARE ABR client that enables 360° video streaming on top of Exoplayer [3] by adding 1.2 KLOC in Java. To save energy on mobile client devices, we implemented both reactive and proactive ENERGY-AWARE ABR on the server side (following [11]). For convenience, we used function-wise power prediction to implement the energy profiler module (using actual throughput) in both types of adaptation schemes and the power predictor module (using predicted throughput) in proactive schemes.

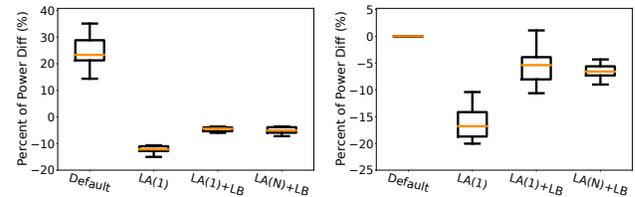

In proactive schemes, the ENERGY-AWARE ABR client checks its buffer occupancy every 0.25 seconds. If it is below the buffer threshold, it reports the current buffer occupancy back to the server. The server then runs the ENERGY-AWARE ABR algorithm to predict the format for the next video chunk, and transmits the video chunk with the selected format to the client. We choose the buffer threshold of 7 seconds based on the observation (using the Youtube built-in tool *stats-for-nerds* [14]) that the Youtube mobile app on the Pixel 2 phone, when streaming 4K 360° videos, requests for the next video chunk when the client-side buffer size is below 7 seconds.

10 Evaluation

In this section, we evaluate the end-to-end performance of reactive and proactive energy-aware ABR streaming players for 360° videos. Our evaluation seeks to answer the following questions: (1) How effective is incorporating energy surplus/deficit in proactive app adaptation? (2) How much does proactive energy-aware adaptation mitigate oscillation and improve QoE compared to reactive approaches? (3) How effective is adaptation smoothing?

10.1 Experimental Setup

We evaluate ENERGY-AWARE ABR performance by streaming videos from a media server to a mobile client, while varying the network condition using network traces from two datasets, YTrace and FCC. We collected YTrace by logging the 2-second average throughput of real users watching 360°

(a) Low power budget

(b) High power budget

Figure 10: Percentage difference between the average power consumption of each streaming session and corresponding power budget for proactive approaches on Pixel 2.

videos on Youtube on mobile devices over around 43200 seconds. FCC [4] is a broadband dataset that has been used in many recent ABR work [15, 59]. Figure 6 shows the distribution of the network throughput of the traces in the two datasets; the average throughput across the traces in the two datasets are 22.89 Mbps and 3.24 Mbps, respectively.

To compare the performance of different ENERGY-AWARE ABR designs under the same network condition, we use the Linux *tc* tool to throttle the throughput along with an 80ms RTT between the server and the client. The video hosting server runs on an Intel i5 2.5GHz processor and runs Ubuntu 18.04. The mobile client streams videos over 802.11n on the Pixel 2/Moto Z3 phones which are connected to a Monsoon power monitor to measure the total phone power draw as the ground truth. Each streaming session lasts for 5 minutes.

The 360° videos chosen from Youtube are characterized into the same three groups as in §2. Each video is segmented into 2-second chunks and encoded into the same six quality settings as in §2. We calculate each encoded video chunk’s SSIM [77] relative to the canonical source as the quality Q_k of the chunk used in the QoE function (Eqn. 1). As the default QoE function, we use the weights $\lambda = 5, \mu = 20$. We also run sensitivity experiments that vary the QoE weights.

We evaluate various streaming approaches under two average power budgets selected as follows. We first stream the 360° videos with the default ABR algorithm without any power constraint, and measure the average power draw of each streaming session and the per-interval average power draw within the same streaming session. Then, for each network trace, we select the 20th-percentile per-interval average power draw as its *low power budget* and the average power draw over the streaming session as its *high power budget* in all our experiments. Figure 7 shows the distribution of the

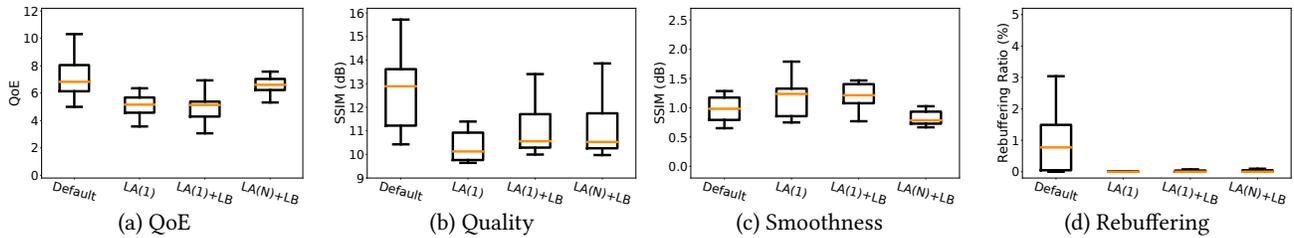

Figure 11: QoE and breakdowns of proactive ENERGY-AWARE ABR under the low power budget on Pixel 2.

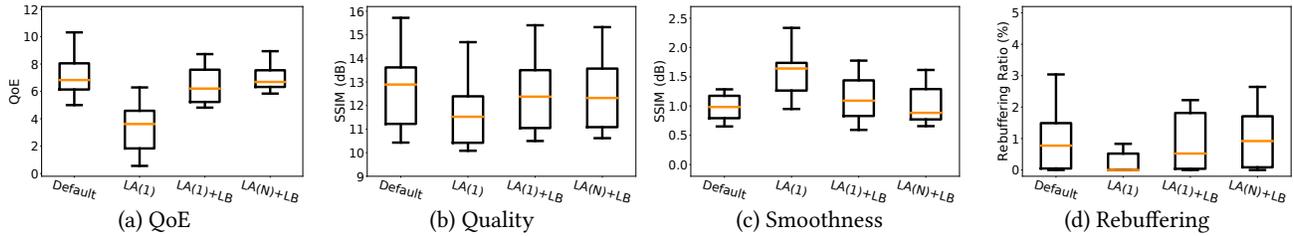

Figure 12: QoE and breakdowns of proactive ENERGY-AWARE ABR under the high power budget on Pixel 2.

two power budgets chosen this way; they vary across the traces of the two data sets. We choose the high power budget in this way to assess the potential penalty of being energy-aware by calculating the performance difference between ENERGY-AWARE ABR and the default ABR.

10.2 Accuracy of Function-wise Power Modeling

We first evaluate the training accuracy of function-wise power modeling for the two functions separately. To train the model for the video decoding and displaying function, we randomly select one video from every video group and play it locally on the Pixel 2 and Moto Z3 phones, respectively. To train the model for the network transmission function, we randomly select 10% network traces from each network dataset and we stream one 360° video for 1.2 hours in total. Figure 8 shows that the average error rate of per-interval power draw in training for the two functions are 4.21% and 1.16% on Pixel 2 and 6.11% and 1.65% on Moto Z3, respectively.

We next validate our power model by comparing the estimated average per-interval power consumption of 360° video streaming against the power monitor readings over 50% of the remaining network traces. Figure 9 shows that function-wise power predictor achieves mean estimation accuracy of 4.87% and 5.86% in estimating the per-interval average power consumption on Pixel 2 and Moto Z3 phones, respectively.

10.3 Proactive Energy-aware ABR

We first evaluate the three designs of proactive ENERGY-AWARE ABR. We focus on Pixel 2; the results for Moto Z3 are very similar and are omitted due to page limit.

Power consumption. Figure 10a shows that for the low power budget, all three proactive designs consume less power than the power budget. The average power consumption for LA(1)+LB and LA(N)+LB are only 4.09% and 4.80% below the given power budget, respectively, suggesting both designs

Table 2: Comparison between reactive and proactive ENERGY-AWARE ABR without and with smoothing under low power budget on Pixel 2 and Moto Z3 (average/standard deviation).

	RA	RA+S	LA(N)+LB	LA(N)+LB+S
Pixel 2				
Power Diff (%)	-3.50/0.96	-3.40/1.43	-4.80/1.90	-3.78/1.61
QoE	4.02/1.31	4.91/0.39	6.74/0.65	7.11/0.60
Quality (dB)	11.19/1.05	11.33/1.09	11.57/1.23	11.59/1.23
Smoothness (dB)	1.43/0.27	1.27/0.20	0.96/0.30	0.90/0.25
Rebuffering (%)	0.00/0.00	0.12/0.29	0.02/0.05	0.00/0.00
Moto Z3				
Power Diff (%)	0.42/1.53	0.24/1.94	-1.73/1.83	-0.59/1.56
QoE	4.27/1.03	5.36/0.81	5.79/0.97	6.39/0.81
Quality (dB)	11.46/0.52	11.52/0.42	11.50/0.55	11.55/0.52
Smoothness (dB)	1.47/0.28	1.21/0.22	1.13/0.27	1.03/0.18
Rebuffering (%)	0.14/0.32	0.22/0.48	0.13/0.28	0.03/0.06

efficiently exploit the energy saved during past intervals in downloading future video chunks; the small gap to the given power budget comes from discretized chunk formats. In contrast, LA(1) significantly under-utilizes the power budget by 12.20% on average, from not exploiting energy surplus accumulated from low network bandwidth intervals.

Figure 10b shows that for the high power budget, the trend is similar; LA(1)+LB and LA(N)+LB only under-utilize the power budget by 5.65% and 6.58%, while LA(1) under-utilizes by 15.39%. The larger gaps compared to the low power budget scenario are because all schemes are juggling among higher chunk formats due to the high power budget, which have larger discretization effects of video encoding.

User experience. We next compare the user experience of the three designs under the two power budgets. Figure 11a shows that for the low power budget, LA(N)+LB achieves the highest average QoE of 6.61, compared with 4.75 for LA(1) and 4.83 for LA(1)+LB.

To understand how different designs affect the QoE for the low power budget, we break down QoE into its three components: video quality, smoothness and rebuffering (Eqn. 1). (1)

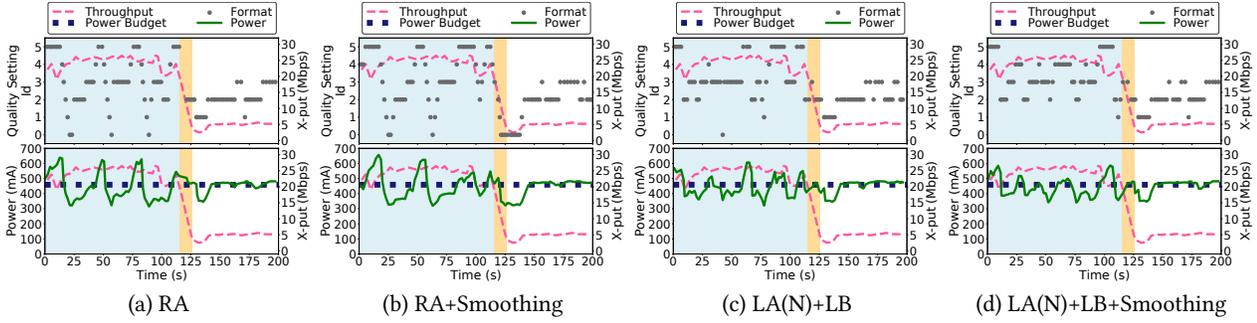

Figure 13: Low power budget case study: format selection and power behavior of reactive and proactive designs with and without smoothing under a sample network trace on Pixel 2.

Figure 11b shows that LA(1)+LB and LA(N)+LB have similar video quality, 11.18 dB and 11.14 dB, respectively, both higher than the quality of LA(1) of 10.57 dB. It suggests that exploiting energy surplus saved during past intervals in LA(1)+LB and LA(N)+LB improves the video quality of future intervals. (2) Figure 11c shows that LA(N)+LB has the smallest mean quality change of 0.89 dB, compared with 1.15 dB for LA(1) and 1.26 dB for LA(1)+LB. It is the same as that of the default ABR control. It suggests that looking ahead the power consumption of future N intervals effectively smooths the quality switching. (3) Figure 11d shows that all three energy-aware designs have similarly low average rebuffering ratio of around 0.14%, since the low power budget leads to lower chunk formats selected by the ENERGY-AWARE ABR controller which reduce the rebuffering time for all designs.

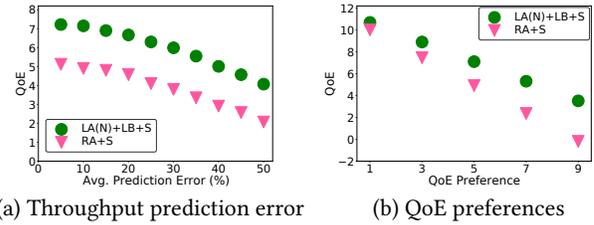

Figure 12 shows that the high power budget scenario has similar user experience results as the low power budget scenario, where LA(N)+LB achieves the highest average QoE of 6.94 and the closest gap with the default ABR of only 4.1%. The slightly low QoE comes from 0.28 dB video quality reduction (2.2%) as shown in Figure 12b. This shows the penalty of proactive energy-aware adaptation compared to the energy-oblivious default ABR is really small.

10.4 Reactive vs. Proactive Energy-aware ABR

We next evaluate the benefits of proactive energy-aware app adaptation by comparing reactive and proactive ENERGY-AWARE ABR, with and without adaptation smoothing, under the low power budget, on Pixel 2 and Moto Z3 phones.

Power consumption. Table 2 shows that all four designs satisfy the power budget with a small gap of 4.80%–3.40% below it on Pixel 2 and -1.73%–0.42% on Moto Z3. The small gap can be explained by the small discretization effects among the low chunk formats selected in the low budget scenario.

User experience. Table 2 shows when the power budget is lower than the default app energy power draw, proactive energy-aware app adaptation shows significant benefits over reactive adaptation on both phones. We next elaborate on the results on Pixel 2. (1) Without smoothing, LA(N)+LB achieves much higher (67.7%) mean QoE than RA, 6.74 over

(a) Throughput prediction error (b) QoE preferences

Figure 14: Sensitivity analysis under low power budget on Pixel 2.

4.02. As expected, the improvement mainly comes from significantly improved smoothness, 0.96 dB for LA(N)+LB and 1.43 dB for RA. (2) Smoothing improves QoE for both reactive and proactive design, by 0.89 and 0.37, respectively, primarily from improved smoothness of 0.16 dB for RA and 0.06 dB for LA(N)+LB. (3) With smoothing, LA(N)+LB+Smoothing achieves 44.8% higher mean QoE than RA+Smoothing, 7.11 over 4.91. The improvement mainly comes from significantly reduced quality switching (0.37 dB reduction) and significantly lower rebuffering ratio (0.12% reduction) and to a small extent the 0.26 dB higher quality. Table 2 also shows LA(N)+LB+Smoothing achieves 19.2% higher mean QoE than RA+Smoothing, 6.39 over 5.36, on Moto Z3.

Case study. Figure 13 shows a case study on Pixel 2 to explain how proactive designs reduce format oscillation compared to reactive designs. The streaming session was under the low power budget, and the network bandwidth went through 3 stages: high (H), high-to-low (H-L), and low (L).

The comparison at the H stage shows that proactive designs can reduce the oscillation when the network bandwidth is high. RA adjusts the format without knowing how much to adapt, which leads to frequent format oscillation to correct energy drain deviation as seen around 20–30s, 50–70s, 80–100s. Instead of aggressively increasing the format when there is no energy deficit, RA+Smoothing increases the format by 1 at each step at around 30–50s and 70–90s. In contrast, LA(N)+LB with and without smoothing do not rapidly go up and down all formats and stay in each format longer, from incorporating the power budget in selecting chunk formats. While LA(N)+LB occasionally jumps formats, e.g., to format 5 from format 3 around 60–70s and 105–115s, LA(N)+LB+Smoothing

further improves smoothness by gradually increasing the format when there is energy surplus, *e.g.*, from format 3 to format 4 around 60-70s and 90-100s,

10.5 Sensitivity Analysis

Throughput prediction accuracy. To study the impact of network throughput prediction error on QoE, we evaluate reactive and proactive designs with smoothing under the low power budget by modeling the throughput prediction as a combination of the ground truth throughput with random noise according to the given average error level. Figure 14a shows that the throughput prediction error influences both reactive and proactive approaches, but the gaps remain similar. In particular, LA(N)+LB+S performs better than RA+S by 41.0%-96.6% for the low power budget on Pixel 2.

User QoE preference. We compare QoE of RA+S and LA(N)+LB+S under 5 different QoE weights for smoothness, {1, 3, 5, 7, 9}, while keeping the weights for quality and re-buffering at 1 and 20, respectively. Figure 14b shows that as users put more penalty weight of smoothness, the difference between QoE of LA(N)+LB+S and RA+S increases from 0.68 (1.07X) to 3.69 (19.4X) for the low power budget on Pixel 2.

11 Discussion

Multiple apps competing for the energy budget. In this paper, we focused on energy-aware adaptation of a single app, *e.g.*, one that dominates the phone energy drain in a four-hour plane ride. In practice, the user may be switching among multiple apps, and there could be unexpected background apps that also drain energy from the total energy budget. In the first case, the integrated proactive app adaptation can be applied to each app while it is running, *e.g.*, constrained by the average power budget for the plane ride. If several apps run concurrently, *e.g.*, some in background and some in foreground, the user can potentially provide input on how the total energy/power budget should be split among the apps. Alternatively, a global energy-aware controller could be developed, *e.g.*, in the OS, to jointly optimize the QoE of concurrently running apps while satisfying the total energy/power budget.

Leveraging hysteresis in proactive adaptation. Reactive adaptation (*e.g.*, [31]) mitigates the oscillation problem by leveraging hysteresis, *i.e.*, imposing a threshold that the energy surplus/deficit must exceed in order to trigger fidelity adaptation (§6). In contrast, our proactive adaptation design, LA(N)+LB, already alleviates oscillation by allowing the energy surplus/deficit and the N -chunk energy budget to be spread over the next N chunks in maximizing the QoE. Incorporating hysteresis into proactive adaptation designs, *e.g.*, leveraging the energy surplus/deficit (while looking ahead N chunks) only when exceeding some threshold, may result

in further smoothness but also lower video quality because of its conservativeness.

12 Related Work

We already discussed previous work on reactive energy-aware app adaptation in §3. Below, we discuss related work on normal and 360° video streaming.

Energy measurements and optimization of video streaming. Many works [41, 79, 89] measure the energy consumption of commercial regular video streaming services in WiFi and LTE networks. Recent studies focus on power measurement of 360° video streaming [48, 87]. Many works [16, 20, 24, 27, 35, 40, 43, 53, 55, 56, 58, 60, 78, 90] propose techniques to minimize energy drain for video streaming via bandwidth control, packet scheduling, screen brightness scaling, *etc.* RnB [84] studies the problem of jointly adapting video bitrate and display brightness to reduce energy consumption while maintaining a quality goal. These works are orthogonal to our work; they focus on energy drain measurement or optimization, while our work focuses on energy-aware adaptation, *i.e.*, how to maximize QoE while satisfying user-configurable power constraint.

360° video streaming. Many works study supporting 360° video streaming on head-mounted displays or commodity phones. Several works [18, 50] propose to pre-cache panoramic frames to provide the clients the freedom of changing orientation during playback. Other works [39, 42, 65, 69, 80, 93] exploit different projection and tile-based or viewport-based video encoding schemes to save network bandwidth. They perform network-aware adaptation rather than energy-aware adaptation. We did not evaluate viewport-based 360° video streaming because commercial video streaming like Youtube does not use it and viewport prediction in the 2-second scale has been shown to be inaccurate; the median longitude error is about 20 degrees [82].

13 Conclusion

In this paper, using 360° video streaming as a case study, we showed that proactive energy-aware app adaptation that integrates the user-specified energy drain budget into the QoE optimizer of modern apps can significantly reduce app fidelity oscillation and improve the app QoE over traditional reactive energy-aware app adaptation. We believe that proactive energy-aware app adaptation is rather general and as future work, we will validate its applicability and effectiveness for other power-hungry modern apps with built-in adaptation logic such as the class of mobile apps that adaptively offload computation to edge servers.

Abstract

Low-cost cameras enable powerful analytics. An unexploited opportunity is that most captured videos remain “cold” without being queried. For efficiency, we advocate for these cameras to be *zero streaming*: capturing videos to local storage and communicating with the cloud only when analytics is requested.

How to query zero-streaming cameras efficiently? Our response is a camera/cloud runtime system called DIVA. It addresses two key challenges: to best use limited camera resource during video capture; to rapidly explore massive videos during query execution. DIVA contributes two unconventional techniques. (1) When capturing videos, a camera builds sparse yet accurate landmark frames, from which it learns reliable knowledge for accelerating future queries. (2) When executing a query, a camera processes frames in multiple passes with increasingly more expensive operators. As such, DIVA presents and keeps refining inexact query results throughout the query’s execution. On diverse queries over 15 videos lasting 720 hours in total, DIVA runs at more than 100× video realtime and outperforms competitive alternative designs. To our knowledge, DIVA is the first system for querying large videos stored on low-cost remote cameras.

1 Introduction

Cameras are pervasive: a survey of 61 organizations shows that from 2015 to 2018 their average number of cameras has increased by almost 70%, from 2,900 to 4,900 [6]. Insights of videos can be extracted by queries such as “get the daily peak pedestrian count in the past week” [36, 67, 82, 101]. Four recent trends motivate our work.

*Mengwei Xu and Tiantu Xu contributed equally to the paper.

*Work done during Mengwei Xu’s visit to Purdue University.

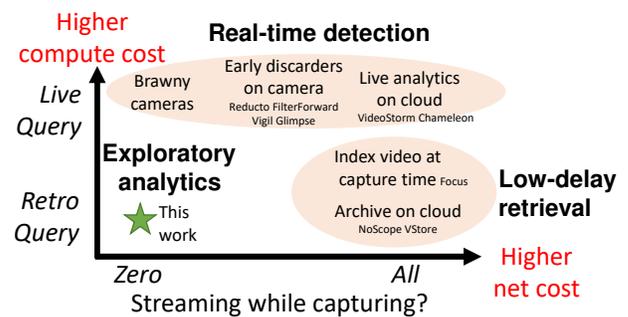

Figure 1: **The design space** of video analytics systems, showing this work and prior systems.

(1) *Low-cost, wireless cameras grow fast* As key complements to high-end cameras, low-cost cameras (<\$40) are increasingly pervasive [17, 18, 34]. These cameras often have limited compute resources yet spacious storage. Being wireless, these cameras are meant to be installed by individuals or small businesses with ease just as other wireless sensors.

(2) *Most videos are cold* Users deploy cameras to knowingly capture excessive videos, expecting that most videos will never be queried [72]. This is because interesting events are often unforeseeable, e.g., car accidents; the need for examining such events emerges well after the fact. §2.1 presents a 6-month study of real-world camera deployment, where only <0.005% of captured videos are eventually queried.

(3) *Transmitting cold videos wastes wireless bandwidth* Cold videos should not compete with human users for network bandwidth. If streaming video in real-time, a single camera generates traffic at 0.2 MB/s–0.4 MB/s (720P@1–30 FPS); with multiple cameras on one network, their always-on streams easily consume most, if not all, bandwidth of consumer WiFi, which is 0.2 MB/s–3 MB/s (median: 0.99) in a recent global survey [9] and less than 1.5 MB/s in an academic study [47]. A dedicated network for cameras is expensive, as the network monetary cost will exceed the camera cost in several months [14].

(4) *Camera storage can retain videos long enough* A cheap

camera can already store videos for weeks or months. Such retention periods already satisfy many video scenarios [2, 10]. In fact, legal regulations often *prevent* retention longer than a few months, mandating video deletion for privacy [1, 7]. Existing measures can assure data security of on-camera videos. §2.3 will provide evidence in detail.

Zero streaming & its use cases How to analyze cold videos produced by numerous low-cost cameras? We advocate for a system model dubbed “zero streaming”. (1) Cameras continuously capture videos to their local storage without uploading any. (2) Only in response to a retrospective query, the cloud reaches out to the queried camera and coordinates with it to process the queried video. (3) While the video is being processed, the system presents users with inexact yet useful results; it continuously refines the results until query completion [50]. In this way, a user may *explore* videos through interactive queries, e.g., aborting an ongoing query based on inexact results and issuing a new query with revised parameters [45, 46]. Zero streaming has rich use cases, for example:

- To trace the cause of recent frequent congestion on a highway, a city planner queries cameras on nearby local roads, requesting car counts seen on these local roads.
- To understand how recent visitors impact bobcat activities, a ranger queries all the park’s cameras, requesting time ranges where the cameras capture bobcats.

Advantages Zero streaming suits resource-frugal cameras in large deployment. When capturing videos, cameras require no network or external compute resources. Only to process a query, the cameras require networks such as long-range wireless [35] and cloud resources such as GPU. Zero streaming adds a new point to the design space of video analytics shown in Figure 1. It facilitates retrospective, exploratory analytics, a key complement to real-time event detection and low-delay video retrieval [51, 55, 65, 99]. The latter demands higher compute or network resources per camera and hence suits fewer cameras around hot locations such as building entrances.

DIVA To support querying zero-streaming cameras, we present a camera/cloud runtime called DIVA. As shown in Figure 2, a camera captures video to local storage; it deletes videos after their maximum retention period. In response to a query, the camera works in conjunction with the cloud: the camera runs operators, implemented as lightweight neural nets (NNs), to *rank* or *filter* frames; the cloud runs full-fledged object detection to validate results uploaded from the camera. DIVA thus does not sacrifice query accuracy, ensuring it as high as that of object detection by the cloud.

The major challenges to DIVA are two. (1) During video capture: how should cameras best use limited resources for future queries? (2) To execute a query: how should the cloud and the camera orchestrate to deliver useful results rapidly? Existing techniques are inadequate. Recent systems pre-process (“index”) video frames as capturing them [51] and answer

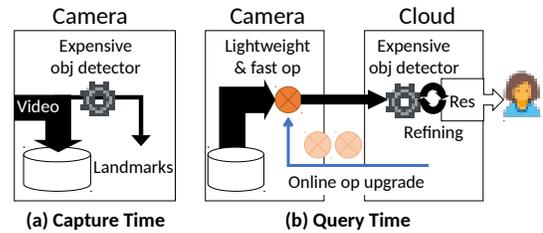

Figure 2: Overview of DIVA

queries based on indexes only. Yet, as we will show in §8, low-cost cameras can hardly build quality indexes in real-time. Many systems process video frames in a streaming fashion [40, 42, 92, 97, 100], which however miss key opportunities in retrospective queries.

To this end, DIVA has two unconventional designs.

• **During video capture: building sparse but sure landmarks to distill long-term knowledge** (Figure 2(a)) To optimize future queries, our key insight is that *accurate* knowledge on a *sparse* sample of frames is much more useful than *inaccurate* knowledge on *all* frames. This is opposite to existing designs that detect objects with low accuracy on all/most frames as capturing them [40, 51]. On a small sample of captured video frames dubbed *landmarks*, the camera runs generic, expensive object detection, e.g., YOLOv3 [77]. Constrained by camera hardware, landmarks are sparse in time, e.g., 1 in every 30 seconds; yet, with high-accuracy object labels, they provide reliable spatial distributions of various objects over long videos. High accuracy is crucial, as we will validate through evaluation (§8.3). DIVA optimizes queries with landmarks: it prioritizes processing of frame regions with object skewness learned from landmarks; it bootstraps operators with landmarks as training samples. Landmarks only capture a small fraction of object instances; those uncaptured do not affect correctness/accuracy (§4).

• **To execute queries: multipass processing with online operator upgrade** (Figure 2(b)) To process large videos, our key insight is to refine query results in multiple passes, each pass with a more expensive/accurate operator. Unlike prior systems processing all frames in one pass and delivering results in one shot [40, 58, 59], multipass processing produces useful results during query execution, enabling users to explore videos effectively. To do so, DIVA’s cloud trains operators with a wide spectrum of accuracies/costs. Throughout query execution, the cloud keeps pushing new operators to the camera, picking the next operator based on query progress, network conditions, and operator accuracy. The early operators quickly *explore* the frames for inexact answers while later operators slowly *exploit* for more exact answers.

On 720-hour videos in total from 15 different scenes, DIVA runs queries at more than 100× video realtime on average, with typical wireless conditions and low-cost hardware. DIVA returns results quickly: compared to executing a query to

completion, DIVA takes one order of magnitude shorter time to return half of the result frames. Compared to competitive alternatives, DIVA speeds up queries by at least 4×.

Contributions We have made the following contributions.

- Zero streaming, a new model for low-cost cameras to operate on frugal networks while answering video queries.
- Two novel techniques for querying zero-streaming cameras: optimizing queries with accurate knowledge from sparse frames; processing frames in multiple passes with operators continuously picked during a query.
- DIVA, a concrete implementation that runs queries at more than 100× realtime with uncompromised query accuracy. To our knowledge, DIVA is the first system designed for querying large videos stored on low-cost remote cameras.

Ethical considerations In this study: all visual data used is from the public domain; no information traceable to human individuals is collected or analyzed.

2 Motivations

2.1 Cold videos are already pervasive

Case study: Cold videos in real-world deployment We conduct an IRB-approved study examining existing camera deployment on PKU campus. Spanning 1 mi², the campus hosts tens of thousands of employees and operates more than 1,000 cameras. All captured videos are stored for a few months for retrospective queries before deletion. The camera deployment supports AI-based queries, e.g., object detection, *not* traceable to unique persons, and reviews by human analysts. We analyzed system logs spanning six continuous months: in over 3,000,000 hours of videos (5.4 PB) have been captured, only <0.005% video data from <2% cameras are queried.

Why are most videos cold? (1) Interesting video events are both unpredictable (thus the need for capturing excessive videos) and sparse (thus low chances for footage being queried). For example, severe traffic breakdown contributes to less than 5% of the time per day [89]; Foreign intelligence surveillance court only reviewed a tiny fraction of video for terrorism events [93]. (2) Analyzing videos is expensive: it still requires a GPU of a few thousand dollars for high-accuracy object detection over a video stream [59]. (3) In years to come, cheap cameras will produce more videos.

2.2 Target queries and their execution

We target ad-hoc queries [51, 59, 96, 100]. The query parameters, including object classes, video timespans, and expected accuracies, are specified at query time rather than video capture time. Such queries are known for flexibility.

High-accuracy object detection is essential Object detection is the core of ad-hoc queries [58]. Minor accuracy loss in object detection may result in substantial loss in query performance, as we will demonstrate in §8. While NNs significantly advance object detection, new models with higher accuracy demand much more compute. For instance, compared to YOLOv3 (2018) [77], CornerNet (2019) [64] improves Average Precision by 28% while being 5× more expensive.

Low-cost cameras cannot answer queries without cloud Cameras in real-world deployment are reported to be resource-constrained [65]. Low-cost cameras (<\$40) have wimpy cores, e.g., Cortex-A9 cores for YI Home Camera [18] and MIPS32 cores for WyzeCam [17]; their DRAM is no more than a few GBs [15, 16]. In recent benchmarks, they run state-of-the-art object detection at 0.1 FPS [8, 66], incapable of keeping up with video capture at 1–30 FPS [51, 59]. NN accelerators still cannot run high-accuracy object detection fast enough at low enough monetary cost, e.g., Intel’s Movidius (\$70) runs YOLOv3 at no faster than 0.5 FPS. In the foreseeable future, we expect that the resource gap between high-accuracy object detection and low-cost camera continues to exist.

2.3 A case for zero streaming

Streaming cold videos wastes bandwidth As discussed in §1, cameras are cheap while wireless spectrum is precious. Deploying streaming cameras on a shared network incurs poor experience [3, 11] and draws researcher attention [40, 100]. Dedicated networks are costly [14] and thus only suit a small number of cameras in critical locations. While wireless bandwidth grows, consumer demand grows even faster, e.g., 20× for VR/AR and 10× for gaming [5]. Cold video traffic should not contend with consumers for network bandwidth.

Streaming optimizations cannot offset the waste One may reduce FPS or resolution of streamed videos. Even if users tolerate the resultant lower query accuracy, the saved bandwidth is incomparable to the waste on overwhelmingly streamed cold videos, as we will experimentally show (§8). On-camera “early filters” [40, 42, 65] are still suboptimal when querying massive *cold* videos. (1) Without knowing query objects/parameters at video capture time, a camera may run a generic filter, e.g., discarding no-motion frames; it still streams substantial survival frames (e.g., consider a street-view camera). As stated above, most of these frames will remain cold and hence wasted. (2) The camera may run a large set of specific filters covering all possible query objects/parameters. Even if possible, this incurs a much higher compute cost to camera.

Edge processing does not justify streaming Cameras may stream to edge servers. Yet, streaming hundreds if not thousands of *always-on, cold* video streams, even if possible on certain wireless infrastructures, still wastes precious wireless spectrum at the edge [69]. Furthermore, deploying and managing video edge servers can be challenging and costly in

many scenarios, such as construction sites and remote farms.

Size	Yr.2017	Yr.2020	720p@30FPS	720p@1FPS
128GB	\$45	\$17	~11 days	~3 weeks
256GB	\$150	\$28	~3 weeks	~6 weeks

Table 1: Cheap μ SD cards on cameras retain long videos for humans to review [4] or for machines to analyze [51].

Cameras can retain videos long enough Table 1 shows the price of μ SD cards has been dropped by $2.6\times\text{--}5.4\times$ in the past few years. Cameras can retain videos for several weeks and for several months soon. Such a retention period is already adequate for most retrospective query scenarios, where videos are retained from a few weeks to a few months based on best practice and legal regulations [1, 2, 7, 10]. For privacy, many regulations *prohibit* video retention longer than a few months and mandate deletion afterwards [1, 7].

Our model & design scope To harness cold videos, we advocate for zero streaming. We focus on cold videos being queried for the first time and querying individual cameras. We intend our design to form the basis of future enhancement and extension, e.g., resource scheduling for multiple queries/users/tenants [40], caching for repetitive queries [95], exploiting past queries for refinement [41], and exploiting cross-camera topology [54]. We address limited compute resource on cameras [15] and limited network bandwidth [47]. We do not consider the cloud as a limiting factor, assuming it runs fast enough to process frames uploaded from cameras.

3 The DIVA Overview

Query types Concerning a specific camera, an ad-hoc query $(\mathcal{T}, \mathcal{C})$ covers a video timespan \mathcal{T} , typically hours or days, and an object class \mathcal{C} as detectable by modern NNs, e.g., any of the 80 classes of YOLOv3 [77]. As summarized in Table 2, DIVA supports three query types: **Retrieval**, e.g., “retrieve all images that contain buses from yesterday”; **Tagging**, e.g., “return all time ranges when any deer shows up in the past week”, in which the time ranges are returned as metadata but not images; **Counting**, e.g., “return the maximum number of cars that ever appear in any frame today”.

System components DIVA spans a camera and the cloud. Between them, the network connection is only provisioned at query time. To execute a query, a camera runs lightweight NNs, or operators, to *filter* or *rank* the queried frames for upload. On the uploaded frames, the cloud runs generic, high-accuracy object detection and materializes query results. Table 2 summarizes executions for different queries:

- The camera executes **rankers** for *Retrieval* and *max Count* queries. A ranker scores frames; a higher score suggests that a frame is more likely to contain *any* object of interest (for Retrieval) or *a large count* of such objects (for max Count).

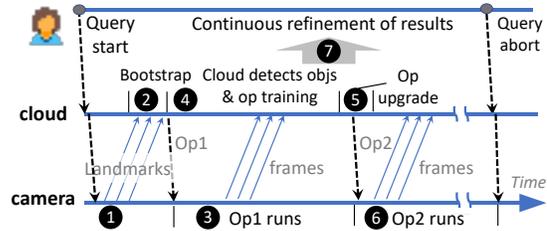

Figure 3: The workflow of a query’s execution.

- The camera executes **filters** for *Tagging* queries. A filter scores frames; it resolves any frame scored below/above two pre-defined thresholds as negative/positive, and deems other frames as unresolved. For each resolved frame, the camera uploads a positive/negative tag; the camera either uploads unresolved frames for the cloud to decide or defer them to more accurate filters on camera in subsequent passes.

Query execution Upon receiving a query, the cloud retrieves all landmarks in queried video as low-resolution thumbnails, e.g., 100×100 , with object labels and bounding boxes (Figure 3 1). The cloud uses landmarks: (1) *to estimate object spatial distribution*, e.g., “90% queried objects appear in a 100×100 region on the top-right”, which is crucial to query optimization (§4); (2) *as the initial training samples* for bootstrapping a family of camera operators (2). The camera filters/ranks frames and uploads the ranked or surviving frames (3). The cloud processes the uploaded frames and emits results, e.g., positive frames. It trains operators for higher accuracy (4). Observing resource conditions and positive ratios in uploaded frames, the cloud upgrades the operator on camera (5). With the upgraded operator, the camera continues to process remaining frames (6). Step (4)–(6) repeat until query abort or completion. Throughout the query, the cloud keeps refining the results presented to the user (7).

Notable designs (1) The camera processes frames in multiple passes, one operator in each pass. (2) The camera processes and uploads frames asynchronously. For instance, when the camera finishes ranking 100 out of total 1,000 frames, it may have uploaded the top 50 of the 100 ranked frames. This is opposed to common ranking which holds off frame upload until all the frames are ranked [38, 53, 61]. (3) The processing/upload asynchrony facilitates video exploration: it amortizes query delay over many installments of results; it pipelines query execution with user thinking [45]. Table 2 summarizes a user’s view of query results and the performance metrics. While such online query processing has been known [43, 71], we are the first applying it to visual data.

Limitations DIVA is not designed for several cases and may underperform: querying very short video ranges, e.g., minutes, for which simply uploading all queried frames may suffice without operators; querying non-stationary cameras for which landmarks may not yield accurate object distribution. DIVA is vulnerable to loss of video data in case of camera stor-

Type & Semantics	Execution	User's view of query results	Performance Metrics
Retrieval. Get positive video frames (i.e., containing C) within T	Camera: multipass ranking of frames Uploaded: ranked frames Cloud: object detection for identifying true positives	<ul style="list-style-type: none"> Positive frames being uploaded; Estimated % of positives retrieved 	The rate of the user receiving positive frames
Tagging. Get time ranges from T that contain C	Camera: multipass filtering of frames Uploaded: unresolved frames; tags of resolved frames Cloud: object detection to tag unresolved frames	<ul style="list-style-type: none"> A video timeline with pos/neg ranges; Tagging resolution, i.e., 1 in every N adjacent frames tagged 	The refining rate of tagging resolution seen by the user
Counting. Get max/mean/median count of C across all frames in T	Camera: multipass ranking (max) or random sampling (mean/median) of frames Uploaded: ranked or sampled frames Cloud: object detection to count objects	<ul style="list-style-type: none"> Running counts that converge to ground truth; % of frames processed; Estimated time to complete the query 	The rate of running counts converging to ground truth

Table 2: A summary of supported queries. \mathcal{T} is the queried video timespan; C is the queried object class

Figure 4: **Class spatial skews in videos.** In (a) Banff: 80% and 100% of cars appear in regions that are only 19% and 57% of the whole frame, respectively.

Figure 5: **Class spatial distribution can be estimated from sparse frames sampled over long video footage.** Among the three heatmaps: while sparse sampling over short footage (left) significantly differs from dense sampling of long footage (right), sparse sampling of long footage (middle) is almost equivalent to the right. Video: Tucson (see Table 4).

age failure. Users can mitigate such a risk via cross-camera data backup (RAID-like techniques) on the same local area network or by increasing camera deployment density.

4 Landmark Design

Surveillance cameras have a unique opportunity: to learn *object class distribution* from weeks of videos. We focus on **spatial skews**: objects of a given class are likely to concentrate on certain small regions on video frames. In examples of Figure 4(a)-(b), most cars appear near a stop sign; most persons appear in a shop's aisle. Such long-term skews are rarely tapped in prior computer vision work, which mostly focused on minute-long videos [52, 54, 78, 81, 102]. Compared to recent work that improved classifier performance by cropping video frames [40], DIVA takes a step further by automatically learning spatial skews from sparse frames with resource efficiency.

The design is backed up by three key observations. (1) One object class may exhibit different skews in different videos (Figure 4(a)-(c)); different classes may exhibit different skews

in the same video (Figure 4(c)). (2) The skews are pervasive: surveillance cameras cover long time spans and a wide field of view, where objects are small; in the view, objects are subject to social constraints, e.g., buses stop at traffic lights, or physical constraints, e.g., humans appear on the floor. (3) The skews can be learned through *sparse* frame samples, as exemplified by Figure 5.

To exploit such an opportunity, DIVA makes the following design choices. **High-accuracy object detection:** at capture time, the camera runs an object detector with the highest accuracy as allowed by the camera's hardware, mostly memory capacity. This is because camera operators crucially depend on the correctness of landmarks, i.e., the object labels and bounding boxes. We will validate this experimentally (§8.3). **Sparse sampling at regular intervals:** to accommodate slow object detection on cameras, the camera creates landmarks at long intervals, e.g., 1 in every 30 seconds in our prototype (§8). Sparse sampling is proven valid for estimating statistics of low-frequency signals [37], e.g., object occurrence in videos in our case. We will validate this (§8.3); without assuming a priori of object distribution, regular sampling ensures unbiased estimation of the distribution [79]. Given a priori, cameras may sample at corresponding random intervals for unbiased estimation.

Key idea: exploiting spatial skews for performance The cloud learns the object class distribution from landmarks of the queried video timespan. It generates a heatmap for spatial distribution (Figure 4). Based on the heatmap, the cloud produces camera operators consuming frame regions of different locations and sizes. Take Figure 4(a) as an example: a filter may consume bottom halves of all frames and accordingly filter frames with no cars; for Figure 4(b), a ranker may consume a smaller bounding box where 80% persons appear and rank frames based on their likelihood of containing more persons. Figure 6 shows that, by zooming into smaller regions, operators run faster and deliver higher accuracy. By varying input region locations/sizes, DIVA produces a set of operators with diverse costs/accuracies. By controlling the execution order of operators, DIVA processes "popular" frame regions prior to "unpopular" regions. DIVA never omits any region when it executes a query to completion to guarantee correctness.

What happens to instances uncaptured by landmarks?

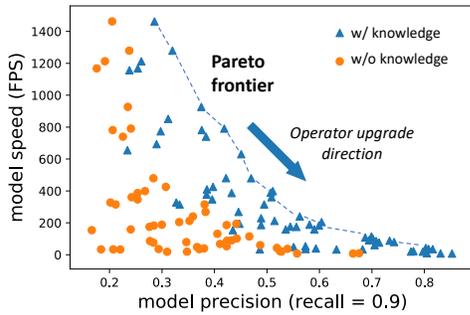

Figure 6: **On-camera operators benefit from long-term video knowledge substantially.** Each marker: an operator. For querying buses on video Banff (see Table 4).

Sparse by design, landmarks are not meant to capture all object instances; instead, they are used as inexact estimators and initial training samples. Reducing landmarks will degrade query speed, as we will experimentally quantify in §8.3. Doing so, however, does not affect query correctness or accuracy: the instances uncaptured by landmarks will be eventually processed by DIVA as a query goes on.

5 Online Operator Upgrade

5.1 The rationale

Three factors determine a query’s execution speed:

1. *Pending workloads*: the difficulty of the frames to be processed, i.e., how likely will the frame be mis-filtered or mis-ranked on camera.
2. *Camera operators*: cheap operators spend less time on each frame but are more likely to mis-filter/mis-rank frames, especially difficult frames. This is shown in Figure 6.
3. *Network condition*: the available uplink bandwidth.

The three factors interplay as follows.

- **Queries executed with on-camera rankers** A camera ranks and uploads frames asynchronously (§3). The key is to maximize the rate of true positive frames arriving at the cloud, for which the system must balance ranking speed/accuracy with upload bandwidth. (1) When the camera runs a *cheaper* ranker, it ranks frames at a much higher rate than uploading the frames; as a result, the cloud receives frames *hastily* selected from a *wide* video timespan. (2) When the camera runs an *expensive* ranker, the cloud receives frames selected *deliberately* from a *narrow* timespan. (3) The camera should never run rankers slower than upload, which is as bad as uploading unranked frames.

As an example, E_{CHEAP} and E_{EXP} on the top of Figure 7 compare two possible executions of the same query, running cheap/expensive rankers respectively. Shortly after the query starts (1), E_{CHEAP} swiftly explores more frames on camera; it outperforms E_{EXP} by discovering and returning more true

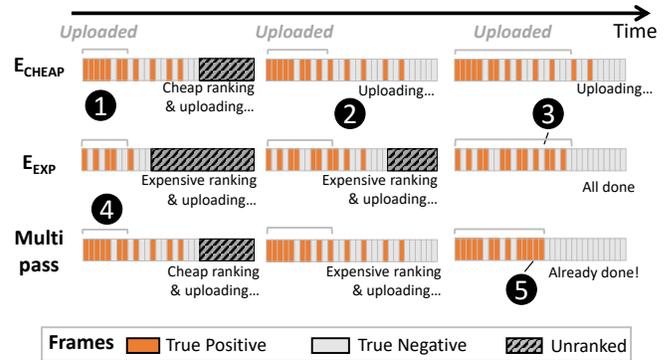

Figure 7: **Three alternative executions of a Retrieval query, showing multipass ranking (bottom) outperforms running individual rankers alone (top two).** Each row: snapshots of the upload queue at three different moments. In a queue: ranking/uploading frames from left to right.

Figure 8: **Cheap/expensive camera operators excel at different query stages.** Each subfigure: two alternative executions of the same query, showing query progress (bars) and the corresponding operator’s progress (arrows).

positive frames. As both executions proceed to harder frames (2), E_{CHEAP} makes more mistakes in ranking; it uploads an increasingly large ratio of negatives which wastes the execution time. By contrast, E_{EXP} ranks frames slower yet with much fewer mistakes, hence uploading fewer negatives. It eventually returns all positives earlier than E_{CHEAP} (3).

The microbenchmark in Figure 8(a) offers quantitative evidence. E1 spends *less* time ($0.7\times$) in returning the first 90% positives, but *more* time ($1.7\times$) in returning 99% positives. Furthermore, *lower* upload bandwidth favors a more *expensive* ranker, as the uploaded frames would contain a *higher* ratio of positives, better utilizing the precious bandwidth.

- **Queries executed with on-camera filters** The key is to maximize the rate of resolving frames on camera. Cheap filters excel on easy frames, resolving these frames fast with confidence. They are incapable on difficult frames, wasting time on attempting frames without much success in resolving. They would underperform *expensive* filters that spend more time per frame yet being able to resolve more frames.

The benchmark in Figure 8(b) shows two executions with cheap/expensive filters. Early in the query, E1 makes faster progress as the camera quickly resolves 50% of the frames ($4\times$ less time than E2). Later in the execution, E1 lags behind as the camera cannot resolve the remaining frames and must

upload them. By contrast, E2 resolves 82% of frames on camera and only uploads the remaining 18%. As a result, E2 takes $1.3\times$ less time in completing 90% and 99% of the query.

Summary & implications It is crucial for DIVA to pick operators with optimal cost/accuracy at query time. The choice not only varies across queries but also varies throughout a query’s execution: easy frames are processed early, leaving increasingly difficult frames that call for more expensive operators. DIVA should monitor pending frame difficulty and network bandwidth and upgrade operators accordingly.

5.2 Multipass, multi-operator execution

DIVA manages operators with the following techniques. (1) A camera processes frames iteratively with multiple operators. (2) The cloud progressively updates operators on camera, from cheaper ones to more expensive ones, as the direction shown in Figure 6. In picking operators, the cloud dynamically adapts operator speed to frame upload speed. (3) The cloud uses frames received in early execution stages to train operators for later stages; as the latter operators are more expensive, they require more training samples.

- **Multipass ranking** This is exemplified by the bottom execution in Figure 7. The camera first runs a cheap ranker, moving positives towards the front of the upload queue (4). Subsequently, the camera runs an expensive ranker, continuously reordering unsent frames in a smaller scope (5). Throughout the query, the camera first quickly uploads easy frames that are quickly ranked and slows down to vet difficult frames with expensive/accurate ranking. Notably, the cheaper ranker roughly prioritizes the frames as input for the expensive ranker, ensuring the efficacy of the expensive ranker. In actual query executions, a camera switches among 4–8 operators (§8).

- **Multipass filtering** The camera sifts undecided, unsent frames in multiple passes, each with a more expensive filter over a sample of the remaining frames. Throughout one query, early, cheaper filters quickly filter easier frames, leaving more difficult frames for subsequent filters to resolve.

6 Query Execution Planning

DIVA plans a concrete query execution by (1) the camera’s policy for selecting frames to process; (2) the cloud’s policy for upgrading on-camera operators. We now discuss them.

6.1 Executing Retrieval queries

Policy for selecting frames To execute the initial operator, the camera prioritizes fixed-length video spans (e.g., 1 hour) likely rich in positive frames, estimated based on landmark frames. In executing subsequent operators, the camera processes frames in their existing ranking as decided by earlier operators, as described in §5. The camera gives opportunities

to frames never ranked by prior operators, interleaving their processing with ranked frames with mediocre scores (0.5).

Policy for operator upgrade As discussed in §3, DIVA switches from cheap operators to expensive ones, and matches operator speed to frame upload rate. To capture an operator op ’s relative speed to upload, it uses one simple metric: the ratio between the two speeds, i.e., $f_{op} = FPS_{op}/FPS_{net}$. Operators with higher f_{op} tend to rapidly explore frames while others tend to exploit slowly. The operator speed FPS_{op} is profiled offline. (1) **Selecting the initial operator** In general, DIVA should fully utilize the upload bandwidth with positive frames. As positive frames are scattered in the queried video initially, the camera should explore all frames sufficiently fast. Otherwise, it would either starve the uplink or knowingly upload negative frames. Based on this idea, the cloud picks the most accurate operator from the ones that are fast enough, i.e., $f_{op} \times R_{pos} > 1$, where R_{pos} is the ratio of positives in the queried video, estimated from landmarks. (2) **When to upgrade: current operator losing its vigor** The cloud upgrades operators either when the current operator finishes processing all frames, or the cloud observes a continuous quality decline in recently uploaded frames, an indicator of the current operator’s incapability. To decide the latter, DIVA employs a rule: the positive ratio in recently uploaded frames are $k\times$ (default: 5) lower than the frames uploaded at the beginning; (3) **Selecting the next operator: slow down exponentially** Since the initial operator promotes many positives towards the front of the upload queue, subsequent operators, scanning from the queue front, likely operate on a larger fraction of positives. Accordingly, the cloud picks the most accurate operator among much slower ones, s.t. $f_{op(i+1)} > \alpha \times f_{op(i)}$, where α controls speed decay in subsequent operators. A larger α leads to more aggressive upgrade: losing more speed for higher accuracy. In the current prototype, we empirically choose $\alpha = 0.5$. Since f is relative to FPS_{net} measured at every upgrade, the upgrade adapts to network bandwidth change during a query.

6.2 Executing Tagging queries

Recall that for *Tagging*, a camera runs multipass filtering; the objective of each pass is to tag, as positive (P) or negative (N), at least one frame from every K adjacent frames. We call K the group size; DIVA pre-defines a sequence of group sizes as refinement levels, e.g., $K = 30, 10, \dots, 1$. As in prior work [51, 58, 59], the user specifies tolerable error as part of her query, e.g., 1% false negative and 1% false positive; DIVA trains filters with thresholds to meet the accuracy.

Policy for selecting frames The goal is to quickly tag easy frames in individual groups while balancing the workloads of on-camera processing and frame upload. An operator op works in two stages of each pass. i) *Rapid attempting*. op scans all the groups; it attempts one frame per group; if it succeeds, it moves to the next group; it adds undecidable

frames (U) to the upload queue. ii) *Work stealing*. op steals work from the end of upload queue. For an undecidable frame f belonging to a group g , op attempts other untagged frames in g ; once it succeeds, it removes f from the upload queue as f no longer needs tagging in the current pass. After one pass, the camera switches to the next refinement level (e.g., $10 \rightarrow 5$). It keeps all the tagging results (P, N, U) while cancels all pending uploads. It re-runs the frame scheduling algorithm until it meets the finest refinement level or query terminated.

Policy for operator upgrade Given an operator op and γ_{op} , the ratio of frames it can successfully tag, DIVA measures op 's efficiency by its effective tagging rate, $FPS_{op} \times \gamma_{op} + FPS_{net}$, as a sum of op 's successful tagging rate and the uploading rate. As part of operator training, the cloud estimates γ_{op} for all the candidate operators by testing them on all landmarks (early in query) and uploaded frames (later in query). To select every operator, initial or subsequent, the cloud picks the candidate with the highest effective tagging rate. The cloud upgrades operators either when the current operator has attempted all remaining frames or another candidate having an effective tagging rate $\beta \times$ or higher (default value 2).

6.3 Executing Counting queries

Max Count: Policy for selecting frames To execute the initial operator, the camera randomly selects frames to process, avoiding the worst cases that the max resides at the end of the query range. For subsequent operators, the camera processes frames in existing ranking decided by earlier operators.

Max Count: Policy for operator upgrade As the camera runs rankers, the policy is similar to that for *Retrieval* with a subtle yet essential difference. To determine whether the current operator shall be replaced, the cloud must assess the quality of recently uploaded frames. While for *Retrieval*, DIVA conveniently measures the quality as the ratio of *positive* frames, the metric does not apply to *max Count*, which seeks to discover *higher* scored frames. Hence, DIVA adopts the Manhattan distance as a quality metric among the permutations from the ranking of the uploaded frames (as produced by the on-camera operator) and the ranking that is re-computed by the cloud object detector. A higher metric indicates worse quality hence more urgency for the upgrade.

Average/Median Count: no on-camera operators After the initial upload of landmarks, the camera randomly samples frames in queried videos and uploads them for the cloud to refine the average/median statistics. To avoid any sampling bias, the camera does not prioritize frames; it instead relies on the Law of Large Numbers (LLN) [48] to approach the average/median ground truth through continuous sampling.

Cameras	Rpi3 (default): Raspberry Pi 3 (\$35). 4xCortex-A53, 1GB DRAM Odroid: XU4 (\$49) 4xCortexA15 & 4xCortexA7, 2GB DRAM

7 Implementation and Methodology

Operators We architect on-camera operators as variants of AlexNet [63]. We vary the number of convolutional layers (2–5), convolution kernel sizes (8/16/32), the last dense layer's size (16/32/64); and the input image size ($25 \times 25 / 50 \times 50 / 100 \times 100$). We empirically select 40 operators to be trained by DIVA online; we have attempted more but see diminishing returns. These operators require small training samples (e.g., 10K images) and run fast on camera.

Background subtraction filters static frames at low overhead [51]. DIVA employs a standard technique [12]: during video capture, a camera detects frames that have little motion ($< 1\%$ foreground mask) and omits them in query execution. On our camera hardware (Table 3), background subtraction is affordable in real time during capture. For fair comparisons, we augment all baselines with background subtraction.

Videos & Queries We test DIVA on 15 videos captured from 15 live camera feeds (Table 4). Each video lasts continuous 48 hours including daytime and nighttime, collected between Oct. 2018 to Mar. 2019. We preprocess all videos to be 720P at 1 FPS, consistent with prior work [51]. We test *Retrieval/Tagging/Counting* queries on 6/6/3 videos. We intentionally choose videos with disparate characteristics and hence different degrees of difficulty. For instance, Whitebay

is captured from a close-up camera, containing clear and large persons; Venice is captured from a high camera view and hence contains blurry and small persons. For each video, we pick a representative object class to query; across videos, these classes are diverse. For *Tagging*, we set query error to be $< 1\%$ FN/FP as prior work did [59].

A query's accuracy is reflected by its execution progress. For retrieval/counting, we report accuracy as the fraction of positive frames returned. There is no false positive because the cloud always runs the high-accuracy object detector as a "safety net", of which the output is regarded as the ground truth. For tagging, we report accuracy as query errors, meaning the percentage of frames mistakenly tagged. To issue a query, the user sets the target error, which by default is 1% as in prior work. Table 2 and §6 provide more details.

Test platform & parameters As summarized in Table 3(a), we test on embedded hardware similar to low-cost cameras [15, 16]. We use Rpi3 as the default camera hardware and report its measurement unless stated otherwise. During query execution, both devices set up a network connection with 1MB/s default bandwidth to emulate typical WiFi condition [47]. Note that this network bandwidth is *not* meant for streaming; it is only for a camera while the camera is being queried. We run YOLOv3 as the high-accuracy object detector on camera and cloud (Table 3(b)). In calculating accuracy, we use the output of YOLOv3 as the ground truth as in prior work [51, 59]. On Rpi3, we partition YOLOv3 into three stages, each fitting into DRAM separately. We will study alternative models, landmarks, and resources in §8.3.

Baselines As summarized in Table 3(b), we compare DIVA with three alternative designs augmented with background subtraction and only process/transmit non-static video frames.

- **CloudOnly**: a naive design that uploads all queried frames at query time for the cloud to process.
- **OptOp**: in the spirit of NoScope [59], the camera runs only one ranker/filter specialized for a given query, selected by a cost model for minimizing full-query delay. To make OptOp competitive, we augment it with landmark frames to reduce the operator training cost. Compared to DIVA, OptOp's key differences are the lack of operator upgrade and the lack of operator optimization by long-term video knowledge.
- **PreIndexAll**: in the spirit of Focus [51], the camera runs a cheap yet generic object detector on all frames. We pick YOLOv3-tiny (much cheaper than YOLOv3) as the detector affordable by Rpi3 in real time (1 FPS). The detector plays the same role as an operator in DIVA, except that it runs at capture time: for *Retrieval* and *Counting*, the detector's output scores are used to prioritize frames to upload at query time; for *Tagging*, the output is used to filter the frames that have enough confidence. PreIndexAll implements all run-time features of Focus except feature clustering. We left out clustering because we find it performs poorly on counting queries. Compared to DIVA, PreIndexAll's key differences

are: it answers queries solely based on the indexes built at capture time; it requires no operator training or processing actual images at query time.

8 Evaluation

8.1 End-to-end performance

Full query delay is measured as: (*Retrieval*) the time to receive 99% positive frames as in prior work [51]; (*Tagging*) the time taken to tag every frame; (*Counting*) the time to reach the ground truth (max) or converge within 1% error of the ground truth (avg/median). Overall, DIVA delivers good performance and outperforms the baselines significantly.

- **Retrieval** (Figure 9(a)). On videos each lasting 48 hours, DIVA spends $\sim 1,900$ seconds on average, i.e., $89\times$ of video realtime. On average, DIVA's delay is $3.8\times$, $3.1\times$, and $2.0\times$ shorter than CloudOnly, PreIndexAll, and OptOp, respectively.
- **Tagging** (Figure 9(b)). DIVA spends ~ 581 seconds on average ($297\times$ realtime). This delay is $16.0\times$, $2.1\times$, and $4.3\times$ shorter than CloudOnly, PreIndexAll, and OptOp, respectively.
- **Counting** (Figure 10). DIVA's average/median take several seconds to converge. For *average Count*, DIVA's delay is $65.1\times$ and up to three orders of magnitude shorter than CloudOnly and PreIndexAll. For *median Count*, DIVA's delay is $68.3\times$ shorter than the others. For *max Count*, DIVA spends 34 seconds on average ($635\times$ realtime), which is $5.8\times$, $5.0\times$, and $1.3\times$ shorter than CloudOnly, PreIndexAll, and OptOp.

Query progress DIVA makes much faster progress in most time of query execution. It *always* outperforms CloudOnly and OptOp during *Retrieval/Tagging* (Figure 9). It *always* outperforms alternatives in median/average count (Figure 10).

Why DIVA outperforms the alternatives? The alternatives suffer from the following. (1) Inaccurate indexes. PreIndexAll resorts to inaccurate indexes (YOLOv3-tiny) built at capture time. Misled by them, *Retrieval* and *Tagging* upload too much garbage; *Counting* includes significant errors in the initial estimation, slowing down convergence. (2) Lack of long-term knowledge. OptOp's operators are either slower or less accurate than DIVA, as illustrated in Figure 6. (3) One operator does not fit an entire query. Optimal at some point (e.g., 99% Retrieval), the operator runs too slow on easy frames which could have been done by cheaper operators.

Why DIVA underperforms (occasionally)? On short occasions, DIVA may underperform PreIndexAll at early query stages, e.g., BoatHouse in Figure 9. Reasons: (1) PreIndexAll's inaccurate indexes may be correct on *easy* frames; (2) PreIndexAll does not pay for operator bootstrapping as DIVA. Nevertheless, PreIndexAll's advantage is transient. As easy frames are exhausted, indexes make more mistakes on the remaining frames and hence slow down the query.

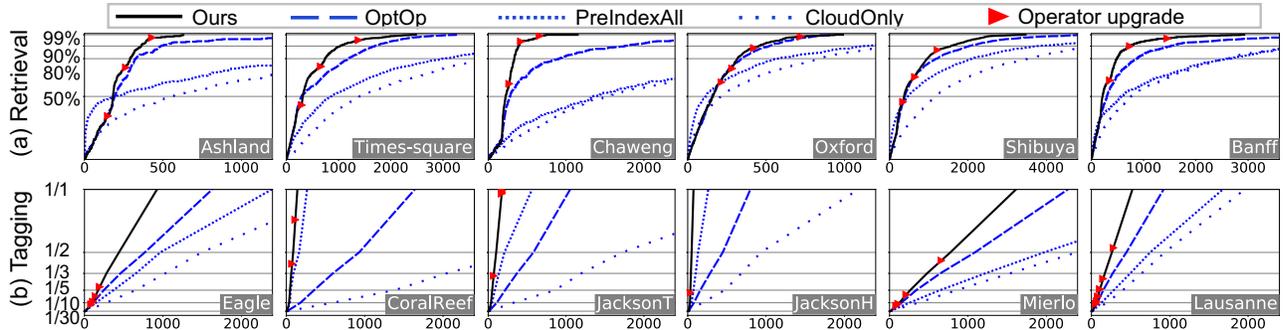

Figure 9: **On Retrieval and Tagging queries, DIVA shows good performance and outperforms the alternatives.** x-axis for all: query delay (secs). y-axis for (a): % of retrieved instances; for (b): refinement level (1/N frames).

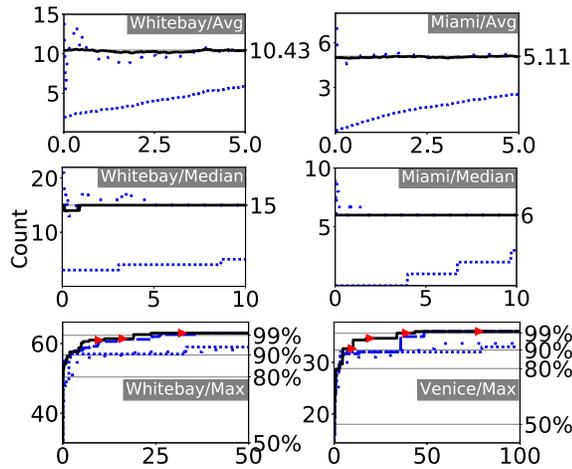

Figure 10: **On Counting queries, DIVA shows good performance and outperforms the alternatives.** Legend: see Figure 9. x-axis for all: query delay (secs). y-axis for left plots: count; for top two right plots: ground truth for avg/median queries; for bottom right plot: % of max value.

Can DIVA outperform under different network bandwidths at query time? Table 5 summarizes DIVA’s query delays at 9 bandwidths evenly spaced in [0.1 MB/s, 10 MB/s] which cover typical WiFi bandwidths [9]. We have observed that: on lower bandwidths, DIVA’s advantages over baselines are more significant; at high bandwidths, DIVA’s advantages are still substantial ($>2\times$ in most cases) yet less pronounced. The limitation is not in DIVA’s design but rather its current NNs: we find it difficult to train operators that are both fast enough to keep up with higher upload bandwidth and accurate enough to increase the uploaded positive ratio proportionally.

vs. “all streaming”: query speed As “all streaming” uploads all videos to the cloud before a query starts, the query speed is bound by cloud GPUs but not network bandwidth. With our default experiment setting (1 GPU and 1MB/s network bandwidth), “all streaming” still runs queries much slower than zero streaming. Adding more cloud GPUs will eventually make “all streaming” run faster than DIVA.

	Retrieval	Tagging	Count/Max	Count/Avg&Med
CloudOnly	4.5/14.9/52.2	3.61/3.9/5.1	2.8/21.1/42.5	6.9/83.4/439.2
OptOp	2.2/4.1/4.9	2.0/2.3/2.6	1.2/1.5/2.1	6.9/83.4/439.2*
PreIndexAll	1.9/3.8/11.6	3.2/3.6/4.9	1.2/8.9/18.2	2.5/14.0/41.3

*: Fall back to CloudOnly as the camera does not execute NN for these query types

Table 5: DIVA’ performance (speedup) with various bandwidths. Numbers: min/median/max of times (\times) of query delay reduction compared to baselines (rows). Averaged on all videos and 9 bandwidths in 0.1MB/s–10MB/s.

vs. “all streaming”: network bandwidth saving Compared to streaming all videos (720P 1FPS) at capture time, DIVA saves traffic significantly, as shown in Figure 11. When only as few as 0.005% of video is queried as in our case study (§2), the saving

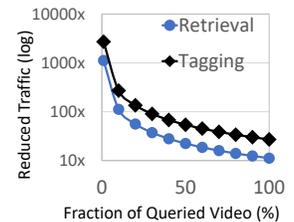

Figure 11: **DIVA significantly reduces network traffic compared to “all streaming”.** Results averaged over all videos.

is over three orders of magnitude. Even if all captured videos are queried, DIVA saves more than $10\times$, as its on-camera operators skip uploading many frames. Among the bandwidth reduction brought by DIVA, only less than 30% attributes to the background subtraction technique. It shows that the disadvantage of “all streaming” is fundamental: streaming optimizations may help save the bandwidth (upmost several times [96]) but cannot offset the waste, as discussed in §2.3.

Training & shipping operators For each query, DIVA trains ~ 40 operators, of which ~ 10 are on the Pareto frontier. The camera switches among 4–8 operators, which run at diverse speeds ($27\times$ – $1,000\times$ realtime) and accuracies. DIVA chooses very different operators for different queries. Training one operator typically takes 5–45 seconds on our test platform and requires 5k frames (for bootstrapping) to 15k frames (for stable accuracy). Operators’ sizes range from 0.2–15 MB. Sending an operator takes less than ten seconds. Only the delay in training and sending the first operator (≤ 40 seconds) adds to the query delay which is included in Figure 9/10.

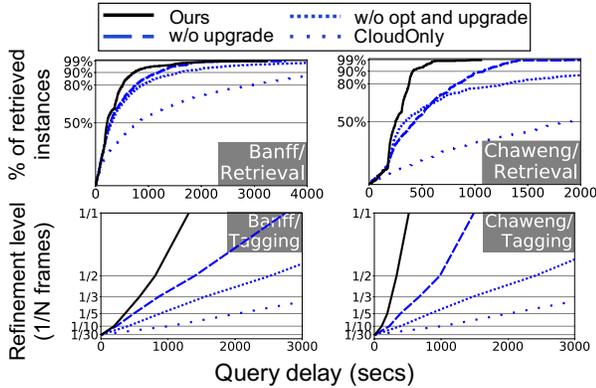

Figure 12: DIVA’s both key techniques – optimization with long-term video knowledge (opt) and operator upgrade (upgrade), contribute to performance significantly.

Subsequent operators are trained and transmitted in parallel to query execution. Their delays are hidden from users.

DIVA elasticity Due to DIVA’s design, the computing resources available on low-cost cameras are used efficiently at both capture and query time. Thanks to its elastic execution, it can avoid interference with a camera’s surveillance task, notably video encoding and storage. For instance, DIVA can produce denser/sparser landmarks per its CPU time allocated by the camera OS. According to our experiments on Raspberry Pi 3B+, recording video at 720P and 30 FPS only uses less than 2% of CPU time, which is negligible as compared to NN execution. We reserve a small fraction of CPU time to surveillance using *cgroup* and observe no frame drop in the surveillance task and negligible slowdown in NN execution.

8.2 Validation of query execution design

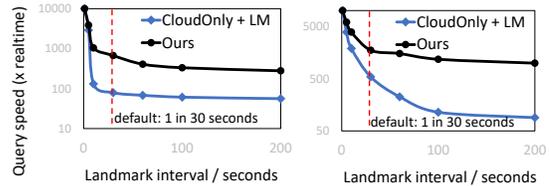

The experiments above show DIVA’s substantial advantage over *OptOp*, coming from a combination of two techniques – optimizing queries with long-term video knowledge (“*Long-term opt*”, §4) and operator upgrade (“*Upgrade*”, §5). We next break down the advantage by incrementally disabling the two techniques in DIVA. Figure 12 shows the results.

Both techniques contribute to significant performance. For instance, disabling *Upgrade* increases the delay of retrieving 90% instances by 2× and that of tagging 1/1 frames by 2×-3×. Further disabling *Long-term Opt* increases the delay of Retrieval by 1.3×-2.1× and that of tagging by 1.6×-3.1×. Both techniques disabled, DIVA still outperforms *CloudOnly* with its single non-optimized operator.

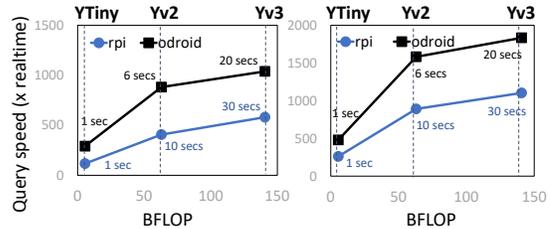

Upgrade’s benefit is universal; Long-term opt’s benefit is more dependent on queries, i.e., the skews of the queried object class in videos. For instance, DIVA’s benefit is more pronounced on Chaweng, where small bicycles only appear in a region in 1/8 size of the entire frame, than Ashland, where large trains take 4/5 of the frame. With stronger skews in Chaweng, DIVA trains operators that are more accurate

(a) DIVA’s performance degrades significantly with less accurate landmarks (produced by Yv2 and YTiny), which can be even worse than no landmarks at all (“w/o LM”).

(b) DIVA’s performance degrades slowly with sparser landmarks. The y-axis is logarithmic.

(c) On given camera hardware (Rpi3/Odroid), sparser yet more accurate LMs always improve DIVA’s performance. Landmark intervals annotated along curves.

Figure 13: **Validation of landmark design.** In (a)/(b)/(c): Left – *Retrieval* on Chaweng; Right – *Tagging* on JacksonH.

and run faster. This also accounts for DIVA’s varying (yet substantial) advantages over the alternatives (Figure 9).

8.3 Validation of landmark design

Next, we deviate from the default landmark parameters (Table 3) to validate the choice of sparse-but-sure landmarks.

DIVA hinges on accurate landmarks. As shown in Figure 13(a), modestly inaccurate landmarks (as produced by YOLOv2; 48.1 mAP) increase delays for Q1/Q2 by 45% and 17%. Even less accurate landmarks (by YOLOv3-tiny; 33.1 mAP) increase the delays significantly by 5.3× and 4.3×. Perhaps surprisingly, such inaccurate landmarks can be worse than no landmarks at all (“w/o LM” in Figure 13): when a query starts, a camera randomly uploads unlabeled frames for the cloud to bootstrap operators. *Why inaccurate landmarks hurt so much?* They (1) provide wrong training samples; (2) lead to incorrect observation of spatial skews which further mislead frame cropping; and (3) introduce large errors into initial statistics, making convergence harder.

DIVA tolerates longer landmark intervals. As shown in Figure 13(b), DIVA’s *Retrieval* and *Tagging* performance slowly degrade with longer intervals. Even with an infinite

interval, i.e., “w/o LM” in Figure 13(a), the slowdown is no more than $3\times$. On *Counting*, the performance degradation is more pronounced: $5\times$ longer intervals for around $15\times$ slow down. Yet, such degradation is still much smaller than one from inaccurate landmarks (two orders of magnitude). The reason is that, with longer LM intervals DIVA has to upload additional frames in full resolution ($\sim 10\times$ larger than LMs) when a query starts for bootstrapping operators; such a one-time cost, however, is amortized over the full query.

Create the most accurate landmarks possible Should a camera build denser yet less accurate landmarks or sparser yet more accurate ones? Figure 13(c) suggests the latter is always preferred, because of DIVA’s high sensitivity to landmark accuracy and low sensitivity to long landmark intervals.

DIVA on wimpy/brawny cameras DIVA suits wimpy cameras that can only generate sparse landmarks. Some cameras may have DRAM smaller than a high-accuracy NN (e.g., ~ 1 GB for YOLOv3); fortunately, recent orthogonal efforts reduce NN sizes [56]. Wimpier cameras will further disadvantage the alternatives, e.g., `PreIndexAll` will produce even less accurate indexes. On higher-end cameras (a few hundred dollars each [13]) that DIVA is *not* designed for, DIVA still shows benefits, albeit not as pronounced. High-end cameras can afford more computation at capture time. i) They may run `PreIndexAll` with improved index accuracy. In Figure 13(a), running YOLOv2 on all captured frames (`PreIndexAll+Yv2`), DIVA’s performance gain is $1.9\times$ (left) or even $0.6\times$ (right). ii) These cameras may generate denser landmarks and rely on the cloud for the remaining frames. Figure 13(b) shows, with one landmark every 5 seconds, DIVA’s advantage is $1.5\times$.

9 Related Work

Optimizing video analytics The CV community has studied video analytics for decades, e.g., for online training [83, 84] and active learning [57]. They mostly focus on improving analytics accuracy on short videos [44, 60, 68, 78, 81, 102] while missing opportunities in exploiting long-term knowledge (§4). These techniques alone cannot address the systems challenges we face, e.g., network limit or frame scheduling. A common theme of recent work is to trade accuracy for lower cost: VStore [96] does so for video storage; Pakha *et al.* [70] do so for network transport; Chameleon [55] and VideoStorm [52, 99] do so with video formats. DIVA’s operators as well exploit accuracy/cost tradeoffs. Multiple systems analyze archival videos on servers [58, 62, 73, 80, 96]. DIVA analyzes archival videos on *remote* cameras and embraces new techniques. ML model cascade is commonly used for processing a stream of frames [39, 59, 85]: in processing a frame, it keeps invoking a more expensive operator if the current operator has insufficient confidence. This technique, however, mismatches exploratory analytics, for which DIVA uses one operator to process many frames in one pass and

produces inexact yet useful results for all of them.

Edge video analytics To reduce cloud/edge traffic, computation is partitioned, e.g., between cloud/edge [40, 76, 97], edge/drone [91], and edge/camera [100]. Elf [94] executes counting queries completely on cameras. Most work targets live analytics, processes frames in a streaming fashion and trains NNs ahead of time. DIVA spreads computation between cloud/cameras but takes a disparate design point (zero streaming) that are inadequate in prior systems. CloudSeg [92] reduces network traffic by uploading low-resolution frames and recovering them via super resolution. DIVA eliminates network traffic at capture time at all.

Online Query Processing Dated back in the 90s, online query processing allows users to see early results and control query execution [49, 50]. It is proven effective in large data analytics, such as MapReduce [43]. DIVA retrofits the idea for video queries and accordingly contributes new techniques, e.g., operator upgrade, to support the online fashion. DIVA could borrow UI designs from existing online query engines.

WAN Analytics To query geo-distributed data, recent proposals range from query placement to data placement [74, 86–88, 90]. JetStream [75] adjusts data quality to meet network bandwidth; AWStream [98] facilitates apps to systematically trade-off analytics accuracy for network bandwidth. Like them, DIVA adapts to network; unlike them, DIVA does so by changing operator upgrade plan, a unique aspect in video analytics. DIVA targets resource-constrained cameras, which are unaddressed in WAN analytics.

10 Conclusions

Zero streaming shifts most compute from capture time to query time. We build DIVA, an analytics engine for querying cold videos on remote, low-cost cameras. At capture time, DIVA builds sparse but sure landmarks; at query time, it refines query results by continuously updating on-camera operators. Our evaluation of three types of queries shows that DIVA can run at more than $100\times$ video realtime under typical wireless network and camera hardware.

Abstract

With mobile applications' ever-increasing demands for memory capacity, along with a steady increase in the number of applications running concurrently, memory capacity is becoming a scarce resource on mobile devices. When the memory pressure is high, current mobile OSes often kill application processes that have not been used recently to reclaim memory space. This leads to a long delay when a user relaunches the killed application, which degrades the user experience. Even if this mechanism is disabled to utilize a compression-based in-memory swap mechanism, relaunching the application still incurs a substantial latency penalty as it requires the decompression of compressed anonymous pages and a stream of I/O accesses to retrieve file-backed pages into memory. This paper identifies conventional demand paging as the primary source of this inefficiency and proposes ASAP, a mechanism for fast application switch via adaptive prepaging on mobile devices. ASAP performs prepaging by combining i) high-precision switch footprint estimators for both file-backed and anonymous pages, and ii) efficient implementation of the prepaging mechanism to minimize resource waste for CPU cycles and disk bandwidth during an application switch. Our evaluation using eight real-world applications on Google Pixel 4 and Pixel 3a demonstrates that ASAP can reduce the switch time by 22.2% and 28.3% on average, respectively (with a maximum of 33.3% and 35.7%, respectively), over the vanilla Android 10.

1 Introduction

With the broad capabilities and flexibility of mobile computing, mobile applications continue to tout rich features to meet users' diverse demands. This entails a continuous increase in both codes and data footprint [4, 31]. This trend has resulted in a constant demand for larger memory capacity on mobile devices to address memory pressure issues. However, the cost of the device and the power/area budget often limit its size.

Modern mobile OSes support virtual memory with compression-based swap [3, 13]. The virtual memory pro-

vides an illusion of physical memory space larger than the actual memory capacity, enabling multiple applications to run concurrently even under high memory pressure. However, the benefits come with additional overhead, degrading performance. Slow I/O accesses increase the latency of fetching non-resident file-backed pages from storage. To fetch anonymous pages in the compressed swap space, they first need to be decompressed by CPUs at a page fault. Allocating free pages also consumes system resources. Fetching pages on-demand via demand paging may not efficiently utilize available resources such as CPU cycles and I/O bandwidth.

Our empirical analysis shows that the application switch time can increase by a factor of $4\times$ (in the order of hundreds of milliseconds) when the system is experiencing memory pressure, possibly when running many background applications. This slowdown is mainly attributed to the long blocking time introduced by demand paging for both file-backed and anonymous pages during the application switch rather than freeing allocated pages.

A recent study shows that today's smartphone users often run more than 10 applications [25], and thus it is likely that the system is often operating under memory pressure unless the phone has a large main memory capacity. It is also known that users switch between applications more than 100 times per day [9]. We speculate that such frequent, long-latency events can potentially affect smartphone user experience negatively. In this paper, we aim to reduce the latency of the application switch by minimizing the demand-paging related slowdown. To achieve this goal, we propose ASAP, a mechanism for fast application switch via adaptive prepaging. ASAP builds on the following key observations:

- Hardware resources for fetching non-resident pages are underutilized during the application switch when the system is under memory pressure. For eight popular Android applications, CPU utilization is 34.2% during the switch. Also, only 19.4% of the maximum disk bandwidth is used on average.
- File-backed pages and anonymous pages have differ-

ent characteristics in their *switch footprint*, a set of accessed pages during the application switch. In particular, the switch footprint for file-backed pages is much more invariant—about 75% of all accessed file-backed pages are invariant across switches, while only 44% of anonymous pages are invariant. This motivates us to use different prediction strategies for prepagating them.

We capitalize on these empirical observations to develop an effective prepagating approach. The first observation suggests that it is promising to utilize available resources to prepage pages likely to be accessed at the beginning of an application switch. The prepagating is helpful to maximize the effective CPU and disk bandwidth utilization, which can translate to performance gains (i.e., reduced switch time). The second observation suggests that the target pages to fetch need to be adapted at runtime to capture the applications' dynamically changing page access patterns. This improves the prediction accuracy for the switch footprint, hence making ASAP more effective.

At an application switch, ASAP wakes up multiple prepagating threads to start fetching both file-backed pages and anonymous pages. These threads run in parallel with application threads to overlap prepagating with application computation. To accurately predict switch footprint pages, ASAP employs an adaptive prediction mechanism. Specifically, a single predictor maintains two tables: a candidate table and a target table. The predictor promotes or demotes pages between the two tables based on the runtime information of their access patterns. The prepagating threads issue fetch requests only for the pages in the target table, while pages having a smaller chance of being accessed are maintained in the candidate table.

We have implemented ASAP in Android OS and evaluated it using a set of eight popular mobile applications on Google Pixel 4 and Pixel 3a. The evaluation results show that ASAP considerably reduces the application switch time under memory pressure. ASAP reduces the switching time by 22.2% and 28.3% on average (33.3% and 35.7% at maximum) on Pixel 4 and Pixel 3a, respectively, over the vanilla Android 10. This improvement is attributed to an average of 39.8% and 25.2% increase in CPU and disk bandwidth utilization, respectively, as well as 79.3% and 68.4% prediction accuracy for file-backed and anonymous pages, respectively.

In summary, this paper makes the following contributions:

- We empirically analyze the performance bottleneck of the application switch to identify opportunities for prepagating as a solution to the problem.
- We propose ASAP, an adaptive prepagating technique to reduce the switch time, which is a key user interaction on the mobile device. ASAP is application-agnostic without requiring any change to application codes.

- We integrate ASAP into Android OS and evaluate its performance by using eight popular mobile applications on high-end and mid-end devices (Google Pixel 4 and Pixel 3a). The results demonstrate the effectiveness of ASAP for reducing the application switch time by 22.2% and 28.3% on average, respectively, over the vanilla Android 10.

2 Background and Motivation

2.1 Android Application Memory Management

Application Lifecycle and Memory Management. In Android OS, an application (specifically the application activity) is either in the foreground (i.e., having focus) or in the background (e.g., not visible). In other words, the application that a user is actively using is considered to be in the foreground, while the applications that have been launched but are not currently being used are considered to be in the background. When the system has sufficient DRAM, all application data are kept in memory. However, a user often utilizes many different applications over time, and eventually, application data exceed the DRAM capacity. In such a case, the Android low memory killer daemon (*lmkd*) identifies the least essential application (e.g., one in the background) and kills it so that the memory space that it occupied is freed [21, 26]. Note that this does not necessarily result in the complete loss of the application state since Android applications often store a minimal set of its states when the application is moved to the background. With this mechanism, Android OS only stores a small set of essential application data in memory. For this reason, when a user starts an application that was moved to the background a long time ago and hence killed by *lmkd*, the application data is not resident in memory. Instead, the application needs to recreate all of its activities from scratch utilizing the saved state information. On the other hand, when a user starts an application that was moved to the background very recently, it is much more likely that this application's data still resides in memory, and the application will be ready-to-use in a much shorter period. The time Android OS requires for the former case is called *launch time* and the latter is called *switch time* (sometimes also called *hot launch time*).

Compression-based Swap. An alternative approach to secure the free memory space is the compression-based swap, which compresses the least essential memory pages and stores them in a separate memory region. Later, when the application accesses the compressed pages, they are decompressed back to memory. Compared to the traditional disk-based swap mechanism, the compression-based in-memory swap is faster since it can avoid long-latency disk accesses. This approach's drawback is that i) compressed memory pages still consume memory capacity, and ii) compression/decompression spends CPU cycles. This mechanism is enabled by

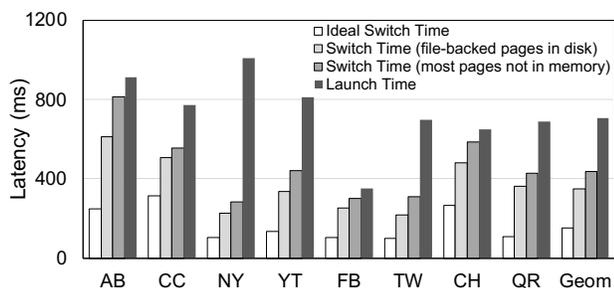

Figure 1: Application switch latency across different scenarios. *Ideal Switch Time* represents a case where all of the applications’ anonymous and file-backed pages reside in memory. *Switch Time (file-backed pages in disk)* represents a case where all of the applications’ anonymous pages are resident in memory, but almost all of file-backed pages do not reside in memory. *Switch Time (most pages not in memory)* represents a case where most of the applications’ anonymous pages are already swapped out, so they are compressed and stored in the compressed memory pool based on the compression-based in-memory swap. Also, almost all of file-backed pages are evicted from memory due to memory pressure. This latency information is equivalent to the baseline switch time illustrated in Section 6.1. Finally, *Launch Time* indicates a case where an application needs to start from scratch. Refer to Section 6.1 for the detailed methodology.

default in many commercial mobile OSes such as Android OS and Apple iOS [3, 13]. However, in practice, Android OS by default does not actively utilize this mechanism since *lmkd* is often triggered first to reclaim memory space before a swap happens [21, 25, 26, 35].

2.2 Launch Time and Switch Time

When a user relaunches an application after a while since its last usage, the latency to reload may differ depending on the system’s memory pressure. For example, if the system’s memory pressure is low (e.g., the system has not used much memory since the application’s last launch), the application’s data will still reside in memory. Thus the application could reload quite quickly (i.e., *ideal switch time*). On the other hand, if the system’s memory pressure is high (e.g., the user utilized many different apps during the time window), the application will be killed by *lmkd*. The relaunch is highly likely to require recreating the application’s activities, incurring a much longer delay (i.e., *launch time*). Finally, if *lmkd* is disabled, the compression-based swap mechanism will come into play. The application’s anonymous pages will be stored in memory in a compressed form, and the file-backed pages will be discarded. In this case, relaunching an application requires decompressing some of the application’s anonymous pages and reloading file-backed pages from the disk.

Figure 1 presents the application launch/switch time of eight real-world applications (AB: Angry Bird, CC: Candy Crush Saga, NY: New York Times, YT: YouTube, FB: Facebook, TW: Twitter, CH: Google Chrome, QR: Quora) on Google Pixel 4. The figure shows that the switch time is lower than the launch time in all applications. This indicates that reconstructing activities of an application from scratch requires more time than retrieving the relevant anonymous pages and file-backed pages from memory and disks, respectively. This implies that an aggressive setting of Android *lmkd* increases the time to relaunch the application, which confirms the findings of the previous literature [18, 20, 21]. To avoid this unnecessary delay in relaunching the application, it is better to lower the *lmkd* threshold (or even disable it) so that the system can utilize compression-based swap more actively.

This figure also shows a significant gap between the ideal switch time and the switch times under memory pressure. The gap between the *ideal switch time* and the *switch time (file-backed pages in disk)* quantifies the overhead of retrieving file-backed pages from the disk. The gap between the *switch time (file-backed pages in disk)* and the *switch time (most pages not in memory)* indicates the overhead of decompressing anonymous pages from the compressed memory pool. In fact, this overhead increases the application switch time by a factor of 4× relative to the ideal switch time on average. Unfortunately, the real-world switch time is often closer to the switch time (most pages not in memory) than the ideal switch time when we consider recent trends: i) an increase in an application’s memory capacity requirements and ii) an increase in the number of apps that a user runs concurrently.

To the best of our knowledge, there are no concrete studies on the threshold of user perception of the application switch. However, previous studies [7, 27] on related contexts imply that the delay of hundreds of milliseconds in the application switch may degrade the user experience. According to Card [7], users feel that a system is reacting instantaneously only when the response time is shorter than 100 ms. Olen-ski [27] reports that a 100 ms delay in web page loading can degrade the user experience, resulting in a 1% drop in a company’s revenue. Thus, we are convinced that maintaining a lower switch time over a wide variety of usage scenarios is critical for user experience.

2.3 Opportunities for Prepaging

Limitations of Demand-Paging. Figure 1 shows that the switch time under memory pressure is substantially worse than the ideal switch time. We find that such a huge overhead resulting from i) decompressing anonymous pages and ii) retrieving file-backed pages from the disk is attributable to the inefficiencies of demand paging. Figure 2(a) shows the CPU utilization and Figure 2(b) shows the disk bandwidth utilization of Google Pixel 4 during switch time of eight applications under memory pressure. Overall, the CPU utilization

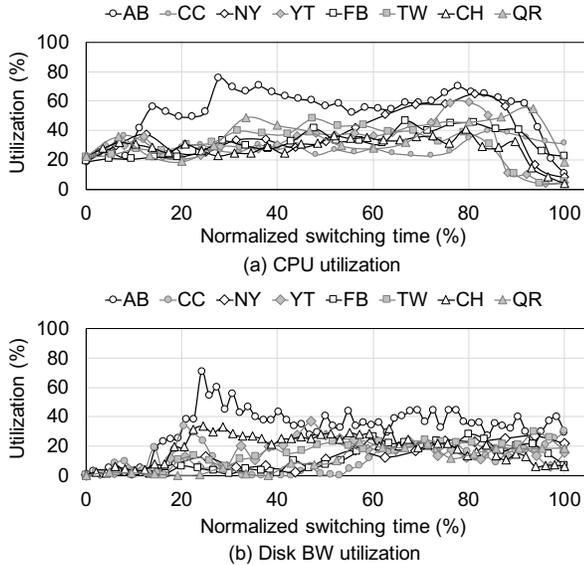

Figure 2: CPU and disk bandwidth utilization of a high-end device (Pixel 4) during the switch time.

remains relatively low (i.e., less than 50%) for all applications except AB. Similarly, disk bandwidth utilization is also much lower than the sustainable peak bandwidth most of the time. As shown in Figure 3 for Google Pixel 3a, its disk bandwidth utilization is higher than that of the high-end device (Pixel 4) because the disk bandwidth is relatively low. However, the empirical results show that the resources are not still fully utilized in both cases.

Ideally, the CPU should have been fully utilized to decompress compressed memory pages, and disk bandwidth should have been saturated to retrieve file-backed pages from the disk. However, since the default demand paging mechanism initiates the decompression of memory pages and I/O accesses only at a page fault, the system wastes available resources and spends more application switch time than necessary.

Opportunities and Challenges of Prepaging. The key idea behind ASAP is that we can significantly improve the switch time by letting prepaging threads aggressively decompress memory pages and perform I/O accesses before the application codes demand them. By doing so, ASAP can fully exploit the available system resources (i.e., CPU cycles and disk bandwidth), making the switch time under memory pressure much closer to the ideal switch time. There are two main challenges in this approach. First, the system should effectively identify the switch footprint, a set of pages to be accessed during the switch. Second, the prepaging threads should be efficiently implemented to fully exploit available resources while minimizing their interference with application threads. The following sections describe how ASAP addresses these two challenges.

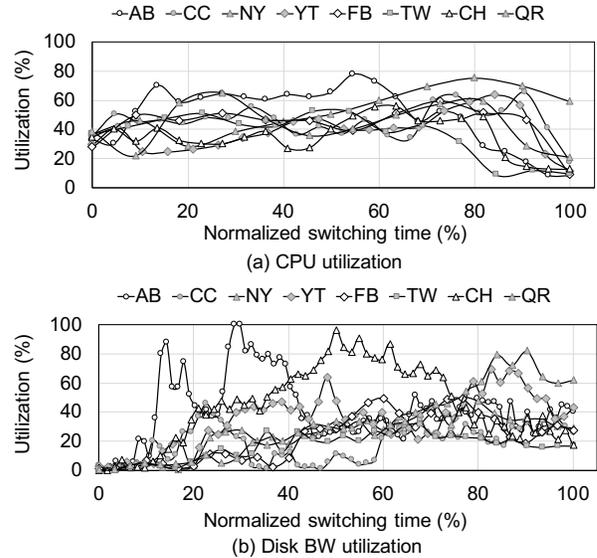

Figure 3: CPU and disk bandwidth utilization of a mid-end device (Pixel 3a) during the switch time.

3 ASAP Design Overview

The empirical observations in the previous section suggest that it is promising to design an adaptive prepaging. We first set two key requirements to design a practical prepaging mechanism:

1. The proposed design should be able to accurately predict a set of pages that are likely to be accessed during an application’s switch time (i.e., switch footprint).
2. The proposed design should be able to maximize the efficiency of prepaging by achieving high system resource utilization (i.e., CPU cycles and disk bandwidth) without interfering with the execution of application threads.

ASAP satisfies these requirements with *Switch Footprint Estimator (SFE)* and *Prepaging Manager*. We have integrated them into the application switching process in Linux kernel. Thus, ASAP is application-agnostic without requiring any changes to application codes.

Figure 4 illustrates the overall structure of ASAP with key components shaded in gray. SFE consists of two estimators: one for anonymous pages and the other for file-backed pages. Based on the analysis on the switch footprint, SFE for file-backed pages utilizes offline profiling results as well as a lightweight runtime module to estimate the mostly invariant switch footprint of file-backed pages. On the other hand, SFE for anonymous pages is designed to track a dynamic switch footprint of anonymous pages by gradually promoting pages that are likely to be fetched again during the next switch.

These estimators generate a set of target pages for prepaging, which are retrieved at the beginning of an application

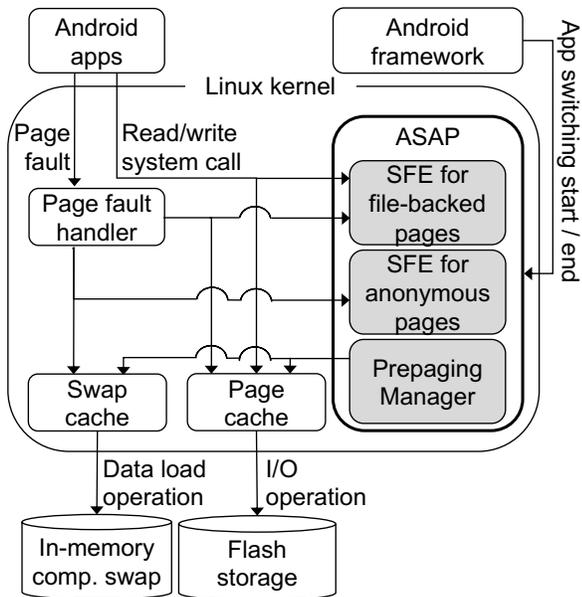

Figure 4: ASAP design overview.

switch. It is possible that page information in the prepping target table becomes obsolete due to inconsistent memory reuse patterns of applications (e.g., application update, post-installation optimization with *dexopt*). Based on the hit/miss history of prepping, the information is updated over time to ensure high prediction accuracy.

Preparing Manager is responsible for prepping threads that are used to fetch target pages from a prepping target table. It monitors a timing signal that notifies the start and the end of the application switch event from the Android framework. Prepping Manager promptly wakes up inactive prepping threads for the switched application when it receives a start signal for application switch, and then it initiates prepping. Multiple prepping threads are created according to the number of available CPU cores and run in parallel with application threads to fully utilize the available system resources such as CPU cycles and disk bandwidth. Once they finish issuing fetch requests for all the pages from the prepping target table, the prepping manager makes them sleep again until the next switch.

4 Switch Footprint Estimator

4.1 Switch Footprint Analysis

To effectively estimate the targets for prepping, it is important to understand the characteristics of the switch footprint: a set of pages that are accessed during the switch time. For this purpose, we perform an experiment that exhaustively records all pages accessed across 10 switches for each application

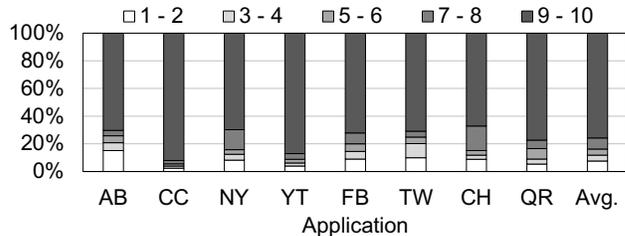

Figure 5: Switch locality analysis for file-backed pages.

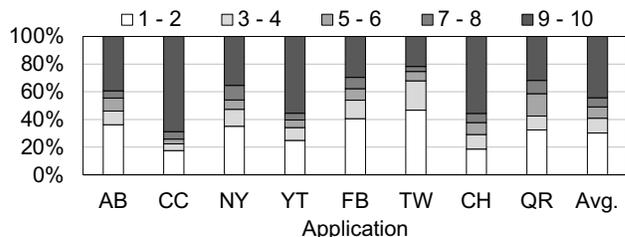

Figure 6: Switch locality analysis for anonymous pages.

(experimental details are available in Section 6.1). For this we cleared the access bit of all present PTE in the address space just before the switch and then checked them right after the switch is completed.

File-backed Pages. Figure 5 shows the switch footprint composition for file-backed pages. The stacked bar shows how many times pages are accessed over the 10 application switches. The switch footprint is largely invariant in this case. On average, about 75% of pages are accessed 9 or 10 times and only 10% are accessed fewer than five times. This highly invariant access pattern of the file-backed pages is due to the fact that a large part of codes and shared library files keep being loaded for the execution of an application.

Anonymous Pages. Figure 6 shows the switch footprint composition for anonymous pages. The access pattern is not as invariant as file-backed pages. About 44% of the anonymous pages are accessed 9 or 10 times across 10 switches. The portion of the invariant (i.e., always accessed) pages is much smaller as the set of accessed anonymous pages easily changes when the application context changes.

Implications. As the characteristics of the switch footprint for anonymous pages and file-backed pages differ, so should their switch footprint estimators. Estimation for file-backed pages can exploit the fact that file-backed pages are highly invariant to minimize the runtime overhead. On the other hand, estimation for anonymous pages needs to rely more on the runtime information so that it can correctly track dynamically changing switch footprints across switch events. Still, the runtime overhead of tracking the switch footprint for anonymous pages is relatively low as the number of anonymous pages in the switch footprint is much smaller than that of the file-backed pages, as shown in Figure 7. The rest of this section discusses the SFE design for both file-backed pages (Section 4.2) and anonymous pages (Section 4.3).

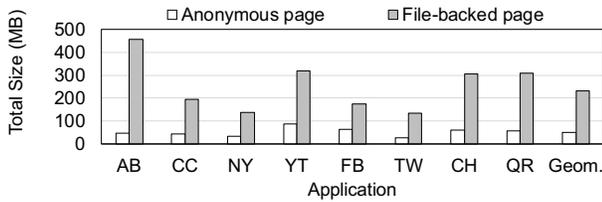

Figure 7: Switch footprint of anonymous and file-backed pages across different applications.

4.2 Estimator for File-Backed Pages

As shown in Figure 5, a major portion of file-backed pages accessed during the application switch are invariant across switches. To exploit this characteristic, SFE for file-backed pages first performs offline profiling to identify the set of potential candidates for prepagging, and then later utilizes minimal runtime information to maintain a concise set of prepagging targets, as shown in Figure 8.

Offline Profiling. The estimator performs offline profiling to obtain a set of prepagging candidates. For this purpose, we measure the file-backed pages that are accessed during ten switch events for each app, as in Figure 5. Then, pages accessed more than eight times (out of ten trials) are considered to be frequently accessed. The resulting set of pages is stored as a file (*Offline Candidate Table*). Specifically, as shown in Figure 8, the profiled result is stored as a map, where a filename is a key and a list of pairs (offset, len) is a value. Each pair represents [offset, offset + len) pages within a file that are accessed during an application switch (we call it an *extent* in the rest of this paper). Later, the profiled result is reloaded at the launch time of this application.

Fault Logging. Fault logging happens at every switch event. Specifically, SFE logs the inode and page indices of all faulted extents received from the kernel until the end of the switch time. This is stored in a *fault buffer*, which is later utilized by the estimator after the end of the switch time to update its prepagging targets.

Prepagging Target Management - Insertion. Once the switch finishes, a background thread performs prepagging target management, exploiting the information from the offline profiling and the fault logging. *Prepagging Target Table* stores information for extents that are to be fetched by the prepagging threads. Ideally, we should insert only those extents that are likely to be fetched in the near future. To identify such an extent, the estimator first inspects an extent in the fault buffer and checks if the extent is also found in the *Offline Candidate Table*. If so, the estimator inserts the corresponding entries into the *Prepagging Target Table*.

Prepagging Target Management - Extent Merging. The *Prepagging Target Table* may have multiple extents on the same file. In such a case, if two extents are close to each other (e.g., the end of one extent is less than 16 pages apart from

the start of the other extent), we merge those two extents and create a larger extent that covers both. This is to avoid issuing multiple fragmented I/O requests and instead issue a single, sequential large I/O request, which is often handled much more efficiently.

Prepagging Target Management - Eviction. Eviction from a *Prepagging Target Table* happens when the fetched page turns out to be not utilized during a switch time. Specifically, the estimator checks the mapcount of each fetched page after the switch, and removes the page from the *Prepagging Target Table* if the mapcount is zero. When a page is part of an extent, the extent is divided into two smaller extents.

4.3 Estimator for Anonymous Pages

As shown in Figure 6, the set of anonymous pages accessed during the application switch changes much more frequently than files. Moreover, anonymous pages are allocated whenever the application is launched, and thus offline profiling is not helpful for identifying prepagging candidates. To effectively track the switch footprint for anonymous pages, we focus on runtime analysis, unlike the case of file-backed pages (Section 4.2). Policies of the estimator are depicted in Figure 9.

Fault Logging. During the application switch time, like the estimator for file-backed pages, the Switch Footprint estimator for anonymous pages logs all anonymous page faults. Fault information is logged at a fault buffer for later usage.

Access Logging. To track access information during switch time, this estimator clears the access bit of every PTE represented by each page identifier in both the *Prepagging Target Table* and the *Online Candidate Table* before every application switch time. Then, right before the end of the switch time, the access bits of all pages in both tables are again checked to identify a set of pages that are accessed during switch time.

Prepagging Target Management - Check & Insertion. After the application switch time, this estimator first checks if each page in the fault buffer is not already present in the *Online Candidate Table* nor the *Prepagging Target Table*. If there are pages that are not already present in the tables, they are inserted into the *Online Candidate Table*.

Prepagging Target Management - Promotion. Also, the estimator checks if each page in *Online Candidate Table* has been accessed during the switch time by inspecting the access log. If a page has been accessed during the last switch time, the page in the *Online Candidate Table* is then promoted to the *Prepagging Target Table*.

Prepagging Target Management - Eviction. Every page in both the *Online Candidate Table* and the *Prepagging Target Table* has its own timeout counter, which is the number of switch events a page can experience before getting evicted from a table. The timeout counter (e.g., 5) of a page is decremented after every switch time. If a specific page is not accessed until the timeout counter reaches zero, it is evicted from the

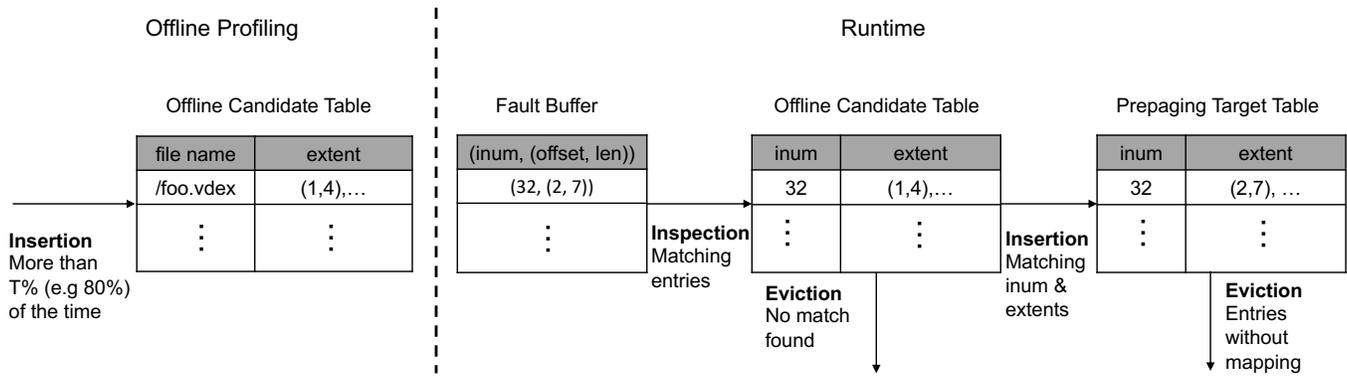

Figure 8: Switch footprint estimator for file-backed pages.

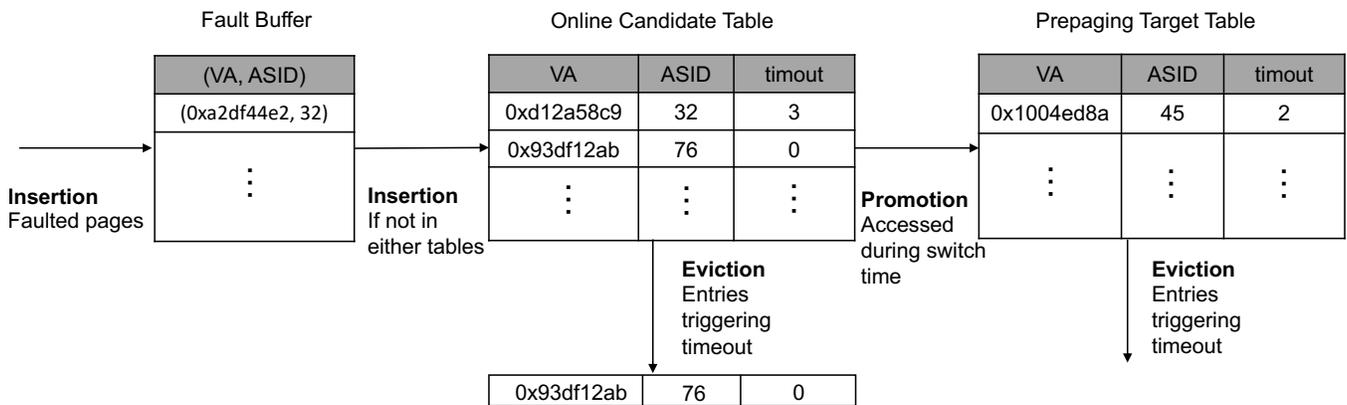

Figure 9: Switch footprint estimator for anonymous pages.

table that it belongs to. But, whenever a page is accessed, the timeout counter of an identifier is reset to the default timeout counter value (e.g., 5).

5 Prepaging Manager

Whenever an application switch event occurs, ASAP’s Prepaging Manager wakes up threads. They prefetch pages in the *Prepaging Target Table*, which eventually constructs corresponding PTEs. We apply different prepaging policies to anonymous pages and file-backed pages as follows.

5.1 Prepaging Anonymous Pages

Prepaging of anonymous pages requires decompressing swapped out pages in the compressed in-memory swap space. Hence, the task is compute-intensive, and the task should be carefully scheduled not to incur CPU contention between application threads and prepaging threads. Although the CPU utilization is low, as we reported in Section 2.3, the application threads can demand more CPU resources due to reduced

page fault events by prepaging operations.

To this end, the prepaging manager maintains a set of threads for anonymous page prepaging. We pinned a thread on each core, and we assigned the lowest priority (i.e., SCHED_IDLE [17]) to them. This allows us to opportunistically utilize the surplus CPU resources for the prepaging of anonymous pages while not incurring any CPU contention with the application threads.

The distribution of prepaging work is done in a work sharing manner. Each thread retrieves a batch (16 pages) from the *Prepaging Target Table*, and then conducts the prepaging operations for pages in the batch. Specifically, for each virtual page in the batch, each thread checks whether the virtual page is present in the process’s address space. If non-present, it issues a swap-in operation for the virtual page to the swap subsystem (i.e., the swap cache). The swap-in operation eventually becomes the decompression operation in the in-memory compressed swap device. After the target page is decompressed, the thread finally makes the corresponding PTE point to the swapped-in page.

5.2 Preparing File-backed Pages

The prepaging manager maintains another set of threads for prepaging file-backed pages. However, file-backed pages impose a higher miss penalty than anonymous pages due to long disk I/O time. Therefore, we take a different prepaging policy for file-backed pages as follows.

First, a file is a unit of prepaging work distribution. Each thread is assigned a file from the *Prepaging Target Table*, and then prefetches pages of the file. For the prepaging operation, each thread issues asynchronous page cache read operations for the corresponding extents in the *Prepaging Target Table*. Note that the *Prepaging Target Table* estimates pages are not only accessed through page faults but are also accessed via read/write system calls. Hence, not all prefetched pages need to be mapped in the process’s virtual address space. Prepaging the pages in the *Prepaging Target Table* places fetched pages into the page cache, and thus page faults can still occur for those prefetched pages. However, their fault handling cost is light when the corresponding pages are in the page cache (i.e., minor faults in Linux). When a page fault occurs for a file-backed page, the page fault handler retrieves pages surrounding the missing page from the page cache and maps them all together in the virtual memory to reduce page fault frequency; hence performing prepaging.

Second, we dedicate at least one thread to continuously perform prepaging of large file-backed pages. Figure 10 shows the cumulative distribution of accessed pages of files in the switch footprint of the applications. As shown in the figure, about 90% of the total number of accessed pages is part of the top 15% of large files. Thus, we can expect spatial locality of such accesses to large files. This indicates that if those files are assigned to the prefetching threads with the `SCHED_IDLE` priority, pages of the files are not likely to be prefetched on time due to the lowest CPU scheduling priority. To avoid this problem, we designate one thread with `SCHED_NORMAL` priority running on the big core to be in charge of prefetching pages of large files. Considering the big-LITTLE heterogeneity of the CPU cores in mobile systems, the thread is assigned to run on a big core to maximize the prefetching performance. We have empirically found that this configuration is effective in reducing the miss ratio as well as the CPU contention with application threads.

Lastly, during the prefetching of file-backed pages, file metadata should be carefully handled. Unless file metadata (e.g., logical block addresses of file pages) is in memory, the metadata retrieval incurs additional delay, which in turn degrades the effectiveness of prefetching [23]. This problem exacerbates because of our extent-based prefetching. The metadata read I/O can stay behind a large prefetching I/O request, thereby blocking the prefetching threads as well as the application threads. To avoid this problem, our scheme attempts to read metadata blocks before prefetching pages of a corresponding file. The metadata block reads are done

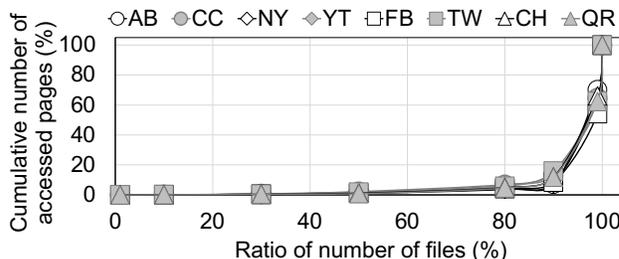

Figure 10: Cumulative number of accessed pages CDF of files across the various applications during switch from one application to another one. Files are sorted by size. 100% indicates the largest file.

by accessing file pages with a large stride in file offset, 512 pages in our case, because a direct block contains LBAs of 512 data blocks in F2FS [22].

6 Evaluation

In this section, we evaluate the effectiveness of ASAP. Section 6.1 describes the evaluation methodology and workloads. Then, we evaluate the latency benefits of our proposal in Section 6.2. Section 6.3 analyzes the accuracy of the switch footprint estimator. We evaluate the efficacy of the prepaging manager by considering improvement of the effective disk bandwidth and CPU utilization.

6.1 Methodology

Switching Latency Measurement. To measure the application switching latency, we used the `am` command in the Android debug bridge (`adb`) [2]. This command starts a selected application and reports two types of switching latency. One is latency from a user’s touch to the first rendering, and the other one is latency from a user’s touch to the full rendering [5]. The latter is reported only when the application developer implements the debug callback. The information is reported only by the YT application among eight benchmark applications. Thus, we use the time to the initial rendering as a metric. For the YT application, we observe that the additional latency overhead of the full rendering is less than 5% of the switch latency (10-20 ms). Users could also start to interact with applications in the middle of the rendering [16]. The actual latency overhead is expected to be insignificant when the performance benefits of ASAP are considered. This justifies our usage of the time to the initial rendering as the metric for evaluation.

System Configuration. For our evaluation, we use Google Pixel 4 and Pixel 3a, which represent high-end and mid-end devices, respectively. Table 1 describes their specifications. We implement ASAP in Android 10. When measuring the application switch overhead under memory pressure, we consider two aspects for our experimental methodology.

Table 1: Device Specifications

Device	Google Pixel 4	Google Pixel 3a
CPU	Octa-core Qualcomm Snapdragon 855	Octa-core Qualcomm Snapdragon 670
DRAM	6GB LPDDR4x (eff. 4GB)	4GB LPDDR4x
Storage	64GB UFS 2.1	64GB eMMC 5.1
OS	Android 10.0.0 (r41) with Linux kernel 4.14	Android 10.0.0 (r41) with Linux kernel 4.9
zram	2GB (default)	2GB (default)

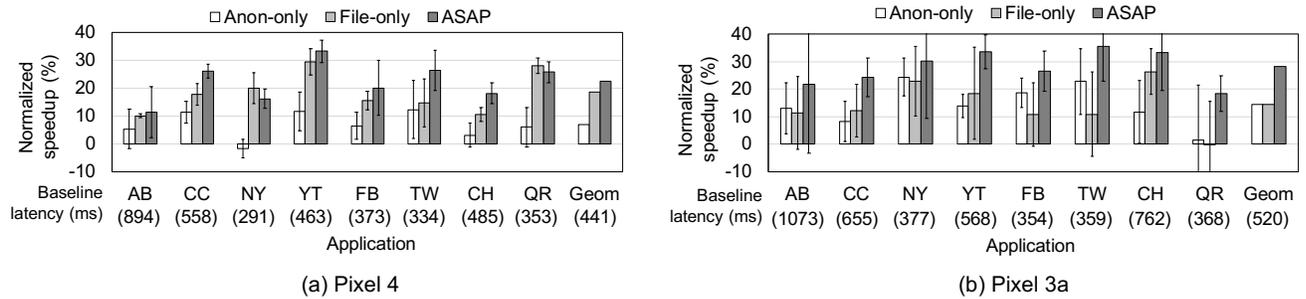

Figure 11: Normalized speedup of application switching latency on (a) Pixel 4 and (b) Pixel 3a. Numbers in parentheses indicate absolute switching latency of the baseline system in ms. Error bar shows standard deviation over different sequences.

Table 2: Applications and automated interactions to change contexts.

Application	Automated Usage Patterns
Angry Bird (AB)	Play a stage
Candy Crush (CC)	Play a stage
New York Times (NY)	Browse and read articles
Youtube (YT)	Watch videos
Facebook (FB)	Browse and read posts
Twitter (TW)	Browse and read posts
Chrome (CH)	Browse keywords
Quora (QR)	Browse questions and answers

Table 3: Chosen 3 application test sequences.

Sequence 1	YT-CH-CC-AB-NY-QR-FB-TW
Sequence 2	QR-NY-CH-CC-YT-TW-FB-AB
Sequence 3	AB-FB-QR-TW-CC-CH-YT-NY

First, we favor the compression based swap approach over the *lmkd*, which often acts first to secure free memory and prevents the system from being under memory pressure. Note that Android currently enables both features by default. We disable the *lmkd* for our evaluation to solely analyze the performance impact on application switch under memory pressure.

Second, users show different application usage patterns such as a spectrum of day-to-day use applications and the use of multitasking features. These lead to different memory usage patterns even among smartphone users who have the same devices.

In this work, thus, we focus on evaluating the memory

pressure impact of the application switch for a fixed set of a wide spectrum of top rated applications (refer to Table 2). We enable memory ballooning by considering the entire footprint of the target applications instead of enabling numerous applications to cause memory pressure for the target devices. The effective memory size of both Pixel 4 and Pixel 3a is 4GB. Throughout our evaluation, we refer to the switch time measured on this configuration as the *baseline switch time*.

Workloads and Automation of Tests. In order to reduce the run-to-run variation in the experimental results, we carefully devise an automation program that closely mimics a set of pre-determined user interactions with *adb*. For example, the Facebook (FB) usage pattern contains scrolling down the main news feed, searching for user profiles, and watching their timelines. Another example would be YouTube (YT), where our program searches and watches different video clips. The details of the usage patterns are listed in Table 2.

After execution of a certain application, e.g., Candy Crush (CC), we switch to the next application, e.g., TW, by following a pre-determined sequence of applications. As there are $8!$ available application sequences for eight applications, we chose three random sequences to evaluate ASAP (Table 3). The start and end time of the application switching operation is informed by the Android activity manager [1, 12]. We iterate the selected sequence 10 times and measure the application switch time. With this user interaction automation program, we repetitively conduct the same evaluation process.

6.2 Application Switch Latency

Figure 11 presents the speedup of ASAP based on Pixel 4 and Pixel 3a, respectively, for 8 applications. We also evaluate the speedup by selectively enabling prepaging for either anonymous pages or file-backed pages. Compared to the baseline, ASAP shows an average of 22.2% and 28.3% performance improvement, and a maximum of 33.3% (YT) and 35.7% (TW) on Pixel 4 and Pixel 3a, respectively. We observe 6.8% and 14.6% performance improvement on each device on average when ASAP performs prepaging only for anonymous pages (*Anon-only*). Among the eight applications, YT and TW show the most noticeable latency reduction on Pixel 4 and Pixel 3a, respectively. With prepaging for file-backed page only (*File-only*), the latency is reduced by 18.3% and 14.4% on average. Here, YT and CH show a substantial latency reduction on each device.

When both SFEs are enabled (ASAP), we observe additional performance benefits for most cases as expected. However, in NY and QR on Pixel 4, integrating both SFEs does not further reduce their switch latency.

6.3 Estimator Efficiency

Figure 12 presents the efficiency of the proposed switch footprint estimators for both Anonymous SFE and File-backed SFE. Since we observe similar performance trends on both devices, we will only present the results on Pixel 4 in the rest of this section. Precision is defined as a fraction of correctly prepaged pages among entire prepaged pages. Recall is defined as a fraction of correctly prepaged pages among all faulting pages during the switch time when the baseline system is considered. Anonymous SFE shows an average of 68.4% precision and 60.4% recall. File-backed SFE shows an average of 79.3% precision and 52.2% recall. The Switch Footprint Estimator for file-backed pages shows better precision relative to that of the Switch Footprint Estimator for anonymous pages. The difference comes from the fact that the switch footprint of file-backed pages is more static, as described in Figure 5.

The gap between precision and recall comes from the coverage of the prepaging target tables. Note that both precision and recall have the same numerator value while the denominator of recall can cover more pages that have not been fetched by the proposed prepaging scheme. We see a larger gap between the precision and the recall of file-backed page prepaging relative to the gap of anonymous page prepaging. This could result from the limited coverage of the candidate pages that is based on the static profiling. The static profiling approach may not capture the entire set of pages that are likely to cause faults at runtime.

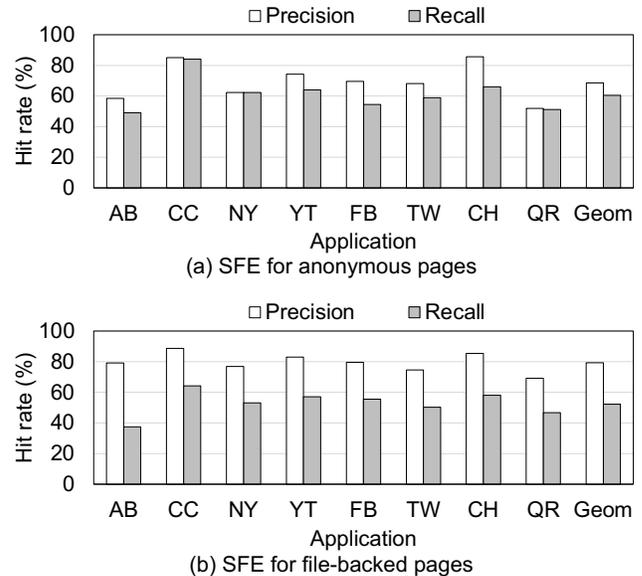

Figure 12: Switch footprint estimator performance.

6.4 Resource Utilization

To show the efficacy of ASAP on prepaging, we evaluated the changes in CPU and memory bandwidth utilization on Pixel 4. The bandwidth utilization is computed as the ratio of achieved file read throughput to the maximum sequential throughput measured in fio [10]. As depicted in Figure 13, ASAP eagerly allocates threads for decompression, which increases the CPU utilization to $1.18\times$ on average over the total switch time, compared to the baseline switch. We also notice the maximum of $1.35\times$ utilization increase. The CPU has been under utilized at the beginning of the application switch. In most cases, the anonymous prepaging threads have a large window of opportunity to fully exploit the available CPU resources. Therefore, when ASAP is enabled, the CPU utilization improves at the early stages of switching. Because the throughput of zram actually scales depending on the number of CPU cores, the anonymous prepaging threads can prepage anonymous pages at great speed. For most applications, prepaging threads finish at around the first 30% of normalized switching time. After that, the CPU utilization follows the CPU utilization pattern of the baseline. On the same page as the CPU, ASAP also improves the I/O bandwidth by 25.2% on average, as shown in Figure 14. In most cases, we observe a noticeable increase in the I/O bandwidth at the early stages of switching and the maximum achieved bandwidth is also higher than that of the baseline. ASAP does not induce significant improvement over the baseline in the case of AB. This is because AB is a highly parallel application with high I/O utilization. Therefore, the I/O bandwidth improvement from our asynchronous I/O threads is limited. The empirical analysis substantiates that ASAP efficaciously exploits the resources at the beginning of the switch to considerably reduce

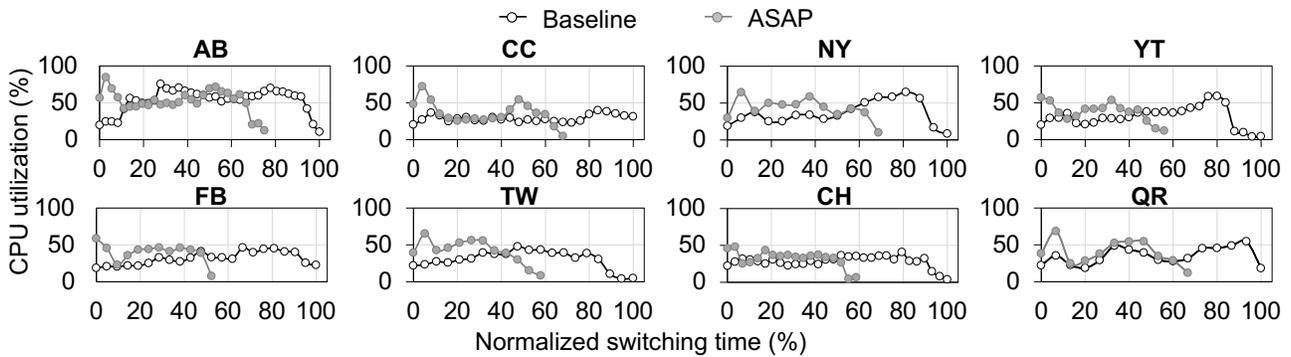

Figure 13: CPU utilization. X-axis is a timeline normalized to baseline’s switch time.

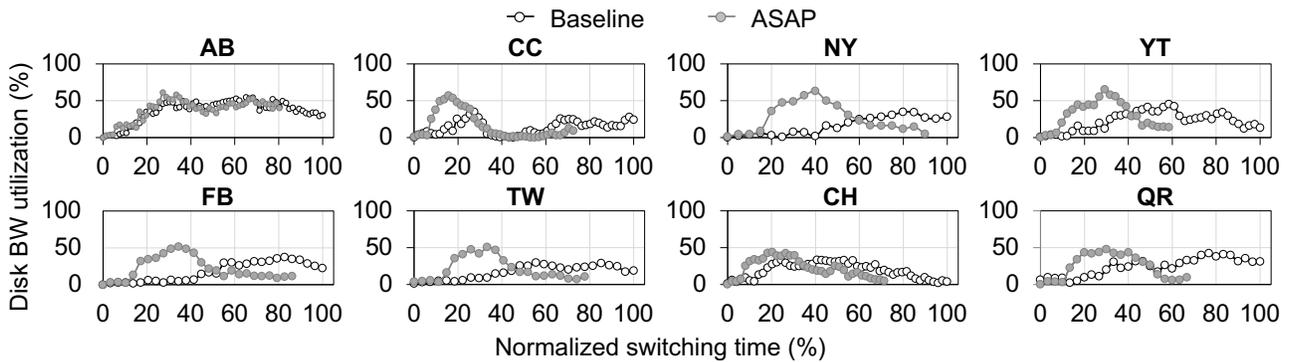

Figure 14: Disk bandwidth utilization. X-axis is a timeline normalized to baseline’s switch time.

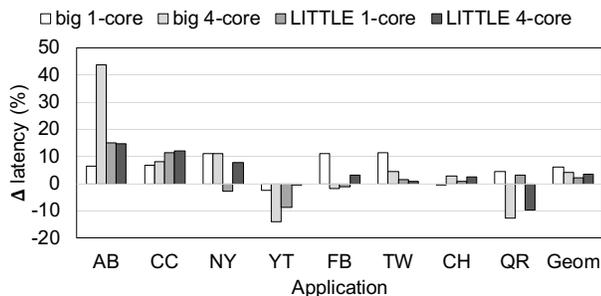

Figure 15: Switching latency changes depending on different core scheduling policy compared to ASAP’s core scheduling policies. Positive latency change means that the static policy is worse than ASAP’s policy.

the application switch latency.

6.5 Efficiency of Core Scheduling

To quantify the effect of core scheduling of the file prepping threads (Section 5.2), we compare our policy on Pixel 4 with four other static policies: big 1-core, big 4-core, LITTLE 1-core, and LITTLE 4-core. For example, in LITTLE 4-core, four file prepping threads are scheduled on the four LITTLE

cores, and the threads are assigned the SCHED_NORMAL priority. And we enabled only file prepping to reduce performance deviation. Figure 15 shows the delta of application switch latency (the latency of the four naive policies minus the latency of our scheme). Each naive policy shows 1.06×, 1.05×, 1.02×, 1.04× times slower than ours on average. Hence, our performance advantage comes from the fact that our policy is versatile to different situations. For example, the big 4-core policy showed 14% and 13% better performance than our policy on YT and QR, however its performance falls dramatically on AB since AB utilizes both CPU and disk bandwidth intensively, so file prepping threads contended a lot with AB’s application threads. On the other hand, the LITTLE 4-core policy is better than ours in QR and AB, but it is vulnerable to applications requiring heavy file I/O because of the slow prepping speed.

6.6 Overhead

Anonymous SFE maintains an *Online Candidate Table*, *Prepping Target Table*, and anonymous fault buffer. Their peak size for 8 applications is 1MB, 2.5MB, and 0.5MB, respectively. The size of the *Offline Candidate Table*, *Prepping Target Table* and file fault buffer used by File-backed SFE is 1.5MB, 0.2MB, and 0.5MB, respectively, at their peak respec-

tively. On average ASAP uses about 800KB per application.

Access bit logging (clearing access bits at the beginning and inspecting them at the end of the switch time) extends the switch time by up to 14ms. Also, prepagating target management operations which opportunistically runs between the switch events takes 40ms CPU time in the worst case.

Finally, mis-prediction events result in extra fetch overhead, which could increase the energy consumption. On average, ASAP fetches an extra 10MB for anonymous pages and file-backed pages, respectively. Also the peak throughput of decompression and the disk bandwidth are 2GB/s and 600MB/s on Pixel 4, respectively. Therefore, each extra fetch takes tens of milliseconds. When the peak power of UFS 2.1 [33] and TDP of Snapdragon 855 [32] are considered, these extra fetches require negligible overhead. Actually, we expect ASAP to save the energy consumption of the entire device including other components (e.g., display) because ASAP reduces the total switch latency. Thus, this marginal energy overhead can be easily offset.

7 Related Work

Efficient Memory Management in Mobile Systems. Modern mobile systems reclaim free pages by killing the least essential applications (e.g., low memory killer in Android [26]). The traditional low memory killer selects a victim process by considering the priority and the number of pages of application only. SmartLMK [19] proposes to kill an application to minimize the expected user-perceived application performance by carefully considering application usage statistics and application launch times. However, killing an application process is the most aggressive policy in memory reclamation [6], and whenever a killed application is launched again, it takes a large amount of computation and I/O operations, which can increase the user-perceived launch latency and the energy consumption of mobile devices [21, 24]

To end this senseless killing, Marvin [21] swaps out predicted unlikely-to-be-used pages to disks using ahead-of-time swap by modifying Android runtime (ART). Similarly, SmartSwap [35] includes process-level early page swap based on the prediction result but by addressing kernel codes. A2S [18] combines the low memory killer and the compressed swap together by carefully selecting the victim pages for swap-out and the victim process to kill. Acclaim [25] prioritizes pages of foreground processes over those of background processes during swapping. Kwon et al. [20] propose to swap-out GPU buffers of background processes to relieve memory pressure on mobile devices. Chae et al. [8] propose to extend the swap space of mobile systems to the cloud.

Accelerating Application Launch. Numerous studies have been conducted to shorten the application launch time, and most have tried to prefetch data effectively [12, 15, 28, 30, 34]. FAST [15] profiles I/O sequences during application launches and uses the profiled sequences for data prefetching.

FALCON [34] adopts machine learning to predict the users' application usage pattern. It predicts the next application a user is going to use and preloads the contents of the predicted applications. Nagarajan et al. [28] uses collaborative filtering to predict the impending applications while PREPP [30] uses prediction by the partial matching technique. IORap [12] in Android 11 profiles the required I/O during several cold-runs of an application and predicts which I/O will be required and does it in advance. These works only focus on predicting applications or I/O patterns during application launch events. However, our work predicts I/O patterns or memory access footprint during application switch events.

Efficiently Utilizing Disk I/O Bandwidth. The disk I/O performance is important to the user-perceived application performance. Accordingly, the efficient use of disk I/O is important. SmartIO [29] discovers that read I/O operations are penalized by write I/O operations and proposes to prioritize read I/O operations over write ones. Joo et al. [14] finds that swap I/O patterns for page faults are not efficient due to their small and random I/O request patterns. To overcome these inefficiencies, they insert pads to build large sequential I/O requests, which is more efficient in flash-based disks. FastTrack [11] prioritizes I/O requests from foreground applications over those from background ones throughout the entire I/O stack. These approaches are complementary to our work in terms of improving the I/O efficiency during disk access.

8 Conclusion

The goal of this paper is to improve user experience on mobile devices, focusing on the application switch, which is one of the most important user interactions. We proposed (ASAP), an adaptive prepagating scheme that accurately retrieves pages ahead of time that are expected to be accessed during application switch by fully exploiting the available system resources. Our experimental results based on real-world Android OS applications show that ASAP can reduce the application switch latency under memory pressure by 22.2% and 28.3% on representative high-end and mid-end smartphones, respectively. While ASAP was evaluated in the context of the application switch, we believe that it can easily be extended to reducing application launch time as well.

We open sourced Linux kernel we modified for ASAP. The code is available at <https://github.com/SNU-ARC/atc21-asap-kernel>.

PYLIVE: On-the-Fly Code Change for Python-based Online Services

Haochen Huang*, Chengcheng Xiang*, Li Zhong, Yuanyuan Zhou
University of California, San Diego

Abstract

Python is becoming a popular language for building online web services in many companies. To improve online service robustness, this paper presents a new framework, called PYLIVE, to enable on-the-fly code change. PYLIVE leverages the unique language features of Python, meta-object protocol and dynamic typing, to support dynamic logging, profiling and bug-fixing without restarting online services. PYLIVE requires no modification to the underlying runtime systems (i.e., Python interpreters), making it easy to be adopted by online services with little portability concern.

We evaluated PYLIVE with seven Python-based web applications that are widely used for online services. From these applications, we collected 20 existing real-world cases, including bugs, performance issues and patches for evaluation. PYLIVE can help resolve all the cases by providing dynamic logging, profiling and patching with little overhead. Additionally, PYLIVE also helped diagnose two new performance issues in two widely-used open-source applications.

1 Introduction

Python has gained wide adoption on developing online services. Many companies use Python to build their main online platforms. For example, Google's Youtube front-end server is built using Python [37, 51, 96]. Instagram's web services and Quora's main web services are also built with Python [36, 81, 94]. In addition to commercial companies, many open-source projects also use Python to build various frameworks for online services. Table 1 shows six categories of them, including web frameworks, e-commerce and message queues, etc.

These online services have critical requirements on high availability. A recent survey shows that 99.99% of uptime (i.e., 52.6 minutes per year) has become the minimum availability standard for most services [57]. A report from Statista shows that in 2020 one hour server downtime can cause more than \$301K cost for 88% of companies and more than \$5 million cost for 17% of companies [87].

However, high availability becomes challenging when there are code changes to apply to systems of running services. Such changes include adding logs to gain more diagnostic information, instrumenting programs to profile performance bottlenecks and applying patches to fix bugs.

*Co-first authors.

Category	Server Frameworks (Github stars)
E-commerce	Odoo (17.5k), Saleor (7.8k), Oscar (4.3k)
Web framework	Django (45k), Flask (48k), Pyramid (3.3k)
Web Server	Gunicorn (6.8k), Tornado (19.1k)
Message queue	Celery (14k), huey (2.7k), rq (6.6k)
Cache backend	Django-cacheops (1.1k), Beaker (429)
FTP server	pyftplib (1k), fbtftp (325), pyrexecd (202)

Table 1: Popular Python-based frameworks for online services.

Motivated by Python's popularity and the demand of applying code changes while keeping high availability, this paper presents a new idea that leverages the unique language features of Python to perform dynamic code changes. Specifically, we design and implement a framework, called PYLIVE, that enables dynamically changing Python programs for on-the-fly logging, profiling, and bug-fixing on *production systems* without restarting them.

PYLIVE's capability to change code during production runs can be used by online services for various purposes including:

- (1) On-the-fly logging for diagnosing production-run errors.** When an online service exhibits some abnormal behaviors, engineers can use PYLIVE to dynamically add logs at certain locations to collect debugging information from production-run. The logs can be enabled only during certain time (e.g. when the load is light) to minimize the performance impact. Production-run information is useful for diagnosing challenging issues (e.g., resource leaking) that are hard to reproduce in a testing environment and only manifest after a long-time (e.g., weeks) running.
- (2) On-the-fly profiling for diagnosing production-run performance issues.** When an online service has performance issues observed for certain types of requests, engineers can use PYLIVE to dynamically profile a set of functions for a short period of time to collect production-run timing information to troubleshoot the issues. The capability to (1) dynamically start and stop profiling during production runs and (2) only profile a small set of specified functions allows engineers to troubleshoot elusive performance issues without introducing much performance overhead. These performance issues may only emerge in production-run but are hard to reproduce during offline testing, making it necessary to perform in-production profiling.
- (3) Urgent dynamic patching (bug-fixing or security**

patch). PYLIVE allows dynamically applying urgent patches to fix some critical bugs or security issues without stopping and restarting an online service. These bugs and issues can either cause major failures or open up vulnerabilities to attackers and thus needs to be patched as soon as possible.

PYLIVE complements the commonly-used system update practice—rollout deployment [7, 42, 84]. Rollout is not the best choice for dynamic logging and profiling for two reasons. First, rollout still requires a restart of each service instance, which can clear the key program states for diagnosis. These states (e.g., resource leaks) may only be reproduced after a long production run, which is undesirable to be cleared by rollout. Second, a rollout deployment is heavyweight and an overkill for just collecting logging/profiling information. For instance, sometimes only a few servers of a fleet exhibit abnormal behaviors because of their unique memory states. If engineers want to diagnose the issue by rolling out a patch with new logging statements, this patch needs to be batched together with many other patches and will not be applied until the next deployment (wait for a few hours or even a few days). PYLIVE provides a better solution from both perspectives. It requires no restart of service instances so it retains the issue states for logging/profiling. In addition, it enables dynamically adding logging/profiling statements to a running program quickly and also removes the statements flexibly.

PYLIVE is designed based on the unique language features of Python. Python is an interpreted language that supports the meta-object protocol [22, 58] and dynamic typing. The meta-object protocol enables programs to dynamically modify their own metadata, including function bodies/interfaces and class attributes, while dynamic typing allows changing variable types during running. This makes dynamic code change much easier for Python than for compiled languages (e.g., C/C++) and other interpreted languages that do not support the full meta-object protocol or dynamic typing (e.g., Java):

- For compiled languages, dynamically changing a program requires many complex transformations to its code (e.g., patch functions) and memory layout (e.g., load new code into memory), as shown in previous work [38, 46, 54, 55, 68, 76, 77]. At run time, a compiled program’s code is binary code and its memory layout is fixed in different segments. Modifying binary code or memory layout may introduce safety concerns.
- Some other interpreted languages, like Java, do not support the full meta-object protocol or dynamic typing. For example, Java does not support many types of dynamic changes, like adding/deleting methods or changing methods’ signatures. Java is also statically-typed, making it hard to change variable types. For such languages, implementing dynamic code change requires modification to the language runtime (e.g., JVM), as in previous work [71, 78, 90]. This introduces portability concerns as different versions of runtime may be used by different systems.

PYLIVE makes two main contributions: (1) PYLIVE realizes safe and portable dynamic code change by leveraging Python’s language features. PYLIVE is safe as it requires no low-level transformations of machine code or memory layout. PYLIVE is portable as it relies only on the interfaces provided by standard Python interpreters and thus can be easily adopted by existing Python-based systems. (2) Besides patching, PYLIVE also enables instrumentation-based code changes for dynamic logging and profiling. PYLIVE provides convenient interfaces to flexibly instrument customized code to a selected set of functions at running time. This is useful for collecting diagnostic information in production-run systems without causing significant performance degradation.

We evaluate PYLIVE with 20 *real-world* cases from seven widely-used Python-based applications (including the popular Django framework and Gunicorn used by Instagram [35]). All these applications have been deployed in various companies to serve millions of customers [5, 13, 23, 26, 27, 34]. PYLIVE successfully helps resolve the cases with on-the-fly logging, profiling and patching with little overhead. Additionally, PYLIVE has helped two widely-used open source e-commerce applications diagnose two new performance issues. We also measure the performance benefit of PYLIVE by comparing it with restarting services to apply code changes. During normal time (no code change), PYLIVE’s overhead is negligible. Upon a code change, PYLIVE causes no downtime and has little performance degradation (<0.1%). In comparison, restarting the applications to apply changes can cause 2-17 seconds downtime and take up to 4.5 minutes to warm up (up to 90% performance downgrade during warmup).

2 Background

This section briefly describes the unique language features of Python that enables PYLIVE’s dynamic code change.

Meta-object protocol. Python is designed with a full support of the meta-object protocol [22, 58]. A meta-object is an object that contains a program’s metadata, including types, interfaces, classes and methods, etc. The meta-object protocol provides programming interfaces for programs to manipulate these metadata at runtime. For example, a new method named `A` can be dynamically added to class `C` simply with `C.A = D` (`D` is `A`’s definition). Similarly, an existing function’s code body can also be changed at runtime with `A.__code__ = D.__code__`. Once it is changed, the new `D` is called when `A` is invoked. Other supported changes include changing a function’s interface, adding a new field to a class, changing a variable’s type, etc. All the above changes are supported by the standard Python interpreter [32].

Dynamic typing. Python defines and checks variable types at running time, which makes it easy to dynamically change them. For instance, a Python variable `a` can be changed from

a string to a bool. And at running time each time before a is used, a type checking is performed. A wrong typed call `compare(a,b)` is detected by the Python interpreter, which will throw a runtime exception. In comparison, for Java, it is impossible to dynamically change a variable's type without changing the underlying JVM. For C/C++, this is also almost impossible as a string is passed by pointer while a bool is passed by value.

Python bytecode. A Python interpreter stores and interprets programs in bytecode, providing an opportunity for dynamically instrumenting code. Compared to machine code, bytecode is much easier to analyze and change with automatic tools. First, it is architecture-independent. Although Python can run on X86-64, ARMv7 and other architecture, it has the same bytecodes for all architectures. So the same tool can be used for Python on all platforms. Second, bytecode also has fewer instructions than machine instructions. Python 3.8 bytecode only has 112 instructions, while X86 alone has 1503 instructions, let alone all various architectures. Third, Python bytecode retains more type information than machine code.

3 PYLIVE Framework

PYLIVE is a runtime framework that accepts dynamic change requests from engineers and applies them dynamically into production-run systems without a restart. PYLIVE can be used for on-the-fly logging, profiling and bug-fixing.

In this section, we begin with the design objectives (§3.1) and interfaces (§3.2) of PYLIVE. We then discuss the three challenges faced by PYLIVE: (1) How to support dynamic changes for function interface, function body and data structure? (§3.3) (2) How to identify safe change points to apply a change without causing inconsistency problems? (§3.4) (3) How to update programs with multi-threads and multi-processes? (§3.5)

3.1 Design Objectives

PYLIVE is designed with the following objectives:

(1) *General.* PYLIVE's generality comes from three aspects: (a) it requires no change to the standard Python interpreter. Therefore, engineers need not to download a modified interpreter, which may not be compatible with their systems. (b) PYLIVE is also general on the types of changes supported. It supports not only changes to function body, but also changes to function interfaces (e.g. add one more parameter) and data structures (e.g. add one more field). (c) Since most online services have multiple threads/processes, PYLIVE also provides support for multi-threads and multi-processes.

(2) *Flexible.* PYLIVE is flexible from two perspectives. First, PYLIVE is flexible in terms of *when* to apply a change and *when* to revert a change, all based on engineers' requirements.

This can help engineers collect logs for a short amount of time to minimize the performance impact. For example, they can perform on-the-fly logging or profiling only during light-load time. Second, PYLIVE is also flexible with *where* to profile or log. PYLIVE allows engineers to specify which modules or functions to instrument logging/profiling code.

(3) *Consistent and Safe.* Dynamic changes to a running program need to be performed at a carefully selected execution point (aka, a safe point) to avoid inconsistency problems. For instance, changing an `unlock` function to its new implementation after an old `lock` function is already executed may cause inconsistency, leading to incorrect states. Unfortunately, choosing a safe point for general changes has proved to be undecidable [53]. So PYLIVE relies on engineers' knowledge to decide when a change is safe to happen: either when the changed functions are not executing, or a user-specified check function (e.g., specifying a lock is not held) returns true.

(4) *Low Overhead.* PYLIVE is designed to impose as little overhead as possible. At normal time when no change needs to be applied, the PYLIVE thread is sleeping and simply waiting for engineers' inputs. Once engineers instruct it to make code changes, PYLIVE's thread is woken up to perform the change. Once a change is already applied in this target program's metadata, PYLIVE gets to sleep again and is no longer involved in the execution of the target program.

(5) *Little Human effort.* PYLIVE aims to minimize engineers' efforts in using it. PYLIVE itself is downloaded as a small Python library that can be easily installed. Only two lines of Python code are needed to set up PYLIVE at the initialization of the target program. To insert a dynamic change, PYLIVE only needs engineers to write a small Python snippet to specify what needs to be changed. As shown in our evaluation of 20 real-world cases from seven widely-used Python software systems (cf. Table 3), each change specification needs only 7-13 lines of code).

3.2 PYLIVE's Interfaces

To make it easy to use, PYLIVE allows engineers to write the specification for dynamic code change in Python code. To enable dynamic changes for various purposes, PYLIVE supports two change interfaces: `instrument` and `redefine`.

Instrument. The `instrument` interface can instrument code to specified locations in certain functions or modules. It is useful for instrumenting log statements or profiling code to diagnose bugs or performance issues. The interface is:

```
instrument(scope, jointpoint_callback, time).
```

`scope` is a list of function/module names that need to instrument. When only the module name is given, all functions in it are instrumented. `jointpoint_callback` is key-value dictionary of jointpoints (instrument location) and callback

code to instrument. PYLIVE supports different granularity of jointpoints: coarse-grained, such as function begin/end, and fine-grained, such as before/after a line and before/after a variable's definition. This allows engineers to flexibly customize the instrument locations. `time` allows engineers to specify when to perform an instrumentation and when to revert the instrumentation. `time` can be either a specific time or a function that decides if an instrumentation should be performed. Engineers may want to profile an online service only when it is lightly-loaded and only for a period of time.

Redefine. The `redefine` interface is for code changes that replace the definitions of existing functions and classes (data structures) with new ones. To perform such code changes, engineers use the following Python interface:

```
redefine(preFunc, old_new_map, safepoint).
```

`preFunc` is a user-defined Python function that engineers need to provide to execute before making the specified change. Inside `preFunc`, engineers can import new modules and perform various initialization tasks. `old_new_map` is a key-value dictionary that specifies the changes. Each pair

```
{'old_func/old_class': new_func/new_class}
```

specifies an old function or class needs to be replaced by a new function or class. Engineers also need to provide the new function or class definition. To add a field to a class, just specify the field name and its initialization code with:

```
{'class.new_field': field_init}.
```

`safepoint` defines at what execution point it is safe to apply the specified change. It can be either "FUNC QUIESCENCE" or a user-specified consistency check function (cf. §3.4).

3.3 Support Dynamic Changes

Change function interface and body. PYLIVE supports changes on both function interfaces and code bodies. Changing function interfaces includes altering the number of parameters, parameter types, and function names. To make these changes, PYLIVE utilizes Python's meta-object protocol and dynamic typing. For parameter number changes, Python functions' parameters are defined in a list (i.e. `co_varnames`), and PYLIVE directly edits the list to add or remove parameters. For parameter type changes, Python uses dynamic typing, and so PYLIVE needs not explicitly change anything. For function name changes, PYLIVE defines a new function and modifies the callers to call the new function.

For function body changes, PYLIVE supports two types of changes: redefine a function body with a new one and instrument the old function body with extra statements (e.g., for logging or profiling). For both types, PYLIVE replaces functions' code object (`__code__`) as a whole, as code objects are immutable and can only be replaced by reference change.

For instrument changes, PYLIVE first copies the function's code object, builds an instrumented version by modifying its bytecode [10], and then sets the function's `__code__` to point to the instrumented code object.

PYLIVE may also need to change caller functions when changing the callee functions. For changes that modify callees' interfaces, PYLIVE needs to change all the callers' function body to call the new interface. PYLIVE expects that engineers include all changes to callers in the same patch as normal patching practice. For changes that only modify callees' function bodies, PYLIVE needs not to change the callers. This is because Python function calls are made by function names instead of addresses. Every time a function call happens, Python interpreters translate its name into address by looking up its metadata. Therefore, as long as the function metadata is updated (e.g. modify the `__code__` as discussed before), function calls can always be directed to the newest code objects. Note this differs from dynamic code changes in C/C++—they may need to update callers' function body as the function calls are made by address directly.

Change data structure. Data structure changes include changes to class attributes, object attributes and methods.

Class attributes are data fields defined in classes and shared by all the object instances. PYLIVE changes class attributes by modifying the namespace tables of the target classes. In order to hook class attributes access for profiling or debugging, PYLIVE adds `getter` and `setter` functions for attributes need to be changed. In Python, `getter` and `setter` are automatically called if an attribute is annotated as `property`.

Object attributes are more difficult to change since they are individually stored in different objects even though they are instantiated from the same class. In order to change an object attribute, it is necessary to go through all objects of the class and change each individually. Previous works typically need to refactor a system ahead of time so they can have Factory objects to keep track of all live objects at runtime [41]. PYLIVE utilizes Python's garbage collector (GC) to track live objects and modify each one when a change is requested. Specifically, PYLIVE calls `gc.get_objects()` to obtain a list of all live objects tracked by GC [14]. As Python uses reference counting to decide objects' liveness, this does not trigger a heap walk but returns a list immediately instead.

Methods are just functions defined in classes and so can be changed in the same way as global functions as described above. Methods' code is only stored in their classes instead of all instantiated objects, and so simply updating the classes' methods is sufficient to apply a change.

3.4 Identify Safe Change Point

Changing code at run time is not always safe. For instance, changing a function when it is executing may cause inconsistency problems. Therefore, dynamic code change systems

```

30 def file_move_safe(old_file_name, new_file_name):
    ...
58 fd = os.open(new_file_name,...)
59
60 try:
61     locks.lock(fd, ...)
    ...
65     os.write(fd, ...)
    ...
66 finally:
67     locks.unlock(fd)
    ...

```

Unsafe points
for changing
lock() / unlock()

Figure 1: An example of unsafe change points for a patch from Django [11]. It is unsafe to change `lock()` or `unlock()` when the program is executing between line 61 and 67, as the change can cause that a new `unlock()` to be called against an old lock, which can lead to undefined behavior.

need to carefully choose a safe execution point to apply a change. Unfortunately, choosing a safe point for general changes has proved to be undecidable [53]. As a result, it is necessary to have engineers' knowledge to choose a safe change point. PYLIVE categorizes safe points into different types and lets engineers select one based on the changes they want to make. Note that choosing the safe update point is only necessary when applying patches. PYLIVE can always apply code changes for logging and profiling as they only add code but do not change the existing code. PYLIVE supports two kinds of safe points:

Quiescence of the changed functions. This requirement means a change is only applied when the changed functions are not under execution. This is also the update point used by many previous dynamic code change systems [38, 38, 39, 86, 91]. It ensures that no function is executed with a mixture of old and new code during changes. PYLIVE provides automatic support for this safe point. To specify it, engineers only need to specify `safepoint='FUNC_QUIESCENCE'`.

PYLIVE supports function quiescence for both changing one function and multiple functions. When changing one function, PYLIVE directly takes advantage of Python meta-object protocol to guarantee the quiescence. In Python, when a function's code is changed, the change only takes effect the next time it is called. When changing multiple functions, PYLIVE checks every thread's stack for any changed function. If any changed function is on a stack, PYLIVE defers the change, retries the checks later and applies the change when no changed function is on any stack.

Consistent state check. When the changed functions modify shared states between them, function quiescence may not be enough for safety. Consider an example shown in Figure 1, two functions `lock` and `unlock` need to be changed, and both of them modify the lock state. Applying the change when the program is executing between the calls to `lock` and `unlock` is not safe, even though the functions themselves are not executed. The new `unlock` may be called with an old lock state

```

def state_check_func():
    for fd in all_fds():
        if locks.check_lock(fd) != locks.UNLOCK:
            return False
    return True

```

Figure 2: An example of state check function for the patch in figure 1. It returns true when the lock is not currently held.

and the behavior is undefined.

To address this, PYLIVE allows engineers to provide a customized boolean function to decide when it is safe to apply a change. This is also noted as state quiescence in previous work [48]. Engineers can easily write such boolean functions in normal Python code. Figure 2 shows the state check function for changing `lock` and `unlock`. It checks if no lock is held before applying the change. PYLIVE periodically evaluates it and only applies the change when it returns true.

Note for most code changes, it does not require any customized consistency check. In our evaluation with 20 real-world cases from seven widely-used Python programs, only a few cases require a simple consistency check.

Guidance for engineers. We provide guidance to help engineers identify and specify safe change points for their needs:

First, if the changed functions have no side effects or negligible side effects on execution state, engineers can specify function quiescence as the safe change point. For example, if the changed functions modify no non-local variables, perform no database write and only write a few logs, it is safe to update them as long as they are not under execution.

Second, if the changed functions have some non-negligible side effects on execution states, engineers need to identify the states that the side effects of the old and new functions will not affect each other. Specifically, the variables V_{old} defined and propagated from old functions f_{old} will not be used by new functions f_{new} , and vice versa. To ensure this, the target consistent states are either no variable in V_{old} is defined or all of them are dead. An example of this is shown in Figure 2 that no lock is held at the point of change. Such states may not exist or may not be easy to express in state check functions, and in such cases it may be better to perform a restart than to use PYLIVE.

3.5 Support for Multi-threads and Multi-processes

Multi-threads. A server program may have multiple threads to serve different user requests. Different threads have different program counters while sharing the same code and global variables. Therefore, it is not straightforward to apply a change at a given safe change point for multiple threads.

To change multiple threads correctly, PYLIVE applies a given change synchronously. The synchronous change is ensured by Python global interpreter lock (GIL). At any execution point, only one thread can hold GIL and so can get

executed [15]. Therefore, when PYLIVE is actively applying a dynamic change, all other threads to be changed are blocked. When applying changes, PYLIVE also explicitly holds GIL lock to make sure no other threads can preempt it [17].

Based on the type of safe point, PYLIVE applies changes differently. If the safe point is function quiescence, PYLIVE either immediately applies the change when only one function needs to change or check program stacks to make sure no target function on stacks when multiple functions need to change. Applying one function change is simpler because Python’s meta-object protocol ensures the change to not take effect during its execution. If the safe point is a consistent state check, PYLIVE first executes the check function provided by engineers. If the consistent check succeeds, PYLIVE then applies the change. If it fails, PYLIVE sets a timer t and goes to sleep to let other threads execute. The timer will wake up PYLIVE later to perform a state check again. The timer t is configurable by engineers. After several attempts, if it still fails, PYLIVE will give up and report an error to engineers.

Multi-processes. Online services may use multiple processes, and dynamic code change needs to be applied to all of them. Different Python processes reside in different address spaces and share code through copy-on-write. When code is changed in a process, a copy-on-write happens and other processes will continue to use the old code. As such, dynamic code change needs to be performed explicitly in all processes. PYLIVE adopts a controller-stub architecture to communicate changes to all processes. A stub is a change thread residing in a target process. PYLIVE starts one stub thread for each target process at its starting time. A stub thread listens to a controller for patches and applies the received patches at a safe change point. A PYLIVE controller is a standalone process that accepts engineers’ change input and sends the specified code change to the stub thread in each process.

4 Use Cases

PYLIVE enables three types of use cases that require a running system to be dynamically changed.

4.1 On-the-fly Logging for diagnosis

Systems may exhibit abnormal behavior during running. To collect run time info for diagnosis, engineers may want to add new log messages dynamically without restarting services.

An example of this is the diagnosis of a bug [28] from the Shuup [24] e-commerce system. This bug is related to its shopping cart: when some users click “add to cart”, the product is not added to the cart. This prevents users from purchasing products and causes direct revenue loss to businesses. Since the bug has no error logs, it is quite challenging for engineers to diagnose it off-line.

Figure 3 shows how engineers can use PYLIVE to add log messages to diagnose the issue. Engineers direct PYLIVE

```
# callbacks to instrument
# logging right/left-hand variables in each line
def call_b(_righthands):
    logging.info(_righthands)
def call_a(_lefthands):
    logging.info(_lefthands)

# instrument code to every line in two functions
instrument(scope=['...add_product',
                 '..._find_product_line_data'],
          jointpoint_callback={line_before: call_b,
                              line_after: call_a},
          time='24:00-2:00')
```

Figure 3: PYLIVE’s dynamic logging spec for an urgent, real world bug in Shuup e-commerce system [28]. This spec tells PYLIVE to dynamically instrument code to log some variable values in two functions `add_product` and `_find_product_line_data` for a period of time. `line_before` and `line_after` are two joint-points PYLIVE provides to instrument code before and after each line in functions.

to add line-by-line logs in two functions `add_product` and `_find_product_line_data`. Engineers also specify to only collect logs during light-load time (24:00-2:00).

4.2 On-the-fly Profiling

Performance issues often occur in production as systems have more and more features and scale up to a larger size. When such an issue emerges, engineers may want to enable profiling to certain parts of a system during production run.

An example [21] of such issues is from the Oscar e-commerce system. This issue happens when there are a lot of product categories in Oscar. The issue causes a performance downgrade in many pages displayed to customers in Oscar, preventing customers from buying products.

Figure 4 shows how to use PYLIVE to dynamically instrument code to profile the system. Engineers instruct PYLIVE to instrument customized profiling code into the methods in two classes, `AbstractCategory` and `CatalogueView`, that are speculated to be related to the issue.

4.3 Dynamic Patching

Online services frequently have urgent bugs (e.g., security bugs) that need to be patched as quickly as possible to minimize damages since they may cause information leakage/system compromise and prevent customers using online services.

An example [1] of such patches is from Django. It fixes a severe cross-site scripting (XSS) [8] issue, CVE-2019-12308 [9]. The issue is scored as “6.1” since it can expose malicious URLs as clickable links to victim users and direct them to vulnerable sites. Django developers quickly post a security release [12] to fix the vulnerability and encourage all online services that use Django to apply it as soon as possible.

```

# profiling code to instrument
def call_b(start):
    start = time.time()
def call_a(start):
    logging.info(time.time()-start)

# instrument code to all functions of two classes
instrument(scope=['...AbstractCategory.*',
                '...CatalogueView.*'],
          jointpoint_callback={func_before: call_b,
                              func_end: call_a},
          time='24:00-2:00')

```

Figure 4: On-the-fly profiling using PYLIVE to diagnose a critical performance issue occurred in Oscar ecommerce system [21]. This example requires PYLIVE to instrument code to profile the execution of every method in two classes AbstractCategory and CatalogueView for a period of time.

Figure 5 shows part of the patch and the change spec that engineers need to provide for PYLIVE to dynamically apply it. This patch is non-trivial to be dynamically applied, as it changes both function interfaces and data structures. It adds a new parameter `validator_class` to the `__init__` function and adds a new attribute `self.validator` to `AdminURLFieldWidget`. The change spec calls the `redefine` interface with three arguments: `preupdate` specifies that PYLIVE needs to import a new class `URLValidator` before applying the change; `old_new_map` indicates that the original `__init__` will be replaced with the new code. `safepoint='FUNC QUIESCENCE'` tells PYLIVE to apply the change when the changed functions are quiescent. This requirement is safe enough in the case as there is no inter-dependency between the changed functions.

5 Evaluation

5.1 Methodology

We evaluate PYLIVE with 20 cases from seven Python-based real-world applications, as shown in Table 2. These applications are deployed in many companies, serving millions of customers [5, 13, 23, 34]. Django is a popular web framework that powered over 94,319 websites, of which many are for e-commerce [85]. Unicorn is a production web server used by many big companies for their main services, such as Instagram [35]. All the online services need to be almost non-stop since any downtime can result in revenue loss.

To evaluate PYLIVE’s benefit, we compare PYLIVE with a typical restart approach: modify code for logging/profiling/patching offline, stop the services and restart the services *immediately*. To precisely measure the restart impact, we only restart the Python part of a service, which does not restart other parts (e.g., database) to avoid the impact of warming up their cache. For profiling, we also compare PYLIVE with cProfile [47], which is Python’s official profiling tool for collecting comprehensive profiling information in test environments.

```

# patch: add a parameter validator_class
# add an object attribute validator
class AdminURLFieldWidget(...):
    def __init__(self, attrs=None,
                validator_class=URLValidator):
        self.validator = validator_class()
        ...

# change specs.
def preupdate_call():
    from django.core.validators import URLValidator

redefine(
    preupdate = preupdate_call,
    old_new_map={
        '...AdminURLFieldWidget.__init__': __init__,
        safepoint='FUNC QUIESCENCE'})

```

Figure 5: A real world security patch to Django [1] and PYLIVE’s dynamic change spec for it. This patch adds a parameter to function `__init__` and adds an object attribute validator to class `AdminURLFieldWidget`. Other part of the patch is omitted due to space limit. The change spec indicates: `preupdate` — import `URLValidator` before the change; `old_new_map` — replace `AdminURLFieldWidget.__init__` with a new one; `safepoint` — apply the change when the changed function is quiescent.

Applications	Category	Logging	Profiling	Patching
Django [33]	Web framework	1	0	2
Gunicorn [16]	Web server	0	0	1
Oscar [6]	E-commerce	1	2	1
Odoo [25]	E-commerce	1	1	2
Shuup [24]	E-commerce	1	0	1
Pretix [27]	E-commerce	1	0	1
Saleor [61]	E-commerce	1	1	2
Total		6	4	10

Table 2: 20 real-world cases evaluated in our experiments. They are from seven widely used Python-based server applications that have powered many commercial e-commerce and ad-based web services including Instagram, serving millions of customers.

Note PYLIVE is not a substitute for cProfile as it collects less information than cProfile. However, as we will present in the results, some cases only need little dynamic information to diagnose. We conduct this comparison to study the benefit that PYLIVE can bring for such cases.

Each application is set up on a machine with a 2.30GHz CPU (6 core), 16GB Memory and 256GB SSD. Each application runs with 2 processes and 4 threads/process. Each application is initialized with ~2000 web pages. To mimic real-world workloads, JMeter [4] is used to generate random web page accesses. The JMeter client is started with 8 threads and can generate up to 15K requests/second.

We use throughput as the performance metric and normalize it to the max throughput of normal service run (41-752 requests/second). All the experiments are conducted within a LAN, which ensures that network is not the bottleneck.

5.2 Overall Performance Results

Overall, PYLIVE avoids 2-17 seconds downtime and avoid up to 4.5 minutes warmup time, during which the performance downgrade can be 55%-90%. PYLIVE causes negligible (<0.1%) overhead during normal run as well as applying changes. PYLIVE causes 0.1%-1.4% overhead during profiling. Compared with cProfile, PYLIVE's selective instrumentation avoids 10.5%-33.6% overhead.

Figure 6,7 show the results of eight representative cases. Two newly identified performance issues and the other twelve existing real-world cases have similar results and due to space limit are put online [3].

For **logging cases**, PYLIVE's benefits mainly come from avoiding the time to restart and warm up. The service restart is relatively fast (2-17 seconds), but the warmup takes much longer time. Our experiments set up applications with only ~2000 web pages, but the warmup still takes 2.3-3 minutes.

For **profiling cases**, PYLIVE makes the performance impact caused by profiling affordable in production-run systems. The benefit comes from two aspects. First, PYLIVE allows engineers to perform customized profiling, so they need not profile applications in a whole as with cProfile. The customized profiling is not a substitute for comprehensive profiling with cProfile because it collects less information. However, it's sufficient to diagnose many cases that only needs limited timing information, as shown later in our case studies (cf. §5.3). Second, PYLIVE avoids restart and warmup time (up to 4.5 minutes), which is needed by cProfile. With PYLIVE, the performance downgrade during profiling is 0.1%-1.4%. While with cProfile, the performance downgrade can be 11%-39%.

For **patching cases**, PYLIVE can apply them dynamically with almost no performance downgrades. This benefits urgent security patches, for which waiting for the next rollout can be dangerous. Our evaluation includes 5 security patches and PYLIVE successfully applied them on-the-fly.

5.3 Case Studies

This section dives into the details of eight representative cases. The remaining twelve cases evaluated are similar and due to space limit we put them online [3].

Case 1: Diagnose a purchase bug in Shuup [28]. This case is about diagnosing a bug related to the shopping carts of Shuup [24], a widely-deployed e-commerce website. As mentioned in §4.1, the bug causes an error in production and prevents customers from adding new items to shopping carts. To help diagnose it, PYLIVE dynamically instruments logging statements on the running application. Figure 6a shows that PYLIVE avoids 3 seconds downtime and 2.3 minutes warmup time. It imposes only < 0.1% performance overhead.

Case 2: Diagnose a payment bug in Odoo [74]. Odoo [25] is an e-commerce website and this bug prevents customers from paying an order. It is an "urgent" bug as it results in

business loss. Odoo engineers diagnosed it by adding two logging statements and restarting the service. With PYLIVE, the logging statement can be added on-the-fly with 11 LOC. As shown in Figure 6b, PYLIVE avoids 4 seconds service downtime with < 0.1% overhead. Differing from other applications, Odoo does not have much cache and so requires little warmup time.

Case 3: Diagnose a purchase bug in Pretix [20]. Pretix [27] is an ticket-booking website that allows event organizers to sell event tickets online. In this case, when customers request a PayPal refund, it fails silently with no error messages. PYLIVE can dynamically instrument logging code to diagnose the reason. Figure 6c shows that PYLIVE successfully avoids 17 seconds downtime and 3 minutes warmup (by restarting Pretix) with < 0.1% performance overhead.

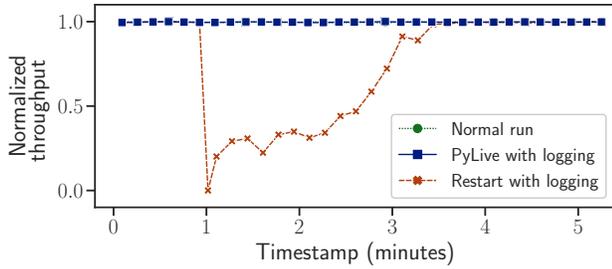

Case 4: Profile a main web page in Saleor [83]. This case is about diagnosing a slowly-loaded web page. This case is difficult to reproduce in testing as it only emerges when the product category grows to large. Currently, engineers use cProfile to profile the whole application [83]. Enabling cProfile needs an application restart, causing downtime and warmup time as shown in Figure 6d. Also, cProfile profiles every function, so after warmup it still imposes 35% performance downgrade.

PYLIVE can benefit the diagnosis in two ways. First, it can dynamically instrument profiling code into a running application. Figure 6d shows this can avoid 3 seconds downtime and 4.5 minutes warmup of Saleor services. Second, it can be customized to only profile the relevant functions suspected by engineers and thus reduces profiling overhead to only 1.4%.

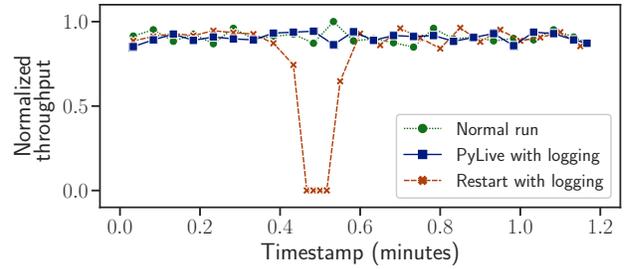

Case 5: Profile a slowly-loaded web page in Oscar [21]. This case is about diagnosing a slowly-loaded product-listing page. It happens when the number of products grows to large. PYLIVE enables dynamic profiling to Oscar with 9 LOC to specify the change. As shown in Figure 6e, PYLIVE causes only 0.5% performance overhead during profiling and nearly no overhead during normal run. In contrast, cProfile causes as much as 11% performance downgrades as well as 2 seconds of downtime and 3 minutes warmup time.

Case 6: Profile a slow action in Odoo [75]. This case is about diagnosing a slow receipt-validating action. It is hard to reproduce in testing as it only emerges when the database contains a large number of products and orders. PYLIVE enables dynamic profiling with 9 LOC. Figure 6f shows PYLIVE's performance benefit. PYLIVE causes only 0.1% performance overhead during profiling and nearly no overhead during normal run. In contrast, cProfile causes as much as 38.5% performance downgrades as well as 9 seconds of service downtime.

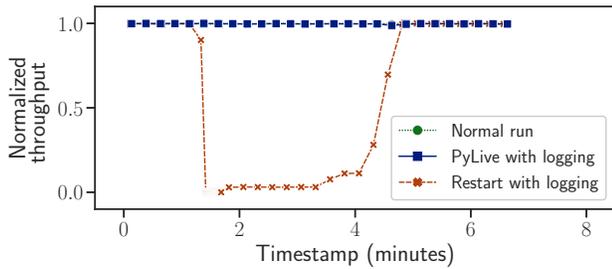

Case 7: Patch CVE-2019-12308 security vulnerability in Django [1]. This patch fixes a severe XSS security issue CVE-2019-12308 [9]. As we discussed in §4.3, it may lead users to click into malicious websites and can possibly affect

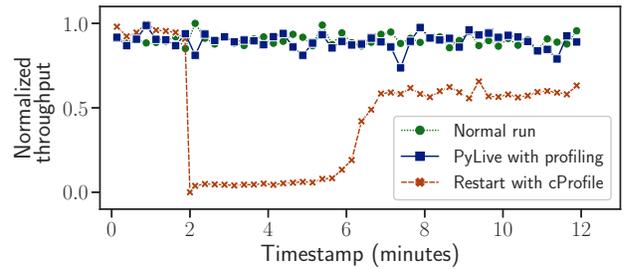

(a) **Shuup: on-the-fly logging to diagnose a payment bug [28].** PYLIVE causes < 0.1% overhead only when adding logs. In comparison, restarting causes 3 seconds of downtime and needs 2.3 minutes to warmup.

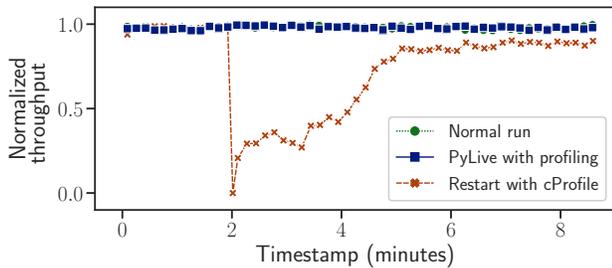

(b) **Odoos: on-the-fly logging to diagnose a shopping-cart bug [74].** PYLIVE causes < 0.1% overhead only when adding logs. In comparison, restarting causes 4 seconds of downtime. Odoos does not have much cache so has a short warmup time.

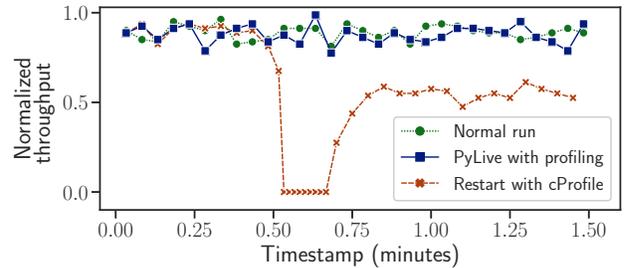

(c) **Pretix: on-the-fly logging to diagnose a payment bug [20].** PYLIVE causes < 0.1% overhead only when adding logs. In comparison, restarting causes 17 seconds of downtime and needs 3 minutes to warmup.

(d) **Saleor: on-the-fly profiling a long-loaded web page [83].** PYLIVE causes 1.4% overhead only during profiling. In comparison, restarting causes 3 seconds of downtime and needs 4.5 minutes to warmup. Using cProfile causes 35% overhead.

(e) **Oscar: on-the-fly profiling a long-loaded web page [21].** PYLIVE causes 0.5% overhead only during profiling. In comparison, restarting causes 2 seconds of downtime and needs 3 minutes to warmup. Using cProfile causes 11% overhead.

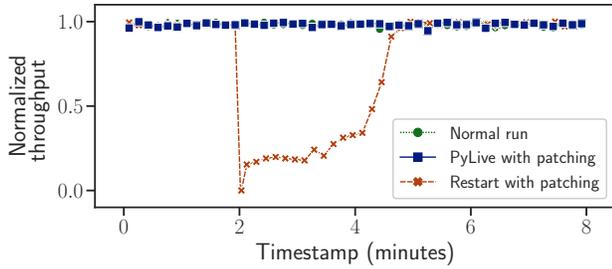

(f) **Odoos: on-the-fly profiling a long-loaded web page [75].** PYLIVE causes 0.1% overhead only during profiling. In comparison, restarting causes 9 seconds of downtime. Using cProfile to profile causes 38.5% overhead.

Figure 6: Throughput comparison of **three on-the-fly logging cases and three on-the-fly profiling cases** with PYLIVE in comparison with today’s practices—stop and restart with logging added and profiling enabled.

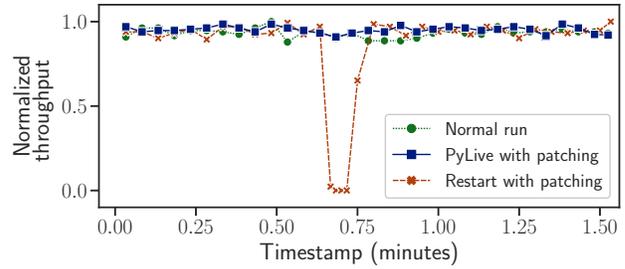

many users. This patch is non-trivial to be dynamically applied, as it involves adding a parameter to a method interface and adding a new class attribute [1]. With PYLIVE, this patch is allowed to be applied safely with 8 additional LOC. Figure 7a shows the performance benefit of PYLIVE and PYLIVE avoids 2 seconds of downtime and 2.8 minutes warmup time. PYLIVE dynamically applies the patch with < 0.1% overhead.

Case 8: Patch CVE-2018-1000164 in Gunicorn [52]. This patch fixes a HTTP Response Splitting Vulnerability [73]. It

has a severity score of “**7.5 High**” in the CVE system [72]. It can be exploited by various attacks, such as Cross-site Scripting (XSS), Cross-User Defacement, Hijacking [73]. The patch requires a modification to a function body. It can be dynamically applied with PYLIVE with only 13 additional LOC. As shown in Figure 7b, PYLIVE avoids 4 seconds of downtime, when a non-cached service runs on Gunicorn. PYLIVE introduces < 0.1% overhead while applying the patch.

(a) **Django: urgent security patching for CVE-2019-12308 [1].** Compared with restarting, PYLIVE avoids 2 seconds of downtime and 2.8 minutes warmup time, with $< 0.1\%$ performance overhead during patching.

(b) **Gunicorn: security patching for CVE-2018-1000164 [72].** Compared with restarting, PYLIVE avoids 4 seconds of service downtime, with negligible overhead during patching. Gunicorn’s workload is Odoo, which has little cache, so it takes a short time to warmup.

Figure 7: Throughput comparison of **two representative patching cases** with PYLIVE and restarting services.

Use Case	Software	LOC	Use Case	Software	LOC
Case1	Shuup	7	Case5	Oscar	9
Case2	Odoo	11	Case6	Odoo	9
Case3	Pretix	9	Case7	Django	8
Case4	Saleor	9	Case8	Gunicorn	13

Table 3: **Lines of code (LOC) of change specification for PYLIVE.** For patches, this only count extra code for PYLIVE.

5.4 Human Effort

PYLIVE requires only a little human effort to adopt it in real-world applications. To enable PYLIVE in a Python-based application, it only needs to add two lines of code in the application’s initialization stage. To apply dynamic change for different purposes, PYLIVE allows engineers to write Python code to specify the intended changes. Table 3 shows the lines of code (LOC) to specify the changes in the eight representative cases. For all cases, it requires only 7-13 lines of code to specify each change.

6 Limitations and Discussion

There are many kinds of code changes that PYLIVE cannot apply. First, PYLIVE cannot apply changes to long-running functions because dynamic changes only take effect next time when the functions are called. Fortunately, online services are usually request based and the major part is the request handling functions, which finish running in a short amount of time. Second, PYLIVE cannot apply patches that assume an initial program state. Patches for memory-leak bugs may need to reinitialize the program state to free the leaked memory, which needs a restart of the target program. Third, PYLIVE is not suitable for applying major changes to a target program. Such changes include adding new features, updating library versions, and refactoring the program structure. These changes may involve major changes to program states and

code logic of many functions. Therefore, it is hard for engineers to write code to initialize the states and to specify a safe update point that considers all the dependencies between the changed functions.

PYLIVE relies on engineers to specifies the safe update points for dynamic patching. PYLIVE targets on simple bug-fixing and security patches that only update a few functions and data structures. For these patches, the safe update points can be specified as when the targeted functions are not executing or when a customized state check passes (e.g. a lock is not held as in Figure 1). However, for more complex patches that change many interdependent functions and data structures, the safe update point may not be easy to specify. For such cases, it is safer to restart the target program than to use PYLIVE. Note the safe update point is only necessary for applying patches but not for logging or profiling. Code changes for profiling and logging can always be safely applied as they only add code but do not change the existing code.

PYLIVE cannot prevent errors introduced by buggy patches. PYLIVE expects that engineers thoroughly test their patches in a testing environment before dynamically applying them to production-run systems. For logging and profiling cases, PYLIVE wraps the instrumented code in try-catch blocks so that buggy logging or profiling code does not affect the normal program execution.

PYLIVE has two security implications. First, in terms of the type of code changes that can be made dynamically, PYLIVE does not expand the attack surface of Python’s own meta-object protocol. PYLIVE does not modify the Python interpreter to enable more types of code changes but just provides convenient interfaces purely based on Python’s meta-object protocol. Second, the introduction of a change controller (cf. §3.5) expands the attack surface from one single process to two processes. The change controller is an additional process that commands a target program process to apply a change dynamically. Therefore, it would be dangerous if attackers gain access to the change controller. It can be mitigated by

setting the change controller's permission to make it only executable by a privileged user. We also plan to implement PYLIVE's own access control for the change controller in future work.

PYLIVE's design and implementation are generally applicable to Python variants and other interpreted languages as long as they support three language features:

- Meta-object protocol—PYLIVE uses this to modify a program's code at running time (cf. §2);
- Dynamic typing—PYLIVE relies on this to modify variable types at running time (cf. §2);
- Interpreter interfaces to freeze non-current threads—PYLIVE uses them to pause the execution of any other threads to safely apply changes (cf. §3.5).

All three features are supported by popular python variants including Pypy [29] and Pyston [2], and so PYLIVE can be easily ported to them. PYLIVE can also potentially be ported to two other popular interpreted languages: JavaScript [19] and Ruby [30]. The first two features are directly supported by JavaScript and Ruby. The third feature can also be implemented in JavaScript and Ruby in different ways. JavaScript uses a single-threaded event loop model—at any time only one event handler is running and it cannot be preempted before its completion. Therefore, when PYLIVE is running in JavaScript, any other thread is ensured not running at the same time. Ruby's official interpreter YARV [31] has a similar GIL lock as Python's GIL, which allows PYLIVE to hold GIL in Ruby to prevent preemption as in Python (cf. §3.5).

7 Related Work

Dynamic Code Change for C/C++ and Java. Many works have been done for dynamic changing C/C++-based operating systems [39–41, 45, 49, 64, 86] and applications [38, 46, 54, 56, 63, 69, 82, 89]. While simple dynamic change (e.g. patch only function bodies) to OS kernels has been used in production, more general change to applications has not been widely adopted. General dynamic change usually requires many unsafe transformations to target programs including modifying both machine code and memory layout. This may introduce safety concerns in production. Contrarily, PYLIVE realizes general changes by utilizing Python's standard language features—meta-object protocol and dynamic typing, making it safer to be adopted in production.

Works on dynamic changing Java either need to modify JVM [71, 90] or rely on some unsafe operations of JVM [78], introducing portability and safety concerns in production. When running a Java program, JVM maintains many metadata such as method signatures and class attributes as internal data but provides no safe operations to modify them. However, it is necessary to modify these metadata in order to support general dynamic change. In comparison, PYLIVE makes use of Python's meta-object protocol to safely modify related metadata when dynamically changing Python programs. This

imposes no modification to a standard Python interpreter and so can be easily adopted in existing production systems.

Dynamic Code Change for Python. Pymoult [66] made a preliminary exploration on the feasibility of dynamically changing Python programs. As a preliminary proposal, it has no experimental result. More importantly, Pymoult relies on a special Python interpreter, Pypy, which is not fully compatible with the standard Python interpreter (i.e. CPython [32]). In order to use Pymoult, engineers need to port their systems to Pypy interpreter, which requires considerable human efforts. Contrarily, PYLIVE is based on the standard Python interpreter and so can be easily adopted in the field.

PyReload [93] is a dynamic code change tool based on the standard Python interpreter. However, it has two key limitations that prevent it to be practical. First, PyReload needs engineers to refactor a target program into modules, which requires huge human efforts. Second, PyReload only supports single-threaded programs. Considering that servers usually have multiple threads, PyReload is not suitable for server systems. In contrast, PYLIVE requires no refactor to the target program and supports updating multi-thread server programs.

Language level support for dynamic code change. Language level support for dynamic code change is not new. Besides Python, many other dynamically-typed programming languages, such as Common Lisp [88], Smalltalk [50], JavaScript [19] and Ruby [30], have provided support for meta-object protocol. Meta-object protocol can be directly used to update a single function/class; however, there are still many challenges in using meta-object protocol to practically update server programs, which usually needs to update multiple functions/classes and threads/processes. Very few works have been done on these challenges. Rivet [67] proposes interesting ideas to leverage JavaScript's reflection capabilities to debug single-threaded browser-side programs. But the ideas cannot be directly borrowed to update server programs, which usually have multiple threads/processes.

Focusing on Python, PYLIVE addresses three challenges of leveraging meta-object protocol to update server programs. First, to make it easy to update multiple functions and classes, PYLIVE provides two APIs: `Redefine` and `Instrument` (§3.2) and adopts the meta-object protocol and bytecode instrumentation to implement them (§3.3). Second, to make it safe to update multiple functions and classes, PYLIVE borrows ideas from previous works [38, 39, 48] and provides two different safe points (§3.4). Third, to support updating programs with multiple-threads and multiple-processes, PYLIVE proposes new synchronous update mechanisms based on Python GIL and a controller-stub architecture (§3.5).

Aspect-oriented programming. PYLIVE's `Instrument` interface is a type of aspect-oriented programming (AOP) [60]. AOP is a programming paradigm to break down independent program logic into different modules. A common usage of

AOP is to allow developers to write a function’s main logic and its logging code separately. The AOP framework then “weaves” the code together at compile time or load time. Several works also aim to enable dynamic weaving at run time for AOP [79, 80, 92]. PYLIVE’s `Instrument` interface is an AOP support for Python and is inspired by previous work on AOP interfaces for Java [59, 65]. However, AOP’s main target is to insert additional code without modifying the existing code. PYLIVE also provides a `Redefine` interface to modify the existing code of a running program, which is challenging especially when the target program has multiple threads/processes. To realize `Redefine`, PYLIVE further considered the challenge of supporting safe update points and multiple-threads/processes programs.

Dynamic Instrumentation. PYLIVE’s `Instrument` interface is related to previous works on dynamic binary instrumentation (DBI), including `Pin` [62], `Valgrind` [70], and `DynamoRIO` [43]. DBI enables modifying a running binary program at the machine instruction level and is usually used for logging and profiling a compiled program. However, DBI cannot be directly adopted for profiling a Python program in production. When DBI is used for a Python program, DBI is instrumenting the Python interpreter instead of the Python program. This can cause two folds of problems. First, the logging and profiling results are verbose and hard to understand by Python developers as they are mostly about the execution of the Python interpreter but not about the Python program. Second, this can introduce an unacceptable performance downgrade to the Python program as interpreting one line of Python code may need to run multiple lines of interpreter code. PYLIVE addresses these problems by instrumenting code at the granularity of Python bytecode. Therefore, the logging and profiling results can be directly mapped back to the Python program and so are easy to understand by Python developers. In addition, much less code is instrumented and so much less performance downgrade.

PYLIVE complements `DTrace` [44] on dynamic instrumentation. `DTrace` is a dynamic instrumentation framework for production systems. To enable `DTrace` for Python, it needs to embed “markers” in Python interpreters. This introduces additional compatibility requirements for Python interpreters to use `DTrace`. As noted by the official Python document [18], “`DTrace` scripts can stop working or work incorrectly without warning when changing CPython versions.” PYLIVE takes a complementary approach to instrument Python application code without modifying Python interpreters, avoiding the compatibility concerns.

Rollout Update. An alternative way to avoid whole system downtime is rollout update [7, 42, 84]. In rollout update, a cluster of servers are restarted one by one or batches by batches so that during an update there are still servers alive to serve users’ requests. However, for just collecting logging/profiling information, rolling out patches to a whole cluster at the

next deployment is heavyweight and an overkill. It would be handy to quickly apply a simple patch that temporarily logs extra information or collects extra metrics to some servers on-the-fly. Furthermore, rollout update is less effective for collecting diagnostic or profiling information for certain types of issues because rollout update still requires restarting every service instance. As a result, errors that appear only after a long running time, such as resource leaks and concurrency issues, may not reappear quickly after restarting to provide diagnostic information [95]. Finally, rollout update can still result in a subset of servers restarting and warming up before providing service at their full capacity. This means during the rollout update, the entire system will suffer from certain levels of throughput degradation.

8 Conclusions

In this paper, we proposed a framework called PYLIVE that leverages Python’s unique language features, meta-object protocol and dynamic typing, to support dynamic code change for on-the-fly logging, profiling and patching in production-run systems. PYLIVE only relies on standard Python interpreters and can be easily adopted by existing systems. We evaluated PYLIVE with seven widely-deployed Python-based systems for online services. PYLIVE successfully helped resolve 20 existing real-world cases from these systems with dynamically logging, profiling and patching. PYLIVE also helped two of the systems diagnose two *new* performance issues. In comparison to restart, PYLIVE avoids service downtime and warmup. PYLIVE imposes no overhead during normal run and negligible overhead during the change. For profiling, PYLIVE adds only 0.1%-1.4% overhead.

Abstract

Coverage-guided fuzzers use program coverage measurements to explore different program paths efficiently. The coverage pipeline consists of runtime collection and post-execution processing procedures. First, the target program executes instrumentation code to collect coverage information. Then the fuzzer performs an expensive analysis on the collected data, yet most program executions lead to no increases in coverage. Inefficient implementations of these steps significantly reduce the fuzzer’s overall throughput.

In this paper, we propose RIFF, a highly efficient program coverage measurement mechanism to reduce fuzzing overhead. For the target program, RIFF moves computations originally done at runtime to instrumentation-time through static program analysis, thus reducing instrumentation code to a bare minimum. For the fuzzer, RIFF processes coverage with different levels of granularity and utilizes vector instructions to improve throughput.

We implement RIFF in state-of-the-art fuzzers such as AFL and MOpt and evaluate its performance on real-world programs in Google’s FuzzBench and fuzzer-test-suite. The results show that RIFF improves coverage measurement efficiency of fuzzers by $23\times$ and $6\times$ during runtime collection and post-execution processing, respectively. As a result, the fuzzers complete 147% more executions, and use only 6.53 hours to reach the 24-hour coverage of baseline fuzzers on average.

1 Introduction

Fuzzing is an automated testing technique that attempts to detect bugs and vulnerabilities in programs [1, 3, 9, 13, 14, 24, 27, 31, 35, 36]. Coverage-guided fuzzing improves bug-detection ability of fuzzers by leveraging program coverage measurements to guide fuzzing towards exploring new program states [4, 8, 20, 29, 40]. These fuzzers perform the following steps: ① the fuzzer selects an input from the corpus and performs mutation operations to generate new inputs; ②

the fuzzer executes the target program with mutated inputs and collects coverage statistics of these runs; ③ the fuzzer saves the input to the corpus if it can trigger bugs or find new program states. With proper coverage guidance, fuzzers can improve their efficiency by prioritizing mutation on *interesting* inputs in the corpus and discarding inputs that do not reach any new program states.

Generally speaking, the coverage pipeline of fuzzers consists of two stages: runtime coverage information collection and post-execution processing: first, the target program is instrumented with coverage collection code, which updates an array of counters to record the runtime execution trace; after the completion of an execution, the fuzzer processes the values in the array to check whether each execution reaches any new program states.

An instrumented program executes many more instructions compared to a non-instrumented binary. Since fuzzers continuously execute random inputs, a slight slow-down can significantly impact overall fuzzing performance. We analyze the source of overhead using many microarchitectural performance counters.

For the target program, fuzzers insert instrumentation code for coverage collection at each basic block. The collection code saves the current register context, loads the base address for the counter region, computes the counter index, updates the corresponding counter value, restores the context, and transfers control back to the program logic (see Figure 2). The code is executed frequently, and can contain dozens of instructions encoded in around a hundred bytes. Furthermore, modern processors use a multi-tier cache subsystem to reduce memory latency. Because the collection code updates the counter array, it adds many loads or stores to the instruction stream. These memory accesses stress the memory subsystem by competing with the program logic for instruction cache. The extra memory latency reduces the overall execution speed of programs.

For the fuzzer itself, the instructions which process coverage do not uncover new states in most cases. While new program states are extremely rare, fuzzers need to perform the

following operations: convert the raw coverage information into features, then check the database of known features, and update the database to add the newly discovered features [42]. This algorithm is implemented using memory write-, integer comparison- and conditional branching instructions. The complex nature of the code prevents the compiler from optimizing it. Consequently, the instructions emitted by the compiler cannot fully utilize instruction-level parallelism supported by the processor’s execution engine.

In this paper, we propose RIFF to reduce instruction footprints of coverage pipelines and improve fuzzing throughput. RIFF utilizes compiler analyses and leverages low-level features directly exposed by the processor’s instruction set architecture. Specifically, ① RIFF reduces the amount of instructions executed for *runtime coverage collection* in the target program. First, RIFF removes edge index computations at runtime by pre-computing the edge transfers at instrumentation-time. Next, RIFF eliminates the instructions for loading the base of the counter region by assigning the region a link-time determined static address. Thus, RIFF can use only one instruction encoded in 6 bytes per instrumentation site. ② RIFF removes unnecessary instructions when *processing coverage* in fuzzers by dividing processing granularity into three stages, where the first stage handles simple scenarios fast, while the last stage is suited for more sophisticated scenarios. For the most common case, RIFF scans the coverage region and skips zero-valued chunks using vector instructions, analyzing 16, 32, or 64 counters per iteration on modern processors.

To demonstrate the effectiveness of our approach, we implement RIFF by augmenting state-of-the-art fuzzers such as AFL [40] and MOpt [29] and evaluate its performance on real-world programs from Google’s fuzzer-test-suite [21] and FuzzBench [30]. On the coverage collection side, RIFF reduces the average runtime overhead of instrumentation from 207% to 8%. On the post-execution processing side, RIFF reduces coverage processing time from 217 seconds to 42 seconds with AVX2 instructions [10] and 31 seconds with AVX512 instructions [34]. As a result, the enhanced fuzzers can complete 147% more executions during the 24-hour experiments, covering 13.13% more paths and 5.60% more edges. Alternatively, the improved fuzzers need only 6.53 hours to reach the 24-hour coverage of baseline fuzzers.

In summary, this paper makes the following contributions:

- We observe that the collection and processing of program coverage measurements significantly affect the speed of fuzzing. We break down the cost of instrumentation and analysis code.
- We eliminate much of the runtime cost by using precomputing information statically, and we accelerate post-execution processing using vectorization.
- We adapt RIFF to popular fuzzers and achieve significant speedup on real-world programs. The coverage

analysis algorithm of our work has been integrated into production-level fuzzer AFL++ [23].

2 Background

2.1 Stages of a Coverage Pipeline

To guide fuzzing using coverage, fuzzers use a multi-stage pipeline. Figure 1 takes AFL as an example to demonstrate how fuzzers handle coverage:

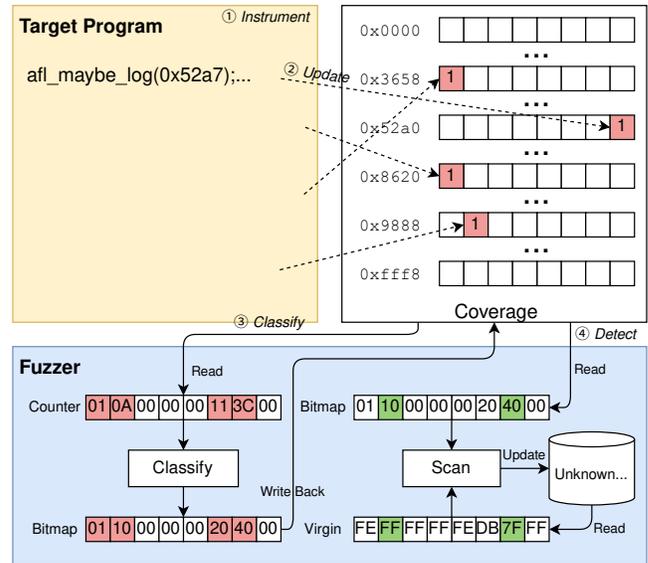

Figure 1: The coverage pipeline of the standard fuzzing tool AFL. After collecting the coverage from the target program (arrows labeled “instrument” and “update”), the fuzzer determines whether the input triggers new program behavior (“classify” and “detect”).

① *Instrument*. At compile time, `afl-clang` allocates an array of 65,536 counters to store coverage as 8-bit counters. For each basic block of the target program, `afl-as` generates a random number ID as its identifier, then inserts a call to `afl_maybe_log(ID)` at the beginning.

After instrumentation, the fuzzer generates random inputs and executes the program on each input. For each input the fuzzer detects whether the input triggers new program states by using a database, as follows:

② *Update*. At run time, `afl_maybe_log` updates the coverage counters to collect edge coverage. The logging function hashes the identifier of the previously executed and the current block, then uses the hash as an index into the counter array to increment the pointed counter by one.

③ *Classify*. After the target program completes execution, AFL reads the coverage counters to classify them into a bitmap of features. Each 8-bit counter with nonzero value is mapped to 8 possible features. The features are represented

as a bitmap, where each feature corresponds to one of the 8 bits inside the 8-bit counter. The classified result is written back to the coverage region.

④ *Detect*. With the edge transfer counts classified as a bitmap, AFL scans the database of unknown program states to detect new program behaviors: if a previously-unknown edge transfer is triggered, then the input will be labeled as “new coverage”; if a known edge transfer has different features, then it will be marked as a “new path”; otherwise, the current input is discarded. After the scan, AFL removes the newly discovered features by updating the database.

2.2 Variants of Coverage Pipeline

While the implementation varies for different fuzzers, the design mostly follows the classic coverage pipeline first introduced by AFL. Table 1 presents the instrumentation mechanism for popular fuzzers. Despite different tool chains and compiler infrastructures, all the collection methods insert code or callbacks to collect coverage. For example, although SanitizerCoverage contains a set of instrumentation options and is implemented in both Clang [7] and GCC [6], it uses callbacks and array updates to report coverage. Note that FuzzBench implements its own instrumentation for AFL [15], we only list it for completeness.

Table 1: Methods for Collecting Coverage

Method	Target	Infrastructure
afl-{clang,gcc}	Assembler	N/A
afl-clang-fast	Clang	LLVM Pass
afl-fuzzbench	Clang	SanitizerCoverage
libFuzzer	Clang	SanitizerCoverage
honggfuzz	Clang/GCC	SanitizerCoverage
Angora	Clang	LLVM Pass

Table 2 summarizes post-processing methods of coverage counters at fuzzers’ side. *honggfuzz* is a special case because it processes coverage in real-time. Other fuzzers first classify the counter array to a bitmap of features, then scan the bitmap to detect the presence of new features.

Table 2: Methods for Processing Coverage

Method	Classify	Scan
AFL	Batch	Bit twiddling
libFuzzer	Per Counter	Statistics update
honggfuzz	N/A	N/A
Angora	Distill	Queued

For example, AFL implements a two-pass design. In the first pass, it performs bitmap conversion in batch; in the second pass, it applies bit twiddling hacks for acceleration. *libFuzzer* employs a one-pass design: for each non-zero byte,

libFuzzer converts it to a feature index, then updates the local and global statistics with complex operations such as binary search. *Angora* takes the queued approach: in the first pass, it distills a small collection of counter index and feature mask out of the original array; in the second pass, it scans the collection to detect new coverage and pushes the modifications to the write-back queue; in the third pass, it locks the global database and applies the queued modifications.

3 Measuring Coverage Pipeline Overheads

To measure the overhead of the coverage pipeline, we select the classic fuzzer AFL as an example: as the forerunner of coverage-guided fuzzing, most coverage-guided fuzzers partially or completely inherit its design. As for the target program and workload, we use libxml2 from FuzzBench.

3.1 Cost of Instrumentation

To evaluate the overhead of coverage collection, we select all instrumentation methods provided by AFL, which cover all compiler infrastructures listed in Table 1. To have a fair comparison, we select afl-clang, afl-fuzzbench, and afl-clang-fast, because they have the same coverage update method and base compiler. We further decrease the optimization level of afl-fuzzbench to `-O2` to match with the other instrumentation methods.

We collect performance metrics by running the target program using perf tools. To remove the one-time cost of program startup, we do a warm-up run of the program with 1 input, then use 11 more inputs separately, then calculate the average of per-execution cost. The Intel Intrinsics Guide [12] is used as the XML input.

Table 3 lists the overhead of each collection method by normalizing each metric to the non-instrumented baseline program. Looking at the “duration” column, we can see that the instrumentation significantly slows down program execution. For example, as soon as the fastest method, afl-clang-fast, finishes executing its first input, the non-instrumented program has executed more than half of the second input.

Table 3: Overheads of Instrumented Programs

Method	Duration	Instructions	L1-I	L1-D	μ ops
afl-clang	3.50x	4.26x	102.36x	5.16x	4.72x
afl-fuzzbench	2.45x	2.83x	19.88x	2.53x	2.14x
afl-clang-fast	1.69x	1.79x	33.58x	2.88x	2.11x

The “instruction count” column explains the slowdown. Figure 2 lists the instructions of afl-clang (the slowest method), and afl-clang-fast (the fastest method). Take afl-clang for example, for each basic block, it inserts 10 instructions encoded in 56 bytes. These instructions save the context, invoke `__afl_maybe_log`, and restore the context. In

__afl_maybe_log, instructions totaling 44 bytes are executed, which update the last code location and increase the counter. They even contain a conditional jump which checks whether the coverage counters are initialized. The same problem is still applicable to the fastest method afl-clang-fast: of all the 7 instructions it executes, only one instruction is used to actually update the counter.

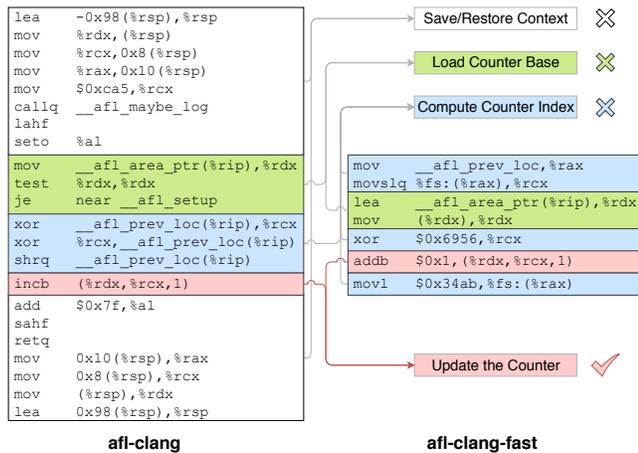

Figure 2: Instructions inserted by afl-clang (22 instructions, 100 bytes) and afl-clang-fast (7 instructions, 39 bytes). Note that only the instruction marked in red updates the counter.

The instrumentation code has a significant processor cost. First, it starves the processor’s front end which translates instructions to micro-ops. For each basic block, afl-clang requires executing extra instructions totaling 100 bytes, i.e. 1/256 of all the available L1 instruction cache. As a result, afl-clang experiences 101.36x more L1 instruction cache misses, and the CPU executes 3.72x more micro-ops for afl-clang produced programs.

3.2 Unnecessary Instructions in Fuzzer

Figure 3 presents the cost breakdown of afl-fuzz by sampling its CPU usage. To reduce noise introduced by fuzzing, we sample the user space CPU cycles for 5 seconds after afl-fuzz has discovered 2,000 paths of libxml2.

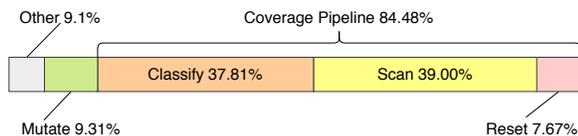

Figure 3: Breakdown of execution costs for afl-fuzz: AFL first mutates the input; after the execution completes, it classifies the coverage to bitmap, scans the bitmap for new coverage, and resets the memory for the next run.

From the figure we can see that afl-fuzz spends the majority

of its time on the coverage pipeline. To detect new program states, AFL spends 84.48% of its valuable CPU time on the coverage pipeline. The overwhelmingly high percent of CPU usage implies significant problems behind the overall system design, which inevitably leads to redundancy in executed instructions.

Table 4 shows that most executions do not improve coverage. We call a counter “useless” if its value is zero, since a zero-valued counter never maps to a feature. We call a program execution “useless” if its bitmap does not contain any new feature with respect to previous executions. After AFL terminates, we collected the coverage of the first discovered 2,000 paths, and calculated useless counters (see the first row). We also compute useless executions during a 5-second time interval (see the second row). During the period, AFL had executed 67,696 inputs, where each execution required processing 64 KiB of coverage. Although it had processed over 4,231 MiB of coverage, it only discovered 2 new paths, and none of the paths covered new counters.

Table 4: Number of Processed Counters and Executions

	Total	Useless	Proportion
Counter	65,536	64,664.37	98.67%
Execution	67,696	67,694	99.997%

As the first row in Table 4 shows, for the coverage of the first 2,000 discovered paths, 98.67% of the processed counters were zero. In other words, executing an input only covers 871.69 counters, yet the total number of counters allocated by AFL was 65,536. Angora’s instrumentation technique suffers even more, because it allocates 1MiB of memory to store coverage. The sparsity of the coverage array implies that skipping zero counters quickly during coverage analysis can be a major performance boost.

As the second row in Table 4 shows, although 99.997% of the inputs did not trigger any new program behavior, AFL still performed many computations: the first pass converted the coverage to a bitmap, and the second pass re-read it to compare with the database of unknown program states. The same applies to libFuzzer, which maintains even more statistics, including the minimum input size, the trigger frequency of each feature, the list of the rarest features, and the list of unique features covered by the current input. The analysis requires complex computations involving table lookups, linear searches, and floating-point logarithms.

The analysis logic cannot be efficiently optimized by compilers. The high-level algorithm is scattered with side effects, control-flow transfers, and data dependencies. Due to the complexity of the analysis logic, the compiler cannot perform important optimizations such as hardware-assisted loop vectorization. Only shallow optimizations, such as loop unrolling, are performed.

4 Design of RIFF

Figure 4 presents the overall design of RIFF. Similar to conventional coverage pipelines, it consists of compile-time instrumentation, runtime execution trace collection, and coverage processing.

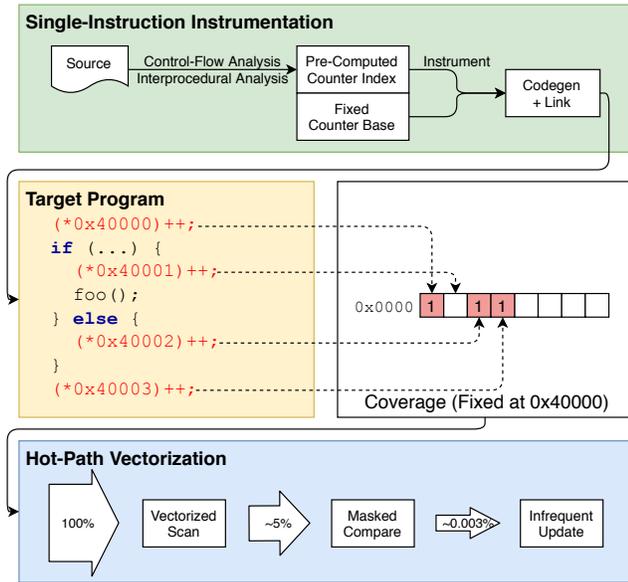

Figure 4: System overview. RIFF first instruments the program to log the execution trace at runtime. After the completion of execution, the fuzzer processes the coverage in three stages, using vectorization on the hot-path.

At compile-time, RIFF performs control-flow analysis and interprocedural analysis to pre-compute all possible control-flow edges; each edge is statically allocated a fixed counter index. The compile-time computation avoids performing the address computation at runtime. Next, RIFF inserts code to log the edge execution by incrementing the counter at the corresponding address. Finally, RIFF generates machine code with the help of the compiler’s backend, without requiring runtime context saving or restoring. When the target program starts, RIFF’s runtime maps the coverage counters at the fixed address specified by the compiler. The simplified instrumentation and aggregated coverage layout reduces the overhead of coverage collection. We describe the optimized instrumentation in detail in Section 4.1.

After the target program completes the execution of an input, the fuzzer enhanced with RIFF processes the coverage in three stages, where the first stage handles simple cases quickly, and the last stage handles infrequent complex cases. According to the simulation of collected coverage in Section 3.2, the first stage vectorized scan can eliminate 95.08% of the analysis cases, leaving only 4.92% of the processing job to the second stage, i.e. the masked comparison. The slowest stage only processes 0.003% of all cases.

4.1 Single-Instruction Instrumentation

As shown in Figure 2, the instrumentation code that collects coverage is expensive. Not only does it need to update the counter for each basic block, but the instrumentation code *saves and restores registers* around each counter update to preserve program logic. Moreover, the code *loads the counter base address* dynamically and *computes the counter index* by hashing the block index. RIFF reduces this code to a single instruction by performing much of this computation at compile time.

Pre-Compute Counter Index AFL uses hashing-based control-flow edge coverage. While edge-level coverage can distinguish between execution traces where block-based coverage cannot, maintaining the previous block’s identifier dynamically and computing hashes at runtime is expensive. Using the compiler infrastructure RIFF performs edge-coverage computation at compile-time, and falls back to runtime computation only if static information is insufficient.

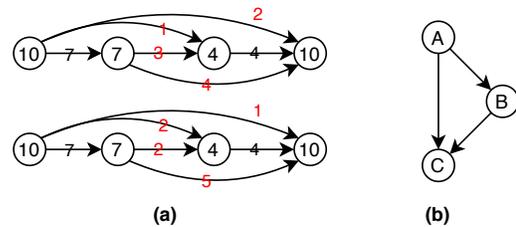

Figure 5: Problems behind raw block coverage: (a) incompleteness: multiple edge counts can map to the same block count; (b) complexity: obtaining the hit count of edge AC requires extra computation at fuzzer’s side.

Figure 5 illustrates the imprecision of block-level coverage. Figure (a) shows two control-flow graphs that have different edge counts but identical block counts. In theory, for a digraph with $|V|$ vertices, there can be $\frac{|V||V-1|}{2}$ edges. Therefore, block count alone cannot determine the exact edge counts. However, in practice, the graph is very sparse, and in some cases, the edge counts can be uniquely determined by the block counts. However, calculating edge counts requires an expensive computation to solve a system of equations. As Figure (b) shows, there are three basic blocks (A, B, and C) and three edges (AB, BC, and AC). Suppose that the instrumentation scheme collects the count for basic block A, B, and C as a , b , and c respectively. While the hit count for edge AB and BC can be directly represented as a or c , the hit count of edge AC must be computed (such as $a - b$). Solving the system of equations will significantly slow down the processing at fuzzer’s side.

RIFF leverages static analysis to allocate one counter for each edge. It does this by creating additional empty basic blocks when needed. As Algorithm 1 shows, if the hit count of an edge can be uniquely determined by its source or sink

Algorithm 1: Control-Flow Edge Instrumentation

Data: A control-flow graph $G = (V, E)$
Result: A new control-flow graph $G' = (V', E')$ and a set of target blocks to instrument $T \subseteq 2^{V'}$

```
 $T \leftarrow \emptyset, V' \leftarrow V, E' \leftarrow E;$   
for  $(x, y) \in E$  do  
  if  $\delta^+(x) = 1$  then  
    The source vertex has only one outgoing edge  $(x, y)$ ,  
    thus the hit count of  $(x, y)$  equals to  $x$ ;  
     $T \leftarrow T \cup x;$   
  else if  $\delta^-(y) = 1$  then  
    The sink vertex has only one incoming edge  $(x, y)$ ,  
    thus the hit count of  $(x, y)$  equals to  $y$ ;  
     $T \leftarrow T \cup y;$   
  else  
    No direct representation is available ;  
    Introduce a temporary vertex  $t_{(x,y)}$  to represent the  
    hit count of  $(x, y)$  ;  
     $V' \leftarrow V' \cup t_{(x,y)};$   
     $E' \leftarrow E' / (x, y) \cup (x, t_{(x,y)}) \cup (t_{(x,y)}, y);$   
     $T \leftarrow T \cup t_{(x,y)};$   
  end  
end
```

vertex, then the block count is used for the edge. Otherwise, an empty block is allocated to represent the edge. For function calls, RIFF uses the hit count of the caller block to represent the hit count for the edge between the caller block and the callee’s entry block because the counts are equal. After collecting the blocks to instrument, RIFF assigns identifiers sequentially for each block and removes instrumentation sites whose hit counts can be represented by other counters. These identifiers are used as runtime indexes for the counters in the coverage array.

Fix Counter Base AFL uses a block of shared memory for the counters. When the target program starts, the runtime library maps the shared memory into its address space and stores the base address as a global variable. While indirect addressing is flexible, computing the counter address dynamically for every basic block is inefficient. To remove extra accesses to the counter base, the address must be compile-time constants for each instrumentation site. Counter allocation with fixed addresses is done in two steps.

At the beginning of each basic block, the instrumentation code should increment its associated counter. If the base address is fixed, and the index of the array is already allocated at compile time (see Section 4.1), the address of the counter can be also computed at compile time. We can then directly increment the counter pointed by the address, using e.g., `incb $ADDR`. However, as Table 5 shows, directly encoding the target address inside the instruction requires a 7-byte instruction (scale-index-base). RIFF uses a RIP-based addressing mode

¹, requiring a 6-byte instruction. Moreover, the expensive register save/restore code is no longer needed.

Table 5: Instruction Encoding of Addressing Modes

Assembly	Length	Opcode	ModRm	SIB	Disp
<code>incb \$ADDR</code>	7	0xfe	0x04	0x25	(4 bytes)
<code>incb \$OFFSET(\$rip)</code>	6	0xfe	0x05		(4 bytes)

Before the target program runs, the memory shared by the fuzzer should be correctly mapped to the address space of the target program. To prevent the static and dynamic linker from reusing the address for other symbols, RIFF fixes the binary’s image base to the address 0x80000 (8 MiB), and reserves the address range of 0x400000 to 0x80000 for the coverage.

Indirect Control Transfers While single-instruction instrumentation is efficient, this solution cannot be used for indirect control transfers. These occur in the following instances: GNU C extensions that allow taking the address of switch labels [18], `set jmp` and `long jmp` [26], function pointers, and unwinds on C++ exceptions.

RIFF uses interprocedural control-flow analysis to discover such cases and falls back to dynamic computation. If the start of an edge representing indirect control transfer is found (e.g. `set jmp`), RIFF stores the source block ID in thread-local storage before performing the transfer. At the target of an indirect control transfer (e.g. `long jmp`), RIFF loads the source block ID and computes the counter index by hashing.

4.2 Hot-Path Vectorized Analysis

As Table 4 shows, among all coverage counters, only a small number of counters are updated by the target program; among all executions, inputs which demonstrate new program behavior are extremely rare. This observation implies that many computations performed by the fuzzer do not produce useful results. If the redundant computation is removed, the simplified logic can be accelerated using SIMD instructions (Advanced Vector Extensions on x86-64 and NEON on ARMv8).

Figure 6 demonstrates how this multi-stage processing design simplifies the logic. Stage 0 is the simplest one, which just fetches 64 bytes chunks and discards all-zero chunks. Stage 1 is invoked with the nonzero positions encoded as a mask. In Stage 1 the counters are classified as a bitmap in registers then directly compared with the database for unknown program states. The counters are discarded if no new features are discovered. Only when it is determined that the current input triggers new program behaviors is the original analysis performed by AFL invoked, in Stage 2. While this stage requires complex computations, it is rarely invoked.

¹RIP is the instruction pointer.

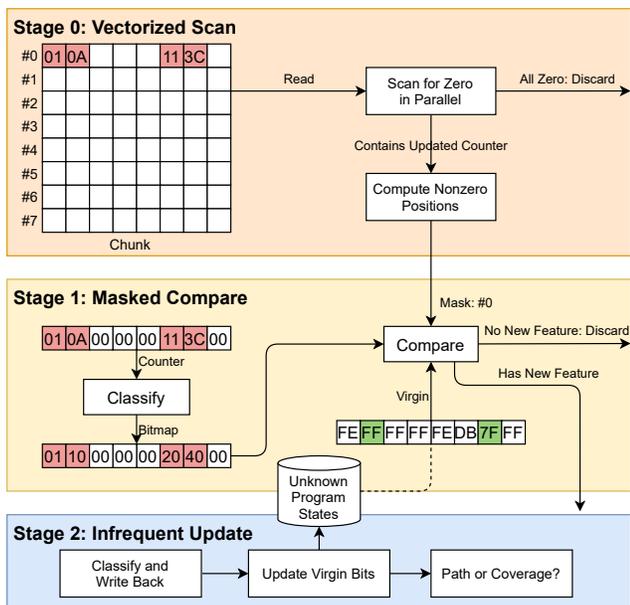

Figure 6: Processing coverage in three stages. Stage 0 filters out large chunks of zero bytes; Stage 1 checks for new coverage using masked comparisons; Stage 2 is invoked only for inputs that trigger new behaviors.

Vectorized Scan Although coverage-guided fuzzing can discover lots of code during the whole fuzz session, the covered code for a single input is lower. Because most counters are not accessed by the target program, their values stay zero after execution. Filtering out these zero counters can remove further processing stages, but the filtering operation itself requires extra computation.

To filter the zero counters efficiently, we use instructions that scan counters in parallel. Modern processors have vector processing abilities. AVX512 is a typical single-instruction-multiple-data design proposed by Intel in 2013, and it is widely supported in modern server processors. Operating on 512-bit vectors, it can compare 64 lanes of 8-bit integers in parallel (`vptestnmb`). For example, on Skylake-X based processors, it completes such a scan in 4 clock cycles. By comparison, the scalar-based processing requires 64 `testb` instructions with a latency of 1 cycle each.

The vectorized comparison encodes the comparison results inside a mask register. Each bit inside the mask register represents whether a lane inside the vector is zero. For example, if we treat 64 bytes of data chunk as 8 lanes of u64, then the result mask register contains 8 bits. If the least significant bit (0x1) is set in the mask, then the first (#0) lane is zero. Similarly, if the most significant bit (0x80) is set in the mask, then the last (#7) lane is zero. Consequently, we can skip the following tiers if all the 8 bits are set (0xff), indicating that all the lanes are zero.

Masked Compare If a chunk contains non-zero bytes, it may represent a new program behavior. Therefore, vectorized scan cannot discard the chunk and should delegate the computation to the next stage, masked compare. In this stage, the coverage is classified then compared with the database to detect new program behavior.

However, even for a non-zero chunk, it is very likely that most of the lanes are zero because of the sparsity of coverage. To remove unnecessary computation, the mask obtained from vectorized scan is used to sift the nonzero lanes: only when the mask indicates that a lane is non-zero, then the following classification is used. Otherwise, the zero lanes are discarded immediately.

For each nonzero lane, the corresponding counters are read into a register. After classifying the raw counters into bitmap using table lookups and bitwise operations, they are directly compared with the database. In most cases, the comparison will not find a difference and the bitmap is discarded. We optimize for the scenario where the bitmap is discarded to avoid updates to both the bitmap and the database.

Infrequent Update For inputs triggering interesting behavior, the processing of its coverage will reach stage 2. This stage is seldom invoked.

This stage performs the original analysis performed by standard fuzzers: first, it classifies the original counters and writes the bitmap back to memory; second, it reads the bitmap, compares it with the database, and updates the database if needed. While scanning the bitmap, it checks for changed counters and declares the run to be a “new coverage” if any are found. Otherwise, the run has discovered a “new path”.

5 Implementation

Because single-instruction instrumentation requires the precise counter address for each instrumentation point, instrumentation must be performed on the whole program, at link-time. The compiler part of RIFF is implemented on LLVM. Specifically, when compiling source files, RIFF instructs the compiler to produce LLVM bitcode instead of object files. These bitcode files are linked to the whole-program bitcode for analysis use. Next, RIFF performs instrumentation on the whole program leveraging the DominatorTreeAnalysis and BasicBlockUtils analyses, then generates machine code as a single object file. During code generation, LLVM prefers to generate 7-byte `addb` instructions over the 6-byte `incb` instructions, because the default configuration of LLVM is optimized for old or mobile-first processors, where `incb` is slower than `addb`. To force instruction selection to generate `incb` instructions, we fine-tune the LLVM target attribute by disabling the `slow-incdec` target feature.

As in conventional linking, the single object file is linked with system libraries. After this step the compiler maps the

symbol denoting the start of coverage counters at a fixed address (SHN_ABS in `st_shndx`). As Listing 1 shows, the generated machine code only requires 6 bytes for most cases. Only on indirect transfers does RIFF fall back to the runtime hashing.

```
# Single-instruction instrumentation
incb $INDEX(%rip) # fe 05 ?? ?? ?? ??

# Rare case: indirect transfer (source)
mov $PREV(%rip),%rcx # 48 8b 0d ?? ?? ?? ??
movl $BBID,%fs:(%rcx) # 64 c7 01 ?? ?? ?? ??

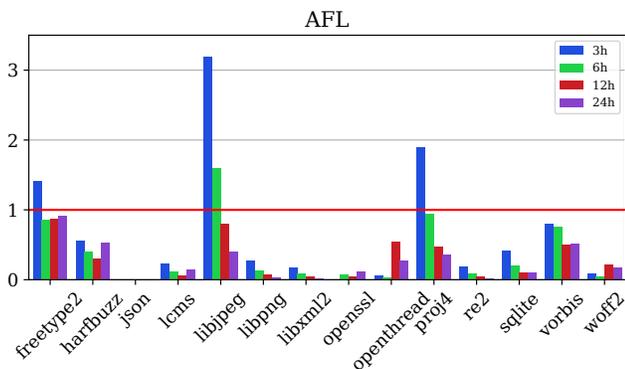

# Rare case: indirect transfer (destination)
mov $PREV(%rip),%rcx # 48 8b 0d ?? ?? ?? ??
movslq %fs:(%rcx),%rax # 64 48 63 01
xor $BBID,%rax # 48 35 ?? ?? ?? ??
incb $BASE(%rax) # fe 80 ?? ?? ?? ??
```

Listing 1: Assembly and machine code generated by RIFF.

Because vectorized coverage processing relies on the hardware support of SIMD instructions, currently we implement two variants on x86-64. If AVX512 Doubleword and Quadword Instructions (AVX512DQ) are supported, then 8 lanes of 64-bit integers are processed as a chunk. If AVX2 is supported, then the 4 lanes of 64-bit integers are processed as a chunk. Otherwise, Stage 0 is skipped entirely, and Stage 1 is executed. We implement the algorithms via intrinsic functions to take advantage of the compiler-based register allocation optimization.

6 Evaluation

To demonstrate how the reduced instruction footprint accelerates fuzzing, we evaluate the performance of RIFF on real-world settings.

For target programs, we select every program included in both Google fuzzer-test-suite and FuzzBench. Carefully picked by Google, they encompass a comprehensive set of widely-used real-world programs. For fuzzers, we select the classic industrial fuzzer AFL and the recently published MOpt.

We compile the programs with `afl-clang` using the default settings and compile RIFF’s version with our instrumentation pipeline. For both cases we use Clang 11.0 with the same configuration (e.g., optimization level). As for the fuzzers, the baseline versions are built from the git repositories without modification. We further apply RIFF’s hot-path acceleration patch to the baseline fuzzers. Note that RIFF and AFL use different instrumentation, we calibrate the raw metrics with fuzzer-test-suite’s coverage binary for fairness. All the coverage used in the following analysis is based on the calibrated data.

We perform the experiments on Linux 5.8.10 with 128 GiB of RAM. The processor used is Intel Xeon Gold 6148. Its Skylake-Server microarchitecture allows acceleration with AVX2 and AVX512.

6.1 Overall Results

Figure 7 compares the time required by RIFF to reach the same coverage as AFL and MOpt respectively running for 3h, 6h, 12h, and 24h. A bar below the red line indicates a speed-up for RIFF.

The purple bars show the speedup of the long experiments run for 24 hours, where fuzzing tends to saturate (discovering few new paths). On average, to reach the final coverage of AFL and MOpt running for 24 hours, RIFF’s improved versions only require 6.23 and 6.82 hours respectively. For individual programs, the improvements are consistent: even for the worst programs (freetype2 for AFL and libjpeg for MOpt), RIFF still reached the final coverage 2.1 and 0.8 hours before the baseline versions. On average, RIFF accelerates

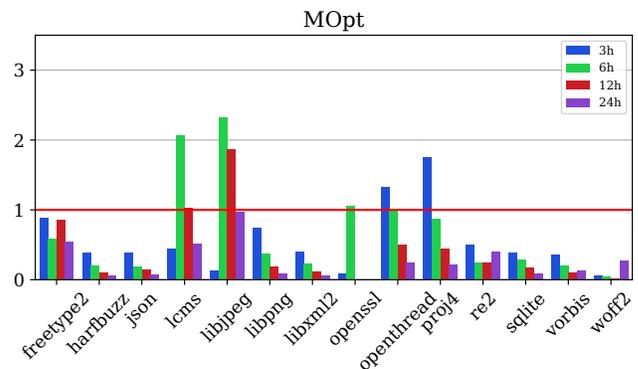

Figure 7: Normalized execution time required by RIFF to reach the same coverage as AFL and MOpt. The X axis is programs, the Y axis is the ratio between the execution times required for reaching the same coverage. A bar below the red line indicates a speed-up.

the 24-hour fuzzing by 268.74%.

The bars of 3h, 6h, and 12h show the speedup for shorter experiments. In such scenarios, saturation is less likely, and the randomness can lead to slowdowns (causing a different set of inputs to be explored). Here we can see that RIFF is still frequently performing best. For example, when fuzzing freetype2 with AFL, RIFF-based version requires 1.22 hours more to catch up with the baseline version, but its performance gradually improves as we extend the experiment, and it leads by 0.85, 1.56, and 2.10 hours at 6, 12, and 24h respectively.

Figure 8 presents the overall results after 24-hour experiments. Inside the figure, the baseline metrics from AFL and MOpt are normalized to the red horizontal line 1.0, while the corresponding metrics from RIFF’s optimizations are drawn as bars. Higher bars indicate better performance.

The “covered edges” graph from Figure 8 demonstrates the overall improvement brought by RIFF. On average, RIFF improves the coverage of AFL and MOpt by 4.96% and 6.25% respectively. The improvement is consistent for individual programs: among all the 28 experiments, RIFF is best for 27. Because RIFF accelerates both the fuzzer and the target program, more executions can be completed in less time. Despite the trend of saturation for the long 24-hour trials, RIFF still managed to cover rare edges requiring a large number of executions.

The “total paths” graph from Figure 8 demonstrates that RIFF has comparably good feedback signal as the baseline versions. For most programs, RIFF improves the total number of discovered paths since it performs more execution: on average, RIFF improves the number of discovered paths by 10.79% and 15.48% over AFL and MOpt respectively. Although RIFF simplifies the computation of edge coverage, its ability in providing fuzzing signal is not reduced because of the compile-time analysis. Take re2 for example, both the baseline versions seem to discover more paths; however, paths only provide fuzz signals, thus more paths do not necessarily lead to more coverage. When the fuzz-oriented coverage

is calibrated to fuzzer-test-suite’s canonical coverage, RIFF-based fuzzers discover more edges.

The advantage of RIFF can be seen in the “total executions” graph. RIFF increases the number of fuzzing executions in the same amount of time to values ranging between 1.03% to 541.38%. While the randomness introduced by fuzzing algorithms can cause diminished coverage, the overall result confirms that RIFF improves the execution in general. The vastly increased number of executions can be attributed to the reduced overhead, in both the target program and the fuzzer’s side.

6.2 Simplified Coverage Collection

Single-instruction instrumentation reduces the overhead of the instrumentation. To evaluate it fairly, we first fix a set of inputs, and we reuse the same inputs for all measurements for all fuzzers. For each program, we mix 1000 inputs discovered by all fuzzers; while executing the programs, we measure the time and normalize it against the non-instrumented version.

Figure 10 shows the instrumentation overhead for both afl-clang and RIFF. The figure demonstrates that the widely used instrumentation scheme afl-clang imposes heavy overhead on all the programs. Compared to the non-instrumented programs, programs instrumented by afl-clang the average execution time increases by 206.83%. The reasons can be explained by Figure 9: it executes 340.63% more instructions, which translate to 338.47% more uops and require 242.97% more L1 instruction cache refills.

RIFF reduces the footprint of instructions down to one instruction per site. On average, the coverage collection of RIFF only requires 8.40% more time to execute, while afl-clang requires 206.83% more time. In other words, RIFF reduces the overheads by 23 times. The improvement can be explained by the reduced instruction footprint: RIFF eliminates loads to counter base, shifts computation of counter index to compile-time, and removes the context saving or restoring code.

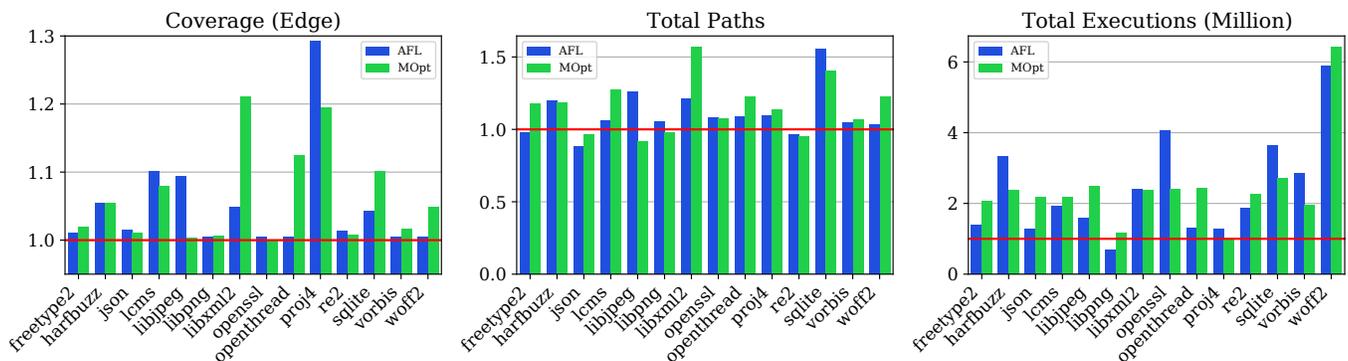

Figure 8: Normalized performance metrics for RIFF-based fuzzers after 24 hours of fuzzing. X axis is programs, Y axis is the normalized performance metric (ratio between RIFF and standard fuzzer). Bars higher than 1 (red line) indicate better performance.

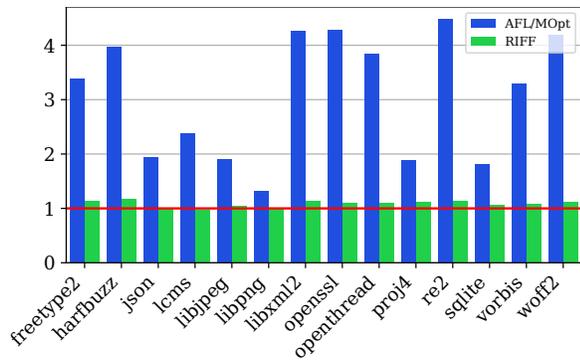

Figure 10: Normalized execution duration of fuzzed programs: time to execute 1000 on fixed inputs normalized to the time of uninstrumented programs. Lower bars indicate better performance.

6.3 Accelerated Coverage Processing

Hot-path vectorization accelerates the coverage processing at fuzzer’s side. To cancel randomness from fuzzing loops and irrelevant speedups from the target programs, we extract the coverage processing routine as a library and evaluate it in isolation.

As in Section 6.2, we fix a set of inputs, then run experiments with these inputs to collect the raw coverage counter arrays. However, because all the saved inputs are rare cases which lead to new coverage, just running coverage processing routine on the saved inputs one by one exaggerates the rate of discovery. Instead, we calculate the average number of executions to discover a new input during the whole fuzz session, and run coverage processing routine on the raw coverage repeatedly this many times on the first 50 inputs. We further calculate the total processing time required to discover the first 50 inputs; we present the normalized values in Figure 11.

Figure 11 shows the benefits of hot-path vectorization. The processing time of AFL and MOpt is normalized to 1.0, shown as the red horizontal line. The bars show the processing time of RIFF.

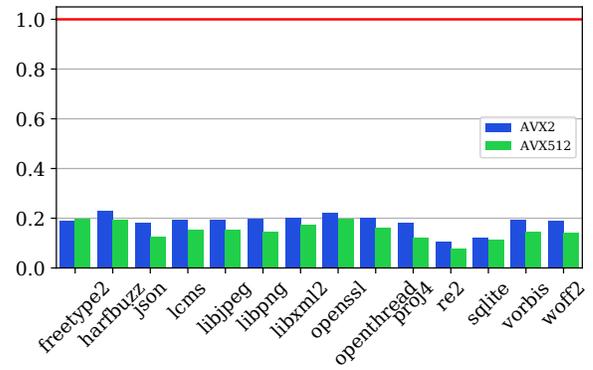

Figure 11: Coverage processing time (normalized against the baseline algorithm). Lower bars indicate better performance.

The bars for AVX2 and AVX512 of Figure 11 demonstrate RIFF’s improved efficiency in coverage processing. Leveraging AVX2, RIFF uses one instruction to compare 32 coverage counters in parallel; AVX512 further extends the parallelism to 64 counters per comparison. With hardware-assisted processing, the vectorized versions improve the efficiency of the original scalar-based pipeline by 4.64x and 6.01x respectively.

7 Discussion

Currently, we only evaluated our work on x86-64 due to insufficient fuzzer support on other platforms. For example, AFL only provides experimental ARM support via QEMU. While the implementation is target-dependent, the general idea applies to all platforms: the minimal instrumentation logic can be implemented with just 4 instructions on ARMv8 or RISC-V systems; the vectorized coverage processing can use ARMv8 NEON ISA instead of AVX2 or AVX512.

As for the applicability of our improvement, we only applied our work to the industrial fuzzer AFL and the academic work MOpt due to limited resources. While they use different fuzzing algorithms, the improvements brought by RIFF are similar (see Figure 7 and 8). Our work can be easily adapted

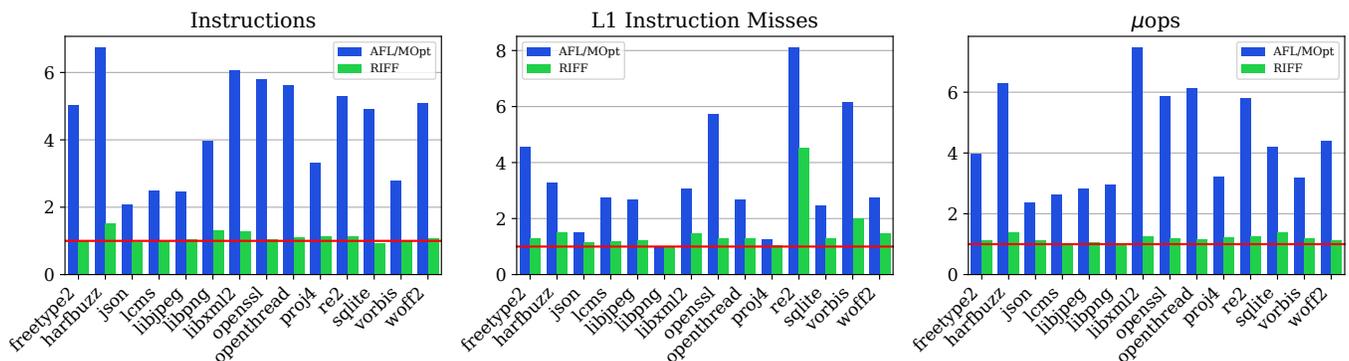

Figure 9: Metrics for RIFF-Based Programs

to more fuzzers. For example, developers of AFL++ [17] have adapted our work to their code base and conducted independent third-party evaluations with Google FuzzBench [30]. According to the result [5], our modification (labeled as “skim”) was the best-performing one among all the 10 variants.

8 Related Work

8.1 Vectorized Emulation

Snapshot fuzzing [2, 16] tests the target program from partially executed system states. The program is broken into small pieces of code, and the execution of the code is emulated by the hypervisor. Because the emulation simplifies the logic to execute, multiple system states can be emulated simultaneously with vectorization.

Rather than accelerating the emulation, RIFF is focused on coverage pipeline: first, RIFF’s single-instruction instrumentation combined with vectorization-based emulation and checkpointing accelerates the execution of target programs; RIFF’s hot-path optimization also accelerates fuzzer’s coverage analysis.

8.2 Enriching Semantics of Coverage

Since the coverage quality is crucial for input prioritization, numerous approaches have been proposed by academia which bring more semantics to coverage. For example, VUzzer [33] stores call stack information to coverage, and Angora enhances coverage with search targets [11]. Sometimes, researchers introduce data-flow features to conventional control-flow-oriented coverage. For example, Steelix [28] stores branch comparison operators, Dowser [22] records branch constraints, GreyOne [19] imports constraint conformance to tune the evolution direction of fuzzing, and [37] traces memory accesses. While these techniques can help a fuzzer to choose better inputs, the complexity introduces heavy overhead and severely limits the execution speed.

8.3 Reducing Overhead of Coverage

Not instrumenting the program eliminates overhead altogether. Researchers utilize debugger breakpoints to detect the first time a block has been covered with hardware support [32, 43]; in this scheme, only the first occurrence of a block has extra cost. However, the information of the number of times that a block has been covered is lost without any instrumentation; on the contrary, RIFF does not reduce the quality of feedback.

Another idea is to reduce the number of instrumentation points [25]. However, the cost of each instrumentation point is still high because it still needs to maintain the edge information by hashing. RIFF simplifies instrumentation points to single instructions; it is not focused on reducing the amount of instrumentation points.

8.4 Reducing Overhead of Operating System

Traditionally, fuzzing is targeted at utility programs where each execution requires `fork` a new process and then `execve` to the new binary. To remove the costly `execve`, AFL implements `fork server mode` [39]. To reduce the cost of `fork`, Xu et al. [38] designs a new system call `snapshot` to restore the execution state in-place. To further reduce the number of invocations of `fork`, AFL implements `persistent mode` [41], where a program runs continuously without restart. `libFuzzer` further eliminates other expensive system calls with in-process fuzzing: if the fuzz target is library, then the fuzzing is performed in-memory.

With these operating system works, the major overhead introduced by context switches of system calls has been greatly reduced. Consequently, the cost of execution has become another prominent problem. RIFF reduces the cost by reducing the instruction footprint of the coverage pipeline.

9 Conclusion

In this paper, we present RIFF to reduce the instruction footprint for fuzzing. We first observe that the coverage pipeline in fuzzing slows down the overall execution speed. We find that the heavy instruction footprint is the root cause: for target programs, the expensive instructions collect coverage inefficiently; for fuzzers, the unnecessary instructions cannot fully exploit the processor’s ability. We implement RIFF to reduce the instruction footprint and achieve a 268.74% speedup for the 24-hour experiments. RIFF is being integrated by popular fuzzers such as AFL and AFL++ for use in industry and has shown significant improvements over the state of the art.

Abstract

TCP stacks provide reliable data transmission in network, and thus they should be correctly implemented and well tested to ensure reliability and security. However, testing TCP stacks is difficult. First, a TCP stack accepts packets and system calls that have dependencies between each other, and thus generating effective test cases is challenging. Second, a TCP stack has various complex state transitions, but existing testing approaches target covering states instead of covering state transitions, and thus their testing coverage is limited. Finally, our study of TCP stack commits shows that 87% of bug-fixing commits are related to semantic bugs (such as RFC violations), but existing bug sanitizers can detect only memory bugs not semantic bugs.

In this paper, we design a novel fuzzing framework named TCP-Fuzz, to effectively test TCP stacks and detect bugs. TCP-Fuzz consists of three key techniques: (1) a *dependency-based strategy* that considers dependencies between packets and system calls, to generate effective test cases; (2) a *transition-guided fuzzing approach* that uses a new coverage metric named *branch transition* as program feedback, to improve the coverage of state transitions; (3) a *differential checker* that compares the outputs of multiple TCP stacks for the same inputs, to detect semantic bugs. We have evaluated TCP-Fuzz on five widely-used TCP stacks (TLDK, F-Stack, mTCP, FreeBSD TCP and Linux TCP), and find 56 real bugs (including 8 memory bugs and 48 semantic bugs). 40 of these bugs have been confirmed by related developers.

1 Introduction

The TCP protocol is a transport-layer network protocol that receives system calls and packets to provide reliable data transmission. It carries over 85% of network traffic nowadays [44, 63]. In practice, the TCP protocol has different implementations, forming different TCP stacks. Each modern operating system (such as Linux and FreeBSD) has its own kernel-level TCP stack to provide fundamental network sup-

port for user-level applications. Besides, to achieve better performance and reduce impact on OS kernels, many user-level TCP stacks (such as mTCP [26], TLDK [59] and F-Stack [19]) have been developed and widely-used in telecom systems and network nodes, to transfer data without OS involvement.

Though TCP stacks are critical, correctly implementing them is difficult [4, 16], as a TCP stack has rich functionalities (such as reliable transmission and congestion control), complex state model and various kinds of possible exceptions to handle. Thus, developers may unintentionally make mistakes when implementing TCP stacks, introducing bugs that can cause serious problems. Memory bugs (such as null-pointer dereferences and use-after-free issues) are common in TCP stacks, and they can cause crashes, data corruption and so on. Moreover, according to our study of TCP stack commits, 87% of bug-fixing commits are related to *semantic bugs* (such as RFC violations), which are related to code logics and RFC documents, instead of memory accesses. For example, CVE-2019-11478 [15] reports that the TCP retransmission queue in the Linux TCP stack can be fragmented when handling certain TCP Selective Acknowledgment (SACK) sequences, and attackers can exploit this bug to cause a denial of service. Thus, it is important to test TCP stacks to detect bugs.

To detect bugs in TCP stacks, some approaches [34, 40, 41, 53] use model checking or formal verification to check the correctness of TCP implementation. But they require much manual effort and TCP-specific knowledge to provide a complete and correct TCP state model, and they are often time-consuming due to high complexity of TCP state transitions. To reduce manual effort and time usage, some approaches [9, 30] perform static analysis of TCP stack source code. But they often introduce false positives, due to lacking exact runtime information. To reduce false positives, some approaches [3–5, 66] analyze the runtime traces of TCP stacks to infer RFC violations. However, they require substantial and effective test cases to achieve high testing coverage.

To generate effective test cases, many recent approaches perform fuzz testing for the implementations of application-layer network protocols, such as DTLS/TLS [17, 52, 54, 60],

FTP [6, 21, 43] and Modbus [37, 38]. But these approaches are limited in testing TCP stacks for three critical reasons: (1) These approaches generate just packets as input test cases, without considering dependencies between inputs; but TCP stacks receive both system calls (syscalls) and packets, which have dependencies between each other. Thus, these approaches are limited in generating effective test cases for TCP stacks. (2) These approaches use code coverage as program feedback to cover different protocol states; but besides states, TCP stacks also have various state transitions that heavily affect TCP execution and can trigger semantic bugs. Thus, these approaches fail to cover many state transitions and thus may miss many real bugs. (3) Many of these approaches use common bug sanitizers (such as ASan [2] and MSan [39]) to detect memory bugs; but many bugs in TCP stacks are semantic bugs that are unrelated to memory accesses, and thus common bug sanitizers cannot find these semantic bugs.

In this paper, we propose a novel TCP-stack fuzzing framework named TCP-Fuzz, which consists of three key techniques. First, to generate effective test cases, TCP-Fuzz uses a *dependency-based strategy* that can generate the sequences of syscalls and packets by considering dependencies between them. Specifically, this strategy considers three kinds of dependencies to generate effective test cases, including syscall-syscall, packet-packet and syscall-packet dependencies. For example, a typical packet-packet dependency is that the sequence number of a new packet should be equal to the sum of the sequence number and data length of the previous packet. Second, to effectively cover state transitions, TCP-Fuzz uses a *transition-guided fuzzing approach* that exploits a new coverage metric named *branch transition* as program feedback to replace code coverage. Branch transition is represented as a vector that stores both branch coverage for the current input item (packet or syscall) and the change of branch coverage between the current and previous input items. In this way, branch transition can describe not only states but also state transitions of two adjacent input items. Finally, to detect semantic bugs, TCP-Fuzz uses a *differential checker* that compares the outputs of multiple TCP stacks for the same inputs. Indeed, different TCP stacks should obey many identical semantic rules (most of these rules are defined in RFC documents), and thus they should produce identical or similar outputs for the same inputs. Otherwise, these TCP stacks have implementation inconsistencies, indicating some of them possibly have semantic bugs. This checker is scalable and does not introduce runtime overhead for TCP stacks.

We have implemented TCP-Fuzz with Clang [33] and Packdrill [8]. TCP-Fuzz can detect both memory bugs with existing bug sanitizers and semantic bugs with our differential checker. Overall, we make four main contributions:

- We study TCP stack commits, and find 87% of bug-fixing commits are related to semantic bugs, which cannot be found by existing bug sanitizers. We also reveal the limitations of existing protocol fuzzing in testing TCP stacks.

- To improve fuzzing in testing TCP stacks, we propose three key techniques: (1) a *dependency-based strategy* that considers dependencies between packets and system calls, to generate effective test cases; (2) a *transition-guided fuzzing approach* that uses a new coverage metric named *branch transition* as fuzzing feedback, to improve the coverage of state transitions; (3) a *differential checker* that compares the outputs of multiple TCP stacks for the same inputs, to detect semantic bugs.
- Based on the three key techniques, we design a novel fuzzing framework named TCP-Fuzz, to effectively test TCP stacks. To our knowledge, TCP-Fuzz is the first systematic TCP-stack fuzzing framework to detect both memory and semantic bugs.
- We evaluate TCP-Fuzz on five widely-used user-level and kernel-level TCP stacks (TLDK, F-Stack, mTCP, FreeBSD TCP and Linux TCP), and find 56 real bugs (including 8 memory bugs and 48 semantic bugs). 40 of these bugs have been confirmed by related developers, and 23 bugs have been fixed. Moreover, we also compare TCP-Fuzz to existing fuzzing approaches (AFL-like, Syzkaller-like, Boofuzz, Fuzzotron and AFLNet), and it finds many real bugs missed by these approaches.

The rest of this paper is organized as follows. Section 2 introduces the background and motivation. Section 3 introduces our key techniques of fuzzing TCP stacks. Section 4 introduces TCP-Fuzz. Section 5 shows our evaluation and compares TCP-Fuzz to existing fuzzing tools. Section 6 makes a discussion about fuzzing TCP stacks. Section 7 presents related work, and Section 8 concludes this paper.

2 Background and Motivation

We first introduce TCP stacks, and then we motivate our work by studying TCP stack commits and revealing the limitations of existing protocol fuzzing in testing TCP stacks.

2.1 TCP Stack

The TCP protocol is a classical transport-layer protocol to provide reliable, ordered and error-checked delivery of byte streams via an IP network. In practice, the TCP protocol has different implementations, forming different TCP stacks. Besides classical kernel-level TCP stacks (such as Linux TCP and FreeBSD TCP), many new user-level TCP stacks (such as mTCP, TLDK and F-Stack) have been developed and widely-used to achieve better performance. However, all these TCP stacks has three common features:

F1: Two-dimensional inputs with dependencies. As presented in Figure 1, a TCP stack receives both packets from network drivers and syscalls from applications as inputs, and it outputs the syscalls' results to applications and response packets to network drivers. TCP-related system calls are used

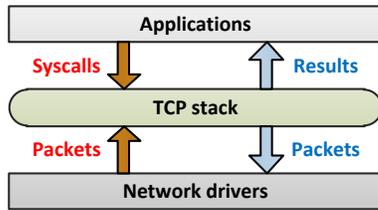

Figure 1: Inputs and outputs of TCP stack.

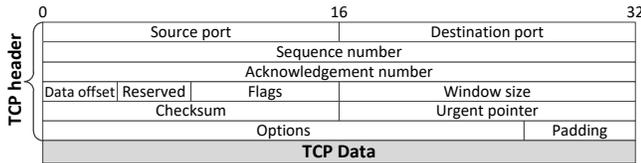

Figure 2: TCP packet format.

to perform fixed network functionalities. For example, the syscall `socket` is used to create an endpoint for communication and it returns a file descriptor of the socket; the syscall `accept` is used to accept a connection on a socket and it returns a new file descriptor of the socket. A TCP packet has a fixed format shown in Figure 2, including a header and data. The TCP header consists of different fields to store the parameters and state of an end-to-end TCP socket.

Packets and syscalls accepted by the TCP stack should have dependencies between each other, otherwise they will be simply neglected by the TCP stack without deep processing. Specifically, there are three kinds of dependencies:

- *Syscall-syscall dependency.* For example, when a connection is passive open, the application must call a series of syscalls including `socket`, `bind`, `listen` and `accept` in order. Otherwise, the application cannot successfully establish the TCP connection.
- *Packet-packet dependency.* For example, after a connection is established, the source port and destination port of each packet should be fixed. Otherwise, the TCP stack identifies the packets to be invalid and thus directly drops them without further processing.
- *Syscall-packet dependency.* For example, the syscall `accept` returns only after the TCP stack receives the last one of the three-way handshake packets.

According to this feature, two requirements should be satisfied when testing TCP stacks. First, it is necessary to generate the sequences of both system calls and packets as input test cases. Second, to make test cases more effective, it is important to consider dependencies between packets and syscalls when generating test cases.

F2: State model. A TCP stack works according to a basic state model defined in the RFC 793 [50] document. Figure 3 shows this basic state model, which has 11 states and 20 state transitions. For a real-world TCP stack, there are often more states and state transitions specific to the TCP stack's implementation.

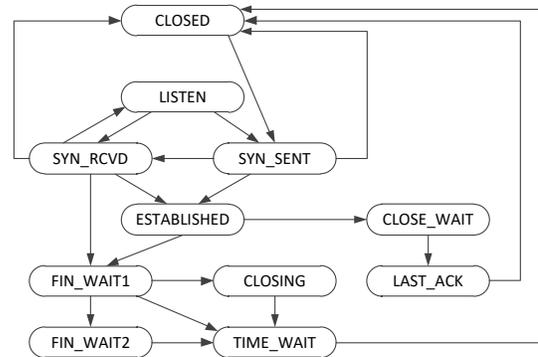

Figure 3: Basic state model of TCP stack.

According to this feature, when testing TCP stacks, it is important to cover both states and state transitions as many as possible. As a state can be reached from different states (for example in Figure 3, `TIME_WAIT` can be reached from `FIN_WAIT1`, `FIN_WAIT2` and `CLOSING`) and there are often more state transitions than states, covering state transitions is actually more important than covering states in testing.

F3: Semantic rules. Each TCP stack works based on some regular semantic rules that stipulate how syscalls and packets should be handled. Most of these semantic rules are explicitly described in RFC documents. For example, the RFC 7323 [49] document describes how to handle the timestamp option in the TCP packet header. An important semantic rule in this RFC document is that once the timestamp option has been successfully negotiated during TCP connection, the TCP stack should accept only packets with non-decreasing timestamps; otherwise the TCP stack should simply drop the packets. However, some semantic rules are not explicitly described in RFC documents. For example, RFC documents defines 32 possible options in the TCP packet header and describes how these options should be handled [58]. But for unknown options, RFC documents do not describe how to handle them. In practice, most TCP stacks simply ignore these options.

According to this feature, when testing TCP stacks, it is important to check these semantic rules and detect related violations. Indeed, these violations are unrelated to problematic memory accesses, and thus we refer them to *semantic bugs*.

2.2 Study of TCP Stack Commits

To understand the proportion of memory bugs and semantic bugs in existing TCP stacks, we select three open-sourced and widely-used TCP stacks, including FreeBSD TCP, mTCP [26] and TLDK [59], to study their commits¹. Among these TCP stacks, FreeBSD TCP is a classical kernel-level TCP stack; mTCP is a well-known user-level TCP stack in academic community; TLDK is a recent user-level TCP stack in industry

¹FreeBSD commits: <https://gitlab.com/FreeBSD/freebsd-src>
mTCP commits: <https://github.com/mtcp-stack/mtcp>
TLDK commits: <https://git.fd.io/tldk/commit/?h=dev-next-socket>

Time	FreeBSD		mTCP		TLDK	
	Memory	Semantic	Memory	Semantic	Memory	Semantic
2017	2	26	2	6	1	11
2018	9	51	0	4	0	4
2019	9	65	1	3	2	5
Total	20	142	3	13	3	20

Table 1: Study results of TCP stack commits.

community and it has been deployed in many telecom systems and network nodes. In our study, we first select the bug-fixing commits from January 2017 to December 2019, resulting in 201 commits; and then we manually read each commit to identify whether it fixes memory bugs or semantic bugs.

Table 1 shows the study results. 87% of bug-fixing commits are related to semantic bugs, namely most of the reported bugs in TCP stacks are semantic bugs. Figure 4 shows an example commit [14] of fixing a semantic bug in FreeBSD TCP stack. The annotation of this commit describes that it fixes a RFC 7323 [49] violation. Specifically, the TCP stack mistakenly accepted the packets with decreasing timestamp values. To fix the bug, this commit adds several checks about the timestamp value to drop invalid packets.

```

FILE: FreeBSD/sys/netinet/tcp_synccache.c
int synccache_expand(...) {
    .....
+   /* RFC 7323 PAWS: if we have a timestamp on this segment and
+    * it is less than ts_recent, drop it.
+   if (sc->sc_flags & SCF_TIMESTAMP && to->to_flags & TOF_TS &&
+       TSTMP_LT(to->to_tsval, sc->sc_tsreflect)) {
+       SCH_UNLOCK(sch);
+       if ((s = tcp_log_addr(s, th, NULL, NULL)) {
+           log(LOG_DEBUG, ...);
+           free(s, M_TCPLOG);
+       }
+       return (-1); /* Do not send RST */
+   }
+   .....
}

```

Figure 4: Example commit of fixing a semantic bug.

In fact, these semantic bugs are introduced for three main reasons. First, because a TCP stack has rich functionalities and complex state model, developers may unintentionally make mistakes about semantic rules when implemented the TCP stack. Second, many semantic rules are used to handle exceptions that infrequently occur in normal execution, and thus the code related to these rules receives insufficient attention in development and testing. Finally, some semantic rules are not explicitly described in RFC documents, and thus developers cannot ensure whether their implemented code obeys these rules. For these reasons, it is important to find semantic bugs in TCP stacks.

2.3 Limitations of Existing Protocol Fuzzing

Fuzzing is an effective technique of runtime testing, and it has shown excellent ability of bug detection in practice. Encouraged by the promising results, many recent approaches perform fuzz testing for the implementations of application-

layer network protocols, such as DTLS/TLS [17, 52, 54, 60], FTP [6, 21, 22, 43] and Modbus [37, 38]. However, we believe that these approaches are limited in testing TCP stacks for three critical reasons:

1) *Fail to generate two-dimensional inputs with dependencies.* Existing fuzzing approaches only generate packets as input test cases, without considering dependencies between inputs. However, as described in *F1* in Section 2.1, TCP stacks receive both syscalls and packets, which have dependencies between each other. If we only generate packets as input test cases, much code about handling syscalls cannot be covered; if we ignore dependencies between system calls and packets, many generated test cases will be meaningless and neglected by TCP stacks without deep processing, which seriously damages fuzzing efficiency. Thus, we need to design a new strategy to generate effective test cases for TCP stacks.

2) *Neglect the coverage of state transitions.* Existing protocol fuzzing approaches use code coverage as program feedback to cover different protocol states. However, as described in *F2* in Section 2.1, besides states, TCP stacks also have many state transitions that heavily affect TCP execution. Moreover, two test cases covering the same states may cover different state transitions. For example in Figure 5, the test case T1 covers the states S1, S2 and S3 in order, and then the test case T2 covers the states S1, S3 and S2 in order. T1 and T2 both cover the states S1, S2 and S3, and thus existing fuzzing approaches identifies T2 to be useless, as it fails to cover new states. But T1 and T2 cover different state transitions, namely T1 covers S1->S2 and S2->S3 while T2 covers S1->S3 and S3->S2. Thus, T2 is useful in covering new state transitions.

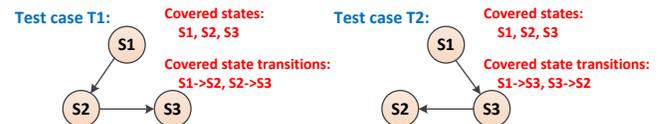

Figure 5: Example of covering states and state transitions.

3) *Lack effective detection of semantic bugs.* Most existing fuzzing approaches use common bug sanitizers (such as ASan [2] and MSan [39]) to detect memory bugs, such as null-pointer dereferences and use-after-free issues. However, as described in Section 2.2, most of the reported bugs in TCP stacks are semantic bugs, which are not caused by problematic memory accesses. Thus, these bug sanitizers cannot detect semantic bugs in TCP stacks.

3 Key Techniques

To solve the limitations of existing fuzzing in testing TCP stacks, we propose three key techniques: a *dependency-based strategy* to generate effective test cases, a *transition-guided fuzzing approach* to improve the coverage of state transitions and a *differential checker* to detect semantic bugs. We introduce these techniques as follows.

3.1 Dependency-Based Strategy

Inspired by existing two-dimensional fuzzing approaches [29, 64] for file systems, we generate *input sequences* containing syscalls and packets as test cases for TCP stacks. Considering that packets and syscalls accepted by TCP stacks have many dependencies with each other, we design a dependency-based strategy to generate more effective test cases for TCP stacks. Given an original input sequence that improves testing coverage, our strategy mutates it to generate new input sequences. As shown in Figure 6, for each item in the original input sequence, our strategy first selects a mutation type and then mutates this item by considering dependencies with the previously handled items.

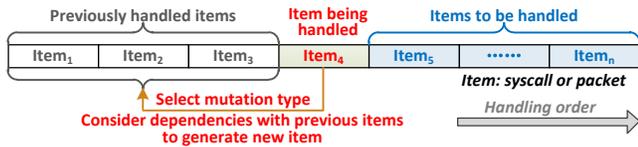

Figure 6: Input sequence mutation.

Mutation-type selection. According to possible operations on a syscall or packet, our strategy provides five available types of mutation (including deletion, addition, replacement and two kinds of changes), as listed in Table 2. Our strategy randomly selects a mutation type to handle each item in the input sequence in order. As a result, different items in the input sequence can be handled with different mutation types.

Item type	Mutation type
Syscall	<i>Deletion</i> : delete this syscall.
	<i>Addition</i> : add a new syscall or packet.
	<i>Replacement</i> : replace this syscall with a new packet.
	<i>Change1</i> : change the parameter of this syscall.
	<i>Change2</i> : change the syscall type with the same parameter.
Packet	<i>Deletion</i> : delete this packet.
	<i>Addition</i> : add a new syscall or packet.
	<i>Replacement</i> : replace this packet with a new syscall.
	<i>Change1</i> : change the TCP header fields of this packet.
	<i>Change2</i> : change the TCP data length of this packet.

Table 2: Available mutation type.

Dependency-based generation. In Table 2, all of the mutation types except deletion generate a new syscall or packet in the input sequence. As described in F1 in Section 2.1, there are three kinds of dependencies between packets and syscalls. If an input sequence violates these dependencies, it is considered to be invalid and can be simply neglected by TCP stacks. Thus, to generate more effective test cases, our strategy considers these dependencies to generate each item in the input sequence. Specifically, when handling an item, our strategy considers the dependencies between this item and the previously handled items. At present, we have implemented 15 dependency rules in Table 3, by referring to RFC documents (packet-packet and syscall-packet dependencies) and syscall-usage conventions (syscall-syscall dependencies).

Kind	Dependency rule
Syscall-syscall	SS1: socket, bind, listen and accept are called in order when a connection is passive open.
	SS2: socket and connect are called in order when a connection is active open.
	SS3: The file descriptor that socket or accept returns is used byfcntl, ioctl, read, write and other syscalls.
	SS4: read and write can be called only after accept or connect is called and returns a success.
	SS5: read and write are never called after close is called.
Packet-packet	PP1: After a connection is established, the source port and destination port of each packet are fixed.
	PP2: The order and control flags of three-way handshake packets and four-way handshake are never changed.
	PP3: The sequence number of a packet is equal to the sum of sequence number and data length of the previous packet.
	PP4: The timestamps of packets are non-decreasing.
	PP5: The echo reply value in timestamp of a packet is equal to the echo value in timestamp of the previous received packet.
Syscall-packet	SP1: accept can be called only after the three-way handshake when a connection is passive open.
	SP2: connect can be called only before the three-way handshake when a connection is active open.
	SP3: Packets can be sent only after accept or connect is called and returns a success.
	SP4: The relative acknowledge number of a packet sent to the stack is no more than total length of data sent by write.
	SP5: After close is called, a packet with the FIN flag should be sent.

Table 3: Implemented dependency rules.

Considering that each TCP stack is implemented according to RFC documents and syscall-usage conventions, we believe that these dependency rules are general to all TCP stacks.

Note that to test whether TCP stacks correctly obey these dependency rules, our strategy also generates some *exceptional input sequences* by deliberately violating packet-packet and syscall-packet dependency rules, with a small probability. Indeed, such input sequences are useful in detecting RFC violations about exception handling.

3.2 Transition-Guided Fuzzing Approach

As described in Section 2.3, code coverage cannot describe state transitions, and thus our fuzzing approach requires a new coverage metric that can effectively describe both states and state transitions.

For a given input sequence, the TCP stack’s state is always changed when handling each item (a syscall or packet) in this sequence. Namely, each such item affects the execution situation of the TCP stack. Thus, after handling each item, the TCP stack can be considered to reach a new state. This state can be described with branch coverage (namely the coverage of code branches), as existing fuzzing approaches do. Accordingly, a state transition can be described as the transition between two covered states due to two adjacent input items, namely the change of branch coverage between these input items. Inspired by this idea, we propose a new coverage metric named *branch transition* to describe both states and state transitions. For a given input sequence, a branch transition is represented as a vector that stores both branch coverage for the current input item and the change of branch coverage between the current and previous input items.

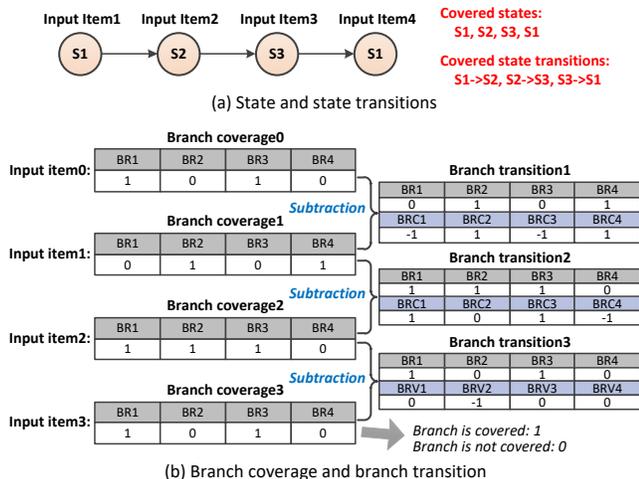

Figure 7: Example of branch transition.

Figure 7 illustrates branch transition using an example. Each state is described using a branch coverage vector, which contains the executed situation (covered or not covered) of each branch in TCP stack code. Then, the state change between the current and previous input items is represented as the subtraction of their branch coverage vectors (*current* – *previous*). Finally, the branch transition of the current input item is obtained as a two-dimensional vector containing its branch coverage vector and the calculated subtraction vector. In Figure 7(a), an input sequence contains four input items which cover the states S1, S2, S3 and S1 in order, and thus it covers three different state transitions S1->S2, S2->S3 and S3->S1. These state transitions are described as three different branch transitions in Figure 7(b). If code coverage is used, *input item3* is identified to be useless, as it covers an old state S1 that is already covered by *input item0*. However, *input item3* actually covers a new state transition S3->S1, which can be successfully described using branch transition.

Our fuzzing approach uses branch transition as program feedback, to effectively cover both states and state transitions. For a given input sequence, if it covers new branch transitions, our fuzzing approach identifies it to be interesting and puts it into the seed corpus for future mutation. Then, our fuzzing approach selects a seed input sequence from the seed corpus and mutates it to generate new input sequences using our dependency-based strategy. We implement most of the fuzzing process by referring to AFL [1].

In fact, besides branch transition, state transition can be also represented as higher-level state change learned by several recent approaches of fuzzing DTLS/TLS protocol implementations [17, 52]. However, the state models learned by these approaches can have mistakes, and thus they still require much manual guidance and validation to ensure correctness. By contrast, branch transition can be automatically and conveniently obtained by collecting runtime information of TCP stacks. Thus, our approach uses branch transition instead of higher-level state change learned by these approaches.

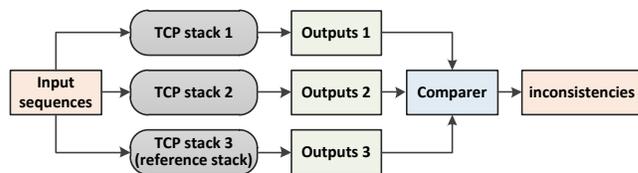

Figure 8: Procedure of our differential checker.

3.3 Differential Checker

To detect semantic bugs, an intuitive solution is to implement semantic checkers by referring to semantic rules in RFC documents. But there are many RFC documents and some semantic rules are even implicit, and thus it is hard to manually implement these checkers. Indeed, different TCP stacks should obey identical semantic rules (many of these rules are defined in RFC documents), and thus they should produce identical or similar outputs for the same inputs. Otherwise, these TCP stacks have implementation inconsistencies, indicating that some of them possibly have semantic bugs.

Based on this idea and inspired by recent approaches of differential testing [11, 12, 65], we design a differential checker for TCP stacks to detect semantic bugs that cause output inconsistencies. As shown in Figure 8, our differential checker provides the same input sequences to multiple TCP stacks, then records their outputs (including return values and parameters of syscalls as well as response packets from TCP stacks), and finally compares these outputs to identify and report inconsistencies. The user can check these inconsistencies to find related semantic bugs.

To improve the efficiency of finding semantic bugs, we suggest using at least one classical and well-tested kernel-level TCP stack (such as Linux TCP or FreeBSD TCP) as a *reference stack* in our differential checker, to test relatively newer TCP stacks. In this case, if our checker reports inconsistencies, it is very likely that one newer TCP stack has semantic bugs.

Our differential checker has three main advantages. First, because different TCP stacks should obey identical semantic rules, the possibility of producing inconsistencies for the same inputs is not large. Thus, the manual work of checking the differences reported by our checker should be much less than that of implementing well-verified checkers of semantic rules. Second, we believe that our checker is also helpful to extracting implicit semantic rules, through identifying and analyzing implementation inconsistencies of multiple TCP stacks. Finally, our checker is scalable and does not introduce runtime overhead for TCP stacks.

At present, our checker records and compares final outputs of TCP stacks, without recording and checking intermediate information (such as window size and packet time) of TCP stacks during packet transmission. Thus, it cannot detect semantic bugs about congestion control and performance. Moreover, our checker detects output inconsistencies between multiple TCP stacks, instead of checking specific RFC doc-

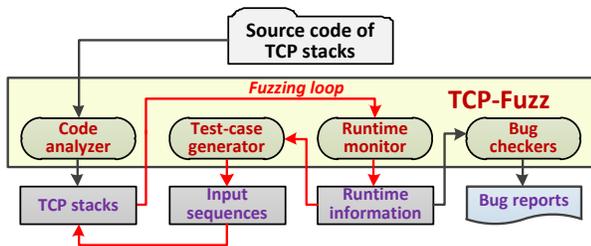

Figure 9: TCP-Fuzz architecture.

uments at runtime. The user needs to manually check RFC documents and analyze the root causes of these inconsistencies, to identify semantic bugs about RFC violations.

4 Framework

Based on the three key techniques in Section 3, we propose a novel fuzzing framework named TCP-Fuzz, to effectively test TCP stacks and detect bugs. We have implemented TCP-Fuzz using Clang 9.0 [13] and Packetdrill [8]. Specifically, we use Clang to perform code instrumentation on TCP stack code, in order to collect covered branches during TCP-stack execution; and we use Packetdrill to send the generated input sequences of syscalls and packets to TCP stacks, and to receive return values and parameters of syscalls as well as response packets from TCP stacks. Overall, TCP-Fuzz consists of four parts:

Code analyzer. It first uses Clang to compile the source code of TCP stacks into LLVM bytecode. Then, it instruments each code branch in the LLVM bytecode. Finally, it compiles the modified LLVM bytecode to generate executable TCP stacks.

Test-case generator. It uses our transition-based fuzzing approach and dependency-based strategy to generate input sequences of syscalls and packets. Each such input sequence is presented as a Packetdrill script, and it is provided to the TCP stacks via Packetdrill. Note that Packetdrill does not support sending some exceptional input sequences that violate dependency rules in Table 3. Thus, we modify Packetdrill by dropping some related checks in its code, to make it support sending such exceptional input sequences.

Runtime monitor. It collects two kinds of runtime information. First, it collects covered branches and calculates branch transitions to provide feedback to our fuzzing approach. Second, it calls Packetdrill interfaces to receive the outputs of each TCP stack, and provides them to our differential checker.

Bug checkers. TCP-Fuzz has three kinds of bug checkers to detect both memory bugs and semantic bugs:

- *Third-party sanitizers.* Existing bug sanitizers (such as ASan [2] and MSan [39]) are used to detect memory bugs by monitoring memory accesses at runtime.
- *Data validator.* We implement this checker to detect semantic bugs leading to incorrect data transfer of TCP stacks, because ensuring data-transfer correctness is a basic property of TCP stacks. Specifically, this checker

performs two kinds of validation: (1) whether the data received by the TCP stack via calling `read` is identical to the data stored in packets sent to the TCP stack; (2) whether the data sent from the TCP stack via calling `write` is identical to the data stored in packets received by the remote end.

- *Differential checker.* This checker is used to compare the outputs of multiple TCP stacks for the same inputs, in order to detect semantic bugs.

Deployment. As shown in Figure 10, TCP-Fuzz is deployed in a server-client mode. In this way, TCP-Fuzz can not only use third-party bug sanitizers and data validator in each TCP stack to detect memory bugs and data-correctness-related bugs, but also use the differential checker in multiple TCP stacks to detect their semantic bugs. The TCP-Fuzz server and clients can be deployed in the same machine and communicate with each other via virtual network controllers; or they can be deployed in different machines and communicate with each other via physical network controllers.

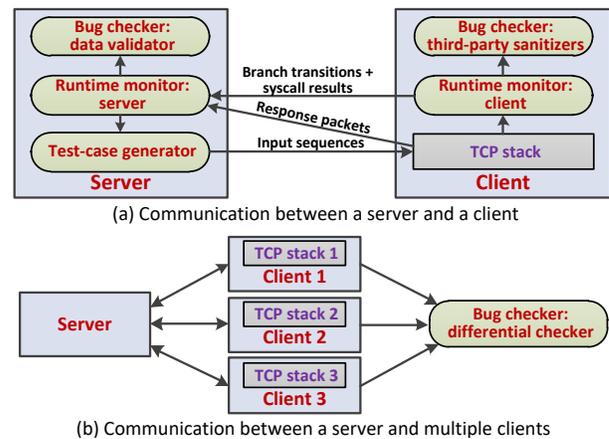

Figure 10: Server-client deployment of TCP-Fuzz.

5 Evaluation

5.1 Experimental Setup

To validate the effectiveness of TCP-Fuzz, we use it to actually test five open-sourced and widely-used TCP stacks, including three user-level ones (TLDK, F-Stack and mTCP) and two kernel-level ones (FreeBSD TCP and Linux TCP). For the three user-level TCP stacks, we test them with the complete fuzzing process of TCP-Fuzz. For the two kernel-level TCP stacks, because they are classical and well-tested, we use them as reference stacks in the differential checker. Moreover, because TCP-Fuzz can only instrument user-level programs at present, we only test the two kernel-level TCP stacks using test cases generated from the user-level TCP stacks, without feedback-driven fuzzing. In the future, we will implement kernel-code instrumentation to support complete fuzzing of kernel-level TCP stacks.

Table 4 shows the basic information about the five tested TCP stacks. Among them, FreeBSD TCP and Linux TCP are two classical kernel-level TCP stacks used in lots of machines; mTCP is a well-known user-level TCP stack in academic community; TLDK and F-Stack are two recent user-level TCP stacks in industry community, and they have been widely deployed in telecom systems and network nodes.

Type	TCP stack	Version	LOC
User-level	TLDK [59]	v2.0	15K
	F-Stack [19]	Commit 8d21adc	25K
	mTCP [26]	Commit 0463aad	18K
Kernel-level	FreeBSD	v12.1	171K
	Linux	v5.6	169K

Table 4: Basic information about tested TCP stacks.

We deploy TCP-Fuzz clients on five regular personal computers, each of which runs a TCP stack to be tested. We deploy TCP-Fuzz server on another personal computer to generate test cases and compare the outputs of these TCP stacks. For each user-level TCP stack, we test it for 48 hours; for each kernel-level TCP stack, we test it by inputting the test cases generated from the three user-level TCP stacks. Besides, we run a third-party sanitizer ASan [2] to detect memory bugs in the user-level TCP stacks.

5.2 Runtime Testing

Table 5 shows the fuzzing results, including covered branches and branch transitions as well as found memory bugs and semantic bugs. Note that TCP-Fuzz does not instrument the two kernel-level TCP stacks, and thus their covered branches and branch transitions are not obtained.

Testing coverage. TCP-Fuzz covers many more branch transitions than branches, indicating that TCP stacks have more state transitions than states during execution. Figure 11 shows the growth of covered branches and branch transitions for the three user-level TCP stacks during fuzzing. Similar to existing fuzzing approaches based on code coverage, TCP-Fuzz covers few new branches during the later tests, but it still covers many new branch transitions during these tests.

Found bugs. TCP-Fuzz finds 56 real bugs in the five tested TCP stacks, including 8 memory bugs and 48 semantic bugs. We reported these bugs to related developers, and 40 of them have been confirmed. We are still waiting for responses for the remaining bugs (for example, the mTCP code in github has not been updated for a long time, and thus we have not received any response to our reported bugs in mTCP). Besides, 23 of the confirmed bugs have been fixed.

Output inconsistencies. TCP-Fuzz reports 15.1K inconsistencies between the five tested TCP stacks, and we analyze their root causes to identify semantic bugs, through our manual review of RFC documents and observation of TCP stack execution. Similar to SQLancer [51] and libFuzzer [32], for inconsistencies that we identify as semantic bugs, we manually

Stack	Testing coverage		Found bugs	
	Branch	Transition	Memory / Semantic	Confirmed / Fixed
TLDK	1.3K	329.4K	2 / 26	28 / 19
F-Stack	7.5K	46.8K	1 / 6	6 / 1
mTCP	1.2K	47.9K	5 / 9	0 / 0
FreeBSD	-	-	0 / 6	5 / 2
Linux	-	-	0 / 1	1 / 1
Total	10.0K	424.1K	8 / 48	40 / 23

Table 5: Results of fuzzing TCP stacks.

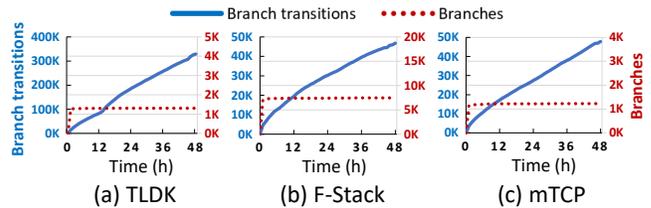

Figure 11: Covered branches and branch transitions.

fix them using the developers' patches or by ourselves, to reduce related inconsistencies. We iteratively repeat this process until inconsistencies never occur, to count unique semantic bugs, resulting in 48 semantic bugs. We observe that many output inconsistencies are repeated, as they are triggered by the same root cause. Only one output inconsistency is considered to be benign. Specifically, when normal packets come after a FIN packet and their sequence numbers are larger than that of the FIN packet, FreeBSD, F-Stack and mTCP drop the FIN packet, while Linux TCP and TLDK reset the connection. As RFC documents do not stipulate how to handle this case, we are not sure which strategies are correct.

Bug-finding process. We also analyze how TCP-Fuzz finds these 56 bugs, and show the results in Table 6. The 8 memory bugs are all found by ASan, 2 semantic bugs are found by the data validator and 46 semantic bugs are found by the differential checker. The results indicate that our differential checker is effective in finding semantic bugs. Besides, we also highlight that 2 semantic bugs found by the data validator are quite dangerous, because they directly cause TCP stacks to send or receive incorrect data, badly damaging data-transfer correctness. Moreover, 28 bugs are found via exceptional input sequences generated by deliberately violating the dependency rules listed in Table 3, while 28 bugs are found via normal input sequences generated by obeying these rules. The results indicate that the TCP stack code about handling exceptional inputs is error-prone in practice. Thus, exception handling in TCP stacks should receive more attention in testing.

Stack	Number of tests	Checker			Input sequence type	
		ASan	Data	Differential	Exceptional	Normal
TLDK	123K	2	1	25	11	17
F-Stack	128K	1	1	5	6	1
mTCP	170K	5	0	9	4	10
FreeBSD	421K	0	0	6	6	0
Linux	421K	0	0	1	1	0
Total	1,263K	8	2	46	28	28

Table 6: Statistics of bug-finding process.

Stack	RFC violation	Syscall issues	Implicit rules
TLDK	15	9	2
F-Stack	5	1	0
mTCP	7	2	0
FreeBSD	5	1	0
Linux	1	0	0
Total	33	13	2

Table 7: Root causes of semantic bugs.

RFC document	791	793	1122	5961	6093	6691	7323	7413
Semantic bug	2	7	1	6	1	1	12	3

Table 8: Distribution of RFC violations.

Root causes of memory bugs. For the 8 found memory bugs, 2 are use-after-free issues, 3 are null-pointer dereferences, 2 are buffer-overflow issues, and 1 is a division-by-zero issue.

Root causes of semantic bugs. For the 48 found semantic bugs, we summarize three root causes in Table 7 and find that:

(1) 33 semantic bugs are RFC violations, and they violate semantic rules explicitly described in the 8 RFC documents shown in Table 8. For example, 6 semantic bugs (3 in TLDK, 1 in mTCP, 1 in F-Stack and 1 in FreeBSD TCP) are RFC 5961 [48] violations. Indeed, the RFC 5961 document is designed to mitigate the influence of blind in-window attacks [36] by changing the range of acceptable sequence numbers in reset packets and acknowledge numbers in normal packets. Thus, these semantic bugs can be exploited by attackers to reset the connection [62] or inject malicious data [7, 10, 45] via blind in-window attacks.

(2) 13 semantic bugs are caused by incorrect results of syscalls. For example, 3 semantic bugs (1 in TLDK, 1 in F-Stack and 1 in FreeBSD TCP) are caused by using an invalid file descriptor obtained from `socket` after `listen` and `accept` are called in order. Indeed, after `listen` and `accept` are called, the previous file descriptor obtained from `socket` becomes invalid, and thus `ioctl`, `read` and `write` should return an error code when using this file descriptor. However, TLDK, F-Stack and FreeBSD TCP return zero to indicate a success in this case, causing semantic bugs.

(3) 2 semantic bugs in TLDK are caused by violating implicit semantic rules. Specifically, RFC documents do not describe how to handle unknown options in the TCP packet header. In our tests, F-Stack, mTCP, FreeBSD TCP and Linux TCP simply ignore these options and accept related packets, but TLDK drops related packets or enters an infinite loop when handling these options.

5.3 Influences of the Found Bugs

We manually review the 56 found bugs to estimate their influences on the reliability and security of TCP stacks. The results are shown in Table 9. We find that 6 semantic bugs about RFC 5961 violations are vulnerable to the MIMT (Man-in-the-middle) attacks; 9 bugs (including 4 memory bugs and 5 semantic bugs) can cause data corruption; 8 bugs (including

Stack	MIMT attack	Corruption	Crash/DoS	Functional error	Inefficiency
TLDK	3	6	4	12	3
F-Stack	1	1	0	3	2
mTCP	1	2	4	3	4
FreeBSD	1	0	0	3	2
Linux	0	0	0	0	1
Total	6	9	8	21	12

Table 9: Reliability and security influence of the found bugs.

4 memory bugs and 4 semantic bugs) can cause crashes or denial of services; 21 semantic bugs can cause functional errors of data communication; and 12 semantic bugs can reduce the efficiency of data communication.

Figure 12 shows three bugs found by TCP-Fuzz, including 1 memory bug and 2 semantic bugs. This figure also shows the related test cases in form of Packetdrill scripts generated by TCP-Fuzz for finding these bugs.

Use-after-free issue in TLDK. In Figure 12(a), the function `rx_fin` free the data of `s->tx.q` by calling `empty_tq`. Then, this data is used by accessing `m->data_len` in the function `txq_rst_nxt_head`, causing a use-after-free issue. Once this bug is triggered, attackers can modify the data of `s->tx.q` to inject malicious data in the TCP connection. To fix this bug, the developer submits a patch to assign zero to `s->tcbs.nd.una_offset` in the function `rx_fin`, in order to avoid accessing the data of `s->tx.q` in the function `txq_rst_nxt_head`.

RFC 7323 violation in FreeBSD TCP. In Figure 12(b), as shown in the annotation of the function `syncache_expand`, if timestamps are not negotiated in the first two packets of three-way handshake, FreeBSD TCP rejects the third packet containing the timestamp option and resets the TCP connection. However, the RFC 7323 document stipulates that the third packet in this case should be normally accepted. Once this bug is triggered, the TCP connection can be abnormally disconnected during three-way handshake, causing a functional error. To fix this bug, the developer submits a patch to modify the problematic code according to the related semantic rule in the RFC 7323 document.

RFC 793 violation in mTCP. In Figure 12(c), if the sequence number of the current packet is smaller than the next expected sequence number, mTCP drops the current packet. However, the RFC 793 document stipulates if the current packet overlaps the range of the expected receive window, this packet should be accepted. Once this bug is triggered, data communication can be inefficient due to abnormally dropping packets. To fix this bug, our preliminary solution is to accept the content of the current packet within the range of expected receive window.

5.4 Comparison to Existing Fuzzing Tools

We perform the comparison in two ways. First, we compare TCP-Fuzz to two classical and widely-used fuzzing approaches, namely AFL [1] and Syzkaller [57]. Considering

the root causes of these inconsistencies requires TCP-specific knowledge that is hard to extract as fixed patterns.

Testing congestion control. Congestion control is an important functionality for TCP stacks, but TCP-Fuzz cannot test it at present, due to ignoring congestion-control-related packet information (such as the length of accepted data for each packet) and code information (such as the variables about congestion window size). In the future, we will collect and check such information by referring to related work [27, 56], to test congestion control implementations of TCP stacks.

Limitations and future works. TCP-Fuzz can be strengthened in some aspects. First, as described in Section 5.1, TCP-Fuzz cannot instrument kernel code in the current implementation, and thus it fails to completely test kernel-level TCP stacks. To solve this limitation, we plan to perform kernel-code instrumentation or tune existing VM-based approaches [25, 55] in TCP-Fuzz. Second, TCP-Fuzz fails to record intermediate information (such as window size and packet time) of TCP stacks during packet transmission, and thus it cannot detect semantic bugs about congestion control and performance. To solve this limitation, we plan to record such intermediate information and implement related checkers to detect these semantic bugs. Third, TCP-Fuzz fails to check concurrent memory accesses, and thus it cannot find concurrency bugs in TCP stacks. To solve this limitation, we plan to introduce existing concurrency-analysis approaches [18, 31] to detect concurrency bugs in TCP stacks. Finally, QUIC [46] is a new and promising transport-layer network protocol proposed, and it is expected to replace TCP in the future. Thus, we also plan to extend TCP-Fuzz to testing QUIC implementations.

7 Related Work

7.1 Network Protocol Fuzzing

Fuzzing is a popular testing technique to detect bugs in software systems. Many fuzzing approaches have been proposed to test the implementations of network protocols.

Some approaches [6, 37, 38, 54, 60] use grammar-based fuzzing. They utilize hard-coded or user-defined grammar specifications to guide test-case generation. These specifications define data structure or field types of packets to be generated. For example, TLS-Attacker [54] is a flexible TLS testing framework for developers to test their TLS implementations by writing Java code or XML-based specifications.

Several recent approaches [17, 43, 52] perform stateful protocol fuzzing. AFLNet [43] can learn basic state models of network protocols to improve seed selection and mutation. Fiterau-Brostean et al. [17] propose a practical tool by extending TLS-Attacker [54], to learn comprehensive state models of multiple DTLS implementations. By comparing these learned state models, the user can infer vulnerabilities in DTLS implementations.

However, these approaches are limited in testing TCP stacks. First, these approaches only generate packets as test cases, but TCP stacks receive both packets and syscalls as inputs, and thus these approaches may miss much code for handling syscalls. Second, these approaches use code coverage as program feedback to cover states, but code coverage cannot effectively describe state transitions in TCP state model. Finally, many of these approaches only use existing bug sanitizers to detect memory bugs, but fail to detect semantic bugs. To solve these limitations, TCP-Fuzz uses a dependency-based strategy to generate effective test cases of packets and syscalls, a transition-guided fuzzing approach to improve the coverage of state transitions, and a differential checker to detect semantic bugs of TCP stacks.

7.2 TCP Stack Checking

Packetdrill [8] is a scripting tool to test the correctness and performance of network stacks. The user can write tcpdump-like scripts to generate and maintain test cases for new feature development and regression testing of network stacks. But writing effective test cases in form of Packetdrill scripts requires a deep understanding of TCP stacks and much manual effort. To solve this problem, TCP-Fuzz automatically generates Packetdrill scripts as test cases according to program feedback and dependencies between packets and syscalls.

Some approaches [24, 34, 40, 41, 53] perform model checking or formal verification of TCP stacks. For example, Lockefeer et al. [34] use μ CRL and LTSmin [35] toolsets to generate state spaces and perform formal verification of TCP extended with the Window Scale Option. Hoque et al. [24] use symbolic execution to precisely simulate program execution with symbolic inputs and explore all possible execution paths, and also use an off-the-shelf model checker to check temporal properties of TCP stacks. But these approaches require much manual effort and TCP-specific knowledge to provide a complete and correct TCP state model, and they are often time-consuming due to high complexity of TCP state transitions.

Some approaches [9, 30] perform static analysis of TCP stack source code. For example, PacketGuardian [9] uses static taint analysis to check the packet handling logic of various network protocol implementations, to detect packet-injection vulnerabilities. However, these approaches often introduce false positives in practice, due to lacking exact runtime information for analysis.

Some approaches [3–5, 66] analyze execution traces of TCP stacks to infer RFC violations. For example, Bishop et al. [4] analyze the execution traces with higher-order logic specifications, to identify differences between multiple network protocols stacks and thus to detect possible RFC violations. However, these approaches require substantial and effective test cases to achieve high testing coverage. To solve this problem, TCP-Fuzz automatically generates effective test cases with fuzzing.

Some approaches [27, 28] perform runtime testing for automated attack discovery of TCP stacks. These approaches strategically generate packets to cover different TCP states, which are tracked according to packet information and pre-defined protocol state machines, without modifying TCP stack code. Different from these approaches, TCP-Fuzz generates both packets and syscalls as test cases, with the guidance of branch transition; TCP-Fuzz does not require pre-defined protocol state machines, but it performs code instrumentation on TCP stacks to collect branch transition.

7.3 Differential Testing

To find semantic bugs, many approaches [11, 12, 23, 42, 47, 61, 65] perform differential testing to identify implementation inconsistencies between multiple programs of the same functionalities. Classfuzz [12] and Classming [11] syntactically mutate Java bytecode files and execute them on different JVM implementations, to identify their inconsistencies. The two approaches both use Markov Chain Monte Carlo (MCMC) sampling to guide mutator selection to improve test-case generation. C2V [65] uses randomized differential testing to detect bugs in code coverage tools (such as gcov and llvm-cov). It randomly generates program code files and compares coverage reports of code coverage tools to identify inconsistencies. Inspired by these approaches, we design a useful differential checker to detect semantic bugs in TCP-stack fuzzing.

8 Conclusion

In this paper, we develop a novel fuzzing framework named TCP-Fuzz, to effectively test TCP stacks and detect bugs. It uses three key techniques: (1) a dependency-based strategy that considers dependencies between packets and system calls, to generate effective test cases; (2) a transition-guided fuzzing approach that uses branch transition as program feedback, to improve the coverage of state transitions; (3) a differential checker that compares the outputs of multiple TCP stacks for the same inputs, to detect semantic bugs. We have evaluated TCP-Fuzz on five widely-used TCP stacks, and find 56 real bugs (including 8 memory bugs and 48 semantic bugs). We also compare TCP-Fuzz to existing fuzzing approaches, and it finds many real bugs missed by these approaches.

In the future, we plan to improve TCP-Fuzz to detect congestion control issues and performance problems, and to apply TCP-Fuzz to other TCP stacks and QUIC implementations.

Acknowledgment

We thank our shepherd, Cristina Nita-Rotaru, and anonymous reviewers for their helpful advice on the paper. We also thank the developers of TCP stacks, who gave useful feedback and advice to us. This work was supported by the Natural Science

Foundation of China under Project 62002195 and the China Postdoctoral Science Foundation under Project 2019T120093. Jia-Ju Bai is the corresponding author.

MLEE: Effective Detection of Memory Leaks on Early-Exit Paths in OS Kernels

Wenwen Wang
University of Georgia

Abstract

Memory leaks in operating system (OS) kernels can cause critical performance and security issues. However, it is quite challenging to detect memory leaks due to the inherent complexity and large-scale code base of real-world OS kernels. In this work, inspired by the observation that software bugs are often hidden in rarely-tested program paths, we focus on detecting memory leaks on *early-exit (E-E) paths* in OS kernels. To this end, we conduct a systematic study of memory management operations involved on E-E paths in OS kernels. Based on the findings, we design a novel leak detector for OS kernels: MLEE, which intelligently discovers memory leaks on E-E paths by *cross-checking* the presence of memory deallocations on different E-E paths and normal paths. MLEE successfully reports 120 *new* memory leak bugs in the Linux kernel. It is the first time these memory leaks are uncovered by a leak detector for OS kernels.

1 Introduction

Memory leaks are a common class of memory management bugs and wide spread in many critical software systems. The accumulation of leaked memory objects can eventually exhaust the limited memory resource, leading to a significant influence on system response time and throughput [6, 18, 37], as well as shortened battery life on mobile devices [43]. Besides, memory leaks have been exploited to launch security attacks, e.g., CVE-2019-12379 [39] and CVE-2019-8980 [40].

Over the past decades, significant efforts have been devoted to detecting memory leaks [4, 7, 14, 16, 22, 27, 31, 32, 44–46]. However, most of them are designed based on the structures and features of user-level applications and thus cannot be applied directly to operating system (OS) kernels. Compared to user applications, OS kernels are much more complicated in terms of program logic and semantic [33], as they need to handle various exceptional statuses, respond to arbitrary interrupts from peripheral devices, perform security checks on untrusted data sources, and etc. Besides, given the gigantic

```
1 /* mm/mempool.c */
2 int mempool_resize(mempool_t *pool, int new_min_nr) {
3     ...
4     spin_lock_irqsave(&pool->lock, flags);
5     if (new_min_nr <= pool->min_nr) {
6         spin_unlock_irqrestore(&pool->lock, flags);
7         kfree(new_elements); // A memory deallocation.
8         return 0;
9     }
10    ...
11    return 0;
12 }
```

Figure 1: An example of E-E path in the Linux kernel.

code base of a typical OS kernel, e.g., 25 million source code lines of the Linux kernel with hundreds of new lines added per hour, it is extremely challenging to complete the leak detection for the entire kernel within an acceptable time.

In this paper, we focus on detecting memory leaks on *early-exit paths* (or E-E paths for short) in OS kernels. This is inspired by the observation that software bugs often lurk in rarely-tested program paths [7, 44]. In general, an E-E path is designed to exit from a kernel routine as early as possible. But, before the routine is exited from the E-E path, some extra work usually needs to be completed, e.g., deallocating a memory object, as shown by the example in Figure 1. Hence, if a memory deallocation is required but *missed* on the E-E path, it constitutes a memory leak. Though recent work also attempts to find software bugs related to E-E paths [19, 21, 35], their schemes are limited to a specific type of E-E paths, i.e., error handlers, and thus cannot cover a broad range of buggy E-E paths. Our study reveals that, besides error handlers, E-E paths in OS kernels are used in many *previously-unknown* scenarios, which inherently render existing approaches ineffective to detect memory leaks on general E-E paths.

There are two typical reasons why memory leaks are particularly common on E-E paths. First, the major purpose of an E-E path is to exit from a kernel routine as soon as possible when a special system status is encountered. With this in

mind, it is fairly easy for a developer to compose an E-E path with some required work missed on the path, especially when the developer does not have a comprehensive knowledge of the required work. Second, in practice, many E-E paths are added to the kernel code base not during the development but after the deployment due to various reasons, e.g., correcting the processing logic, achieving better performance/reliability, or enhancing the security. This inevitably leads the E-E paths to the lack of complete and thorough testing, which has been demonstrated by previous work [17].

To understand how E-E paths are used in OS kernels and how memory management operations are involved on E-E paths, we systematically investigate a substantially large portion, i.e., around 1 million lines, of the source code of two popular OS kernels, Linux [2] and FreeBSD [1]. The study uncovers some interesting findings on common usage scenarios of E-E paths and general principles of memory deallocations on E-E paths. In particular, we observe that the presence *in-consistencies* of memory deallocations on different E-E paths and normal paths usually indicate potential memory leaks. Inspired by this observation, we design MLEE to intelligently detect memory leaks on E-E paths through *cross-checking* the presence of memory deallocations on different paths. MLEE also employs several novel static analysis techniques to balance the analysis efficiency and detection accuracy.

We have implemented MLEE based on LLVM [24], which is a popular compiler infrastructure. We evaluate MLEE by applying it to the Linux kernel. MLEE is able to complete the analysis for the entire Linux kernel in around half an hour. This shows the analysis efficiency and scalability of MLEE. By manually analyzing the report produced by MLEE, we finally confirm 120 new leaks. It is the first time these bugs are uncovered by a leak detector. Most of them have been acknowledged by Linux developers and fixed using our patches. For the others, we are working closely with the kernel developers to finalize the patches.

In summary, this paper makes the following contributions:

- We conduct a comprehensive study of E-E paths in OS kernels and involved memory management operations. The study discovers some interesting and inspiring findings. To the best of our knowledge, this is the first systematic study of memory management operations on E-E paths.
- We design MLEE, which employs effective and scalable static program analysis techniques to identify E-E paths and analyze memory deallocations for memory leak detection. We believe the proposed analysis techniques will also benefit similar bug-detection systems.
- We find 120 new memory leak bugs in the Linux kernel with the help of MLEE. It is the first time that these bugs are reported by a leak detector. Most of these bugs have been acknowledged by Linux maintainers and fixed by our patches. This demonstrates the capability of MLEE to detect memory leaks in a real-world OS kernel.

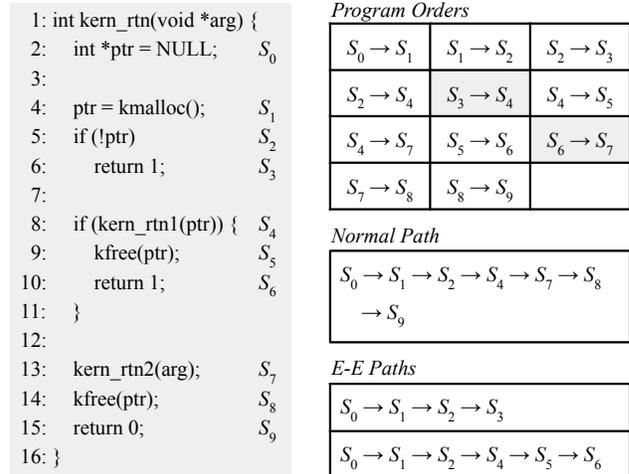

Figure 2: An example of the definition of E-E paths.

2 Background and Motivation

This section gives a formal definition of E-E paths and elaborates common usage scenarios of E-E paths in OS kernels.

2.1 What is E-E Path?

Intuitively, an E-E path intends to exit from a kernel routine *earlier* than normal program paths, by skipping some of the program code in the routine without execution. Hence, an E-E path generally has less program statements than a normal program path. We next give a definition of E-E paths.

A Formal Definition. We use a two-tuple to denote a kernel routine: $R = \langle S, O \rangle$, where S is a set of statements: S_0, \dots, S_n , and O is a set of program orders between two statements: $S_i \rightarrow S_j, 0 \leq i, j \leq n$. Each statement represents a basic and concrete operation, e.g., assigning a value to a kernel variable or invoking a callee routine. The program orders specify how the statements can be executed according to the orders in which they show up in the source code. For example, $S_i \rightarrow S_j$ means that S_j can be executed after the execution of S_i because, for example, S_j shows up in the source code immediately after S_i . In this paper, we call S_j a *successor* statement of S_i . It is worth noting that a return statement may also have a successor statement under O , as it may show up in the middle of a routine. This is the key point of E-E paths.

Given $R = \langle S, O \rangle$, a *program path* of R is an ordered list of statements: $P = S_0 \rightarrow S_1 \rightarrow \dots \rightarrow S_m$, where

- $S_i \in S, 0 \leq i \leq m$;
- $S_i \rightarrow S_{i+1} \in O, 0 \leq i \leq m - 1$;
- S_m is a return statement.

We enforce a return statement at the end of a program path to facilitate the following definition of E-E path. In case there

```

1 /* ipc/mqueue.c */
2 static void mqueue_evict_inode(struct inode *inode)
3 {
4     ...
5     clear_inode(inode);
6     if (S_ISDIR(inode->i_mode))
7         return;
8     /* Evict the inode from the message queue. */
9     ...
10 }

```

Figure 3: An E-E path for irrelevant kernel state bypassing.

is no return statement in a kernel routine, we can append an implicit return statement at the end of the routine source code. P is an E-E path if the following condition satisfies:

$$\exists S_n \in \mathcal{S}, \text{ s.t. } S_m \rightarrow S_n \in \mathcal{O} \quad (1)$$

The rationale behind this definition is that the return statement of an E-E path P is *not* the last statement of the routine, i.e., it has a successor statement under \mathcal{O} . Hence, if the routine exits from P , the successor statement and the following statements will not be executed, leading to an *early* exit.

An Example. We next use the example in Figure 2 to explain the above definition. The left side of the figure shows the source code of the kernel routine, which has ten statements with two if branches: S_2 and S_4 , and three returns: S_3 , S_6 , and S_9 . The top right side of the figure shows the program orders. Note that the two return statements S_3 and S_6 have successor statements, as highlighted in the figure. This routine has three possible program paths and two of them are E-E paths. For example, $S_0 \rightarrow S_1 \rightarrow S_2 \rightarrow S_3$ is an E-E path, as S_3 has a successor statement under the program orders: $S_3 \rightarrow S_4$.

2.2 Usage Scenarios of E-E Paths

Though E-E paths are often used to handle unexpected errors, e.g., memory allocation failures and invalid function arguments, our study on popular OS kernels, i.e., Linux and FreeBSD, reveals that E-E paths are also composed in other usage scenarios. We next describe each scenario in detail.

Error/Exception Handling. In general, an OS kernel needs to deal with various exceptional system statuses and unexpected program errors. For example, when a permission check fails, the kernel should not continue to perform the following privileged and safety-critical operations. Otherwise, potential security risks will be raised. Therefore, E-E paths are extensively used in OS kernels to terminate unsafe and invalid execution when an error/exception happens.

Typically, an E-E path in this usage scenario returns an *error code* to indicate that an error is triggered. This is also the reason why existing approaches leverage error codes to detect error handlers [12, 19]. However, our study shows that this is not always true. Specifically, we find that 52% (out of

```

1 /* fs/fat/misc.c */
2 void fat_time_unix2fat(struct msdos_sb_info *sbi, ...)
3 {
4     ...
5     if (tm.tm_year < 1980 - 1900) {
6         *time = 0;
7         *date = cpu_to_le16((0 << 9) | (1 << 5) | 1);
8         return;
9     }
10    if (tm.tm_year > 2107 - 1900) {
11        *time = cpu_to_le16((23 << 11) | (59 << 5) | 29);
12        *date = cpu_to_le16((127 << 9) | (12 << 5) | 31);
13        return;
14    }
15    ...
16 }

```

Figure 4: Two E-E paths for kernel functionality extension.

5910) and 25% (out of 1700) E-E paths in Linux and FreeBSD respectively do not return any error code even if they handle errors/exceptions. In fact, whether an E-E path returns an error code primarily depends on what error/exception is handled by the E-E path. Thus, it is insufficient to detect E-E paths merely relying on whether an error code is returned.

Irrelevant Kernel State Bypassing. In this scenario, the E-E paths are used to bypass specific kernel states, as it is not necessary for the following program code to process these states. The specific kernel states are often represented in the form of flags, modes, sizes, capacities, properties, etc. Figure 3 shows such an example. Here, if `inode` indicates not a regular file but a directory, it is unnecessary to evict it from the message queue. Thus, an E-E path is created to skip such inodes.

It is worth pointing out that this usage scenario is *not* same as the previous scenario. The major difference is that the E-E paths in this scenario handle *legal* and *valid* kernel states, while the E-E paths in the previous scenario tackle *unexpected* kernel errors/exceptions. That is, the E-E paths in this scenario may show up in a routine even if no error/exception needs to be handled. Besides, if an E-E path in this scenario returns a value, it usually returns the same value as normal paths. In contrast, an E-E path in the previous scenario typically returns a value (if any) different from those of normal paths.

Kernel Functionality Extending. An E-E path in this usage scenario extends existing program logic in a kernel routine to incorporate additional functionalities. Figure 4 shows an example. Here, the routine converts a UNIX date to a (time, date) pair in the FAT file system. However, FAT only supports years between 1980 and 2107. Hence, two E-E paths are created for years outside of this range. E-E paths in this scenario often contain extra statements to extend the functionalities. A representative example of E-E paths in this scenario is *fast paths*, which aim to accelerate the processing of some special cases. Previous research shows that fast paths are very likely to introduce bugs [17], which aligns with our observations.

2.3 Memory Management on E-E Paths

On the surface, memory management has no relationship with E-E paths. However, our experience shows that more than 60% kernel routines that have memory management operations contain at least one E-E path. So a further study is necessary to understand how memory management operations are involved on E-E paths. We next report our observations.

Observation 1. *If a memory object is allocated in a kernel routine, it usually needs to be deallocated on the following E-E paths in this routine.* In principle, after a memory object is allocated, it should be used in the following computations. However, in reality, it is possible that an E-E path is reached before the object is actually used. Hence, the object has to be cleaned up on the E-E path, otherwise a memory leak may be introduced. This observation implies that memory deallocation is an important component of the cleanup work on E-E paths. In fact, 58% and 41% E-E paths investigated by our study in Linux and FreeBSD respectively contain at least one memory deallocation. On the other side, if an allocated memory object is used before an E-E path is taken, it is probably not required to deallocate this object on the E-E path. But, we indeed witness some cases where memory objects are deallocated on the following E-E paths even if they are used before. This demonstrates the close correlation between memory deallocations and E-E paths.

Observation 2. *If a memory object is deallocated on the normal paths of a kernel routine, it usually also needs to be deallocated on the E-E paths in this routine.* This observation shows the consistency between normal paths and E-E paths on deallocating memory objects. If an object is deallocated on normal paths, it implies that the live range of this memory object is limited to the current kernel routine, so it should be deallocated on E-E paths as well. We find that 50% and 48% of kernel routines in Linux and FreeBSD respectively have similar deallocations on E-E paths and normal paths. This provides a strong evidence for the analyses in MLEE, as we will see in Section 4. In particular, MLEE pays special attention to memory deallocations on normal paths and employs effective and scalable static analyses to check whether these deallocations are also required on E-E paths. This allows MLEE to detect required but missed deallocations on E-E paths.

Observation 3. *If a memory object is deallocated on an E-E path in a kernel routine, it usually needs to be deallocated on the following E-E paths with same/similar return values (if any) in the routine.* If two E-E paths in a routine return same/similar values, it usually indicates that these two paths are constructed for same/similar purposes, e.g., in the same usage scenario. Particularly, if a memory object is deallocated on an E-E path, it means the caller routine is irresponsible to deallocate this object under the return value of the E-E path, and thus, this object should be deallocated on the following E-E paths with same/similar return values. Therefore, MLEE

creates scalable and precise static analyses to detect memory deallocations present on some E-E paths but missed on others.

Observation 4. *If multiple memory objects are allocated in a kernel routine, all objects allocated before an allocation failure usually need to be deallocated on the E-E path corresponding to this allocation failure.* One of the common reasons for multiple memory allocations in the same routine is to allocate *semantically-correlated* memory objects. For example, the allocation of a memory object with a subfield pointing to a child object is often realized by firstly allocating the object itself and then allocating the child object. Thus, if the allocation for the child object fails, the previously-allocated object has to be deallocated. This observation drives MLEE to thoroughly inspect kernel routines with multiple memory allocations to detect memory leaks. If one of the memory objects is deallocated on an E-E path but not on a following E-E path, it probably indicates a memory leak.

3 Issues and Challenges of MLEE

The design of MLEE is inspired by the key insight that an *inconsistency* between the presence of a memory deallocation on an E-E path and its presence on a normal path or another E-E path in the same kernel routine very likely indicates a potential memory leak. Therefore, it is possible to detect memory leaks by *cross-checking* memory deallocations on different E-E paths and normal paths in the same routine. Though the idea is intuitive, there are several technical challenges.

How to identify early-exit paths? Given the vast amount and the complicated logic of the source code in an OS kernel, e.g., more than 25 million lines in Linux, it is quite challenging to precisely identify E-E paths in a wide range of kernel modules with significant semantic diversities. Besides, the various usage scenarios of E-E paths, as described in Section 2.2, may lead E-E paths to exhibit different characteristics at the source code level. A simple solution for this issue is to enumerate all possible program paths of a kernel routine and exhaustively examine each of them to see whether it satisfies the definition of E-E paths in Section 2.1. However, this solution is obviously impractical due to the poor scalability caused by the well-known path explosion problem.

To address this challenge, we further investigate the structures and semantics of numerous E-E paths, in particular, with detecting memory leaks in mind. We find that the key for MLEE to detect memory leaks on an E-E path is to find out the crucial features of this E-E path that distinguish it from normal paths and other E-E paths in the same routine. Furthermore, such features are often reflected in a specific portion of the E-E path, i.e., the last several statements at the end of the E-E path. Recall the example in Figure 2. Compared to S_0 , S_1 , and S_2 , the statement S_3 is more representative of the first E-E path, because S_3 is manifested *uniquely* on this E-E path. In a similar way, S_5 and S_6 are more unique for the second

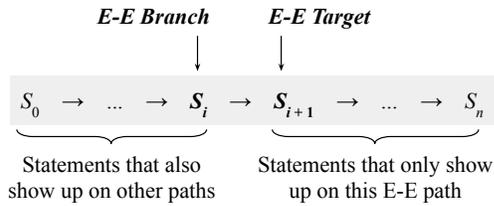

Figure 5: E-E branch and E-E target of an E-E path.

E-E path, as they only show up on this E-E path and thus can be used to distinguish this E-E path from other paths.

In addition, we find out that such statements often follow a conditional branch statement, e.g., an if statement. In this paper, we call such a conditional branch as an *E-E branch*, which is essential to differentiate an E-E path from normal paths and other E-E paths. Similarly, we call the target of the E-E branch that is included by the E-E path as an *E-E target*, which initiates the following statements after the E-E branch on the E-E path. Figure 5 shows the basic structure of an E-E path. It is worth noting that an E-E branch typically show up on both E-E paths and normal paths. Also, it is possible that an E-E path encompasses more than one E-E branch. Here, we primarily consider the *last* E-E branch on the E-E path because it is this one that leads to the unique statements.

In summary, to detect memory leaks on E-E paths, MLEE first collects E-E branches in a kernel routine and then utilizes them as anchor points of following analyses. This allows MLEE to compose precise and scalable static analyses to identify E-E paths and avoid the path explosion issue.

How to analyze memory deallocations? After the E-E branches in a kernel routine are recognized, MLEE moves forward to analyze memory deallocations in this routine to identify the inconsistencies between their presence on different E-E and normal paths. A simple analysis scheme is to examine each deallocation in the routine and check whether it shows up on an E-E path, in particular, after the E-E branch. If not, MLEE then reports a memory leak on this E-E path. Though this scheme sounds reasonable, it may produce plenty of false positive cases and require significant manual efforts to screen them. The major cause of false positives is that the deallocation may not be required on a specific E-E path. For instance, the memory object to be deallocated may be used, e.g., as the return value, on the E-E path and thus should not be deallocated.

To address this issue, MLEE firstly checks whether a missed memory deallocation is required to show up on an E-E path. This is realized in three steps. First, MLEE ensures that the deallocated object is live on the E-E path via a classical context-sensitive and flow-sensitive liveness analysis. Second, MLEE guarantees the validity of the deallocated object on the E-E path, i.e., the object is successfully allocated and remains allocated. Finally, MLEE confirms that the deallocated object

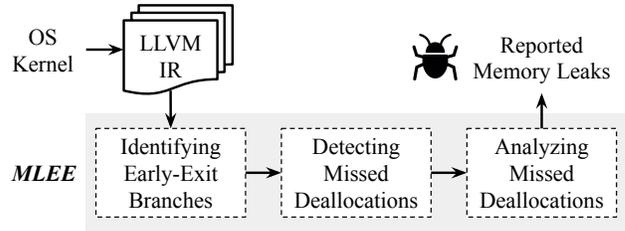

Figure 6: The work flow of MLEE.

is not used on the E-E path, particularly after the E-E branch (see Section 4 for more details). This way, MLEE can infer whether the deallocation is required on the E-E path or not.

4 MLEE System Design

In this section, we firstly present an overview of how MLEE works and then describe the technical details of MLEE.

Figure 6 illustrates the high-level work flow of MLEE. Essentially, MLEE takes as the input the LLVM IR of the target OS kernel and reports potential memory leaks on E-E paths in each kernel routine. We choose to start from LLVM IR because LLVM has plenty of static analysis passes in place, such as control/data-flow and alias analysis. Besides, LLVM IR has quite comprehensive debugging information (generated with the “-g” option), which can map the IR back to the corresponding source code. This allows MLEE to report the source code locations of the detected memory leaks to facilitate further manual inspection and bug fixing. Even though the implementation of MLEE leverages the LLVM infrastructure to reduce engineering effort, it is worth pointing out that the static analyses used by MLEE are *not* provided by LLVM. These analyses are a primary contribution of our work.

For each kernel routine, MLEE firstly analyzes all conditional branches in this routine to identify E-E branches. Next, MLEE gathers memory deallocations in this routine. For each pair of an E-E branch and a memory deallocation, MLEE then checks whether the memory deallocation is *missed* on the E-E paths associated with the E-E branch, i.e., the memory object freed by the deallocation operation is not deallocated after the E-E branch. MLEE focuses the analysis particularly on the statements after the E-E branch, including the E-E target and its following statements, because they are unique and thus more representative of the E-E paths. This also allows MLEE to delimit the analysis scope and scale up the analysis. Besides, it is possible that a memory object is deallocated implicitly after the E-E branch, e.g., in a callee routine. Hence, MLEE creates an inter-procedural analysis to cover all statements in callee routines invoked after the E-E branch.

If the result of the above step is yes, it means the memory deallocation is not present on the associated E-E paths. MLEE then further infers whether the missed deallocation should show up on the E-E path, i.e., whether the correspond-

ing memory object should be deallocated after the E-E branch. To this end, MLEE gathers the liveness, validity, and usage information of the memory object after the E-E branch to guide the analysis. Also, MLEE leverages additional information, e.g., the relative locations of the memory deallocation and the E-E branch in the source code of the kernel routine, to assist the necessity inference, according to the observations in Section 2.3. If the analysis concludes that the memory object needs to be deallocated after the E-E branch, MLEE will report a memory leak bug along with the source code locations of the E-E branch and the missed memory deallocation.

4.1 Identifying E-E Branches

Typically, a conditional branch comes with two branch targets, which are taken when the specified condition is satisfied or not, respectively. The major difference of an E-E branch, compared to a regular conditional branch, is that one of the branch targets is an E-E target, which only shows up on E-E paths, and thus leads to the last several statements on an E-E path. Hence, MLEE determines whether a conditional branch is an E-E branch based on the following two conditions:

- **Condition-1:** The program paths starting from one target always reach to a return statement that has a successor statement under the program orders of the routine.
- **Condition-2:** The program paths starting from another target always have a possibility to reach to a return statement that has no successor statement under the program orders of the routine.

A conditional branch is identified as an E-E branch if its two branch targets satisfy the above two conditions. Here, it is not hard to understand **Condition-1**, because one branch target of an E-E branch should always lead to E-E paths. In fact, the branch target that satisfies **Condition-1** is the E-E target of the E-E branch. The purpose of **Condition-2** is to emphasize the possibility of an E-E branch to show up on normal paths. In essence, an E-E branch divides the following execution space of the current routine into two *disjoint* sets. One of the sets comprises executions only ending with early exits, while another set includes at least one execution ending with normal exit. Therefore, **Condition-2** is crucial to distinguish an E-E branch from a conditional branch both of whose branch targets merely lead to E-E paths.

According to these two conditions, MLEE creates an effective static analysis to identify E-E branches by carefully checking branch targets of each conditional branch. Algorithm 1 shows the details of the static analysis. Overall, for each conditional branch in the kernel routine, MLEE firstly collects its two branch targets, i.e., the two first statements executed immediately after the conditional branch is taken and not taken, respectively, and then checks whether they satisfy the two conditions. If yes, MLEE then identifies this conditional branch as an E-E branch and places it into the set

Algorithm 1: Identification of Early-Exit Branches

Input: R - a kernel routine
Output: $EEBSet$ - the set of early-exit branches in R

```

1  $EEBSet \leftarrow \emptyset$ ;
2  $CBSet \leftarrow \text{Collect\_Conditional\_Branches}(R)$ ;
3 for  $CB \in CBSet$  do
4    $BTSet \leftarrow \text{Collect\_Branch\_Targets}(CB)$ ;
5   for  $T_1 \in BTSet$  do
6      $RetSet_1 \leftarrow \text{Collect\_Reachable\_Returns}(T_1)$ ;
7      $Flag \leftarrow TRUE$ ;
8     for  $Ret \in RetSet_1$  do
9       if  $Ret$  has no successor statement then
10        |  $Flag \leftarrow FALSE$ ;
11        | break;
12      end
13    end
14    if  $Flag \neq TRUE$  then
15      | continue;
16    end
17    for  $T_2 \in BTSet \setminus \{T_1\}$  do
18       $RetSet_2 \leftarrow \text{Collect\_Reachable\_Returns}(T_2)$ ;
19      for  $Ret \in RetSet_2$  do
20        if  $Ret$  has no successor statement then
21          |  $EEBSet \leftarrow EEBSet \cup \{CB\}$ ;
22          | break;
23        end
24      end
25    end
26  end
27 end
28 return  $EEBSet$ ;

```

of identified E-E branches. Otherwise, MLEE continues to check next conditional branch.

To determine if a branch target satisfies one of the two conditions, MLEE traverses the control-flow graph (CFG) of the kernel routine to gather all return statements that are reachable from the branch target. A potential issue in this traversing process is how to handle loop structures. Since MLEE mainly intends to visit all reachable nodes starting from the branch target on the CFG, MLEE iterates a loop as many times as necessary until all of its nodes are visited. This allows MLEE to exhaustively capture all return statements in a loop, which actually are quite common in OS kernels. Once the reachable return statements are collected for the branch target, MLEE next checks each of them to confirm whether it has a successor statement under the program orders of the routine. Given that the static analysis works at the LLVM IR level, MLEE needs to resolve the source location of a return statement. To this end, MLEE leverages the debugging information embedded into the LLVM IR to establish the mapping between the LLVM IR and the corresponding source code [41]. This way, MLEE can determine whether the branch target satisfies one of the two conditions mentioned above.

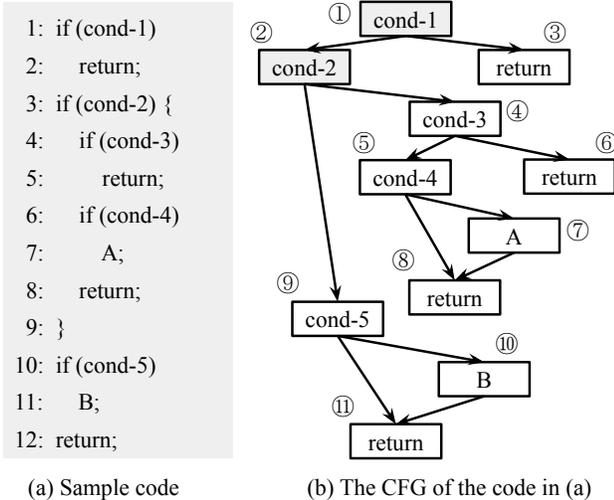

Figure 7: Conditional branch analysis for E-E path detection.

Now, let us use the example in Figure 7 to understand how MLEE identifies E-E branches. The left side of the figure presents the source code and the right side shows the corresponding CFG. From the figure, we can see that there are five conditional branches and four return statements in this example. Besides, each return statement has a successor statement under the program orders except the one at line 12.

MLEE consecutively analyzes each conditional branch to determine whether it is an E-E branch. Take the conditional branch of `cond-1` at line 1 as an example. The *true* target of this conditional branch can only reach to the return statement at line 2, i.e., ① → ③ in the CFG. On the other hand, the *false* target of this conditional branch may reach to the return statement at line 12, e.g., through the program path ① → ② → ⑨ → ⑪ in the CFG. As a result, MLEE identifies this conditional branch as an E-E branch. In a similar way, the conditional branch of `cond-2` is also identified as an E-E branch by MLEE. However, the conditional branches of `cond-3`, `cond-4`, and `cond-5` are not recognized as E-E branches. This is because MLEE figures out that their branch targets do not satisfy the above two conditions after the analysis. For example, the branch targets of the conditional branch of `cond-3` reach to two different return statements at line 5 and line 8, respectively. But both of these two return statements have a successor statement under the program orders. Hence, the conditional branch of `cond-3` is not considered as an E-E branch by MLEE.

4.2 Detecting Missed Memory Deallocation

Given an identified E-E branch *EEB*, the next task of MLEE is to detect memory deallocations that are potentially missed on E-E paths associated with *EEB*.

To this end, MLEE first collects memory deallocations in the same kernel routine as *EEB*. Next, for each deallocation

D, which is suppose to deallocate a memory object *M*, MLEE checks whether *M* is always deallocated before *EEB*. MLEE achieves this by traversing the CFG to search for another deallocation *D'* that also deallocates *M*. More importantly, *D'* dominates *EEB* in the CFG, which means *D'* is on all program paths from the entry of the routine to *EEB* and executed before *EEB*. In other words, if there exists such a *D'*, it implies that *M* has already been deallocated before *EEB* and therefore, *D* should not be considered as a missed deallocation on the E-E paths of *EEB*. Otherwise, MLEE continues to check whether *M* is deallocated by the program statements after the E-E target on the E-E paths. If not, MLEE treats *D* as a missed deallocation of *EEB* and further checks whether it is necessary on the E-E paths of *EEB*.

It is possible that *M* is deallocated in a callee routine of the current kernel routine. Thus, MLEE devises a path-sensitive and context-sensitive inter-procedural analysis to achieve the above goal. Specifically, MLEE analyzes every backward reachable statement starting from the return statement on the E-E paths corresponding to *EEB*. In case the statement is a call statement, MLEE further includes the statements in the callee routine into the analysis.

MLEE pays special attention to each memory deallocation statement during the analysis, because MLEE needs to validate whether it is used to deallocate *M*. A memory object is often accessed through *pointers*, which hold the address of the object. Given that an object can be accessed through different pointers, it is *incomplete* to determine whether two objects freed by two memory deallocations are same or not by simply checking whether the two deallocations use the same pointer. To solve this issue, MLEE leverages the alias analysis in LLVM to discover the potential alias relationship between two pointers. This allows MLEE to differentiate memory deallocations for different objects.

4.3 Analyzing Missed Memory Deallocation

Once a missed memory deallocation *D^M* is identified for an E-E branch *EEB*, the final step of MLEE is to check whether *D^M* is necessary on the E-E paths corresponding to *EEB*, i.e., the memory object *M* deallocated by *D^M* should also be deallocated on the E-E paths.

MLEE firstly composes an effective static analysis to validate the liveness and validity of *M* at the point of *EEB*, as it may cause unexpected program errors to deallocate an out-of-scope memory object. Specifically, MLEE relies on the analyses in LLVM to determine whether *EEB* is covered by the liveness range of *M*. Regarding the validity, MLEE needs to verify the possibility for *M* to be in an “allocated” state when *EEB* is reached. This is because *EEB* may be on a program path that does not allocate *M*. Hence, MLEE firstly conducts a backward slicing on *M* starting from *D^M* to find out the statement that successfully allocates *M*. Then MLEE performs a reachability analysis from the allocation statement

to *EEB* by traversing the CFG.

MLEE needs to take care of two special cases during the above analysis process: 1) No allocation statement is found for *M* because, for example, *M* is allocated in another kernel routine. To solve this issue, MLEE treats the entry point of the current routine as a *nominal* allocation point of *M*. 2) Multiple allocations are found for *M*, due to, for example, different allocation mechanisms adopted by the kernel to allocate *M*. MLEE deals with this case soundly by collecting all allocation statements that can reach *EEB*.

In addition to checking the liveness and validity of *M*, MLEE also needs to ensure that *M* is not used by the statements after *EEB* on the related E-E paths. To this end, MLEE employs a forward slicing on *M* starting from the E-E target of the E-E branch to confirm that *M* is not used by the following statements. The analysis stops when the return statement on the E-E paths of *EEB* is reached. Some common usage examples include but not limited to passing *M* to a callee routine as an argument, accessing a memory location inside of *M*, calculating effective memory addresses based on the start address of *M*, and etc. If *M* is indeed used, MLEE will skip the following analysis on D^M and *EEB*.

Finally, MLEE infers the necessity of D^M for *EEB*. To achieve this, MLEE creates a set of *checking rules* mainly based on the observations described in Section 2.3. The rules check various factors of *EEB* and D^M to heuristically determine whether D^M is required on E-E paths corresponding to *EEB*. To give an example, one of the rules checks the order of D^M and *EEB* in which they appear in the source code. This is inspired by the observation that if D^M shows up earlier than *EEB* in the source code, it typically implies that D^M is executed before *EEB* and therefore, it is very likely that D^M is not necessary on the corresponding E-E paths. In contrast, if the order is reversed, it is probably essential for the corresponding E-E paths to deallocate *M*. The output of each rule is either 1 or 0, meaning the deallocation is required or not on the E-E paths, respectively. MLEE assigns an empirical weight in (0, 1) for each rule and calculates the final result using the following formula:

$$f(EEB, D^M) = \sum_i w_i R_i(EEB, D^M) \quad (2)$$

where w_i is the weight of the *i*th rule: $\sum_i w_i = 1$, and $R_i(EEB, D^M)$ is the output of the *i*th rule for *EEB* and D^M . If the final result exceeds a predefined threshold 0.5, MLEE determines that D^M is required for *EEB* and reports a memory leak with the detailed information of *EEB* and D^M .

5 Implementation

We have implemented MLEE as an LLVM (version 8.0.0) tool composing of multiple analysis passes. This section reports the issues we encountered during the implementation of MLEE as well as the solutions we adopted to address them.

Compiling Linux to LLVM IR. Currently, LLVM is not fully compatible with the Linux kernel. To solve this issue, we compose a Python script to automatically extract and adapt the compilation commands to compile the kernel source code to LLVM IR. We simply skip a source file if LLVM cannot compile it. To include as many kernel modules as possible, we use the “*allyes*” option to configure the kernel. At last, our compilation covers around 11K kernel modules.

Global Call Graph. MLEE conducts the path-sensitive and context-sensitive inter-procedural analyses on a global call graph. To build the graph, MLEE incrementally compose a child call graph for each kernel module when it is loaded and parsed by LLVM [42], and eventually combines them together to obtain the global call graph. Note that MLEE does not need to link all kernel modules together to produce a single LLVM IR file and thus avoids potential linking errors in this process. MLEE also employs a type-based analysis to identify all possible call targets for an indirect call [29, 36].

Alias Analysis. MLEE relies on the alias analysis in LLVM to analyze the alias relationship between two memory pointers. This is achieved by querying the LLVM alias analysis framework with the two memory pointers along with the size of the memory locations. There are four possible relationship outcomes for such a query: *MustAlias*, *PartialAlias*, *MayAlias*, and *NoAlias*. For accuracy consideration, MLEE considers two pointers are alias pointers only when *MustAlias* or *PartialAlias* is returned by the alias analysis framework.

Handling Goto Statements. Some Linux routines use goto statements to realize sophisticated control logic. This entails difficulties for MLEE to detect E-E paths, as the return statement of an E-E path implemented using a goto statement may be placed at the end of a kernel routine. To deal with this issue, MLEE creates a source transformation tool to remove goto statements by replacing them with the target statements they jump to. Note that MLEE only replaces *forward* goto statements because backward goto statements are mostly used to implement loops. Fortunately, the Linux kernel does not use indirect goto statements [11], which take as input label variables and can complicate the transformation.

6 Experimental Study

This section evaluates MLEE by applying it to the Linux kernel (version 5.0, which was the most recent version when we finished the implementation of MLEE). Due to time limitations, MLEE is not evaluated with other OS kernels, e.g., FreeBSD, and non-kernel applications. This is a direction for future work. The evaluation presented in this section would like to answer two research questions about MLEE: i) *Effectiveness*: can MLEE discover new memory leaks in a real-

Table 1: Detection statistics of MLEE. “KEE”: kernel routines that have E-E paths. “KMD”: kernel routines that have memory deallocations. “KEM”: kernel routines that have both E-E paths and memory deallocations. “MMD”: E-E branches that are reported by MLEE to have missed memory deallocations.

Total	Kernel Routine			Mem Dealloc	E-E Branch	
	KEE	KMD	KEM		Total	MMD
887877	121829	14540	7685	20751	297451	126
	13.7%	1.6%	0.9%			0.04%

world OS kernel? ii) *Efficiency*: can MLEE complete the analysis of an entire OS kernel in an acceptable time?

Table 1 shows the detection statistics. As shown in the table, MLEE finds out that 0.9% kernel routines comprise of both E-E paths and memory deallocation operations. After the analysis, MLEE reports that 126 suspicious E-E branches have missed memory deallocations. These E-E branches span across various kernel modules and account for 0.04% of the total E-E branches identified by MLEE. With further manual analysis and investigation, we can finally confirm memory leak bugs on the corresponding E-E paths.

Finding New Bugs. It takes around 3~5 minutes for a researcher to manually investigate one suspicious E-E branch. Finally, we confirm 120 memory leaks related to 103 buggy E-E branches. Note that one buggy E-E branch may correspond to multiple missed deallocations. All of these memory leaks are *new* bugs. This demonstrates the capability of MLEE to discover unknown memory leaks in a real-world OS kernel.

Table 2 shows the details of the found memory leaks. We have reported these bugs along with the patches to Linux developers. During the communication with the developers, we were surprised that the developers responded to our bug reports promptly, e.g., in half an hour or even less, and actively worked with us to revise and update the patches. Given the developers’ heavy maintenance workload, this once again shows the high priority and severity of fixing memory leaks in OS kernels. In summary, at the time of the paper submission,

- 89 bugs (74.2%) have been fixed in the latest version of the Linux kernel using our patches;
- 16 bugs (13.3%) have been fixed in the latest version of the Linux kernel using others’ patches;
- 15 bugs (12.5%) have been confirmed and we are working with the kernel developers to finalize the patches.

Table 2 also shows that a vast majority of memory leaks are detected in the driver (60%), sound (17.5%), and file system (16.7%) directories. This means memory leaks are a general type of software bugs across various kernel modules. We find that 74% missed deallocations are also found on other E-E paths. This shows that E-E paths in the same kernel routine often exhibit similar behaviors in memory management

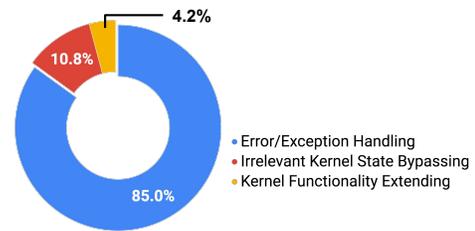

Figure 8: The usage-scenario distribution of the E-E paths on which the memory leaks are detected by MLEE.

```

1 /* drivers/net/ethernet/mellanox/mlx4/en_rx.c */
2 int mlx4_en_config_rss_steer(struct mlx4_en_priv *priv)
3 {
4     ...
5     err = mlx4_qp_alloc(mdev->dev, priv->base_qp, ...);
6     if (err) {
7         en_err(priv, "Failed to allocate RSS ...");
8         goto rss_err; // rss_map->indir_qp is leaked
9     } // on this early-exit path.
10    ...
11    kfree(rss_map->indir_qp);
12    rss_map->indir_qp = NULL;
13    rss_err:
14    ...
15    return err;

Figure 9: A real memory leak in Linux detected by MLEE.

operations. On the other side, this implies memory deallocations on normal paths may also be required on E-E paths.

An interesting observation on the E-E paths of the E-E branches in Table 2 is that these buggy E-E paths are used in not only the scenario of error/exception handling, but also two other scenarios described in Section 2.2. Figure 8 shows the detailed distribution of the scenarios. This demonstrates that MLEE can detect buggy E-E paths in different usage scenarios. However, existing bug-detection schemes that focus only on error handlers may fail to detect these memory leaks.

To understand when and how the found memory leaks are introduced into the kernel code base, we further investigate the code revision histories of the kernel routines in which the memory leaks are found. We find that many memory leaks were actually brought in at the first time when the corresponding E-E paths were added into the kernel source code. This was also acknowledged by some Linux maintainers. Taking the Bug#100 in Table 2 as an example, when we submitted it to the Linux patch mailing list, a kernel maintainer quickly commented our bug report and said that “*this bug exists till its first commit for v2.6.39.*” One possible reason behind this phenomenon is that the author of an E-E path may have a partial and incomplete understanding of the work that are necessary on the E-E path. In addition, this also reveals that many E-E paths in OS kernels are error-prone due to the lack of extensive testing when they are committed to the kernels.

Table 2: New memory leaks in the Linux kernel discovered by MLEE. “O”: the bug has been fixed in the latest version using our patch. “L”: the bug has been fixed in the latest version using others’ patch. “C”: the bug has been confirmed.

Comparing with Existing Leak Detectors. A further study of the memory leaks reported by MLEE shows that many of the leaks actually cannot be detected using existing static detection approaches due to their fundamental limitation. We use the Bug#50 in Table 2 as an example to explain this limitation. Figure 9 shows the source code of this bug. Here, the memory object `rss_map->indir_qp` is not deallocated when `mlx4_qp_alloc()` fails. MLEE successfully reports this memory leak by figuring out that the memory deallocation at line 11 is missed on the E-E path of the E-E branch at line 6.

However, most of existing static detectors are established based on a basic assumption that a memory object should be deallocated at the end of the kernel routine, in which it is allocated, if it does *not* escape from this routine. This assumption itself has no problem, but it cannot cover memory leaks involving *escaped* objects, which are fairly common in OS kernels. Obviously, in this example, `rss_map->indir_qp` is still alive after the routine is returned. Hence, it is extremely hard for existing detectors to reason about whether `rss_map->indir_qp` should be deallocated or not for the buggy E-E path.

False Negatives. For a bug detection tool like MLEE, it is important to study false negatives of the detection results. However, given the large code base of the Linux kernel, it is hard to study false negatives of the detection results of MLEE at the scale of the entire kernel, because of the lack of the ground truth. Nevertheless, during the implementation and evaluation of MLEE, we conducted several false negative experiments to understand the completeness of the static analysis techniques developed in MLEE. For example, we manually examined many kernel routines to verify whether MLEE can identify all E-E paths in these routines, especially when the E-E paths are used in different usage scenarios. In addition, we intentionally modified several randomly selected source files in the kernel to introduce some known memory leak bugs by commenting out memory deallocations

on related E-E paths and checked whether MLEE is able to detect them. Our experimental results showed that MLEE can successfully identify all E-E paths and report the injected memory leaks without any false negative. This demonstrates, to some extent, the completeness of the analysis techniques in MLEE on detecting memory leaks on E-E paths in Linux.

False Positives. As a static leak detector, MLEE inevitably suffers from false positives. Among the reported 126 suspicious E-E branches, 23 (18%) are confirmed having no memory leaks. Generally, a false positive is reported by MLEE due to two categories of reasons. First, the missed memory deallocation is required but invoked after the E-E path is completed, i.e., the current kernel routine is returned. Second, the missed memory deallocation is not required on the E-E path due to various corner cases not handled by MLEE.

We summarize the detailed reasons in each category and the associated percentages in Table 3. The most accountable reason is #5, where the target E-E path is composed for a different semantic purpose compared to the path(s) on which the missed deallocation is found. For example, a memory deallocation may be necessary on E-E paths that handle exceptional kernel statuses but unnecessary for E-E paths that handle expected statuses. To filter out these false positives, we can extend MLEE to capture the semantic differences between paths in the same routine. For other false positive reasons, e.g., #2, we need to develop scalable techniques to continue the tracking of the path after the E-E path is completed.

Analysis Efficiency. The evaluation platform is equipped with an Quad-Core Intel Xeon E5-1620 v4 CPU at 3.50 GHz and 32 GB main memory. The OS is Ubuntu 16.04 with Linux-4.4. The platform was exclusively occupied by MLEE during the analysis process. It took around half an hour for MLEE to complete the analysis of the Linux kernel. Given that the Linux kernel contains 25M lines of source code, we believe this analysis performance is acceptable.

Table 3: Detailed reasons of false positives reported by MLEE and the percentage of each reason.

Required	1	The memory object is deallocated by another kernel thread after the E-E path.	8%
	2	The memory object is deallocated by the same kernel thread in a callback routine after the E-E path.	18%
Not Required	3	The missed deallocation itself is redundant as the allocated object can be reused.	8%
	4	The E-E path does not satisfy a specific condition.	13%
	5	The E-E path is not used for the same semantic purpose as the path(s) of the missed deallocation.	53%

7 Related Work

Static Leak Detection. Static detection approaches analyze programs to discover memory leaks without running the programs. Clouseau [15] identifies program statements inconsistent with an ownership model as memory leaks. Hackett and Rugina [13] propose a region-based shape analysis to detect memory leaks. Xie et al. [44] represents computations as boolean constraints for memory leak detection. Orlovich et al. [31] disprove the presence of memory leaks through a backward data-flow analysis. FastCheck [7] reduces memory leak detection to a reachability problem over a guarded graph. LeakChecker [46] identifies memory leaks through a common code pattern of memory leaks. SMOKE [9] develops the use-flow graph to detect leaks in two stages.

MLEE is also a static memory leak detector. But, MLEE is inspired by the observations and findings from our study of memory management on E-E paths in OS kernels. This enables MLEE to invent effective and scalable static analyses to detect memory leaks on E-E paths. The detection results show that MLEE is a practical leak detector. In contrast, it is quite difficult to directly apply most of existing static mechanisms to OS kernels, due to the extreme complexity of the kernel code base and the widespread use of E-E paths in various scenarios. Although Xie et al. [44] applied the proposed leak detector to the Linux kernel, it took around one day to complete the analysis and, among the reported 123 leaks, only 2 were actually confirmed and fixed. Moreover, the code base of the Linux kernel has expanded significantly since then.

Dynamic Leak Detection. Dynamic detectors identify memory leaks by running the programs. Purify [14] adapts garbage collection techniques to detect memory leaks in C/C++ programs. SWAT [8] and Sleight [4] identify a *stale* object as a memory leak if it has not been accessed for a long time. Cork [22] uses a dynamic heap-summarization technique to detect memory leaks. Rayside et al. [32] leverage object ownership profiling to find instances of memory management anti-patterns in object-oriented programs. Xu et al. [45] propose a heap-tracking technique to detect leaks in Java programs. Hound [30] organizes the heap layout to facilitate the staleness tracking of heap objects for leak detection. Li et al. [26] develop a dynamic technique to validate and categorize memory leak warnings reported by static detectors. GC assertions [3] allow developers to diagnose leaks through a system interface. Maxwell et al. [28] apply a graph grammar mining approach

to detect leaks. Sniper [23] utilizes hardware performance monitoring units to track object staleness for leak detection. Lee et al. [25] train a machine learning model during the software testing stage and apply the model to the production stage for leak detection. MemInsight [20] performs a lifetime analysis on objects to detect leaks in JavaScript programs.

Compared to static detectors, dynamic approaches suffer from the coverage issue, i.e., only the exercised paths are examined. How to generate sufficient test inputs to cover rarely-executed paths, e.g., E-E paths, is an interesting but hard problem. Also, dynamic detectors deployed in production runs may incur performance overhead. MLEE may utilize dynamic techniques to further enhance the detection accuracy.

Others. Some research work aims to automatically fix or tolerate memory leaks. LeakSurvivor [34] and Melt [5] swap out leaked objects to disks to free up memory resources. Leak-Fix [10] checks each allocation and inserts a deallocation if necessary. BLeak [38] provides a leak debugging framework for web applications. Generally, MLEE can collaborate with them to provide integrated solutions for memory leaks.

8 Conclusion

Memory leaks can lead to critical performance and security issues, especially in OS kernels. Inspired by the observation that memory leaks often lurk in rarely-tested program paths, e.g., E-E paths, we firstly conduct a comprehensive and in-depth study on memory management operations involved on E-E paths in OS kernels. With the findings derived from the study, we then design MLEE, which aims to intelligently detect memory leaks on E-E paths. MLEE employs novel static analysis techniques to automatically identify E-E paths and infer whether a missed memory deallocation is required on an E-E path. The static analyses in MLEE are effective and scalable. With the help of MLEE, we discover 120 new memory leaks in the Linux kernel and most of these memory leaks have been fixed using our patches.

Abstract

Modern desktop applications involve many asynchronous, concurrent interactions that make performance issues difficult to diagnose. Although prior work has used causal tracing for debugging performance issues in distributed systems, we find that these techniques suffer from high inaccuracies for desktop applications. We present Argus, a fast, effective causal tracing tool for debugging performance anomalies in desktop applications. Argus introduces a novel notion of strong and weak edges to explicitly model and annotate trace graph ambiguities, a new beam-search-based diagnosis algorithm to select the most likely causal paths in the presence of ambiguities, and a new way to compare causal paths across normal and abnormal executions. We have implemented Argus across multiple versions of macOS and evaluated it on 12 infamous spinning pinwheel issues in popular macOS applications. Argus diagnosed the root causes for all issues, 10 of which were previously unknown, some of which have been open for several years. Argus incurs less than 5% CPU overhead when its system-wide tracing is enabled, making always-on tracing feasible.

1 Introduction

Diagnosing performance anomalies is an essential need for all kinds of software. For modern desktop applications, performance diagnosis can be very difficult. Such applications are often built with assorted frameworks and libraries. For responsiveness, they divide handling of user interface (UI) events into many small execution segments [30] that run concurrently on multi-core hardware. For instance, macOS applications handle UI events by sending messages to delegate objects that contain code to react to these events asynchronously. The messages are generated by the closed-source Cocoa framework [11], which in turn interacts with the operating system (OS), daemons, and other libraries. The asynchronous, predominantly concurrent interactions obscure the true cause of a performance anomaly.

Traditional debugging and profiling tools are not well suited to troubleshoot performance issues in desktop applications. macOS tools such as `spindump` [10] and `lldb` [45] allow users to analyze a buggy process' stack traces. Profilers like `Gprof` [28], `perf` [5], and macOS Instruments [12] mainly analyze what functions take the most time. None of these tools provide insights regarding the sequence of events that

span across the many frameworks, libraries, system daemons, kernel, application processes/threads, and result in the performance issue. Traditional tools excel at analyzing system state at a specific point in time in an individual component. They are not amenable to analyzing concurrent execution flows over time whose interactions may cause performance issues.

To debug cross-component performance issues, causal tracing has been proposed [14, 20, 27, 32, 37, 38, 40, 41, 43, 44, 46, 56], especially for distributed systems. Causal tracing utilizes a trace graph to help developers understand performance issues that involve complex interactions. A trace graph consists of vertices and edges, where vertices are *execution segments*, such as an operation, system event, message, etc., and edges indicate causal relationships between vertices. To diagnose a performance issue, these solutions usually run a critical path analysis on the constructed trace graph that finds the sequence of vertices and edges which start from the vertex where the problem occurs and take the greatest amount of time for completion.

Unfortunately, we observe that previous causal tracing approaches are ineffective for desktop applications because they cannot accurately identify the boundaries of execution segments and their causality relationships. For example, a long-standing Google Chrome web browser performance anomaly [2] on macOS occurs when a user enters non-English words in the search box, causing Chrome to hang with the infamous macOS spinning pinwheel, which appears when an application is not responsive to user input. Using previous approaches to construct trace graphs for the multi-threaded, multi-process browser results in many missing execution segments and many additional irrelevant execution segments. Attempting to diagnose the problem using these incomplete and inaccurate graphs would incorrectly pinpoint no events or wrong events as the culprit. In theory, these tracing inaccuracies could be fixed by adding instrumentation, such as adding constraints in noisy trace points to filter irrelevant events. However, frameworks and libraries used by desktop applications have diverse programming idioms and are often closed-source, making deep instrumentation difficult. Extensive instrumentation would also incur prohibitive overhead, resulting in unacceptable performance.

To address these problems, we have created Argus, a causal tracing tool specially designed to help users diagnose performance anomalies in desktop applications. Argus is

based on the insight that tracing inaccuracies are inherently unavoidable in real desktop systems, so instead of trying to eliminate all inaccuracies, we should design tracing solutions that can accommodate some inaccuracies. Argus introduces a new notion of annotated trace graphs, in which edges are explicitly annotated as *strong* and *weak* edges. Strong edges represent connections among segments based on typical programming paradigms that must be causal, such as sending and receiving an IPC message. Weak edges represent ambiguous relationships among segments. For example, when one thread wakes up another thread, it could be a causal relation, e.g., `lock/unlock`, or just an artifact of regular OS scheduling. Argus further boosts or prunes unnecessary weak edges by leveraging operation semantics and call stacks.

Argus introduces a new beam search diagnosis algorithm based on edge strength and a novel method of comparing trace subgraphs across normal and abnormal executions of an application. The algorithm is motivated by our observation that critical path analysis used in prior work is ineffective due to inaccuracies inherent in trace graphs. Beam search embraces more possibilities while exploring the annotated noisy trace graph. Our algorithm efficiently selects likely causal paths in the massive trace graph and tolerates noises. Comparing trace subgraphs across normal and abnormal executions also helps with diagnosis when the problem is due to missing operations in the abnormal execution.

Argus provides system-wide tracing by extending existing tracing support in the OS kernel and applying binary patching for low-level libraries. This allows Argus to easily track objects across process boundaries, account for kernel threads involved in communications among processes, and cover customized programming paradigms by operating in a common low-level substrate used by higher-level synchronization methods and APIs that may be introduced and evolve over time. Argus does not require any application modifications.

We have implemented and evaluated a prototype of Argus across multiple versions of macOS. This presents a harsh test for Argus given the many complex, closed-source frameworks, libraries, and applications in the macOS software stack. We evaluated Argus on 12 real-world spinning pinwheel issues in widely-used macOS applications, such as Chrome, Inkscape, and VLC. Argus successfully pinpoints the root cause and sequence of culprit events for all cases. This result is particularly notable given that 10 of the 12 cases are open issues whose root causes were previously unknown to developers. Argus incurs runtime overhead low enough such that users can leave Argus tracing always-on in production without experiencing any noticeable performance degradation. Source code for Argus is available at <https://github.com/columbia/ArgusDebugger>.

2 Motivation and Observations

We experienced first-hand the Chrome web browser performance issue on macOS. Typing non-English words in a search

box while a web page is loading causes Chrome to freeze and trigger a spinning pinwheel. The spinning pinwheel appears when an application is not responsive to user input for more than two seconds. Others have also experienced this issue with the Chromium web browser and reported it to Chromium developers [2]; Chrome is based on Chromium.

We study the bug in Chromium since it is open-source, so we can verify its ground truth. Chromium is a multi-process macOS application involving a browser process and several renderer processes, each process having dozens of threads. When a user types a string in the browser search box, a thread in the browser process sends an IPC message to a thread in the renderer process, where the rendering view code runs to calculate the bounding box of the string, which in turn queries `fontd`, the font service daemon, for font dimensions.

To diagnose the bug, we first tried using `spindump` [10], a widely-used macOS debugging tool, which shows the main thread of the browser process is blocking on a condition variable. However, `spindump` provides no clue as to why the condition variable is not signaled. Using macOS Instruments [12] was also ineffective, as it simply analyzes what functions take the most time, which are not the root cause in this case. These traditional debugging and profiling tools are fundamentally not well suited to analyzing causality in highly concurrent execution flows across multiple components over time.

We next tried state-of-the-art causal tracing techniques. Specifically, we use Panappticon [56], a system-wide tracing tool originally built for Android. We reimplemented a version for macOS with more complete tracing of asynchronous tasks, using non-intrusive interposition to trace asynchronous tasks, IPCs, and thread synchronizations from the system and libraries. We use the tool when running Chromium and reproduce the anomaly by typing non-English search strings. After the browser handles the first few characters normally, the remaining characters trigger a spinning pinwheel. We then stop the tracing. The entire session took around five minutes.

Dividing up the trace graph into separate graphs each beginning from a user input event results in 359 trace graphs; user input events are dispatched from the macOS `WindowServer` process to Chromium. The trace graphs are highly complex, with 888,236 vertices and 751,332 edges in total. They span across 11 applications, 79 daemons including `fontd`, `mdworker`, `nsurlsessiond`, and various helper tools started by the applications. They cover 90 processes, 1177 threads, and 644K IPC messages.

Studying the trace graphs, we observe: (i) connections exist between graphs from different UI events; (ii) some long execution segments have no boundaries; (iii) there are orphaned vertices with no edges; (iv) the trace graph that contains the anomalous event sequence triggering the spinning pinwheel contains 12 processes—3 are clearly unrelated to the transaction, and 6 are daemons whose relationships are unclear without further investigation. Based on further analysis of these graphs with call stacks and reverse

```

1 // worker thread in fontd:
2 block = dispatch_mig_server;
3 dispatch_async(block);

1 // implementation of dispatch_mig_server
2 dispatch_mig_server()
3 for (;;) { // batch processing
4     mach_msg(send_reply,recv_request)
5     call_back(recv_request)
6     set_reply(send_reply)
7 }

```

Figure 1: Dispatch message batching. `dispatch_mig_server` can serve unrelated applications together.

engineering techniques, we conclude that they have significant inaccuracies. Running diagnosis on them leads to a wild goose chase, investigating components such as `fontd`, as it sends out messages after a long execution, which turn out to be completely unrelated to the root cause. We observe two general inaccuracies: *over-connections* and *under-connections*.

Over-connections usually occur when intra-thread execution segment boundaries are missing. We summarize three common programming patterns responsible for this—dispatch message batching, piggyback optimization, and superfluous wake-ups.

Dispatch message batching. Frameworks and daemons often implement event loops for handling multiple events inside callback functions. For example, Figure 1 shows two threads from the `fontd` daemon in macOS; the worker thread installs a callback function `dispatch_mig_server()` in a dispatch queue and the main thread dequeues and calls the function via `dispatch_client_callout`. `dispatch_mig_server()` has an event loop which batch processes requests from different applications, presumably for performance. It invokes `call_back` to process a message and `set_reply` to post a reply. However, previous causal tracing tools like Panappticon assume the execution of a callback function is entirely on behalf of one request. `dispatch_mig_server` is thus treated as a single execution segment and edges are added between the vertex representing `dispatch_mig_server` and the many unrelated applications for which it handles requests. These edges incorrectly indicate causal relationships that would result in misleading diagnoses.

Piggyback optimization. Frameworks and daemons may piggyback multiple tasks in a system call to reduce kernel boundary crossings. For example, Figure 2 shows the macOS system daemon `WindowServer` uses a single system call `mach_msg_overwrite` to receive data and piggyback the reply for an unrelated event. However, previous causal tracing tools like Panappticon treat the execution of a system call as a single execution segment for one event, artificially making many events appear causally related.

Non-causal wake-up. Desktop applications typically have multiple threads synchronized via mutual exclusion, such that a thread’s unlock operation wakes up another waiting thread. Such a wake-up may be, but is not always, intended as causality. For example, in Chromium, a wake-up is commonly followed by a batch processing block, but it is unclear whether

```

1 //a thread in WindowServer
2 while (true){
3     //postpone a reply
4     CGXPostReplyMessage(msg);
5     //receive requests
6     CGXRunOneServicePass();
7 }

8 CGXRunOneServicePass(){
9     if (_gOutMsgPending)
10        mach_msg_overwrite(
11            SEND|RECV,
12            _gOutMsg, RecvMsg)
13        else
14            mach_msg(RECV,RecvMsg)
15 }

```

Figure 2: Piggyback optimization and intra-thread data dependency. `mach_msg_overwrite` combines the reply of a previous event. Operations inside a thread have dependencies on `_gOutMsg`.

```

1 // worker thread needs
2 // UI update
3 obj->need_display = 1

1 //main thread
2 if (obj->need_display == 1)
3     render(obj)

```

Figure 3: Shared data flag across threads.

the following events being batch processed depend on the wake-up event. Previous causal tracing tools assume any wake-up is causal, which may artificially make events appear causally related when they are not.

Under-connections usually occur due to missing intra-thread data dependencies and inter-thread shared flags.

Data dependency. Frameworks and daemons may have internal state that causally link different execution segments of a thread. For example, Figure 2 shows that a `WindowServer` thread calls the function `CGXPostReplyMessage` to save the reply message, which it internally stores in a variable `_gOutMsg`. When the thread later calls `CGXRunOneServicePass`, it sends out `_gOutMsg` if there is any pending message.

Shared data flags. Frameworks and daemons may use shared flags that causally link different threads. Figure 3 shows a worker thread sets a field `need_display` inside a `CoreAnimation` object whenever the object needs to be repainted. The main thread iterates over all animation objects and reads this flag, rendering any such object. Existing tools do not track these kinds of shared-memory communication.

3 Overview of Argus

We have designed Argus to diagnose performance issues in desktop applications. Argus satisfies four key requirements not met by previous causal tracing tools: (1) use minimal instrumentation, (2) support closed-source components, (3) extract rich information from heterogeneous components with minimal manual effort, and (4) incur low runtime overhead.

Central to its design is the construction of *annotated trace graphs* from low-level trace events. Argus introduces the notion of *strong* and *weak* edges in trace graphs to mitigate inherent inaccuracies in tracing. When there is strong evidence of causality, such as an IPC message event, Argus adds a *strong edge* between vertices. When an execution segment is created by events that may not necessarily represent causality, such as non-causal wake-ups, Argus adds a *weak edge*. During diagnosis, Argus prefers traversing through strong edges when possible. Argus also stores extra semantic information in the graph vertices, including user input events, system calls, and

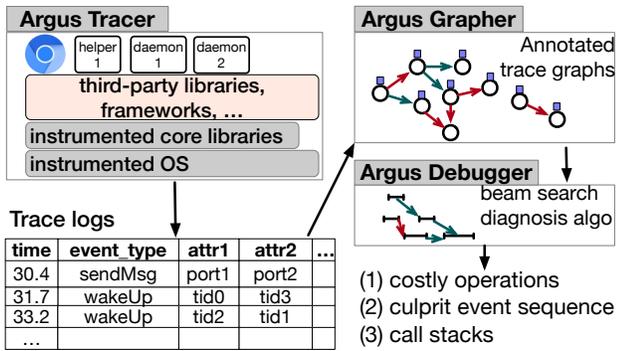

Figure 4: Overview of Argus.

sampled call stacks. This extra information is used to improve weak edge annotation and align and compare trace graphs for normal and abnormal execution to aid diagnosis.

Figure 4 shows an overview of Argus. It consists of three main components—a tracer, a grapher, and a debugger. The tracer runs continuously in the background on a user’s machine, transparently logging events from low-level system libraries and the kernel, without any need to modify applications. When a user encounters some performance anomaly, she reports the issue about the problematic application, along with the timestamp of the anomaly occurrence. The reported issue and trace logs are sent to the developer, the logs containing events for both normal execution and abnormal execution when the performance anomaly occurs. The developer feeds the logs into the grapher to construct the annotated trace graphs for both normal and abnormal execution, and runs the debugger on the graphs to output the diagnosis results.

4 Argus Tracer

Argus traces events inside the kernel and low-level libraries, with minimal instrumentation. This provides three advantages over tracing in user applications. First, tracing in the kernel and libraries ensures coverage of custom programming paradigms. For instance, Argus traces general thread scheduling events and wake-up and wait to ensure coverage of a variety of custom synchronization primitives in desktop applications, because their implementations almost always use kernel wake-up and wait. Second, tracing in the kernel helps connect tracing events across process boundaries, because the addresses of the traced objects in kernel space are usually unique, while tracing in user programs requires maintaining and propagating unique identifiers. Third, tracing kernel threads helps bridge communications among processes. For instance, a kernel thread sends out a message to a process when the process needs to execute a delayed function.

In the macOS XNU kernel, Argus traces system calls, thread scheduling, interrupts, time-delayed calls, and Mach messages. Argus leverages existing macOS kernel tracing support [13], but adds enhancements to log more information and enable always-on tracing using a ring buffer to avoid exhausting

storage. The enhancements require roughly 500 lines of code (LOC) in the XNU kernel, which are straightforward to add given that the kernel is open source. Trace events are asynchronously flushed to a file with a size limit. The limit is by default 2 GB, which can store roughly 20 million trace events; this is about 5 minutes of tracing when running large applications like Chrome. It can be easily adjusted to accommodate longer execution times. We used the default limit for all experiments in Section 7.

Argus logs kernel events to identify when threads are executing and their causal relationships. All system calls are traced to provide high-level semantics that can be used to identify causal relationships. Argus simply records return values for most system calls, but call stacks are also logged for a small set of system calls, namely those pertaining to Mach messages and synchronization using conditional variables and semaphores. Call stack information is later used by the Argus debugger to provide debugging information for developers. Thread scheduling is traced to track when a thread becomes idle and which thread wakes it up. Argus logs three types of thread scheduling events: *wait* to indicate when a thread becomes idle, *wake-up* to indicate when the current thread wakes up another thread, and *preempt* to indicate when a thread is preempted due to its timeslice being used up or priority policies. Interrupts are logged to indicate when threads are preempted by interrupts, with call stacks also logged for interprocessor interrupts (IPIs). Argus traces the internal kernel implementation of time-delayed calls, which are used to implement asynchronous calls in libraries such as Grand Central Dispatch (GCD). Finally, Argus traces the internal kernel implementation of Mach messages, not just their invocation via system calls, to enabling tracing of all use of Mach messages, including use within the kernel among kernel threads.

To aid developers in interpreting the virtual addresses in call stacks via `lldb`, Argus also logs in userspace the virtual memory layout of images for all processes. The tracer records the virtual memory maps for all running processes when tracing is enabled or terminated; processes launched during tracing are also recorded. The memory layout information is also fed to the Argus debugger.

In addition to kernel tracing, Argus traces four closed-source macOS frameworks, `AppKit`, `libdispatch.dylib`, `CoreFoundation`, and `CoreGraphics`, to track UI events and batch processing paradigms used by applications. Because these frameworks are closed source, the trace events are added via binary instrumentation using a mechanism similar to `Detour` [31]. `AppKit` is used to dispatch UI events to handlers. Argus traces where a UI event is fetched from the `WindowServer` and dispatched to an event handler. `libdispatch.dylib` implements GCD, managing dispatch queues to balance work across the entire system. Argus adds trace events to track when objects are pushed into a dispatch queue and popped off of the dispatch queue and executed. `CoreFoundation` supports event loops for GUI applications, which are widely used to process requests

from timers, customized observers, and sources such as sockets, ports, and files. Argus adds trace events so the handling of different requests inside event loops can be tracked separately.

To deal with the under-connection issues (Section 2), we annotate a handful of data flags in CoreGraphics. Given the shared flag variable names, Argus monitors the respective virtual addresses with watchpoint registers. Reads or writes to the addresses will invoke a signal handler that records trace events with the values stored in those addresses. Argus adds code to CoreFoundation to install this signal handler.

Argus can use the same watchpoint mechanism to trace shared data flags in applications. To assist developers in finding these shared data flags, Argus provides a lightweight tool that uses lldb to record the operand values of each instruction and finds ones that lead to divergence in control flow, which are likely data flags. The shared flag variable names are recorded in an Argus tracer configuration file, which are then traced using the same signal handler installed by CoreFoundation. Since CoreFoundation is imported by all GUI applications, Argus can trace these shared data flag accesses without any application modifications.

Note that the annotation effort for shared data flags is in general small. This is because execution segments that access shared variables are usually connected already by some types of causality, e.g., wait/signal events; developers mainly need to provide Argus with shared flags that are accessed through ad-hoc synchronization [49]. In our experience, only a few shared flags need to be monitored. Also for this reason, although hardware watchpoint registers are limited, Argus is unlikely to exhaust them. In fact, none of the applications we evaluated in Section 7 needed shared flags to be identified or traced in the applications themselves. Mechanisms such as Kprobe [3] could potentially be used to extend Argus to support monitoring more shared flags.

5 Argus Grapher

Argus uses the trace logs to build an annotated trace graph by first identifying the boundaries of execution segments in each thread to determine the graph vertices, then adding annotated edges between vertices. The annotated edges contain type metadata to indicate *strong* versus *weak* edges, which is used during diagnosis to mitigate inaccuracies due to over-connections and under-connections, as discussed in Section 2.

Argus first determines the execution segments that will form the graph vertices. Using various trace events as boundaries, Argus splits the execution of each thread into separate execution segments. First, Argus splits nesting of tasks executed from dispatch queues. If an execution of `dispatch_callout` invokes several other `dispatch_callout`, each dispatched task is separated. Second, Argus recognizes batch processing patterns such as `dispatch_mig_server()` in Figure 1 and splits the batch into separate execution segments. Third, when a wait operation blocks a thread execution, Argus splits the execution

Edge	Rules for Edge Annotation
Strong	1. IPC message send and receive; 2. Asynchronous calls (work queue, delayed call); 3. Direct wake-up of a thread on purpose; 4. Data dependency.
Weak	1. Non-causal wake-up; 2. Execution segments divided between a wait event and a wake-up event, excluding following cases: wait or wakeup are introduced by system call <code>workq_kern_return</code> , or they are in <code>kern_task</code> ; 3. Split suspicious batching execution segments, except known batching APIs: <code>RunLoopDoObservers</code> , <code>CGXServer</code> , etc.
Boosted Weak	Continuous execution segments matching weak edge rules but are on behalf of the same task.

Table 1: Edge annotation rules.

into separate segments at the entry of the blocking wait. The rationale is that blocking wait is typically done as the last step in event processing. Finally, Argus uses Mach messages to split execution when the set of communicating peers differs. Argus maintains a set of peers, including the direct sender or receiver of the message and the beneficiary of the message; macOS allows a process to send or receive messages on behalf of a third process. Argus splits execution when two consecutive messages have non-overlapping peer sets. By splitting thread execution using these four criteria, Argus avoids potential over-connections due to batching and piggyback optimizations.

Argus next determines the edges that should be added between vertices. Edges are introduced to reveal the causality of two execution segments and thus guide the causal path exploration. Based on the rules in Table 1, Argus annotates three types of edges: *strong*, *weak*, and *boosted weak*.

First, Argus adds strong edges by identifying Mach message, dispatch queue, time-delayed call, and data flag trace events associated with a vertex and finding the corresponding peer events and peer vertices. For Mach message events, Argus adds a strong edge from the vertex with the message send event to the vertex with its associated receive event. If a message requires a reply, the received message can produce a reply message, which can be sent by a third thread, in which case Argus adds a strong edge from the vertex with the received message event to the one with the send event for the reply message. For dispatch queue events, Argus adds a strong edge from the vertex where the callback function is pushed to a dispatch queue to the vertex where the callback function is invoked. For time-delayed calls, Argus adds a strong edge from the vertex where the timer is armed to the vertex where the callback function is fired. For shared data flags, Argus adds a strong edge from the vertex with a data flag write event to the vertex with its corresponding read event, avoiding potential under-connections.

Second, Argus adds edges by identifying thread scheduling trace events and finding the events and vertices corresponding to the pair operations. Argus adds strong edges only when the context clearly indicates causality, such as the signal and wait operations of a condition variable. Otherwise, Argus adds only weak edges. One hint Argus takes from macOS is

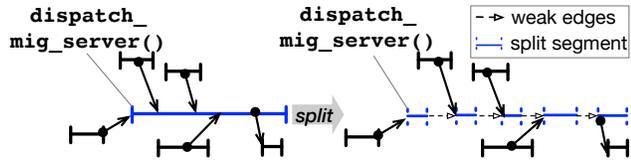

Figure 5: The segment for batch processing in `dispatch_mig_server` is split into multiple segments to distinguish different items. Weak edges are added among the split segments.

that, if a wake-up is not followed by a specific communication operation (e.g., message receive), and does not target a specific thread but all threads on the wait queue, then it is likely not causal, in which case a weak edge is added.

Third, because Argus splits the execution of a thread into segments (graph vertices) based on heuristics that may not always be valid, Argus adds weak edges between these adjacent execution segments, as shown in Figure 5. Argus converts a weak edge into a *boosted weak edge* if two continuous execution segments are on behalf of the same task. It infers whether the segments are for the same task by leveraging call stack symbols. We calculate frequencies for all symbols across the whole tracing and notice a low-frequency (bottom 10%) symbol usually only appears in a task from a specific application, compared to high-frequency symbols from system routines or framework APIs. Thus, if the two segments share the same low-frequency symbols, Argus infers they are collaborating on the same task and sets a boost flag for the weak edge between them.

However, abuse of weak edges could generate excessive false positives during diagnosis, so Argus takes advantage of high-level semantics to avoid adding unnecessary weak edges between adjacent execution segments. First, if the call stacks of two segments of a thread share no common symbols or share a recognized system library batching API, Argus does not add a weak edge between them. Second, because wait and wake-up events are mostly from system calls, Argus leverages system call semantics to determine the necessity of weak edges. For example, we find the wait event from system call `workq_kern_return` indicates an end of a task in the thread, while the wake-up event formed in `workq_kern_return` intends to acquire more worker threads for concurrent tasks in the dispatch queue. Execution segments containing such event sequences do not need bridging with weak edges. Finally, the kernel task in macOS acts as a delegate to provide service for many applications, such as I/O processing and timed delayed invocations. The kernel task threads contain execution segments beginning with a wake-up event and ending with a wait event. Each segment serves different requests and they are not causally related, so weak edges are not added between those kernel task execution segments.

6 Argus Debugger

Argus uses the constructed trace graphs to diagnose performance issues by starting with the vertex that contains the

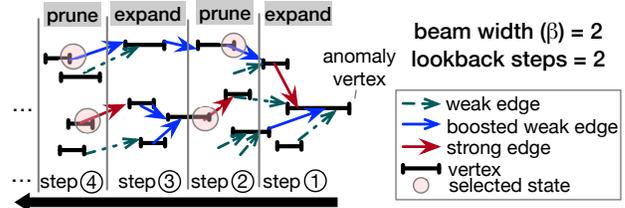

Figure 6: Beam search diagnosis algorithm. Search backwards from the anomaly vertex; choose the best β states to expand next. For every lookback steps, prune the existing states to at most β paths.

performance anomaly and traversing the graphs to identify the causal paths including the root cause vertices. The typical critical path analysis used in existing causal tracing solutions cannot effectively handle the noises in the trace graphs. Argus introduces a new diagnosis algorithm based on *beam search* to efficiently explore the causal paths likely related to the performance anomalies. It also introduces a novel subgraph comparison mechanism to find missing vertices not present in the trace graph for abnormal execution that are present in the graph for normal execution. This comparison is helpful to identify the root cause that would be otherwise unknown.

6.1 Causal Path Search—Beam Search

From a given vertex that contains the anomaly, such as the spinning cursor, Argus finds what path “caused” the anomaly by using beam search based on a cost function for annotated edges. Beam search is similar to breadth-first-search, but at each search step, it sorts the next level of graph vertices based on a cost function and only stores β —the beam width—best vertices to consider next. Argus customizes its beam search with a *lookback* scheme such that the algorithm evaluates the cost function for multiple levels of edges before pruning. Argus evaluates the vertices and prunes them with β only after the search advances the configured *lookback* steps to avoiding pruning paths with weak edges too early.

Argus’s beam search algorithm provides two key advantages. First, compared to brute-force search, beam search only explores the most promising vertices, which is essential given that trace graphs are highly complex with millions of edges; searching all paths would be too inefficient and, given graph inaccuracies, result in an overwhelming number of options to consider. Second compared to local search methods such as hill-climbing, beam search embraces more possible causal paths because it ranks partial solutions and the ranking changes during the exploration. For example, assuming strong edges are preferred to weak ones, a path with a weak edge followed by a series of strong edges is likely to get a higher ranking and be returned by beam search, but will be missed by a hill-climbing search algorithm.

Figure 6 illustrates the algorithm. It searches for causal paths *backwards* from the anomaly vertex. For each incoming edge of the current vertex, the algorithm computes the *penalty score* for the new path. At every lookback step, the search branches

Algorithm 1: Causal Path Search Algorithm (Beam Search).

Data: g - event graphs, $curVertex$ - vertex inspected in current search state, $beamWidth$ - search branches at most, $lookbackSteps$ - searching steps taken before pruning current search branches

Result: paths

```

1 Function BeamSearch( $g, curVertex, beamWidth, lookbackSteps$ ):
2    $curStates.init(curVertex)$ ;
3    $curSteps \leftarrow 0$ ;
4   while  $curStates.incoming\_edges() > 0 \ \&\& \ beamWidth > 0$  do
5      $++curSteps$ ;
6      $newStates.clear()$ ;
7     for each  $state \in curStates$  do
8       if  $beamWidth \leq 0$  then
9          $break$ ;
10      end
11      if  $state.path.reach(UI) \ || \ state.path.incoming\_edges = 0$ 
12        then
13           $paths.add(state.path)$ ;
14           $--beamWidth$ ;
15        end
16        for each  $edge \in state.path.incoming\_edges$  do
17           $newState.path \leftarrow state.path + edge$ ;
18           $newState.score \leftarrow state.score + penalty(edge.val)$ ;
19           $newStates.add(newState)$ ;
20        end
21         $curStates \leftarrow newStates$ ;
22        if  $curSteps = lookbackSteps$  then
23           $pruneStates(curStates, beamWidth)$ ;
24           $curSteps \leftarrow 0$ ;
25        end
26      end
27       $pruneStates(curStates, beamWidth)$ ;
28       $paths.append(curStates.paths)$ ;
29      return  $SortIncPenaltyScore(paths)$ ;
30 Function  $pruneStates(newStates, beamWidth)$ :
31    $SortIncPenaltyScore(newStates.paths)$ ;
32   while  $newStates.size() > beamWidth$  do
33      $newStates.pop\_back()$ ;
34   end
35   return;

```

are pruned: it sorts the paths by their penalty scores and only retains at most β paths with low penalties. A path is added to the result if a vertex is reached containing a UI event or has no incoming edges, and the beam width decreases by one. Using such vertices as for path termination helps developers understand causality in an end-to-end request handling transaction.

Algorithm 1 lists the pseudo-code of the search algorithm. Lines 16 – 18 compute penalty scores for new paths after incoming edges are added to the path. Lines 22 – 25 prune the searched branches every L lookback steps. Paths are sorted by their penalty scores and paths with high penalties are discarded. Penalty scores are calculated with a linear function on edge values, where a strong edge is -1, a weak edge is 1, and a boosted weak edge is 0. A path with n edges has a penalty $p = \sum_{i=1}^n (a \times E_i + b)$, where E_i is the i th edge value. This approach guides search towards paths with stronger causality. While more complex non-linear functions may be feasible, this simple function works well for many diagnosis cases.

The beam width setting affects the search efficiency and diagnosis accuracy. A setting too large would cause path explosion and noisy paths to be returned. A setting too small may easily miss the true causal path. We set $\beta = 5$ to strike a good balance. Tuning this parameter is relatively easy in practice. The lookback step setting is set based on observing

Algorithm 2: Subgraph Comparison Algorithm.

Data: $anomVertex$ – problematic vertex, $anomGraph$ – trace graph for anomaly case, $normGraph$ – trace graph for normal case

Result: ret- potential culprits of anomaly

```

1 Function SubGraphCompare( $anomVertex, anomGraph, normGraph$ ):
2    $ret.clear()$ ;
3    $similarVertices \leftarrow FindSimilarVertices(normGraph, anomVertex)$ ;
4    $baselineVertex \leftarrow GetBaseLine(similarVertices, anomVertex)$ ;
5    $targetVertex \leftarrow woken(normGraph, baselineVertex)$ ;
6    $causalPaths \leftarrow BeamSearch(normGraph, targetVertex, beamWidth, lookbackStep)$ ;
7   // sub-graph is constituted with paths;
8   for each  $causalPath \in causalPaths$  do
9     for each  $vertex \in causalPath$  do
10       $expectVertex \leftarrow SimilarVertex(anomGraph, vertex)$ ;
11      if  $expectVertex = \emptyset$  then
12        // missing similarity to vertex;
13         $anomThr \leftarrow SearchThread(anomGraph, vertex.thread)$ ;
14        // get the vertex that causes the dissimilar;
15         $suspVertex \leftarrow VertexInThread(anomGraph, anomThr)$ ;
16      else if  $DifferentVertices(expectVertex, vertex)$  then
17        // vertex acts different from normal case;
18         $suspVertex \leftarrow expectVertex$ ;
19      else
20         $continue$ ;
21      end
22       $ret.push\_back(suspVertex)$ ;
23    end
24    if  $!ret.empty()$  then
25       $return ret$ ;
26    end
27  end
28  return  $ret$ ;

```

that traversal of most graphs encounters a weak edge within five steps. We set $L = 5$ to tolerate weak edges. Given this setting, a path of x strong edges, y weak edges, and z boosted weak edges has a penalty of $p = -a \times (x - y) + 5 \times b$. If all edges are strong, the penalty is negative only when $b < a$. If there are weak edges, the penalty is positive only when $(x - y) \times a < 5 \times b$, where $-3 < x - y < 3$. Therefore, we set the default penalty function coefficients $a = 3$ and $b = 2$.

6.2 Subgraph Comparison

If we run causality analysis only on the trace graph constructed with the anomalous performance issue, the root cause may not be exposed in some cases. For example, a blocked function could be caused by a missing wake-up from one of the background threads. If the thread does not perform the wake-up during abnormal execution, there will be no execution segment with the wake-up, and therefore no vertex in the anomalous trace graph that can be identified correctly as the root cause. Argus addresses this problem by first constructing the trace graphs for both normal and abnormal execution. It then uses its beam search method on the normal trace graph to identify the causal paths in that graph that corresponds to the desired normal behavior that does not occur during abnormal execution. We refer to those causal paths a *subgraph*. Argus then uses the vertices in the subgraph to identify the missing root cause in the abnormal execution. This is done by introducing a novel sub-

graph comparison method between the trace graphs for both normal and abnormal execution, which is listed in Algorithm 2.

Argus first determines a baseline vertex in the normal graph that is comparable to the anomaly vertex in the anomalous graph. Argus computes a signature for each vertex based on the trace event sequence in its execution segment. The signature is composed of two parts, one that encodes the types corresponding to the event sequence e.g. 0 for IPC event, 1 for syscall event, etc., and another that is a hash of the event parameters, e.g., process names of IPC events. Argus calculates the similarity of two vertex signatures using string edit distance. Among the vertices in the normal graph that are similar to the anomaly vertex, Argus chooses one that behaves differently from the anomaly vertex, based on return values of system calls and execution times. For example, a vertex whose last event is a blocking system call with a timed wait may behave in two different ways, timing out or quickly woken up.

After Argus identifies a baseline vertex, it obtains its causal paths using Algorithm 1. The result is a subgraph of the normal trace graph rooted from the baseline vertex to some ending vertex. Argus examines the subgraph from the most related causal path. Starting with the ending vertex V , whose execution segment was executed by some thread T , Argus identifies vertices in the abnormal trace graph that were also executed by T . For each identified vertex, Argus checks whether it behaves differently from V , in which case it is flagged as a suspicious vertex. If no such vertices are found, Argus repeats this procedure with the next vertex in the subgraph. Otherwise, for each suspicious vertex that has incoming edges, Argus recursively repeats the subgraph comparison by treating the suspicious vertex as the initial anomaly vertex. The recursive procedure effectively keeps working backwards through vertices to eventually find a set of root cause candidate vertices in the anomalous trace graph with no incoming edges. Argus then returns the vertex whose path to the original anomalous vertex has the lowest penalty score, identifying that vertex as the root cause.

Figure 7 shows a simplified example of the subgraph comparison method applied to the Chromium performance issue discussed in Section 2. Vertex E' in the anomalous graph is the initial anomaly vertex. Argus identifies vertex E in the normal graph as having a similar signature but behaving differently, and treats it as a baseline vertex. Argus applies beam search to the normal graph starting with vertex E , resulting in the subgraph $A \leftarrow B \leftarrow C \leftarrow D \leftarrow E$. Argus starts with A , identifies its browser thread, and determines that A cannot be the root cause since the same browser thread contains the performance anomaly E' in the anomalous trace graph. Argus then considers B , identifies its renderer thread, and finds all vertices in the anomalous trace graph executed by the renderer thread. F' is similar to F , so it is not considered a suspicious vertex, but J' is not similar to any vertex in the normal trace graph, so it is considered suspicious. J' has no incoming edges and is identified as a root cause candidate. If there are no other candidates identified, J' is returned as the root cause.

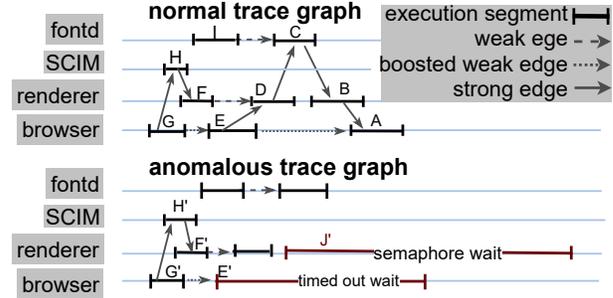

Figure 7: Chromium normal and anomalous trace graphs after user typed in a search box (vertex G/G'). Vertex E' (requesting a bounding box for input) is the anomaly vertex. Sub-graph in normal trace graph is extracted from baseline vertex E . Vertex J' (javascript processing blocks on semaphore) is the root cause Argus reported. Trace graphs are simplified for clarity; only processes are shown and communications with processes such as `imklaunchagent` are omitted.

6.3 Debug Information

Argus further provides the calling contexts of the anomaly vertex and the root cause vertex to help developers localize the bug in code. To do so, Argus examines the call stacks it attaches in the graph vertices. If the anomaly or root cause vertex has a blocking call, the call stack Argus tracer collects would reveal the context of the blocking call directly. If the vertex has a long runtime cost, the problematic vertex usually contains periodic IPIs, where the Argus tracer collects call stacks. In this case, the Argus debugger calculates the longest common sequence of frames from those call stacks. The top frame in the sequence reflects the costly function call.

For instance, in Figure 7, Argus reports the following information: (i) the calling context of problematic vertex E' and its causal path $E' \leftarrow G'$; (ii) the calling context of root cause vertex J' along with its *unmatched causal path* in baseline trace graph: $A \leftarrow B \leftarrow C \leftarrow D \leftarrow E \leftarrow G$, and vertex B is marked because its thread should have woken up the blocking thread in the anomaly case.

6.4 Diagnosis for Spinning Pinwheel in macOS

Argus's debugger can be used to effectively diagnose spinning pinwheel performance issues in macOS applications. Recall that a spinning pinwheel appears when the UI thread of an application can not process any user inputs for over two seconds. During normal execution, the two-second interval may cover many vertices, but when the spinning pinwheel appears, the main thread of the application is stalled and the two-second interval covers only a single vertex. Leveraging this timing information, Argus identifies the anomaly vertex in the main thread of the targeted application and classifies the issue as either a *LongRunning* and *LongWait* anomaly.

LongRunning. The main thread is busy performing lengthy CPU operations and therefore its execution segment is in the anomalous trace graph. Argus uses its beam search method

to identify the causal path between the anomaly vertex and the vertex with the UI event resulting in the issue. Argus reports the costly API, event handler, and causal path to the developer.

LongWait. A UI thread is blocked, but it is hard to tell why. Argus uses its subgraph comparison method together with its beam search method to deduce which vertex is missing from the anomalous trace graph. A long-wait event could be caused by another long-wait event. Argus supports recursively diagnosing “the culprit of the culprit.” Therefore, it can reveal deep root causes. At the end of each iteration of diagnosis, the calling context of problematic vertex, root cause vertices in the anomalous trace graph, and causal paths are ranked and reported to users.

Some LongRunning issues may be diagnosed with existing tools such as `spindump` if the profiling is accurate and complete. However, Argus is better in that a call stack is usually not enough to connect the busy processing to the event handler, due to the prevalence of asynchronous calls. Also, call stack profiles after the anomaly may miss the real costly operations. LongWait issues usually involve multiple components and are extremely hard to understand and fix with current tools. Those issues may remain unresolved for years and significantly hurt user experience and developer productivity.

7 Evaluation

We have implemented Argus across multiple versions of macOS, ranging from El Capitan to Catalina. We evaluate Argus to answer several key research questions: (1) Can Argus effectively diagnose real-world performance anomalies for modern desktop applications? (2) How does Argus compare to other performance debugging tools? (3) How useful are Argus’s weak edges and their optimizations in mitigating tracing inaccuracies? (4) How much overhead does Argus’s tracing tool incur? Unless otherwise indicated, all applications and tools were run on a MacBookPro12,1 with an Intel Core i7 CPU, 16 GB RAM, and an APPLE SM0512G SSD.

7.1 Diagnosis Effectiveness

We evaluated Argus on 12 real-world user-reported performance issues in 11 popular desktop applications, which we collected and reproduced, as listed in Table 2. We are especially interested in evaluating performance issues that have been hard to troubleshoot. Except for B11, all of these are open issues, meaning their root causes were previously unknown to developers. For B2, the reported issue was “fixed” in the latest version (due to refactoring or platform upgrade) but the root cause remained unknown. Nine applications, or some of their components, have source code available, whereas two applications are closed-source. Source code was used to validate whether the correct root cause was diagnosed for the performance issues, but all evaluation was performed on the released application binaries. We have also used

ID	App	Performance Issue	Age
B1	Chromium	Typing non-English in searchbox, page freezes.	7 yr
B2	TeXstudio	Modifying Bib file in other app gets pinwheel.	2 yr
B3	BiglyBT	Launching BiglyBT installer gets pinwheel.	1 yr
B4	Sequel Pro	Reconnection via ssh causes freeze.	4 yr
B5	Quiver	Pasting a section from webpage as a list freezes.	5 yr
B6	Firefox	Connection to printer takes a long time.	1 mo
B7	Firefox	Some website triggers pinwheel in the DevTool.	3 yr
B8	Alacrity	Unresponsive after a long line rendering.	6 mo
B9	Inkscape	Zoom in/out shapes causes intermittent freeze.	1 yr
B10	VLC	Quick quit after playlist click causes freeze.	7 mo
B11	QEMU	Unable to launch on macOS Catalina.	1 mo
B12	Octave	Script editing in GUI gets pinwheel.	2 yr

Table 2: Real-world performance issues in macOS applications.

Argus with proprietary applications like Microsoft Word for macOS, but without source code, we need to wait for vendors’ confirmation and responses; in our experience, vendors are reluctant to communicate issues with an external party.

Table 3 shows that Argus was able to diagnose all 12 performance issues, including all longstanding open issues. As listed in Table 4, we checked the correctness of Argus’s diagnosed root causes in three ways: (1) inspecting the corresponding source code if available, (2) dynamic patching with `lldb` based on the diagnosed root cause to fix the problem, and (3) confirmation by developers. The last one is ideal, but not always feasible; we reported our findings to developers for seven issues, but only received two responses. Only the root cause of B11 was previously known, which Argus returned correctly (Grd). For B1, B7, and B10, we validated the diagnosed root causes by analyzing the source code (Src). For B2 and B4, we received confirmation from the respective application developers that Argus correctly diagnosed the root cause for these open issues [8, 9] (Dev). For example, for B4, the Sequel Pro developers suspected a particular Cocoa Framework API does not work as expected, but could not pinpoint the exact place to fix it. Argus determined the defect was in their installed callback function, and we submitted a pull request [8] to fix the issue. B8 was fixed in an official developer patch after we reported the root cause (Fix). For the remaining issues, we confirmed the issue was resolved by dynamically patching the application based on the root cause (Dyn). We describe a few of the performance issues in further detail, but omit others due to space constraints.

B1-Chromium: This is the Chromium performance issue discussed in Section 2. Argus analyzes the trace graph, pinpoints the circular waits between renderer main thread and browser main thread with the interactions of daemon processes like `fontd`. Argus not only localizes the problematic execution segment (waiting on a condition variable), but also the sequence of events leading to this issue. The same issue occurs in Chrome. We also reported our findings to Chrome developers, but received no reply.

B2-TeXstudio: TeXstudio [55] is an IDE for creating LaTeX documents. Users reported when they modified a bibliography

ID	Root Cause Identified
B1	circular wait between renderer and browser main threads.
B2	long running function calculating line indices in document.
B3	recursive invocations of accessible objects in GUI.
B4	UI event loop mishandling input causes deadlock with ssh.
B5	paragraph value never equals last paragraph inside web view.
B6	sleep waiting on chain of daemons, the last being nsurlsessiond.
B7	excessive garbage collection on the main thread.
B8	excessive copy of rendering cells when searching potential URL.
B9	excessive memory operations for trimming and compositing.
B10	termination signal before displaying thread ready; deadlocks.
B11	window adjustment before it finishes launching; deadlocks.
B12	readline thread writing tty repeatedly, main thread waiting.

Table 3: Root causes identified by Argus.

file with another application, TeXstudio froze with a spinning pinwheel. We reproduced this case by running `touch` from a terminal on a 500 entry bibliography file, which immediately caused a spinning pinwheel to appear in *TeXstudio*'s window. Argus analyzes the trace graph and identifies five causal paths, ordered by likelihood of causality. The first path connects multiple entities: `Terminal`→`WindowServer`→`bash`→`kernel_task`→`fseventd`→`TeXstudio`—and suggests the following root cause chain. `touch` triggers a change in the file metadata. `fseventd` notifies `TeXstudio` and invokes a callback handler. `TeXstudio` executes a function `QDocument::startChunkLoading`, and causes busy processing in `TeXstudio`'s main thread. Argus also outputs the call stack with the busy APIs, `startChunkLoading` and `QDocumentPrivate::indexOf()`. We reported our findings to the developers and received confirmation that the diagnosis is correct.

B5-Quiver: *Quiver* [7] is a closed-source notebook application for mixing text, code, Markdown, LaTeX, etc. Users report that applying bullet points to a text cell without an empty line at bottom causes a spinning pinwheel [6]. Based on the Argus trace graph, there is a hanging vertex in the WebKit component used by Quiver. In particular, WebKit hangs in executing `InsertListCommand::doApply` when applying the list command to the Webview context from Quiver. The hang occurs because of an infinite loop bug in WebKit rather than Quiver. We verified the root cause by changing the comparison result of the loop with `lldb`, which enables Quiver to display the bulletin points without a spinning pinwheel. We reported our findings to the developers, but received no reply.

7.2 Comparing with Other Approaches

We compared Argus versus other state-of-the-art tools for diagnosing the performance issues in Table 2. We used two widely-used traditional debugging and profiling tools from Apple, `spindump` [10] and `Instruments` [12]. For `spindump`, we enable it once the performance issue appears, and repeat the process five times to eliminate bias on the start timing.

	B1	B2	B3	B4	B5	B6	B7	B8	B9	B10	B11	B12
<code>spind.@top1</code>	X	X	X	X	X	X	X	X	X	X	✓	X

Argus result validation Src Dev Dyn Dev Dyn Src Fix Dyn Src Grd Dyn

Table 4: Comparing Argus with other debugging tools.

`spindump` separately ranks the symbols from all sampled call stacks and only the top of call stacks. We examined the top N symbols and their corresponding call stack information. For `Instruments`, we enable its time profiler in the background when reproducing the bugs, and analyze its data from two seconds before the performance issue occurs to three seconds after. We rank APIs in the reported call trees with CPU time percentage and filter out system routines. Then, we select the top N APIs for investigation. We used values from $N = 1$ to $N = 10$. We also used two causal tracing tools, the macOS version of `Panappticon`, as discussed in Section 2, and `AppInsight` [40]. Since `AppInsight` was originally built for Windows, we reimplemented a version for macOS which captures trace events, constructs trace graphs, and follows the path analysing rules for diagnosis according to `AppInsight`'s design.

Table 4 shows the results for using the different tools, including the results for Argus discussed in Section 7.1; checks indicate correct root cause diagnosis. All of the other tools diagnosed much fewer performance issues than Argus. `spindump` diagnosed at most five issues. It captures the state near the symptom point but cannot deduce how the execution reaches a problematic point, especially in the presence of highly concurrent and asynchronous execution across different entities. `Instruments` diagnosed at most four issues. It only outputs the most costly functions, which are helpful for performance optimizations but may not be for troubleshooting specific performance issues. Neither of the causal tracing tools did any better because the constructed trace graphs are highly inaccurate. `AppInsight` only diagnosed two issues while `Panappticon` diagnosed four issues.

7.3 Mitigation of Trace Graph Inaccuracies

We evaluated the effectiveness of Argus in mitigating trace graph inaccuracies in diagnosing the performance issues in Table 2. Table 4 shows the benefits of weak edges and Beam

	Events	Vertices	Edges		
			Total	Strong	Weak
Max	12.3M	1.68M	1.62M	751.3K	864.6K
Min	260.8K	15.1K	25.5K	17.5K	8.01K
Mean	3.31M	349.5K	358.4K	188.8K	169.6K
Med	1.02M	97.3K	172.6K	111.9K	60.71K

Table 5: Argus trace graph statistics.

search. Argus diagnoses eight issues if it discards weak edges (no weak edges), and seven issues if it uses traditional critical path analysis instead of Beam search (w/critical path). In both cases, Argus still performs better than other tools.

Table 5 shows that the Argus trace graphs include hundreds of thousands to millions of events, and on average have 350K vertices and up to 1.68M vertices. Graphs are in general dense, with an average of 358K edges. A significant percentage, 40% on average, of the edges are tagged as weak edges. To avoid abusing weak edges and overwhelming the diagnosis, Argus applies the optimizations discussed in Section 5. Figure 10 shows the percentages of potential weak edges that Argus excludes from the trace graph for different techniques: call stack similarity, wait on end of task in a thread, acquire worker threads, and kernel task delegate. Call stack similarity was most effective in pruning potential weak edges.

We evaluated the sensitivity of Argus’s beam search settings: beam width, lookback steps, and penalty function coefficients a and b . Figure 9 shows the number of diagnosed issues when changing one setting and leaving the rest at their defaults. The settings for beam width and lookback steps are robust. Larger settings increase the diagnosis effectiveness, but if they are too large, the Argus debugger could run out of memory or time out for large trace graphs. Changing penalty function coefficients can significantly change the number of diagnosed issues. In general, small coefficients from two to four are better. Overall, the results indicate that Argus is practical, and developers do not need to spend much effort to tune search settings.

7.4 Performance

We measured the time to run the Argus grapher and debugger for diagnosing each of the performance issues in Table 2. Figure 8 shows the time varies for different issues, ranging from 49 s (B12) to 9870 s (B1). Constructing the trace graph is the dominant cost. Running the beam search diagnosis algorithm on the graph is fast, taking at most 144 s (B10).

We also measured the overhead of the Argus tracer using various CPU, memory, and I/O benchmarks running on a live deployment of Argus on a MacBookPro9,2 with an Intel Core i5-3210M CPU, 10 GB RAM, and a 1 TB SSD. We first measured five runs of the iBench Cocoa benchmark [35], with and without Argus, to measure overall performance. The reported scores were 6.14 with 0.027 standard error without Argus trac-

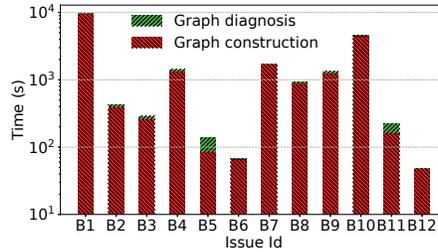

Figure 8: Argus diagnosis time.

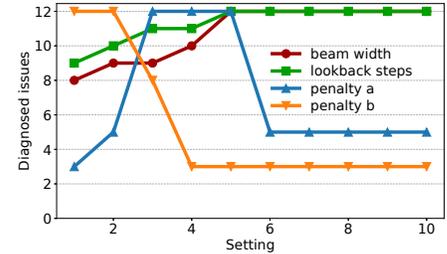

Figure 9: Sensitivity of beam search settings.

ing and 6.13 with 0.025 standard error with Argus tracing enabled. Argus only has a 0.16% performance degradation on average. In comparison, with Instruments, the reported score was 6.04, showing a 1.6% performance degradation. We next ran the Chromium Catapult benchmarks [1] to evaluate CPU performance, with and without Argus tracing. Figure 11 shows that Argus overhead is less than 5%. The average overhead for real and user time was 3.36% and 2.15%, respectively. sys overhead was higher because Argus tracing in libraries involves crossing the user-kernel boundary. Finally, we ran Bonnie++ [22] and IOzone [19] I/O benchmarks to evaluate I/O performance, with and without Argus tracing. Figure 12 shows the I/O throughput measurements. Argus tracing has almost no overhead for sequential character read and write operations and less than 10% overhead for block read and write operations.

8 Discussion and Limitations

Diagnosis in Argus may require the anomalous execution trace as well as the normal one for comparison. Obtaining the latter is not difficult. Persistent performance problems are typically eliminated before release, so the remaining issues are often non-deterministic, only occur with specific input events (e.g., typing special characters), and disappear with other events.

The quality of the Argus diagnosis results is affected by edge annotation accuracy. Beam search helps tolerate errors by inspecting multiple paths, but its settings can affect diagnosis effectiveness, as discussed in Section 6.

Argus addresses performance issues that are reflected in the underlying execution sequences and CPU time. It does not handle performance issues due to contentions among userspace threads or incorrect settings of UI elements.

Argus supports closed-source applications and libraries, but its tracing infrastructure requires slight source-level kernel modifications. System libraries such as CoreFoundation are patched at the binary level. Binary instrumentation could also be used to implement kernel changes, but is more cumbersome. Vendors of proprietary OSes have incentives to enhance their existing tracing mechanisms, and may conceivably adopt Argus kernel modifications.

We have not yet ported Argus to other OSes, but modern OSes share many similarities and provide tracing facilities that can support Argus, such as ETW [39] in Windows and LTTng in Linux [4]. Therefore, we are hopeful that our ideas are generally applicable to other OSes.

9 Related Work

Many causal tracing solutions have been proposed for networked and distributed systems, including Magpie [14], XTrace [27], Dapper [44], and Pivot Tracing [38]. These systems typically attach metadata to each request, propagate the metadata to all components, and stitch the traces. This approach assumes (1) the system is composed of white-box components that can be easily modified; (2) these components communicate in uniform interfaces. Neither assumption is true for desktop systems. Magpie [14] does not use metadata propagation but assumes a manual schema to extract and join events from different components’ logs. The extracted traces are limited by what each component chooses to log. However, desktop components typically are packaged as release builds that only log critical events, and logging practices among components vary greatly, which makes writing uniform schema difficult, time-consuming, and fragile.

Some causal tracing tools have been developed for mobile applications. AppInsight [40] interposes on the interface between applications and Windows Mobile frameworks and assumes that applications follow the event callback programming idiom. Panappticon [56] traces low-level events in Android and assumes two asynchronous programming idioms, message queue and thread pooling. Neither of these approaches is effective for desktop applications such as those in macOS.

Profiling or static code analysis are typically ineffective for detecting performance issues [23, 34]. Several solutions [29, 54] detect performance anomalies by leveraging logs and call stacks. Other works [21, 24, 42, 50] apply machine learning methods to identify anomalous events. Yu *et al.* [52] study the performance impact of Windows device drivers in real-world execution traces and propose to extract wait graphs from the execution traces. Several solutions [15–17] infer models from logs for distributed and concurrent systems, and use them to automate the detection of anomalous behavior when systems are exposed to new workloads and environments. These systems are orthogonal to Argus, as Argus’s goal is to diagnose an already-detected performance anomaly.

Argus is complementary to the work on concurrency bugs and race detection [18, 25, 26, 33, 36, 47, 48, 51, 53]. The former typically checks one (server) program, while Argus targets desktop applications where the defect often involves user inter-

action events, daemons, external frameworks or other applications. The latter usually focuses on testing and eliminating bugs before software is released, while Argus focuses on helping developers diagnose performance issues in the wild. Argus also addresses performance issues caused by other types of bugs.

10 Conclusions and Future Work

Argus is the first comprehensive causal tracing system to diagnose performance anomalies in complex desktop applications. We observe that although causal tracing is powerful and extensively studied in distributed systems, it is brittle when applied to desktop systems due to inherent tracing inaccuracies. Argus addresses this problem by introducing annotated trace graphs with strong and weak edges to account for these inaccuracies. Argus pairs annotated trace graphs with a novel beam search diagnosis algorithm and subgraph comparison mechanism to determine causal paths in the presence of these inaccuracies. We have implemented Argus across multiple versions of macOS and evaluated its effectiveness on complex desktop applications. Argus successfully pinpoints the root causes for 12 real-world performance issues in these applications, many of which had remained open for several years. Argus imposes less than 5% CPU overhead, making it fast enough for regular use.

We believe Argus’s strong and weak edge notions and inaccuracy-tolerant diagnosis algorithm may extend beyond the scope of desktop systems. In causal tracing of distributed systems, many solutions assume systems are perfectly instrumented, but in practice this is not the case. We plan to explore using Argus’s techniques in the context of distributed systems as an area of future work.

Abstract

Graph processing is an invaluable tool for data analytics. In particular, pattern-matching queries enable flexible graph exploration and analysis, similar to what SQL provides for relational databases. Graph queries focus on following connections in the data; they are a challenging workload because even seemingly trivial queries can easily produce billions of intermediate results and irregular data access patterns.

In this paper, we introduce aDFS: A distributed graph-querying system that can process practically any query fully in memory, while maintaining bounded runtime memory consumption. To achieve this behavior, aDFS relies on (i) almost depth-first (aDFS) graph exploration with some breadth-first characteristics for performance, and (ii) non-blocking dispatching of intermediate results to remote edges. We evaluate aDFS against state-of-the-art graph-querying (Neo4J and GraphFrames for Apache Spark), graph-mining (G-Miner, Fractal, and Peregrine), as well as dataflow joins (BiGJoin), and show that aDFS significantly outperforms prior work on a diverse selection of workloads.

1 Introduction

Graph processing is a very active area of research, with a plethora of prior work focusing on classic graph algorithms [35, 36, 38, 48, 53, 58, 61, 62, 82, 85], graph mining [27, 29, 32, 34, 42, 54, 69, 74, 77], as well as graph querying [1, 3, 8, 10, 12, 18, 31, 86] and graph-query languages [4, 5, 11, 14, 17]. Graph algorithms (such as PageRank [57]) are typically used in batch computations, while graph mining is used to extract structural properties and compute cumulative statistics of a graph by exploring its subgraph structures.

Graph queries are a key tool for graph analysis, as indicated by the large number of existing systems and graph-query languages. Graph queries provide an expressive interface for interactive graph exploration with rich dynamic projection and filtering support that is analogous to SQL for relational databases (see Section 5 for further details). They focus on data connections, i.e., edges, allowing users to submit queries

with any pattern, filter, or projection. For instance, the following PGQL [14] query:

```
SELECT a1.name, a2.name, a1.country = a2.country,  
       ABS(a1.salary - a2.salary) AS salary_diff  
MATCH (a1:author)-[:likes]->(a2:author),  
       (a2)-[:likes]->(a1)  
WHERE ABS(a1.age - a2.age) <= 10  
ORDER BY salary_diff DESC
```

enumerates the authors of similar age that like each other. Answering such a query requires finding all homomorphic [45] matches of the query pattern in the target graph, while enforcing filters (e.g., `a1 IS author`) and projecting the requested output (e.g., `whether a1.country = a2.country`).

The dynamic user-defined patterns, filters, and projections, the focus on edges, and the homomorphic matching make graph query execution a challenging workload that needs to handle very large intermediate and final result sets, with a combinatorial explosion effect. For example, on the well-researched Twitter graph [47], the single-edge query `(a) -> (b)` matches the whole graph, amounting to 1.4 billion results, and the two-edge query `(a) -> (b) -> (c)` amounts to 9.3 trillion matches. This means matching the `(a) -> (b) -> (c) -> (a)` cycle needs to consider 9.3 trillion intermediate results. Compared to relational queries, graph queries can exhibit extremely irregular access patterns [51, 63] and lack of spatial locality, while calling for low-latency data access.

High-performance graph-querying systems ideally need to (i) keep the computation in main memory to guarantee low latency, (ii) scale out to multiple machines in a distributed manner to handle graphs and queries that exceed the capacity of a single machine, and (iii) control their memory usage at the machine level. Controlling memory consumption during query execution becomes paramount for cloud graph-processing services, in which multiple users submit queries that produce results of unpredictable size. Allowing a single query to monopolize memory would hinder service quality for users running other queries.

Query execution on graphs is typically based on one of the two classic graph-traversal strategies: Breadth-first search (BFS) or depth-first search (DFS). Both BFS and DFS have major advantages and drawbacks for distributed graph queries:

BFS traversals are easier to parallelize but, as with distributed joins, suffer from explosion in the size of intermediate results, cannot be easily pipelined, and stress the network bandwidth to shuffle data across levels of pattern matching. DFS traversals reduce the size of intermediate results, but are challenging to parallelize and result in random data access patterns, wasting locality when iterating over neighbors.

In this paper, we introduce aDFS (almost-DFS): A novel distributed graph-querying system that brings the best of both DFS/BFS worlds. aDFS extends the graph-processing capabilities of PGX.D [39] with queries and processes graphs partitioned across multiple machines *fully in memory*, combining BFS and DFS traversals to *bound the maximum amount of memory* required for query execution, while achieving a *high degree of parallelism*. DFS, together with a distributed flow-control mechanism, guarantee that the amount of runtime memory remains within limits, while the BFS exploration allows for better locality and parallelization during execution.

Worker threads in aDFS mainly prioritize DFS execution for completing—and thus freeing—intermediate results. The execution switches to BFS when matching a remote edge (i.e., an edge pointing to a remote machine) or when the runtime detects that the query contains limited parallelism (i.e., a small set of intermediate results). To elaborate, for local edges, worker threads perform DFS, unless aDFS detects that there is a limited amount of available work on the local machine, in which case they switch to per-thread BFS exploration until there is enough parallelism. For remote edges, threads buffer the matched intermediate results and continue with matching the next edge in a BFS manner (i.e., the next edge is possibly at the same depth as the current one). Once a buffer is full, the worker thread sends its contents to the target machine, unless it is blocked by the flow-control mechanism, which enforces target memory limits. Section 3 expands on the design and implementation of aDFS.

Section 4 thoroughly evaluates aDFS and shows that it is capable of executing trillion-scale queries, with a 10GB per-machine runtime memory cap. When running our largest query, aDFS computes a 9.3 trillion count pattern on the Twitter graph with a rate of 7.3 billion matches per second. We compare aDFS to two graph systems (i.e., Apache Spark GraphFrames [31] and Neo4j [10]) and two relational databases (i.e., MonetDB [9] and PostgreSQL [15]) using the LDBC graph and query suite [68]. aDFS completes the set of queries 43 and 53 times faster than GraphFrames and Neo4j,¹ respectively, and 8 and 26 times faster than MonetDB and PostgreSQL, respectively (as Section 4.2 shows, LDBC is “relational-friendly”). We also compare aDFS to these four systems with schema-less graphs and show that either aDFS is 16 to 9,200 times faster than the rest, or the other systems simply fail to complete the queries. Finally, we compare aDFS with (i) three state-of-the-art graph-mining systems: G-Miner [27], Fractal [32] and Peregrine [42], as well as (ii) BiGJoin [19], a dataflow join system. We show

that aDFS is up to 12, 625, and 18 times faster than G-Miner, Fractal and Peregrine, respectively, and performs comparably to BiGJoin on mining-oriented workloads. We discuss related work further in Section 5.

The main contributions of this paper are the following:

- aDFS, which is, to the best of our knowledge, the first graph-querying system that strictly bounds runtime memory while operating with fully-distributed computations over partitioned graphs;
- The novel combination of DFS (for eager completion of intermediate results), BFS (for performance), and flow control (for controlling the size of the intermediate state) to achieve performance and scalability while capping memory usage; and
- The evaluation of aDFS, which shows that aDFS significantly outperforms the state of the art and is capable of executing queries with trillions of matches.

2 Background and Motivation

Representing data as a graph is becoming increasingly popular. The main advantage of graphs is that they focus on modeling fine-grained relationships between entities. In contrast, the relational model concentrates more on rows and relies on the heavyweight primary-key foreign-key (PK-FK) and join mechanisms to link entities. However, when using graphs, different models, data representations, and ways of exploring them have a major effect on processing performance.

2.1 The Property Graph (PG) Model

Property graphs represent the graph topology as vertices and edges, and store *properties* and *labels* separately. Properties can be associated to any vertex or edge and take the form of typed key-value pairs. Labels are key-only and represent types or categories, e.g., *person* or *animal*. Separating the topology from properties avoids the proliferation of edges and allows for quick traversals of the graph over its real structure.

2.2 Graph Pattern-Matching Queries

Several languages for graph querying exist, such as PGQL [14], SPARQL [17], Gremlin [5], and Cypher [11]. In its simplest form, graph querying makes it possible to find patterns in graphs, with filters and projections. aDFS uses PGQL, which is modeled after SQL: Projection and aggregation operations are the same as in SQL, including `GROUP BY` and `ORDER BY`. PGQL adds support for graph patterns and vertex and edge labels. For example, the query presented in Section 1 adds the `MATCH` clause to an otherwise valid SQL query. It matches patterns that are *homomorphic* [45] to the `(a1) -> (a2) -> (a1)` cycle while enforcing filters (e.g., `a1` has label `author`), and it projects or aggregates the requested data—including even arbitrary expressions—out of the matched vertices and edges.

Graph queries require homomorphic matching of the pattern, as data is projected out of all matches, even if they are permutations of each other. In contrast, graph-mining systems

¹Using Neo4j Community Edition (benchmarks not audited by Neo4j).

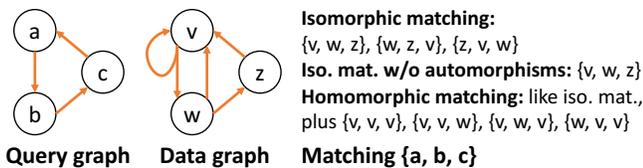

Figure 1: Homomorphic vs. isomorphic matching of a pattern.

focus on *isomorphic matching* [34] and often use automorphism elimination to prune the search space further. Figure 1 highlights the differences between isomorphic and homomorphic matching of a query pattern. In graph queries, isomorphic matching and automorphism elimination can be simulated with filters and/or with query specifiers, such as `GROUP BY`.

In this work, we focus on the backbone of graph pattern-matching queries. Accordingly, aDFS only supports a subset of PGQL 1.1 [14]; in particular, two following features are missing: Regular path expressions and subqueries. Nevertheless, we design aDFS with these features in mind and we intend to work on them in future work.

2.3 Graphs vs. Relational Joins and RDF

In PG graph systems, edges are stored explicitly and can be traversed directly. In contrast, in relational databases, relationships are represented with PK-FK. Following any relationship means joining two tables—or doing a self-join if the keys belong to the same table—and producing the intermediate result. Therefore, while matching multiple-hop paths is a relatively cheap operation in graph systems, doing the same in SQL requires a chain of multiple expensive join operations that materialize intermediate results. Thus, graph systems can be much more efficient than relational databases when it comes to matching graph patterns (see Section 4 for a comparison).

Another alternative model is the Resource Description Framework (RDF) that uses $\{subject, predicate, object\}$ triples to represent graphs, which can be queried with languages such as SPARQL [17]. RDF became popular with the semantic web [21] and has been the model of choice for many graph databases starting in the early 2000s [37, 80]. A number of works have focused on distributed RDF graphs [40, 64].

Although the RDF model is equivalent to PG in terms of expressiveness, there are differences: (i) RDF adds links for every graph data piece, including constant literals, (ii) it does not have explicit vertices/edges—yet it can be viewed as representing graphs, and (iii) it does not store properties separately. The de-facto implementation of RDF triples results in similar PK-FK behavior as aforementioned for relational databases. Triples force RDF systems to process and join a much larger number of intermediate results using e.g., a key-value-style storage, and lose the graph structure, resulting in slower neighbor lookup. To address these drawbacks, some RDF systems use asynchronous processing [37], or compute graph indices, using e.g., the CSR representation, to mock the graph structure [80]. aDFS focuses on PGQL queries and the

PG model, avoiding complex and expensive joins. We note that the pattern-matching part of query execution is largely orthogonal to the graph model and aDFS’s techniques could be used for RDF graphs.

2.4 DFS, BFS, and Intersections for Graph Exploration

DFS can expand one intermediate result at a time, starting from the first variable in the pattern and continuing to the next ones until the whole pattern is matched. However, this behavior results in totally random accesses and is impractical for distributed graph traversals: The only way to continue with strict DFS is to directly send the intermediate result to the remote machine and wait until it is picked up and completed.

Thus, graph exploration is traditionally done using BFS: For each query edge (hop), the entire result set is computed, and only then does the exploration of the next hop start. This approach has two main advantages: (i) it is easy to implement, as work is naturally divided into simple steps (hops), and (ii) it is relatively easy to parallelize, as the entire input is known before processing a hop (of course, skewed vertex degrees still pose a problem). However, BFS has one major shortcoming: Because the intermediate result set is produced between stages, an intermediate result-set explosion can quickly occur.

Figure 2 illustrates this issue showing the average total per-machine memory usage and execution time when matching cycles of various lengths using aDFS and BFS (implemented in our runtime) on a small graph [16] (875K vertices and 5.1M edges). While both approaches are able to match cycles of length one to four with similar performance, the memory consumption of BFS explodes for five-hop cycles at approximately 60GB on each of the eight machines in the experiment, and BFS crashes with six-hop cycles after 96 minutes when one machine runs out of memory (~768GB). Meanwhile, the memory consumption of aDFS is almost constant.

Recent graph-mining and graph-querying systems [22, 42] adopt a pattern-matching approach that relies on intersecting neighborhood lists. Instead of being vertex-centric (i.e., starting from vertices and following edges), the intersection-based approach focuses on edges. The benefit of the intersection-based model is that it takes $O(|V|)$ steps since it allows intersecting multiple incoming edges at a time, as compared to the vertex-based approaches that are $O(|E|)$. However, intersections require complete subgraph parts to operate. This necessitates pulling/gathering possibly large amounts of data from remote machines. To make things worse, queries enumerate all automorphisms (i.e., the exploration space could locally explode) and offer arbitrary user filters and projections, meaning that in an intersection-based model, one would need to pull not only the vertex/edge data, but also all the properties required by the query. Therefore, we use a vertex-centric approach in aDFS that builds mini-frontiers based on the first query vertex and enables aDFS to operate on fully partitioned graphs with limited memory.

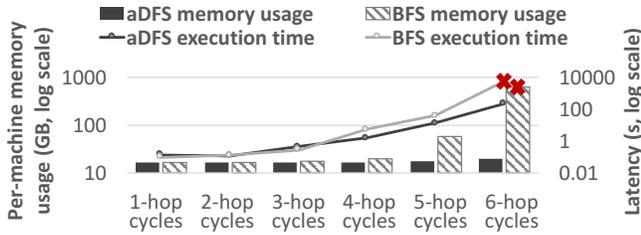

Figure 2: Matching cycles using aDFS vs. BFS.

3 aDFS: A Pattern Matching and Querying System for Distributed Graphs

The main design goals of aDFS are (i) enabling fast, fully in-memory distributed queries of any size, while (ii) allowing for limited, controllable memory consumption during execution. The rationale for these two goals is as follows. First, high-performance graph queries demand in-memory execution and the ever-increasing size of data calls for distribution. Second, server systems, especially in cloud deployments, are shared by multiple concurrent users, hence no single query can be permitted to saturate the system memory. aDFS achieves these two goals through the following design principles.

1. **§3.3: DFS-first and asynchronous communication.**

The eager match completion of DFS gives aDFS fine-grained control on the size of intermediate results during query execution, but strict DFS would be inefficient when matching a remote edge, i.e., an edge that leads to a remote machine. For that reason, worker threads do not block when encountering a remote edge, but place the intermediate result in a message buffer and continue with other local work instead. Buffers batch intermediate results: once full, a buffer’s contents are asynchronously sent to the remote machine for further processing. Threads only need to block if flow control dictates so. This buffering results in essentially BFS exploration of the remote edges of a vertex.

2. **§3.4: Flow control.** Cross-machine communication is controlled through a flow-control mechanism that caps the number of in-flight intermediate result buffers. The finite nature of these message buffers allows strictly configuring the amount of runtime memory that aDFS requires, while the flow-control mechanism guarantees query termination and deadlock freedom.

3. **§3.5: Dynamic local DFS/BFS.** Besides the BFS style of buffering for remote edges, aDFS includes a dynamic approach for deciding whether to go DFS or expand with BFS for local matches in order to improve parallelism, locality, and work sharing across threads.

Before diving into these design principles, we first present the architecture of aDFS from a high-level point of view (Section 3.1) and describe how aDFS generates execution plans for graph queries (Section 3.2).

3.1 High-Level aDFS Architecture

Figure 4 shows the high-level architecture of aDFS. Graphs are kept in memory and are partitioned across machines based on simple random vertex partitioning. Random partitioning achieves cross-machine balance and does not overfit to the workload. Of course, intelligent partitioning schemes could bring performance benefits and are left for future work. aDFS’s approach is orthogonal to partitioning, i.e., it can work with any partitioning approach.

For efficient traversals, graphs are stored in the classic CSR (Compressed Sparse Row) graph format. Due to graph partitioning, messaging is necessary for moving intermediate results to the machine which holds the target vertex. aDFS maintains two threads on dedicated cores on each machine for messaging; a sender and a receiver. Consequently, worker threads in aDFS place their messages in software queues, from where they are picked up by the sender.

3.2 Distributed Query Execution Planning

Users submit declarative PGQL queries [14] to aDFS. As Figure 3 illustrates, each query goes through three transformation steps (marked i through iii) before being executed in step iv.

Step i: Logical query planner. The first step translates the PGQL query into a logical query plan, which consists of the logical operators of Table 1. Similar to relational query planning, a given query can be executed by multiple logical query plans. In the example of Figure 3, an alternative plan could rewrite the query as $(a) - [e] - (c) \rightarrow (a) \rightarrow (b)$. This first step directly translates the query to an admissible plan, which is then optimized in the following steps.

Step ii: Distributed query planner and optimizer. This step specializes the logical query plan by taking into account the specific characteristics of aDFS’s runtime. The query planner rewrites the logical plan in terms of *stages* and transitions from one stage to another (called *hops*). A stage is responsible for matching or accessing exactly one vertex and contains all the information necessary for matching the corresponding vertex and for transitioning to the next vertex with a hop. In the example of Figure 3, the topmost stage “a” matches the first vertex a of the query, while the next one matches b. An out-neighbor hop takes the execution from a to b.

aDFS supports four types of hops that specialize for distributed execution: *neighbor match*, *edge match*, *output*, and *inspection*. Neighbor and edge hops have the same behavior as the corresponding logical operators in Table 1. An *output* hop produces a final match using the current intermediate result and is always used in the last stage of a match.

Inspection hops are specific to distributed processing: They bring the current intermediate result back to an already matched vertex in order to continue query evaluation. In the example of Figure 3, after matching a and b of $(a) \rightarrow (b)$, the query again needs the neighbor list of the already matched vertex a in order to continue with matching $(a) \leftarrow (c)$. Since the matched vertex b might be in a different machine than a,

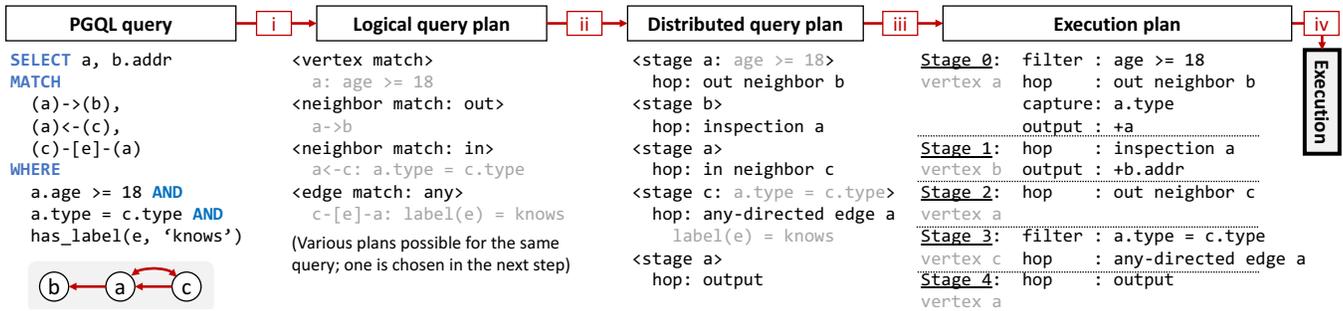

Figure 3: From a PGQL query to aDFS execution. Three transformation steps before execution.

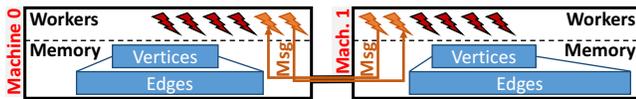

Figure 4: High-level architecture of aDFS.

the query planner introduces an inspection step to “link” this disconnected pattern and bring back the context to the machine of a . If a resides in the current machine, an inspection hop is essentially a no-op.

In this step, aDFS rewrites the logical query plan with a cost-based optimizer, implemented using dynamic programming, that is based on the following heuristics: (i) heavily filtered vertices are preferred for the earlier stages of the plan, (ii) inspection hops are not free and increase the plan’s cost, and (iii) the cost of an edge hop is approximately \log of the cost of a neighbor hop, as it can be implemented with a binary search in the neighbor list of the source vertex. The optimizer further detects whether a query has a single starting vertex, by extracting ID equality filters (e.g., $ID(\text{person}) = 123$). In the example of Figure 3, the optimizer rewrites the query as $(a) - [e] - (c) \rightarrow (a) \rightarrow (b)$ because it avoids an inspection hop and a and e are more filtered as compared to b .

Steps iii–iv: Execution plan and execution. Finally, aDFS generates a concrete execution plan. Apart from stages and hops, the execution plan contains filters (on vertices and edges), as well as information on what data should be included in the intermediate results in order to execute filters of later stages and produce the final output. For example, in the query of Figure 3, Stage 0 must collect $a.type$, since it is

Op.	Example	Short description
Vertex match	(x)	Match vertices of the graph (without following any edge)
Neighbor match	$(x) \rightarrow (y)$	Having matched the left vertex x , match its neighbors y ; can be in-, out-, or any-directional
Edge match	$(x) \rightarrow \dots$ $(y) \rightarrow (x)$	The vertex x is known (already visited)—test whether x exists in the neighbor list of the left vertex y ; can be in-, out-, or any-directional

Table 1: Graph operators used in the logical query plan.

required by the filter of Stage 3. Similarly, Stage 0 must put vertex a in the intermediate result as it is part of the projection of the query. Overall, each stage builds up the intermediate result such that another thread, local or remote, can pick it up and continue the computation. The resulting execution plan is then submitted to the aDFS runtime, on which we focus next.

3.3 aDFS’s Depth-First Runtime

The runtime of aDFS is based on the *stage* and *hop* constructs described above. aDFS initiates query execution by applying Stage 0 (matching of the first vertex variable of the execution plan) to each vertex of the graph. This bootstrapping process happens (i) across machines, i.e., each machine starts from the locally-stored vertices, and (ii) concurrently within each machine, i.e., each worker thread handles a distinct set of vertices and performs the bootstrapping process on these vertices one after the other. Hops that follow remote edges send the intermediate match (batched) to the destination remote machine where they are picked up and taken over by a local thread.

Bootstrapping a match. Figure 5 includes a high-level activity diagram of the aDFS runtime. Completing the execution of this diagram from Stage 0 to the last query stage implements the complete matching starting from a single vertex of the graph. We explain these steps using the example of Figure 6. Text in the *blue italic face* represents the activities in Figure 5. The aDFS runtime assigns vertex *Joe* (the dark gray rounded rectangle of Figure 6) to a worker thread t , which tries to generate new matches. The thread first tries to match *Joe* with Stage 0’s $p1$ using *apply stage*. If the filter $p1.name = \text{"Joe"}$ returned `FALSE`, the thread would try to *backtrack* to a previous stage and, because there is none, it would simply complete this invocation. If there were more top-level vertices to explore, t would start again with a different vertex.

In the example of Figure 6, we assume that the execution plan matches vertex $p1$ as Stage 0. $p1$ matches *Joe* and t continues with the *hop: follow next edge* operation, starting from edge ①. Since the `:friend` label filter is satisfied and the edge is local, t proceeds via *DFS next stage* to Stage 1 where $p2$ is matched with the vertex that has `age = 20`. At this point, since the filter $p2.age < 35$ is satisfied and there is no next stage, t produces a query output row and *backtracks*

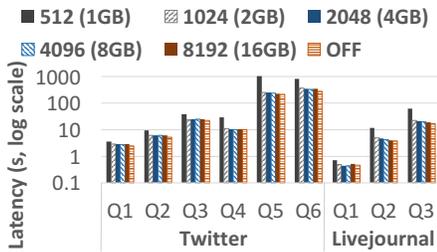

Figure 7: Performance of simple queries (8 machines) with different flow-control limits. In parentheses: Total per-machine maximum memory consumption.

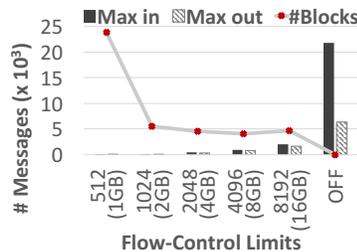

Figure 8: Messaging and blocking statistics on Q3/Livejournal with different flow-control limits. In parentheses: Total per-machine max. memory consumption.

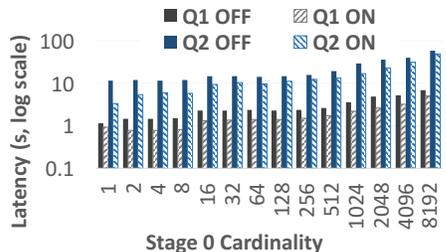

Figure 9: aDFS with dynamic local-edge BFS “ON” or “OFF” for two queries while varying the number of intermediate results of the first query stage.

amount of blocking is very high, which penalizes performance (more than $3\times$ higher latency). Still, the overhead for switching stages due to flow control is generally low: Setting N to 8,192 results in only $\sim 10\%$ performance loss as compared to no flow control (OFF), while reaching $10\times$ fewer maximum incoming messages (2,087 vs. 21,793) and $4\times$ fewer outgoing messages (1,636 vs. 6,430).

3.5 Dynamic BFS for Local Edges in aDFS

For remote edges, aDFS essentially does (per-thread) BFS: A thread matching a remote edge simply buffers the intermediate result and continues exploring and matching the same stage, which might produce new intermediate results.

While local processing could happen in pure DFS, doing so can result in artificially limited parallelism for queries that produce small sets of intermediate results. A characteristic example is queries with a very narrow starting Stage 0, such as `MATCH (a)->... WHERE ID(a) = X`; this narrow-start behavior appears in several real-life queries (e.g., the LDBC queries of Section 4). In such a query, the whole Stage 0 might produce a single intermediate result, giving limited opportunities for parallelism. For these workloads, DFS can significantly delay the expansion of intermediate results that are produced in the system (both locally and through messages).

In aDFS, we solve this DFS limitation by dynamically switching from depth-first exploration to per-thread breadth-first for local edges. aDFS maintains per-stage counts of the number of buffers with intermediate results that are ready to be taken care of by worker threads. A low number of intermediate results means that the stage has not expanded enough, hence some threads could end up not having sufficient work to perform. When threads in aDFS are processing a local edge, they use this information to decide whether to go for BFS, i.e., buffer the intermediate result in a local buffer and continue at the same stage.

In practice, we keep these local buffers small, i.e., up to a few kilobytes, in order to promote quick local work creation. We further use a *DFS threshold* to decide when to work depth-first: When the sum of the number of local buffers (produced by the breadth-first expansion) plus the number

of message buffers from remote machines is greater than $4\times$ the number of threads, threads switch to DFS. Having a low threshold plus small local buffers allows aDFS to keep the maximum additional memory consumption limited: If the DFS threshold is set to n , the maximum number of threads is t , the size of local buffers is b , and the query contains s stages, the maximum additional memory in a machine is $(n+t) * (s-1) * b$. In the configuration used for our experiments ($t = 28$, $n = 4t = 128$, $s \leq 11$, and $b = 8,192$), local buffers consume less than 12MB additional memory.

Controlled Experiment. Figure 9 illustrates the benefits of this local-match BFS mode on 8 machines (see Section 4 for detailed experimental settings) with the following two queries:

```
1: (a)->()->() WHERE ID(a) < $i
2: (a)->()-[e]->()->() WHERE e.cost < 0.5
   AND ID(a) < $i
```

using the Twitter graph extended with a uniform random edge property with values in $[0.0, 100.0)$. In both queries, the `ID(a) < $i` filter determines the cardinality of the first query stage and is used to narrow the starting point. In Q2, the edge filter also guarantees that the third stage includes a small number of intermediate results. The dynamicity of aDFS brings significant performance benefits, especially for queries with very narrow starting points. For example, for Q1 with $\$i = 1$, Machine 0 hosts the match for Stage 0; without the breadth-first mode (“OFF”), a single thread handles all the 55K local edges which lead to Stage 1. In contrast, enabling dynamic local BFS (“ON”) generates more work early on and allows splitting the work among local threads, each of which operates on approximately 2,000 vertices for Stage 1.

LDBC Q20. We also briefly analyze the BFS-mode benefits on LDBC Q20 (see Section 4 for more details):

```
MATCH (tC:tagClass) <-[:subClassOf]-(:tagClass)
  <-[:hasType]-(:tag) <-[:hasTag]-(:post|comment)
  WHERE tC.name IN ('Politics', 'Art', 'Country')
```

In this query, the first two stages match `tagClasses` and Stage 0 results in only three intermediate results due to the filter. The local BFS optimization brings 32% latency benefits (8 vs. 5.5 seconds), by better parallelizing the work across threads. Without the optimization, the most busy thread, i.e., the one that “gets stuck” in performing local DFS work the

most, spends 4 seconds in these local explorations: It matches about 1,000 vertices in Stage 1, which result in 5.2 million local matches in Stage 2 and 5 million in Stage 3. In comparison, with the optimization, the most busy thread spends only 1.6 seconds in DFS work: It handles 4 million local edges in Stage 2, which it successfully distributes to other threads with approximately 500 local BFS buffers. Overall, enabling dynamic local BFS provides significant speedup on realistic workloads, while incurring at most a 5% slowdown.

4 Evaluation

The goals of our evaluation are (i) to understand how well aDFS performs as compared to other systems (graph, relational, mining and dataflow join systems) that could be used in similar use cases, (ii) explain how different parts of aDFS contribute to performance and memory, and (iii) show how aDFS scales as we increase the number of machines.

4.1 Experimental Settings

Hardware details. We use a cluster of eight nodes, each having two Intel Xeon E-2690 v4 2.60GHz CPUs with 14 cores (hyperthreads disabled/DVFS enabled), for 28 cores in total. Each processor contains 756GB of DDR4-2400 memory and LSI MegaRAID SAS-3 3108 storage. Each node includes a Mellanox Connect-X InfiniBand card, all connected to an EDR 100Gbit/s InfiniBand network.

Graphs and queries. Unless specified otherwise, our experiments use the five graphs of Table 2. As we mention in Section 2, the scope of this paper covers user-provided fixed-pattern queries, thus aDFS implements only a subset of PGQL 1.1. Accordingly, we use the 12 LDBC Business Intelligence (BI) standard queries [68] supported by PGQL 1.1 (later PGQL versions support the remaining LDBC queries). Out of these 12 queries, four represent simple path patterns (i.e., Q4, Q17, Q23, Q24) and are directly supported in aDFS. The remaining ones either include regular path queries (e.g., ... MATCH (a)-[:knows*]->(b)), or include sub-queries in projection or filters (e.g., SELECT ... FROM (SELECT ...) ...). We devise a simplified variant of these queries in order to support the benchmark specification as closely as possible. For example, the original Q6 is:

```
SELECT id(person),
SUM((SELECT COUNT(*) MATCH (m)<-[:replyOf]-(:cmt)) AS rN
SUM((SELECT COUNT(*) MATCH (:prsn)-[:likes]->(m)) AS lN,
COUNT(*) AS msgN
MATCH (tag:tag) <-[:hasTag]- (m:post|comment)
-[:hasCreator]-> (person:prsn)
WHERE tag.name = ?
GROUP BY person, tag
ORDER BY msgN + (2 * rN) + (10 * lN) DESC, id(person)
```

We simplify the query by removing the two COUNT subqueries in projections and from ORDER BY. We plan to extend the PGQL support of aDFS in future work.

Note that the queries include patterns of varying complexity, e.g., the one in Q6 above is rather simple, while Q17 matches the following complex pattern:

```
(x:person)-[:livesIn]->(c1:city)-[:partOf]->(cy:country),
(y:person)-[:livesIn]->(c2:city)-[:partOf]->(cy),
```

```
(z:person)-[:livesIn]->(c3:city)-[:partOf]->(cy),
(x)-[:knows]->(y)-[:knows]->(z)
```

Methodology. We perform 15 runs of each query and report the median latency (in Figure 10, the error bars cover all runs). For each experiment set, we execute the queries in a per-graph round-robin fashion in order to reduce caching effects (e.g., data in the LLC or instruction caches). We use eight machines for aDFS, GraphFrames, G-Miner, Fractal as well as BiGJoin, and make sure all systems are configured to use InfiniBand. The four other systems are single machine.

Engines and their configurations. We configure aDFS to use up to 4,096 messaging buffers of 256KB per machine for messaging. This setting translates to approximately 1GB of intermediate results that can be produced per machine and limits the worst-case maximum memory consumption of a single machine to approximately 8GB (1GB outgoing, plus 7GB incoming). We further use the configuration of Section 3.5 for the local-edge dynamic BFS, resulting in up to a few MBs of extra memory per machine. Altogether, the aDFS runtime consumes approximately 10GB per machine. Of course, the graph (that resides in memory) and the final query results consume extra memory than these 10GB. We use such a low-memory configuration because (i) aDFS is designed for server deployments and we want to evaluate the performance at a realistic setting, where a single query cannot monopolize memory, and (ii) as we show in Figure 7, this configuration is already sufficient for aDFS to perform well.

We first compare aDFS to two graph systems and two relational systems which we describe below. In Section 4.5, we further compare aDFS to three graph-mining systems and a dataflow join system.

GraphFrames [31] is a distributed graph-querying system built on top of Apache Spark [2, 79]; we use version 0.7 on top of Spark 2.4.1 with 600GB executor memory per machine. **Neo4j** [10] is a single-machine graph database, which stores its data on disk but uses an in-memory cache for performance (caching effects are obvious in the first run of each query). We use Neo4j Community Edition 3.5.3 and allow it to manage the full memory of the machine. **MonetDB** [9, 26] is an in-memory column-store relational database. Its distributed support is rather rudimentary, resulting in worse than single-machine performance for our join-heavy workloads. Therefore, we use MonetDB 11.31.13 on a single machine, configured to use the whole 756GB of memory. **PostgreSQL** [15] is a relational database. We use version 11.2, tuned for a single connection with memory cache size of 564GB and 198GB of

Graph	#V	#E	Schema	Description
Livejournal [20]	484K	68.9M	No	Users and friendships
URandom	100M	1B	No	Uniform random edges
Twitter [47]	42.6M	1.47B	No	Tweets and followers
LDBC(100) [68]	283M	1.78B	Yes	LDBC social
Webgraph-UK [25]	77.7M	2.97B	No	2006 .uk domains

Table 2: The set of graphs we use in the evaluation.

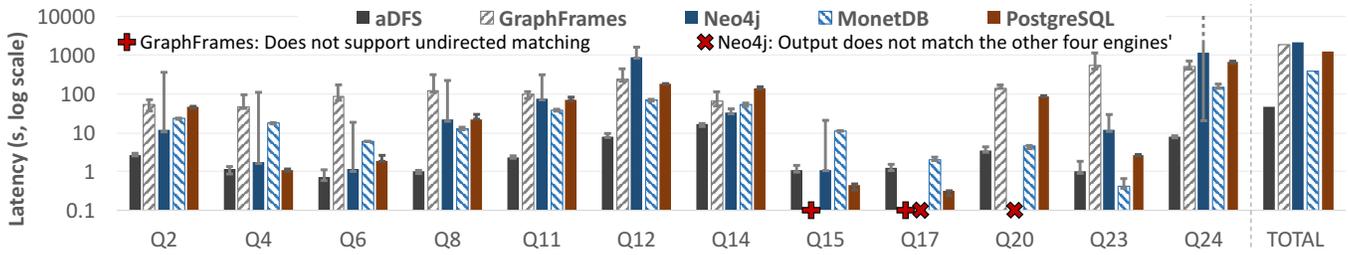

Figure 10: aDFS vs. other graph/relational systems on LDBC. Q_N is the N th LDBC BI query. Error bars show min/max latencies. TOTAL is the sum of all latencies—i.e., the time to complete a single run of all 12 (10 for GraphFrames and Neo4j) queries.

shared buffers. For both MonetDB and PostgreSQL, we use the optimized schema/indices designed for the original LDBC evaluation paper [68]. We choose these four systems as they cover a broad spectrum of data processing: Distributed graph dataframes, single-machine graph databases, and in-memory or traditional relational databases.

4.2 aDFS vs. Other Engines: LDBC

Experiment. We perform an end-to-end comparison of aDFS to the four aforementioned systems. We use the LDBC graph and BI queries which constitute an unfavorable workload for aDFS and GraphFrames: the LDBC graph has a relational schema, carefully partitioned in tables, such as `person` and `post`. For relational databases (as well as Neo4j), this schema enables the exploration of small parts of the graph for most queries. For example, the pattern `(:post)-[:hasCreator]->(:person)` (taken from an actual query) needs to only access the tables `post` and `person`, which are a relatively small part for the graph. In contrast, aDFS and GraphFrames operate on the original graph model, where the whole dataset is a single graph. The end result is that these two systems perform more broad exploration even on queries that are very narrow in terms of schema accesses.

Optimizing for relational schemas is outside of the scope of this work. Still, we choose LDBC with BI queries for our end-to-end comparison as it shows how aDFS performs on queries that can be expressed well both in graph and relational systems. The next sections focus on schema-less graphs.

Results. Figure 10 depicts the query latencies of the five systems. For most queries, aDFS is one to two orders of magnitude faster than GraphFrames. aDFS delivers $102\times$ average speedup and takes $43\times$ less total time than GraphFrames to complete the 10 out of 12 supported queries. GraphFrames translates graph queries into dataframe joins, offered by Apache Spark, which are significantly slower than aDFS’s graph traversals. Additionally, GraphFrames is memory hungry, consuming hundreds of gigabytes of memory in comparison to the small footprint of aDFS. Furthermore, aDFS completes the 10 supported queries $53\times$ faster than Neo4j, with a $35\times$ average speedup, even though Neo4j leverages the graph schema, as well as the large amount of available memory with its graph cache. With Neo4j, the whole graph

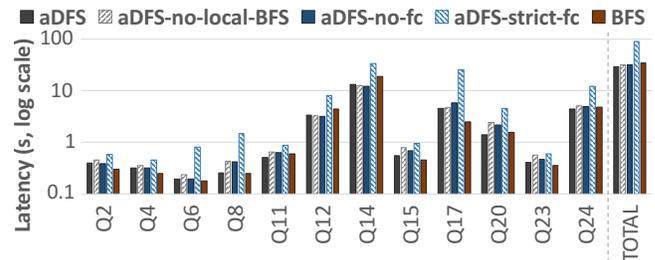

Figure 11: aDFS with various configurations on LDBC.

resides in memory after the first run: the error bars clearly show the effects of the first slow run.

Comparing aDFS to the relational systems, MonetDB and PostgreSQL, shows two different behaviors depending on the query size. For large queries, such as Q12 and Q24, which expand to large parts of the graph with long paths, aDFS is significantly faster. On the contrary, for small, very relational queries, such as Q15, Q17, and Q23, the relational systems can be faster than aDFS. This is expected given that just the distributed bootstrapping and coordination overheads in aDFS account for several tens of milliseconds. These different queries highlight the tradeoff between the relational table-focused joins and the graph exploration approach of aDFS. Overall, aDFS completes the whole set of queries 8.4 and 26 times faster than MonetDB and PostgreSQL, respectively. The average speedups are $10\times$ and $25\times$ against MonetDB and PostgreSQL, respectively. Conversely, MonetDB is $2.4\times$ faster than aDFS on Q23, while PostgreSQL is on average $2.6\times$ faster for Q4, Q15, and Q17.

In conclusion, aDFS achieves better overall performance than the four other systems while consuming lower/capped runtime memory.

4.3 Dissecting aDFS with LDBC

Experiment. We again use the LDBC benchmark to show how different design characteristics of aDFS contribute to performance and memory usage. In particular, we compare the pattern-matching-only latency of the default *aDFS* (as used in Section 4.2) to *aDFS-no-local-BFS* (we disable the machine-local dynamic BFS), *aDFS-no-fc* (we further disable flow

control), *aDFS-strict-fc* (we make flow control very strict), and *BFS* (we use the BFS implementation of Section 2.4).

Results. Figure 11 includes the results for these configurations. All in all, aDFS is the fastest. With the “dynamic BFS for local edges” option, aDFS is 31% faster on average than *aDFS-no-local-BFS* for 10 queries, while incurring 4% overhead for the remaining two queries. As we described earlier, queries often have some very “narrow” execution points with a handful of intermediate results, which leads to poor parallelization with strict local DFS. In terms of memory consumption, aDFS consumes slightly more memory than *aDFS-no-local-BFS*, not only due to the local buffers, but also thanks to better parallelization, which results in more parallel message traffic.

Disabling flow control on top of *aDFS-no-local-BFS* can bring some benefits as shown by *aDFS-no-fc*. However, the performance gains are low, as *aDFS-no-fc* hits almost no flow-control limits for this workload—i.e., local DFS and prioritizing messaging buffers from later stages of the queries result in an efficient execution flow, since none of the stages “explodes” in terms of memory. Still, *aDFS-no-fc* exhibits a 20% speedup with up to 5× higher memory consumption.

aDFS-strict-fc represents the closest realistic configuration to DFS. Processing one intermediate result at a time would naturally perform poorly, hence, we instead disable dynamic local BFS and configure each stage to have exactly one outgoing buffer to the next stage per target machine. The results show that excessive flow control reduces performance. In particular, *aDFS-strict-fc* is up to 6× slower than aDFS, while consuming up to 4× less memory.

Finally, as a reference, *BFS* implements a basic BFS-only runtime. As expected, *BFS* performs better than aDFS for certain queries, as it better leverages locality and parallelization. Still, aDFS executes the total workload 16% faster than *BFS*, while *BFS* consumes up to 6× more memory.

In conclusion, aDFS includes a set of design characteristics that when put together achieve great performance with low and controlled memory consumption.

4.4 aDFS vs. Other Engines: Large Schema-Less Queries

Experiment. The classic property graph model is schema-less, which enables users to easily query the whole dataset (unlike the relational model which requires several joins and unions of results). Therefore, we now compare aDFS to the other four systems with the schema-less graphs of Table 2: this workload shows the full power of aDFS in handling very large queries. For the relational systems, the graphs consist of two tables: One for vertices and another one for edges. Regarding queries, we use two simple patterns, a cycle $(a) \rightarrow (b) \rightarrow (a)$ as Q1 and a two-hop path $(a) \rightarrow (b) \rightarrow (c)$ as Q2, combined with aggregations in the SELECT clause (variant “a” performs a COUNT(*) and variant “b” AVG aggregations on a random vertex property). The conclusions remain the same for other patterns

and projections (not shown). Note that it is impossible to evaluate more elaborate patterns, as the competing systems can barely handle the simple patterns that we use.

Results. Figure 12 depicts the results. In most cases, aDFS is about 2 orders of magnitude faster than the other systems. For the large queries and graphs, we also see that the other systems are either not able to complete the queries within eight hours, or crash. In particular, GraphFrames crashes after having consumed its 600GB of executor memory.

The speedups of aDFS over the other systems (for the completed queries where there is no timeout) are: 16 to 62× for GraphFrames, 1,105 to 9,200× for Neo4j, 20 to 169× for MonetDB, and 60 to 190× for PostgreSQL. Neither the join-based systems (GraphFrames, MonetDB, and PostgreSQL) nor Neo4j are able to handle well these immense graph explorations, although they have access to hundreds of gigabytes of memory. In particular, Neo4j spills to disk, hence the extreme performance difference compared to aDFS. Clearly, for graphs and queries at this scale, a fast graph-optimized solution such as aDFS, which easily handles these queries, is required. With the largest query (Q2a on Twitter) aDFS performs a 9.3T COUNT in 1,286 seconds, resulting in 7.3B matches per second, while consuming less than 10GB per-machine memory for intermediate results.

4.5 aDFS vs. Graph Mining, Dataflow Joins

Experiment. We compare aDFS to (i) three graph-mining systems,² namely *G-Miner* [27], *Fractal* [32], and *Peregrine* [42], as well as a dataflow join system, *BiGJoin* [19]. We use workloads from the G-Miner paper [27]: TC, i.e., Triangle Counting, and counting instances of a more complex pattern referred to as the P-pattern, with the four graphs that are used to evaluate these operations in the paper. All systems are distributed apart from Peregrine. For BiGJoin, we only perform the evaluation on TC as it does not support filters, and tune the batch size for performance (10^8). For aDFS, we express both triangles and the P-pattern as graph queries.

Results. Figure 13 includes the performance of the four systems. Triangle counting (TC) highlights the difference between matching and not matching automorphisms: For the three graph-mining systems, the search for “unique” triangles is baked in the pattern-matching algorithm, whereas in aDFS, we implement isomorphism with automorphism elimination using dynamic filtering (i.e., $(a) \rightarrow (b) \rightarrow (c) \rightarrow (a)$ WHERE $ID(a) < ID(b)$ AND $ID(b) < ID(c)$). This results in expensive filtering and heavier cross-machine communication than with the other systems. Still, aDFS is faster than G-Miner and Fractal for all graphs by up to 14× for G-Miner and by up to several orders of magnitude for Fractal. Peregrine outperforms all other graph-mining systems including aDFS on three out of the four graphs, as it is able to intersect adjacency lists to quickly find common neighbors, an optimization that

²We requested the artifact of Automine [54] for evaluation, but the authors were not able to provide us with it.

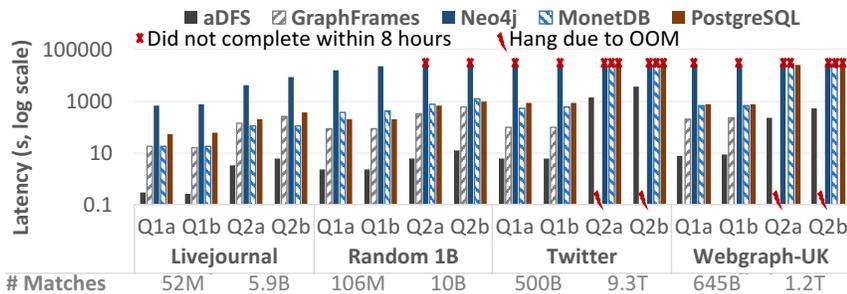

Figure 12: aDFS vs. other graph and relational systems on simple-pattern queries.

performs particularly well for triangles and which can be implemented in a straightforward manner on a single machine, where the whole graph is accessible. There is no clear winner between aDFS and BiGJoin on TC, with each system outperforming the other on two graphs. By intersecting local edges, BiGJoin’s approach allows for reduced communication and better performance on the two graphs with the highest average degrees (Orkut and Friendster).

The P-pattern does not require automorphism checks, as its vertices are differentiated by labels. We express it as:

```
(c:c) -> (b1:b) -> (:a) -> (c) -> (b2:b) -> (:d)
WHERE b1 <> b2
```

in PGQL. When matching the P-Pattern, aDFS significantly outperforms all other systems for all but one datapoint (G-Miner on BTC); it is on average 12 and 366× faster than Peregrine and Fractal, respectively, and 8× faster than G-Miner on three graphs. G-Miner achieves the best performance on BTC mainly because it replicates the target vertex label with each edge, which increases locality and reduces communication traffic. Such an optimization is not practical in a real-world system in which vertices can have many labels and properties of various types: Replicating these for each edge can have unacceptable memory overhead.

Overall, although aDFS is designed for different workloads, i.e., expressive graph queries, it is still very competitive with state-of-the-art graph-mining systems and a dataflow join system on triangle counting and/or a mining-oriented workload.

4.6 aDFS Scalability

Experiment and results. We use the LDBC workload to illustrate the scalability of aDFS as we vary the number of machines. Figure 14 includes the speedups, normalized to the latency of a single machine. Overall, aDFS exhibits

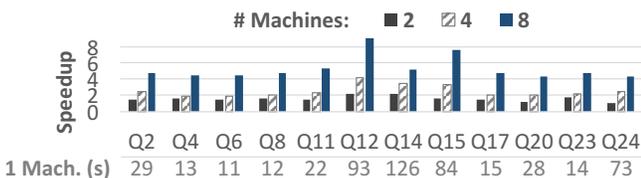

Figure 14: Scalability of aDFS vs. using a single machine.

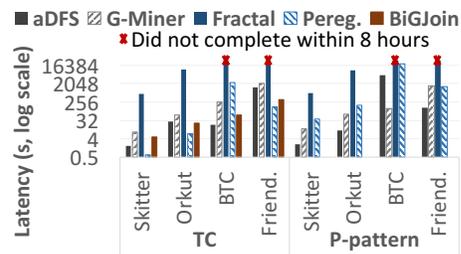

Figure 13: aDFS vs. graph-mining and dataflow join systems on triangles, patterns.

very good scalability: The average speedup is 1.6× from one to two machines, 2.5× from one to four machines, and 5.4× from one to eight machines. These numbers include various distributed coordination and query compilation overheads, as well as additional fixed costs. The core runtime of aDFS actually has even better scalability: looking at pure pattern-matching execution time, without coordination overheads, GROUP BY, and ORDER BY, the speedup improves to 1.7×, 2.6×, and 6× from one to two, four, and eight machines respectively (not shown). aDFS is designed to scale: More machines translate to more compute resources, more buffers for intermediate results, and often more BFS exploration and higher network utilization, as the percentage of remote edges increases with the number of machines.

5 Related Work

Database Management Systems (DBMSs). DBMSs offer graph support via a multi-model premise, but focus on SQL-like rather than pattern-matching querying [7, 12, 13, 52]. Kalinsky et al. [43] acknowledge that using DBMS joins for graph pattern matching is suboptimal, and propose hardware support to alleviate the issue. In contrast to DBMSs, aDFS is an efficient in-memory distributed graph-querying system that considers graph storage and queries as first-class citizens and focuses on analytical rather than transactional workloads.

Graph Algorithms. There is a plethora of related work for executing graph algorithms (such as PageRank [57]). Single-machine solutions focus on various topics such as proposing DSLs [38] or programming models [55] for graph algorithms, performance optimizations [65, 67], leveraging hardware features such as NUMA [81] and GPUs [56, 84], or supporting out-of-core computing [83]. Distributed solutions focus on topics such as asynchronous processing and performance [35, 50], efficient partitioning [78, 82, 85], leveraging hardware features such as RDMA [75], support for secondary storage [61], distributing sequential algorithms [33], approximate computing [70], alternative programming paradigms [76], or fault tolerance [30, 71]. aDFS focuses on graph queries rather than algorithms, but it shares features with some of these distributed solutions, such as the use of asynchronous processing or (random) graph partitioning.

Graph Querying. A number of single-node graph-querying systems were proposed by academia: Sun et al. [66] and Lin et al. [49] build relational and transactional systems, Graphflow [44] is an active graph database that supports evaluating one-time and continuous subgraph queries, TurboFlux [46] optimizes fast continuous subgraph matching over a fast graph update stream, and CECI [22] uses multiple embedding clusters and intersections of neighborhood lists to optimize subgraph matching (CECI can be distributed through graph replication/sharing, not graph distribution as with aDFS, due to the challenges mentioned in Section 2.4). In earlier work, we prototyped simple distributing DFS exploration [60].

There are numerous industrial graph-querying solutions. Neo4j [10] is single-machine and supports Cypher [11] queries. Amazon Neptune [1] is built for the Amazon cloud. Facebook Dragon [3] builds indices on updates for accessing data. Microsoft Graph Engine [8] is an in-memory data processing system based on Trinity [63], and TigerGraph [18] distributes GSQL [4] queries based on the source vertex data for a given query hop. Furthermore, there are also open-source distributed solutions. JanusGraph [6] uses distributed graph storage but does not distribute computation. GraphFrames [31] implements graph pattern matching with Spark using joins of dataframes. Wukong [64, 73] is a distributed graph-based RDF store that leverages hardware features, such as RDMA and GPUs, which we do not focus on. To the best of our knowledge, aDFS is the first truly distributed graph-querying system that works on fully-partitioned graphs and strictly bounds memory while maintaining great performance.

Graph-Mining systems. Graph-mining focuses on extracting structural properties and computing complex aggregate statistics [34, 74] of a graph by exploring its subgraph structures. Examples include triangle counting, maximal clique finding, community detection, and graph matching [27, 54, 59]. Graph-querying systems typically employ a vertex/edge-centric processing approach: A state is maintained per vertex and communicated to its neighbors [54, 69]. Graph-mining systems typically follow a subgraph-centric (often undirected and schema-less) processing approach: They attach information to a large amount of intermediate results composed of subgraphs [54] rather than specific vertices. Additionally, graph-mining systems typically leverage automorphism elimination [29, 32, 42], while while graph-querying engines generate homomorphisms to answer user graph queries.

Recent single-machine systems include RStream [72], AutoMine [54], and Peregrine [42]. Distributed systems include Arabesque [69], NScale [59], G-thinker [77], BiGJoin [19], G-Miner [27], ASAP [41], and Fractal [32]. aDFS shares features with some of these systems. For example, forms of asynchronous computations are used in G-Miner [27] (with a “task-pipeline” to hide communication overheads) and BiGJoin [19] (with data-parallel dataflow computations that pick up dynamically joined columns with the least matches). Techniques to reduce memory consumption are

used by G-Thinker [77] (buffering excess subgraph-tasks in a disk-based priority queue), BiGJoin [19] (primarily using batching to limit memory consumption but not for intermediate results as with aDFS) and Fractal [32]. Fractal combines a DFS strategy with a “from-scratch processing” paradigm which leads to re-computation overheads (absent in aDFS), as well as imbalances across workers that are mitigated by work stealing: workers break the DFS strategy to steal enumerations, which can be at any level of the matched graph pattern, from other workers. aDFS uses asynchronous DFS-based graph traversals together with flow control to strictly bound memory consumption, and can switch to BFS, in the same graph pattern-matching level, to generate more local work and to buffer remote edges (see Section 3). Our in-depth evaluation shows that the performance of aDFS for graph pattern-matching is competitive with that of state-of-the-art graph-mining systems.

BFS/DFS. The BFS/DFS tradeoff has been explored in the context of single-machine parallel task-scheduling runtimes. Typically, DFS is used to schedule a task graph in order to curtail memory [28], and BFS is used opportunistically (often called “work stealing”) to maximize parallelism [23, 24]. aDFS leverages these insights in the context of distributed graph query processing.

6 Concluding Remarks

Conclusions. We have introduced aDFS: A system that uses an efficient, almost-DFS approach to execute pattern-matching queries on distributed graphs. aDFS is able to execute virtually any query on any in-memory graph using at most a fixed, configurable amount of memory. aDFS is also very fast and scalable. We compared aDFS to eight state-of-the-art systems with diverse characteristics—graph or relational/join-based, distributed or single machine, in-memory or disk-based—and showed that aDFS is up to orders of magnitude faster than them.

Limitations and future work. aDFS uses simple algorithms for query optimization and graph partitioning, as this paper focused on runtime support for distributed graph querying. In the future, we will improve query planning and optimization, together with graph partitioning and caching. We will also consider query optimization opportunities to enable pruning of the traversal space when the underlying data has a relational-style schema, as described in Section 4.2.

Abstract

Graph learning is an emerging technique widely used in diverse applications such as recommender system and medicine design. Real-world graph learning applications typically operate on large attributed graphs with rich information, which do not fit in the memory. Consequently, the graph learning requests have to go across the deep I/O stack and move massive data from storage to host memory, which incurs considerable latency and power consumption. To address this problem, we developed GLIST, an efficient in-storage graph learning system, to process graph learning requests inside SSDs. It has a customized graph learning accelerator implemented in the storage and enables the storage to directly respond to the graph learning requests. Thus, GLIST greatly reduces the data movement overhead in contrast to conventional GPGPU based systems. In addition, GLIST offers a set of high-level graph learning APIs and allows developers to deploy their graph learning service conveniently. Experimental results on an FPGA-based prototype show that GLIST achieves $13.2\times$ and $10.1\times$ average speedup and reduces the power consumption by up to 98.7% and 98.0% respectively on a series of graph learning tasks when compared to CPU and GPU based solutions.

1 Introduction

Graph is a fundamental data structure widely seen in modern computer systems and applications. Real-world social networks, molecular graph structures, biological protein networks, social networks, and data from many other fields can be modeled as graphs, particularly the attributed graphs (AGs), which carry richer property information than well-studied plain graphs [19, 40, 42]. Attributed graphs occupy a growing proportion of storage space in the datacenters of service providers such as Facebook, Amazon and Alibaba, and the trend will continue especially with the popularity of graph database and graph analytics platforms for citation networks and recommender systems [4, 7, 43, 58]. Taobao, one of the

largest online consumer-to-consumer (C2C) platforms, for example, manages attributed graphs that consist of one billion users and two billion items [43]. Therefore, as the machine learning technology advances, the question of how to make prediction, discover new patterns, and mine useful information from such rich attributed graphs, which is known as the area of Graph Learning (GL), is gradually becoming important in private and public cloud datacenters where the massive graph data can be ingested to learn the basic classification, clustering, visualization and prediction functionality [5, 29, 35, 43, 52–54].

Conventionally, common graph learning tasks require numerous CPU or GPU nodes to deal with large-scale graph learning problem and the related user queries, which directly translates to sheer growth of power and cost overhead. For instance, a typical GL-based recommender system in Alibaba [43] employs hundreds of GPUs in service to mine billion-scale attributed graph data associated to numerous customers and shopping items. To investigate more cost-effective GL systems, in this work we first characterize the real-world GL applications by building a conventional single-node GPU+SSD based graph learning system. In this system, several critical tasks found in realistic datacenter infrastructures are implemented and simulated (See Section 3). We discovered that there are several important impactful performance in these mainstream graph learning tasks. (1) For typical graph learning systems that respond to graph analysis requests as shown in Table 2, the storage-and-compute decoupled systems are bottlenecked by I/O operations, and they are not energy efficient in dealing with the GL requests due to the costly data movement from the storage to CPUs/GPUs. (2) Large-scale graph learning tasks exhibit poor data locality, which can hardly be exploited in the limited on-chip or even off-chip memory due to the large footprint of attributed graphs such as social networks or recommender systems. (3) We found that, although graph learning tasks are much more complicated than plain-graph processing, they are generally solvable by emerging graph neural networks (GNN), which means a compact specialized GL accelerator is a viable alter-

native to GPUs and CPUs in storage-centric GL systems.

To replace the power-hungry CPU/GPU based solutions and eliminate the unnecessary power consumed by graph data movement, we propose a near data computing system to realize efficient Graph Learning In-Storage (GLIST). As depicted in Figure 1(b), GLIST is a combination of in-SSD computing and customized graph learning accelerator architecture, and it enables the storage device to directly respond to attributed graph analysis requests and queries, making the data warehouse machines more energy efficient.

However, fitting large-graph learning tasks into compact storage devices remains very challenging and worth investigating. First, large graphs generally have too large footprint to fit in the DRAM memory or the caching memory of storage devices [20], thus processing a large attributed graph on request tends to have poor locality, which must be well exploited in the design of GLIST. In the graph learning process, how to efficiently and directly fetch graph learning model parameters and the graph itself from the flash devices, how to preserve locality in the working-set of GL, and how to exploit the abundant channel-level flash bandwidth in SSDs is also very important.

Second, fitting large-scale graph learning workloads into storage SSDs is challenging due to the limitation of power and computing resource inside the SSDs that generally have embedded CPU or MCU for flash device management, because deep learning technology based graph analysis workloads are bandwidth and computational intensive at the same time. This calls for a more efficient architecture to practice in-storage graph learning with SSDs.

Third, though analyzing a single graph request does not exhibit good memory locality, it is found that the inter-request locality does exist as the working-sets of temporally correlated requests overlap with one another to some degree as will be discussed in Section 3. Thus, to achieve the best efficiency of the in-storage computing, fully exploiting the concurrency and the inter-request locality in the graph analysis requests is also important. As a consequence, more consideration should be given to the working-set caching and the request scheduling strategy in the GLIST controller to reuse GL model and graph data in storage.

In all, we make the following contributions in this paper:

- We profiled real-world GL workloads in different categories and obtained two main observations for optimizing the architecture of GNN systems in terms of data locality, especially for systems with block-based storage devices.
- Based on our observations, we proposed the GLIST architecture to enable high-throughput graph learning services. We handle concurrent requests issued to the power-limited graph learning storage with specialized caching system and locality-centric request scheduling policy to exploit the data locality in and between the attributed

graph analysis requests. The graph analysis requests are processed inside SSDs with a unified hardware accelerator to handle various graph learning tasks instead of going across a deep I/O stack. To the best of our knowledge, GLIST is the first in-storage acceleration system for graph learning workloads such as recommender systems and automated customer service.

- We build a GLIST prototype on the Cosmos Plus OpenSSD platform [1]. Experimental results show that the GLIST caching and scheduling policy can improve the performance by up to 13.2× and 10.1× compared to CPU+SSD, GPU+SSD based system, respectively.
- GLIST provides a software abstraction with a set of programming APIs that enable developers to create and deploy their graph learning models and analysis service into the in-storage graph learning system.

2 Background

2.1 Graph Learning Tutorial

Graph neural network applications can be modeled as an encoding-decoding method [15, 58]. The encoding function encodes the vertices in a graph into latent representation (also called embedding) that summarizes both the location and neighboring information. The decoding function decodes the embedding to the original vertex information, which is directly related to graph learning tasks, such as labeling a vertex in classification task.

Table 1: GNN Notations.

Notations	Description	Notations	Description
\mathbf{G}	attributed graph $G(V,E)$	$Nb(v)$	vertex v 's neighbor set
\mathbf{h}_v	the embedding vector of vertex v	$N(v)$	subset of vertex v 's neighbor set
$e(i,j)$	the edge between v_i and v_j	R	analysis result

Typically, the encoder function is composed of three types of functions including **Sample**, **Aggregate**, and **Combine**. **Sample** controls the scope of the information to be processed in a graph. As formulated in Eq. 1, it samples a subset of the neighbor vertices and constructs a new sub-graph for embedding [6, 14, 53]. The notations used in the formulation is summarized in Table 1. **Sample** can also be omitted according to GCN [21] and GIN [48]. In this case, all the neighbor vertices are used for embedding calculation.

$$\mathbf{S}_v = \mathbf{Sample}^k(Nb(v)) \quad (1)$$

Aggregate aggregates the features of all the incoming vertices to update the feature of current vertex v .

$$\mathbf{h}_v^k = \mathbf{Aggregate}(\{\mathbf{h}_u^{(k-1)}\}_{u \in N_v}) \quad (2)$$

where $\mathbf{h}_v^{k'}$ is the feature of vertex v aggregated from features of neighbor vertices $\mathbf{h}_u^{(k-1)}$ at the $(k-1)$ th layer.

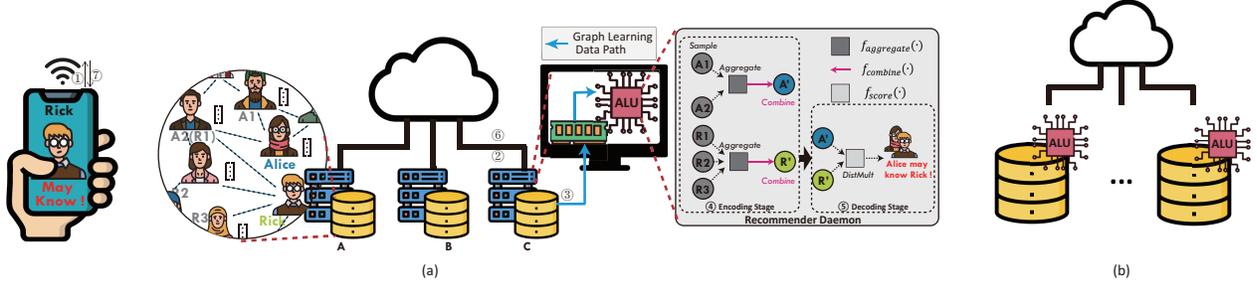

Figure 1: **A processing example of typical GL-based social network recommendation service [14, 21, 46]** When Alice tries to extend her connection via a social network App, a request is generated by the App and sent to the data center①. The request is then converted to multiple graph analysis operations to predict users who Alice may be interested in. One of the operations is assigned to Server C② to predict the potential connection between Alice and Rick. With conventional storage, the relevant sub graph of the huge social network must be loaded from the external storage to main memory and will be processed with an encoder function on host. The processing is to generate embedding vectors that can represent the two users’ social network characteristics③. Then a DNN-based predictor is invoked as a decoder to determine whether the two users may agree to connect④. Finally, the recommendation is obtained based on all the prediction results and sent to the user App⑤. (b) GLIST can simplify the graph learning processing. There is no data movement between the storage and the host system.

In order to obtain the updated feature of vertex v at layer k i.e. \mathbf{h}_v^k , **Combine**, which is essentially an MLP operation, is applied.

$$\mathbf{h}_v^k = \mathbf{Combine}(\mathbf{h}_v^k) \quad (3)$$

With multiple iterative processing, the obtained embedding vectors are fed to the decoder function to perform graph analysis tasks. The graph learning tasks can be categorized into three types [47]: **Node-level analysis**, **Edge-level analysis**, **Graph-level analysis**. Meanwhile, the decoder function varies from specific graph learning tasks, and they will be detailed as follows.

Node-level analysis aims to classify nodes without labels in graphs. It can also be applied for the classical community classification task in online social network analysis [3, 26], which essentially classifies nodes into several communities. The decoder function of **Node-level analysis** can be formulated as Eq. 4 [21].

$$\mathbf{R}_v = \mathbf{Decoder}(\mathbf{h}_v) \quad (4)$$

Edge-level analysis focuses on the prediction of missing edges or edges’ attributes. A typical use is to predict the potential connections between users and items in recommender systems, revealing a user’s interest in an item. The decoder function of **Edge-level analysis** can be formulated as Eq. 5 [38].

$$\mathbf{R}_{e(i,j)} = \mathbf{Decoder}(\mathbf{h}_i, \mathbf{h}_j) \quad (5)$$

Graph-level analysis operates on the entire graph as formulated below [48] and mainly targets for graph classification.

$$\mathbf{R}_G = \mathbf{Decoder}(\{\mathbf{h}_u\}_{u \in G}) \quad (6)$$

GNN can be used for many applications as summarized in Table 2. We take a GL-based social network recommender system shown in Figure 1 (a) as an example to illustrate the

use of GL. When the server receives an edge analysis request to predict the potential relationship between two users②, the algorithm will load the relevant sub-graphs of the social network in external storage with a **Sample** function to host memory, and then generates embedding vectors for the analyzed users③ with an **Aggregate** function and a **Combine** function. This will lead to high processing latency mainly caused by (1) random data access to storage and (2) massive data transfer across the bandwidth-limited PCIe bus and deep OS software stack. Then, the two generated embedding vectors are used by a DNN-based predictor to determine the existence of social connection between the two users④. Finally, the prediction result, which is usually a scalar, is sent back to the host machine and the user App eventually to make a recommendation. The proposed GLIST system, as shown in Figure 1 (b), however, performs the graph learning tasks only in SSDs to mitigate the drawbacks mentioned above.

2.2 In-storage Graph Processing

By enabling computation in storage that can avoid massive data movement between storage devices and host memory, in-storage computing (ISC) has become a promising computing paradigm for big data processing [8, 11, 17, 18, 28, 32, 37]. Graph processing on large-scale graphs is considered to be I/O intensive and requires frequent accesses to the graph in storage, so it fits well to the ISC paradigm. A number of prior works have intensively investigated the use of ISC for graph processing and demonstrated competitive performance and energy efficiency [18, 22, 23, 25, 31, 34, 41, 56]. GraphSSD [34] proposed a semantic-aware translation layer for efficient data access in graph processing. GraphOne [23] proposed an efficient dynamic graph store to facilitate both runtime graph update and processing. It supports various graph processing operations from distinct perspectives. G-Store [22] and MO-

SAIC [31] also achieved efficient in-storage graph processing with redundant data elimination methods and locality optimizations. Graphene [30] and FlashGraph [57] were proposed to address the I/O challenge in graph processing by managing frequently accessed data in DRAM.

However, due to the power constraint, the low-end processors in storage usually have limited computing capability to deal with complicated and demanding tasks. In this case, many powerful hardware accelerators are built in the context of ISC in recent years. GraFBoost [18] develops a specialized accelerator to coalesce the random accesses to the storage in large-scale graph processing and achieves server-class performance with small memory and low power footprint. ExtraV [25] utilizes a cache-coherent hardware accelerator to achieve both high performance and high flexibility for plain graph analysis.

While prior in-storage graph processing works mainly target to analyze plain graphs which only have simple scalar attributes, they cannot fulfill the processing requirements of the graph learning workloads that mostly operate on graphs with large vector attributes, because the graph learning tasks have distinct data access patterns and computation intensity. In addition, the primitive operations used in graph learning can also be unique. For example, the **Sample** function is not supported by any of the conventional plain graph processing abstractions [33, 36, 55]. Thus, we are motivated to investigate a novel ISC architecture for cutting-edge learning tasks on large and sparse graphs.

3 GL Workload Study for GLIST Design

3.1 Single Workload Characterization

Experimental setup In order to characterize and gain insight of various graph learning workloads, we conduct an in-depth study on a series of real-world representative GL applications on GPU [44]. The details of the applications and the datasets used for evaluation are illustrated in Table 2. The models and evaluation datasets are all stored in a 1 TB Samsung 970 PRO NVMe SSD. The computation device is an NVIDIA V100 GPU (Volta) equipped with 16 GB HBM2 memory.

Result analysis The latency of a graph learning task is broken down into three parts: GPU compute time(Computation)

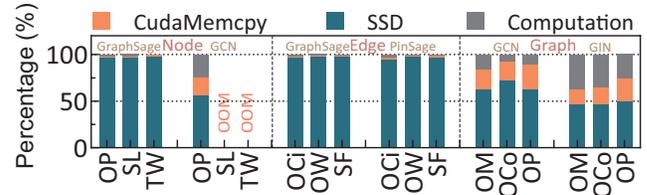

Figure 2: Performance breakdown of compute and I/O time for different graph learning workloads.

which implies the computation overhead, CudaMemcpy time(CudaMemcpy) which represents the time spent on the data movement between GPU and host, and the SSD to DRAM communication time (SSD). Figure 2 shows the profiling results, from which we can safely land two conclusions: First, the I/O bottleneck significantly penalizes the performance of graph analysis requests for most graph learning tasks. As we can see, all the graph learning tasks evaluated in this experiment spend more than half of their execution time on I/O operations, which means that GL workloads are limited by I/O bandwidth.

Second, it is hard for real-world large graphs to fit the memory. For example, twitter (TW) and soc-LiveJournal1 (SL) in the tested datasets cannot be fully loaded into 16 GB GPU memory. Thus, the algorithms have to load data from last-level storage on demand (Sampling based algorithms, i.e. GS-Pool and PinSage) or even cannot run (Non-Sampling based algorithms, i.e. GCN and GIN). Huge graphs not only increase the I/O access overhead, but also seriously restrict the throughput of general purpose processors, due to the memory capacity limitation. However, if the working set of graphs can be preprocessed where they originally stay and only the relevant sub-graph are moved, the data movement and processing overhead can be significantly reduced.

3.2 Locality in Graph Learning Workloads

To enable graph learning inside storage and service GL requests from users, we must exploit the locality in graph learning workloads to alleviate the SSD bandwidth limitation while preventing the long-latency flash accesses from penalizing the response performance. Two major exploitable locality observations that help fit the graph learning workloads into SSDs will be illustrated as follows:

1. *There exists working set reusability in between graph learning requests.*

Because SSD typically has much longer latency and coarser access granularity like pages and blocks, it is essential to take advantage of the limited DRAM or SRAM cache in it and exploit the locality in between the graph analysis requests for performance improvement. There are two potential types of locality in between the graph learning requests. The first type is Graph Data Locality (GDL) while the second is model parameter locality (MPL). For GDL, processing each vertex in the graph will involve a working set consists of its neighbors' property data. Graph analysis requests that happen to hit vertices in the proximate regions in the graph probably share a common working set. For MDL, many graph learning requests like node classification may utilize the same model parameters, so it will be beneficial to select and combine the graph learning requests with the same model parameters from all the batched requests.

2. *The layout of graph data in flash channels significantly impacts the locality of in-storage graph learning.*

Each single vertex/edge feature vector in attributed graphs is usually at the size of hundreds of bytes or few KB [19, 39, 50] and is smaller than a flash page size (i.e. 16 KB), the minimum operation granularity of flash devices. However, recent graph neural networks that respond to GL requests usually adopt **Sample** function which samples a subset of the target vertices' multi-hop neighbors [10, 14, 53]. This means that there may exist bandwidth under-utilization when the vertices located in the same flash page are not sampled simultaneously because the multi-hop structural correlation may not be captured by the **Sample** function.

For *Observation 1*, the request scheduling and caching strategy should be designed to fully exploit the temporal data locality that exists between requests. For *Observation 2*, the feature data layout in flash devices should be reorganized to improve the data reuse in a flash page.

4 GLIST Design

4.1 System Overview

To move the graph learning ability into storage devices, a state-of-the-art GL framework must support for system designers to develop and deploy the service of GL functions, e.g. GNN-based recommender systems and vertex classification, in storage devices. Inspired by the GL framework described in [58], we construct a multi-layered system architecture for the GLIST system, including user interface, run-time management, and specialized hardware as shown in Figure 3.

For the purpose of processing various graph data with GLIST, users can interact with it using the provided commands (see Table 3) via the GLIST Application Interface to define or invoke the specific GL functions in storage devices. Except the interface of defining and calling graph analysis

functions in storage, GLIST also implicitly performs locality-aware graph reorganization for the newly registered and updated graphs on the host machine, so that the GLIST system can improve storage operations and the response efficiency when processing the received user analysis requests.

Take the recommender system shown in Figure 1 as an example. At the offline stage, the social network graph which embeds the users' friendship information with connected edges is registered and stored in the flash devices of the GLIST system by *GraphRegister()*. The API also quantizes the vertex feature vector and chooses appropriate bit-width for edge data representation. The registered graph will further be used to make recommendation via GNN algorithms by predicting the existence of an edge. The GNN-based recommender model, e.g. PinSage from Pinterest [53] is trained and obtained by the application developers, and is then registered and kept in storage via *ModelRegister()*. It will be later invoked on requests.

After the model deployment, the users' clicks on the relevant App are converted to GL queries and sent to the data center machines. Particularly for the friend recommendation queries, essentially they belong to typical link predictions over the social network graph and will be handled by the daemon process running on the host of the GLIST system. On receiving the requests, the daemon process calls *GraphAnalysis()*. To exploit the data reuse between requests and ensure the request processing latency at the same time, the GL requests are batched in fixed time windows before being issued to the computing storage in GLIST ①. In the computing storage, a runtime environment is maintained to manage the incoming link prediction requests②. It translates each link prediction request to primitive analysis commands including a vertex embedding command that invokes the encoder function and a prediction command that executes the decoder function. The link prediction can be obtained after the execution of the corresponding primitive analysis commands.

In addition, the GLIST runtime also provides optimizations to exploit the data reuse within the batched requests and roughly includes two parts: (1) It reorders the primitive vertex analysis commands that generate flash accesses (i.e. vertex embedding requests) to explore the graph data reuse and fits the flash accesses to the flash channel-level parallelism. (2) It groups the reordered primitive vertex analysis commands into small batches to increase the bandwidth utilization of ways and channels, instead of sequentially handling each graph analysis command with limited footprint [14, 53]. After the commands are received and handled by the GLIST runtime, they are further decoded and sent as instructions to the GLIST processor that eventually executes and accelerates the graph learning functions. The instructions are served by the Sampler first, which fetches the feature vectors from the flash devices ⑦-⑧ or the Page Cache directly ⑨ from the on-board DRAM. Then, it constructs a larger sub-graph by merging multiple small sub-graphs obtained from the grouped

Table 3: GLIST APIs

Category	APIs

Graph Registration	GraphRegister, Graph Unregister
Model Registration	ModelRegister, ModelUnregister
Graph Analysis	GraphAnalysis, GetAnalysisResult

sampling functions [6, 14, 43]. The newly assembled graph is further loaded to the on-chip buffers of GLA. When all the required data are ready, the processing element array is instructed by the commands to execute the invoked vertex analysis model. Afterwards, when the feature vectors of the queried edge’s endpoints are ready, the primitive prediction function is scheduled onto the GLA to predict the link probability between target vertices. Finally, the GLA triggers the GLIST Runtime to collect the results and return the analysis results to the daemon process via *GetAnalysisResult()*.

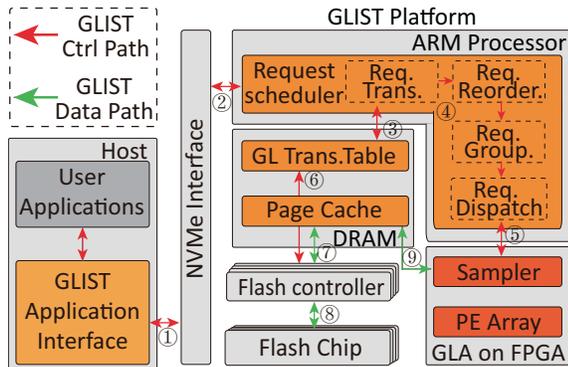

Figure 3: System architecture of GLIST.

4.2 The GLIST Runtime

The GLIST runtime is designed to decode, schedule, and issue the input requests to flash devices and the GLA. It manages the incoming requests as commands from the host machine, and also exploits the locality in between concurrent requests, and re-schedule the requests to maximize the available locality. To improve the flash bandwidth utility and exploit the inter-request locality, the GLIST runtime maintains two key structures, the Page Cache and the Graph Learning Translation Table, which enable the reuse of graph data and GNN models fetched from the flash devices in and between consecutive requests.

GLIST Page Cache is adopted to exploit temporal data locality between user requests. It caches the edges, vertex feature vectors and model data touched by the previously executed requests. Besides, the intermediate data such as the embedding vectors of vertices are also cached. We adopted the Least Recent Use strategy as replacement policy. The Page Cache works in the process of request response, and it is also used to hide the latency of operations correlated to the GNN function deployment stage, e.g. registering new function models.

Graph Learning Translation Layer, denoted as GL-TL, is provided to index reusable objects in SSDs including the graph property data, edge information, and analysis model parameters. GL-TL replaces the conventional LBA-to-PPN (logic block address to physical page number) paging used in commercial SSDs. GL-TL includes three translation tables, i.e. the Vertex Mapping Table, the Property Mapping Table, and the Model Mapping Table. The Vertex Mapping Table records the mapping between the vertex ID and the flash page which keeps its neighbors. Besides, it also records other meta-data of each vertex such as the number of adjacent vertices. Similarly, the Model Mapping Table and the Property Mapping Table keep the logical object index and physical block address. All the tables are kept in the DRAM when GLIST is activated.

4.2.1 In-storage Graph Learning Request Scheduling

Though the GLIST Page Cache and GL-TL enable the reuse of graph in between requests, how to group the requests into batch of concurrently executed commands impacts the efficacy of locality enhancement. When being requested, GNNs usually at first sample the large graph and operate on certain sub-graphs. Due to the random sampling strategies, analyzing a single vertex usually touches several flash pages to fetch the feature vectors of the sampled sub-graph, which has very unpredictable locality and sometimes causes a huge waste of flash bandwidth. However, if multiple analysis requests are concurrently processed and tactically reordered by the GLIST runtime, the flash bandwidth utilization will be improved. Nevertheless, due to the limited size, the DRAM in storage cannot accommodate the whole working set of a large request batch. Reordering and grouping the requests will help improve the cache reusability. In this way, multiple groups are served sequentially to reuse the shared data including the attribute information and intermediate data of vertices, because the groups of different requests may overlap with one another and share the intermediate or the input property data in the requests. Moreover, the requests in each group are fused and processed as a batch can better utilize both the flash bandwidth and the PE array of GLA.

The process of GL requests scheduling is shown in [Algorithm 1](#). To exploit the intermediate data reuse, GLIST leverages an encoding-decoding manner by splitting the GNN workflow into vertex embedding phase and prediction phase. In vertex embedding phase, the intermediate data can be reused by other analysis requests. For example, as shown in [Figure 1](#), the latent representation of each user obtained from this phase can be used to generate any recommendations related to that user. The operations in the prediction phase, however, are highly dependent on each specific user request, which hardly share intermediate data. Therefore, GLIST parses the requests (Line 3), so that only the primitive vertex embedding requests are re-scheduled. After re-scheduling, the primitive

Algorithm 1: Request Scheduling

```
Input: Graph  $G$ , Request  $R_i$ , Group Size  $S$   
Output: Scheduled Requests  $R_o$ , Embedding-Prediction Mapping Table  $EP\_MT$   
1  $req\_mapping\_table = \text{dict}()$   
2  $par\_ri = \text{usr\_req\_partition}(R_i)$   
3 for  $user\_req \leftarrow par\_ri$  do  
4   if  $user\_req.type == "Edge"$  then  
5      $primitive\_req\_mapping\_table =$   
6        $\text{extract\_edge}(primitive\_req\_mapping\_table, user\_req)$   
7   else if  $user\_req.type == "Graph"$  then  
8      $primitive\_req\_mapping\_table =$   
9        $\text{extract\_graph}(primitive\_req\_mapping\_table, user\_req)$   
10  else  
11     $primitive\_req\_mapping\_table =$   
12       $\text{extract\_vertex}(primitive\_req\_mapping\_table, user\_req)$   
13  $reordered\_primitive\_req, primitive\_req\_mapping\_table =$   
14    $\text{reorder\_primitive\_req}(task\_primitive\_req, primitive\_req\_mapping\_table)$   
15  $R_o, EP\_MT = \text{request\_grouping}(\text{Config}, reordered\_primitive\_req,$   
16    $primitive\_req\_mapping\_table)$   
17 return  $R_o, EP\_MT$ 
```

requests are reordered, and an embedding-prediction mapping table (EP_MT) will be used to record the mapping information between the re-ordered embedding phase and the intact prediction phase, so that GLIST can correctly execute the prediction phase.

Requests decomposition and reordering. The sub-graphs associated to the GL requests may overlap with each other to different extent, and contribute to different degree of locality. Thus, to maximize the temporal data locality in-between embedding requests that hit the same graph, the runtime scheduler reorders the primitive requests according to the affinity of their sampled regions in the graph. Though there are different categories of reusable data worth exploiting, the scheduler prioritizes the reuse of intermediate embedding data over that of input property data. For example, the requests on graph edge analysis, all begins with the embedding of the endpoints that can be reused while the latter prediction can be done independently. Thus, the Edge-level analysis request is decomposed by the scheduler into two primitive **Node-level Analysis** requests and one prediction request. In this way, the requests in embedding phase can be scheduled to maximize data locality and the prediction phase of different requests can reuse the embedding vectors of vertices in the DRAM cache. As shown in Algorithm 1, the batch of requests is initially separated into the primitive requests on vertices according to the requested graphs and the type of requests (Line 2). Then, the scheduler scans through the requests and reorders the primitive requests that may hit different sub-graphs (Line 4 — Line 9). Because each primitive request is correlated to a vertex as the analysis target, estimating the locality in-between requests is to measure the size of overlapping area of the corresponding vertex sub-graphs, which includes all the vertices that are n -hops away from the target vertex. Thereby, in scheduling, the $reorder_primitive_req()$ function is used to obtain the vertex whose sub-graph share more vertices with the previous scheduled requests than others. In practice, we

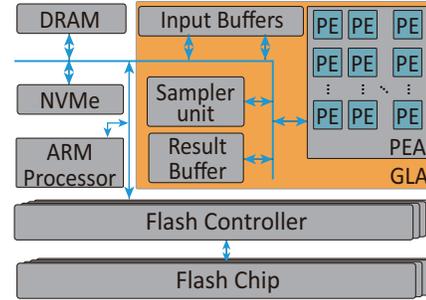

Figure 4: The GLA architecture and its integration to the hardware system.

implement the function by simply finding the vertex that has the minimum distance from the previously requested vertex.

Requests grouping. As mentioned above, the sub-graph obtained by the Sample function for each requested vertex usually causes random but small-footprint memory access, which tends to cause low flash bandwidth. In addition, for most of the GNN models, the bottom layers are witnessed to contribute less computation overhead than the top layers [6, 14, 43]. As a result, a single request hitting a vertex may not fully utilize the Processing Element (PE) resources of the GLA especially in the last layer of the GNN models. Therefore, GLIST batches all the reordered requests obtained from the request reordering stage into several groups as described in Line 11 of Algorithm 1. By fusing multiple requests of the same tasks into a batched task, both the utilization of flash bandwidth and the GLA are improved.

4.3 In-storage Graph Learning Accelerator

4.3.1 The Accelerator Architecture

Based on the design presented in [27], the Graph Learning Accelerator presented in Figure 4 is composed of a graph Sampler, on-chip buffers, and a Processing Element Array (PEA) to perform graph neural network inference.

The Sampler unit. For attributed graph analysis, the Sampler unit samples the vertices and edges from a large graph according to the predefined manner, before invoking GNN inference. It supports uniform distribution sampling or other predefined sampling functions [6, 14, 53]. In the sampling stage, the property data and their connection of the sampled vertices under request are loaded from flash devices to the DRAM of the GLIST embedded platform and further to the corresponding on-chip buffers. Besides, the Sampler in GLIST also supports non-sampling based GNN models [21, 49] by loading tiled graph sequentially according to the predefined tiling configuration.

According to the GNN framework introduced in Figure 2.1, the **Combine** and **Aggregate** functions should also be supported by the GLA. A Processing Element Array (PEA) is designed to address the matrix operations in **Combine** function. Each column of the PEA handles a single dimension

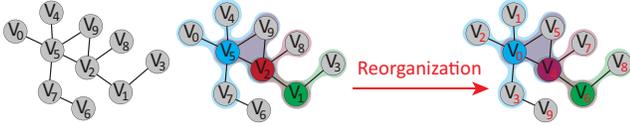

Figure 5: Graph reorganization.

of the input property for all the input vertices while the PEs in the same row are dedicated to one single vertex, so that the PEA structure is independent to the dimension of graph vertex properties.

To support the **Aggregate** function, we adopted a full mesh topology in our design by fully connecting columns of PEs in the array to achieve high-throughput message passing. Each PE in the same column broadcasts its data to all other columns and select data from other PEs’ output according to the control signal generated by the controller in PEA.

Algorithm 2: Graph Reorganization

Input: Graph G , Hop count h , Degree threshold Td , Center vertex number threshold Cn
Output: Reorganized Graph

```

1 important_vertices = Top  $Cn$  nodes whose in degree  $< Td$  of  $G$ 
2 for  $i \rightarrow \text{important\_vertex}$  do
3   | workingset[ $i$ ] = Sample from workingset[ $i$ ]
4 end
5 vertex_sequence = []
6  $i = 0$ 
7 while workingset is non-empty do
8   | Add vertex  $j$  that has the maximum intersection with vertex  $i$  in
9   | workingset[] to vertex_sequence
10  | Remove workingset[ $i$ ] from workingset
11  |  $i = j$ 
12 end
13 map_table = map()
14 for  $i \rightarrow \text{vertex\_sequence}$  do
15   | Assign new  $ID$  to vertex  $i$  and its  $h$  hop neighbors
16   | Record the mapping information in map_table
17 end
18 new_graph = Construct new graph with  $G$  and map_table
19 return new_graph

```

4.3.2 Graph Reorganization

When analyzing a vertex in a Sampling based graph learning workflow, its closer neighbors are more likely to be accessed, which shows the existence of spatial locality in GL workloads. However, the property of the vertices usually takes hundreds of bytes or few KB, which is much smaller than a flash page size and may cause flash bandwidth under-utilization. Therefore, we designed a heuristic algorithm to re-index the vertex IDs in a graph to maximize the spatial locality of GL requests as Algorithm 2 shows. Firstly, the reorganization algorithm selects the top Cn highest in-degree vertices with in-degree below the threshold Td as important vertices, where the threshold Td is used to exclude excessively high degree vertices since their neighborhood footprint often outsize the flash page and their locality can hardly be exploited. After that, it fetches each important vertex’s h hop neighbors as its working set. To reduce the complexity, the algorithm usually randomly samples a subset of the true working set (i.e.

Table 4: FPGA Resource Usage

Module	LUT	FF	BRAM	DSP
Flash Controller	44141	30156	80	0
NVMe Interface	8586	11455	28	0
GLA Accelerator	66287	51527	172	514
In Total	136506	117261	293	514
Percent(%)	62.45	26.82	53.76	57.11

\sqrt{N} from N vertices in our implementation) to represent the whole set. Then the important vertices are sorted according to the size of overlapping working set with others so that the potential spatial locality associated to the vertices are kept in the vertex sequence. Finally, the chosen important vertices and their corresponding h hop neighbors are assigned new IDs in sequence.

A tiny example shown in Figure 5 illustrates the graph reorganization procedure with given parameters: $h = 1$, $Cn = 3$, $Td = 0$. The procedure chooses three important vertices: $V5$, $V2$, and $V1$ according to the number of adjacent vertices and their one-hop neighbors are recorded as working-set respectively, as the shades shown in Figure 5. Then the algorithm sorts the three important vertices according to the size of overlapping working-set and obtains the sequence: $V5 \rightarrow V2 \rightarrow V1$ ($V5$ ’s working set has three common vertices with $V2$ ’s, and $V2$ ’s working set has two common vertices with $V1$ ’s). After that, each important vertex and the corresponding working set are assigned new IDs in the previously sorted order. Specifically, $V5$ and its five one-hop neighbors $V0$, $V4$, $V2$, $V7$, and $V9$ are assigned new IDs: $V0 \sim V5$. Then $V2$ and $V1$ follows. Finally, the procedure finds the remaining vertex that does not belong to any working set ($V6$) and assigns new ID to it to make sure that all the vertices in the graph are re-indexed.

5 Evaluation

5.1 GLIST Overall Evaluation

Experiment Setup. The Cosmos Plus OpenSSD platform was employed for the proposed GLIST system implementation, and it consists of an XC7Z045 FPGA chip (ARM-FPGA), 1 GB DRAM, an 8-channel NAND flash interface, an Ethernet interface, and a PCIe Gen2 8-lane interface. We implemented the GLA with Chisel [2] and integrated it in the hybrid ARM-FPGA processor as the major GL processing engine. The hardware project was synthesized and implemented with Vivado 2016.2 and the design works at 150MHz. Table 4 shows the logic resource usage of our hardware project. The firmware of the prototype runs on Dual 1GHz ARM Cortex-A9 core of XC7Z045. The board was connected with the host server via a PCIe link. We also profiled the prototype system and built a simulator for scalable evaluation.

We take a set of **Node-level**, **Edge-level**, and **Graph-level** GL workloads shown in Table 2 as benchmarks. The models used for benchmark are all quantized to 8bit fixed point. We

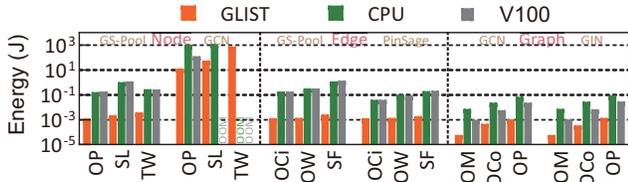

Figure 6: Energy consumption of a single request on different GL systems.

have the benchmark implemented with GLIST on Cosmos Plus OpenSSD platform to gain insight into the advantages of the in-storage graph learning. We compared GLIST with DGL [45] on a CPU-based platform and a GPU-based platform respectively. The CPU-based platform is equipped with two Intel Xeon E5-2690 V3 processors and 64 GB DRAM. The GPU-based platform includes two Intel Xeon E5-2690 V3 processors and an NVIDIA V100 GPU. Both platforms have all the graphs and GNN models initially stored in a Samsung 970 EVO 1 TB SSD with 3.5 GB/s peak read bandwidth because the large graphs used in many graph learning applications can exceed the capacity of the main memory. To evaluate the different systems, we randomly generated 10,000 graph learning requests over the graph and measured the average processing latency and energy consumption.

Performance. The performance of the proposed GLIST-based GL system is illustrated in Figure 7. It shows $13.2\times$ and $10.1\times$ average speedup compared to the CPU baseline and GPU baseline, respectively. Particularly, GLIST shows significant higher performance speedup on GS-Pool and PinSage which need to sample over the large input graphs. The main reason is that the random sampling over large input graphs incurs substantial random accesses to the flash and rather low flash bandwidth utilization when GS-Pool and PinSage are deployed on the CPU platform and the GPU platform. We also measured the flash bandwidth, and it shows only 100 MB/s, which is much lower than the peak bandwidth of the device and dramatically bottlenecks the computing capability of CPUs and GPUs accordingly. As a result, the performance of the CPU platform and the GPU platform is also similar. In contrast, GLIST with intensive data layout optimization and intra-request reuse optimization greatly improves the data reuse and reduces the random accesses over the flash. Thereby, it benefits most on GS-Pool and PinSage. Different from GS-Pool and PinSage, GCN and GIN operate on the entire graph instead of sampling sub-graphs. In this case, the graph will be accessed sequentially and the flash bandwidth can be fully utilized. With sufficient data supply from the flash, the GPU platform with more parallel processing engines shows much higher performance over the CPU platform according to the experiment. GLIST takes advantage of the specialized accelerator and still outperforms the CPU platform and the GPU platform given the same flash bandwidth provision.

Energy Consumption. In this experiment, we utilized a power meter to measure the power consumption of the pro-

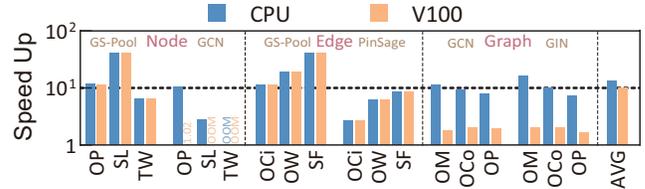

Figure 7: Single node performance of GLIST

posed GLIST system, the CPU-based, and the GPU-based graph learning systems respectively. Then, we obtained the energy consumption by calculating the production of the average power got by power meter and the benchmark execution time. The resulting energy consumption of the different benchmark GNN models are illustrated in Figure 6 and the per-request average power and benchmark time of different settings are listed in Table 5. It shows that GLIST reduces the average energy consumption by 98.7% and 98.0% respectively when compared to the CPU-based platform and the GPU-based platform. The significant energy reduction can be attributed to both the lower power consumption brought by the dedicated GLA in GLIST and the much lower execution time of GLIST as discussed in prior subsection. At the same time, we also noticed that the GPU-based platform shows higher energy consumption on PinSage and GS-Pool over the CPU-based platform. This is mainly caused by the fact that GPU fails to exploit its massive parallel processing engines due to the massive random access induced flash bandwidth bottleneck and much higher power consumption over the CPU-based platform. When the flash bandwidth utilization is improved for GCN and GIN that include more sequential data accesses, the execution time dominates the energy consumption in the GPU-based platform. Hence, the GPU-based platform exhibits lower energy consumption in these cases.

5.2 The GLIST Optimizations

Experimental Setup. To gain insight into the advantages of the GLIST optimization including graph reorganization (R), request scheduling (S), request grouping (G), and caching (C), we conducted a request generation server to continuously issue different graph analysis requests to the GLIST system for evaluating the above optimization strategies. In order to make the distribution of requests issued by generation servers closer to the real production system, we first analyze the real-world request trace from the commercial data center. The analysis results indicate that the requests have different levels of locality depending on the services provided by the data center and the data types accommodated in the warehouse nodes. Thereby, for simplicity, we introduce the $N\%$ -Locality, denoted as $N-L$, to describe the degree of locality in between the batch of requests that arrives in a fixed time window sent to GLIST. This term represents the $N\%$ neighbor vertices and edges can be reused between any adjacent request on average,

Table 5: Per-request average power and benchmark time of different platforms.

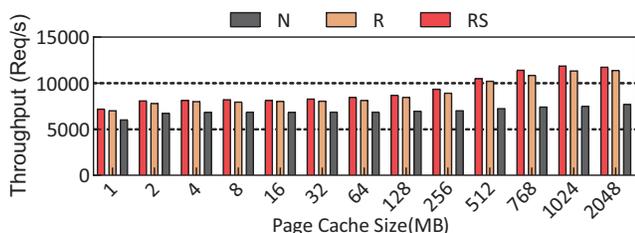

Figure 8: Throughput of GLIST w.r.t. page cache size.

which is defined as the follows:

$$N-L = \frac{N_{Common\ vertices\ of\ subgraph\ related\ to\ the\ two\ requests}}{N_{Vertices\ in\ subgraph\ related\ to\ the\ latter\ request}} \quad (7)$$

We randomly generated 10,000 vertex classification requests on the ogbn-papers100M dataset, whose property data is over 50 GB in size. We shuffled the requests to evaluate the advantages of the above optimization approaches. First, as discussed in Section 4.2, the benefits brought by the graph reorganization (**R**) and request scheduling (**S**) optimization methods are impacted by the cache size and the feature dimension. Thereby, in order to evaluate the influence of these factors on system performance, we evaluate the throughput of the GLIST system under different Page Cache sizes. After that, we adjusted the dimension of the vertex property data to distinguish the gains brought by the graph reorganization and request scheduling optimizations. Second, due to the locality level that can influence the performance of request scheduling, we fixed the property size of the vertices to 16 KB and adjust the locality level of the generated requests to show the variation of the gain of the request scheduling. Third, we explored the performance variation of the GLIST system under the different group size configurations of the GLIST runtime. Finally, we fixed the Page Cache size and measured the performance speedup of the GLIST system under different combinations of optimization methods compared to the GLIST system without optimization methods.

Evaluation. Figure 8 shows the throughput of the GLIST system under the three configurations including GLIST without optimization (**N**), GLIST with graph reorganization (**R**), and GLIST with graph reorganization and request scheduling (**RS**). It can be observed that the throughput of the system with **RS** and **R** increases as the Page Cache size increases because larger cache size can avoid vertex access being dispatched to flash memory and reduces access latency. Meanwhile, the GLIST system that adopts reorganization methods **R** pos-

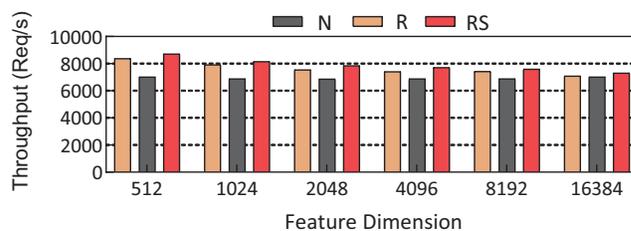

Figure 9: Throughput of GLIST w.r.t. property dimension.

sesses higher spatial data locality, which highly exploits the data reusability in each flash pages and alleviates the penalty of Page Cache misses, thereby, it performs better than the system without any optimizations, though the Page Cache is large. Furthermore, when both the request scheduling and graph reorganization are adopted in **RS** configuration, the spatial data locality of each single request can be exploited and released. In this case, as shown in Figure 8, the GLIST system with **RS** methods gains the highest throughput compared to **N** and **R** settings.

Figure 9 illustrates the system throughput of the GLIST system under the three configurations mentioned in the above paragraph with respect to various configurations on the property dimension. It can be observed that the GLIST with **R** and **RS** optimization methods achieve 19.5% and 24.2% higher throughput compared to the system without optimization **N**, respectively. As the feature dimension increases, a flash page can only accommodate a few property vectors, which results in the graph reorganization methods fails to exploit spatial data locality. Thereby, the system performance with **R** and **RS** optimization methods drops sharply and the **RS** still outperforms **R** because of the gain brought by request scheduling method. In addition, as the dimension of property vector increases, the performance gap between the **R** and **N** optimization methods gradually disappears until the property dimension arrives at the size of a flash page (16 KB). In this case, the system with request scheduling still maintains 4% higher throughput than the other settings.

Figure 10 (a) shows the speedup of the GLIST system with request scheduling methods **RS** under different locality level configuration compared to a system without optimization methods. The increase of locality level indicates the rise of data reusability, thus the GLIST system adopting request scheduling method achieves performance improvement up to 2.65 \times . As shown in Figure 10 (b), the GLIST system achieves performance improvement compared to the system without

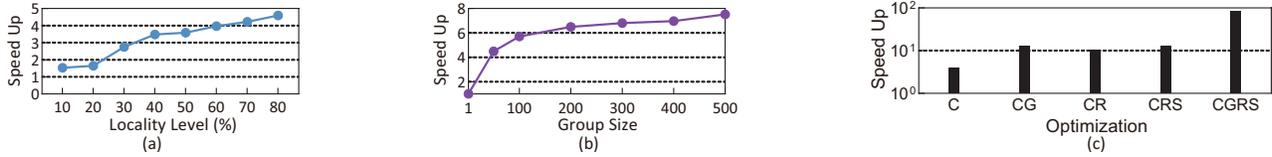

Figure 10: (a) Speedup of request scheduling w.r.t. locality level. (b) Performance improvement of different group size in request grouping. (c) Performance improvement of different optimization enabled.

request grouping optimization with the increase of group size. The reason can be attributed to two folders: (1) larger group size can fully utilize the internal bandwidth provided by multiple flash channels; (2) large group size can fully exploit the data parallelism and thus making the computation unit of the graph learning accelerator in high utilization. In addition, the limitation of internal flash bandwidth makes performance improvement slow down when the group size is larger than 200. Figure 10 (c) shows the performance speedup of the GLIST system under the combination of various optimization (R, S, G, and C) compared to the system without optimization (N). It can be observed that neither the combination of node embedding caching and request grouping ($12.94\times$), denoted as CG, nor the combination of node embedding caching, graph reorganization, and request scheduling ($12.89\times$), denoted as CRS achieves the best performance. This is because CG fails to exploit the data locality brought the graph reorganization and request scheduling methods under the high utilization of flash bandwidth and graph learning accelerator, which results in the Page Cache hit rate only reaches to 67.86%. Meanwhile, although CRS can exploit the data locality using graph organization and make Page Cache hit rate reach to 94.73%. CRS is unable to fully utilize the flash bandwidth and PE-Array in GLA. Not only does the CGRS optimization method exploit the data locality but also fully utilize the available resource, making the GLIST system achieve the highest performance improvement.

5.3 Bit-width Scalability Exploration

The bit-width of vertex feature vector and GNN model parameters has a great impact on performance, resource overhead, and energy consumption of the GLIST prototype. To explore an appropriate setting for quantization, we choose GCN [21] and Cora [39] as target model and dataset respectively to evaluate how the four configurations including **floating-point, 32 bit fixed-point, 16 bit fixed point, and 8 bit fixed-point** impact on accuracy, latency, energy consumption, and resource usage. We leverage a static quantization method which enumerates every possible configuration at each layer and choose the best one with the lowest loss. The results are as shown in Table 6. Though **floating-point** and **32 bit fixed-point** achieve higher accuracy, the logic resource usage is extremely high and can hardly be implemented on current FPGA platform. And wider word size makes it hard to enable high-throughput graph learning services because of high bandwidth

Table 6: Comparison of accuracy and resource utilization

Config.	Acc.	LUT	FF	DSP	Latency	Energy
float-32	79.1%	1891986	192372	1	-	-
fixed-32	77.8%	632777	242506	889	-	-
fixed-16	77.5%	125253	112730	513	2.74ms	$5.7\times 10^{-2}J$
fixed-8	77.1%	66287	51527	514	1.80ms	$3.6\times 10^{-2}J$

requirements. For the lower bit configurations, the latency decreases by 34.3% and the energy consumption decreases by 36.8% with only a 0.4% loss on accuracy when changing bit width from 16 to 8. Moreover, the resource usage of 8-bit GLA is significantly less than another one, making it possible to implement more GLA cores in the GLIST system to perform higher throughput graph learning services. Note that the quantization method used for evaluation is only a naive one and the accuracy of low-bit configurations will show better results when changing to state-of-the-art methods [9, 12, 13].

6 Conclusion

In this paper, we formulated that the conventional GPU+SSD graph learning platforms are limited by I/O operations after studying a diverse set of graph learning tasks. We then study the data locality that exists in flash-based graph learning applications. To tackle the bottlenecks of conventional graph learning systems, we proposed an in-storage graph learning accelerating system, GLIST, which features multiple optimizations proposed based on our observations to fully exploit data locality. Finally, we implemented a GLIST prototype with FPGA and showed it achieves $13.2\times$ and $10.1\times$ average speedup and reduces the power consumption by 98.7%, 98.0% compared to conventional CPU and GPU based graph learning systems, respectively.

Abstract

Many Internet of Things (IoT) applications are time-critical and dynamically changing. However, traditional data processing systems (e.g., stream processing systems, cloud-based IoT data processing systems, wide-area data analytics systems) are not well-suited for these IoT applications. These systems often do not scale well with a large number of concurrently running IoT applications, do not support low-latency processing under limited computing resources, and do not adapt to the level of heterogeneity and dynamicity commonly present at edge environments. This suggests a need for a new edge stream processing system that advances the stream processing paradigm to achieve efficiency and flexibility under the constraints presented by edge computing architectures.

We present DART, a scalable and adaptive edge stream processing engine that enables fast processing of a large number of concurrent running IoT applications' queries in dynamic edge environments. The novelty of our work is the introduction of a dynamic dataflow abstraction by leveraging distributed hash table (DHT) based peer-to-peer (P2P) overlay networks, which can automatically place, chain, and scale stream operators to reduce query latency, adapt to edge dynamics, and recover from failures.

We show analytically and empirically that DART outperforms Storm and EdgeWise on query latency and significantly improves scalability and adaptability when processing a large number of real-world IoT stream applications' queries. DART significantly reduces application deployment setup times, becoming the first streaming engine to support DevOps for IoT applications on edge platforms.

1 Introduction

Internet-of-Things (IoT) applications such as self-driving cars, interactive gaming, and event monitoring have a tremendous potential to improve our lives. These applications generate a large influx of sensor data at massive scales (millions of sensors, hundreds of thousands of events per second [20,26]). Under many time-critical scenarios, these massive data streams must be processed in a *very short time* to derive actionable intelligence. However, many IoT applications [22,23] adopt the server-client architecture, where the front-end sensors send time-series observations of the physical or human system

*Liting is affiliated with Virginia Tech, but was at Florida International University during this work.

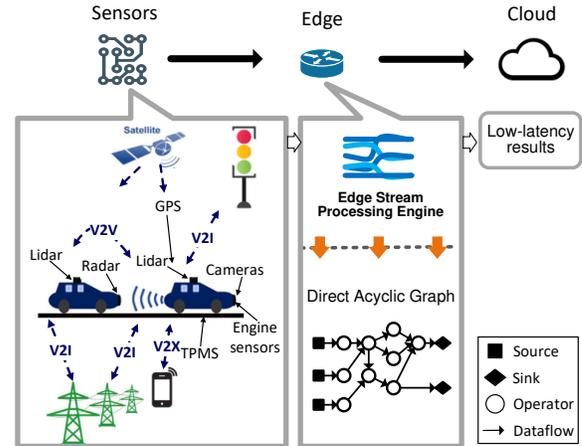

Figure 1: Edge stream processing use case.

to the back-end cloud for analysis. Such a long-distance of processing makes it *not* appropriate or time-critical IoT application because: (1) the high latency may cause the results to be obsolete; and (2) the network infrastructure cannot afford the massive data streams.

A new trend to address this issue is edge stream processing. To put it simply, edge stream processing applies the stream processing paradigm to the edge computing architecture [37,50]. Instead of relying on the cloud to process sensor data, the edge stream processing system relies on distributed edge compute nodes (Gateways, edge routers, and powerful sensors) which are near the data sources to process data and trigger actuators. The execution pipeline is as follows. Sensors (e.g., self-driving car sensors, smart wearables) generate data streams continuously. They are then consumed by the edge stream processing engine, which creates a logical topology of stream processing operators connected into a Directed Acyclic Graph (DAG), processes the tuples of streams as they flow through the DAG from sources to sinks, and outputs the results in a very short time. Each *source* node is an IoT sensor. Each *inner* node runs an operator or operators that can perform user-defined computation on data, ranging from simple computation such as *map*, *reduce*, *join*, *filter* to complex computation such as ML-based classification algorithms. Each *sink* node is an IoT actuator or a message queue to the cloud.

Figure 1 illustrates a use case scenario [10] that benefits from an edge stream processing engine. In future Intelligent Transportation Systems such as the efforts currently funded

by the US Department of Transportation [27], cars are interconnected and equipped with wide-area network access. Even at low levels of autonomy, each car will generate at least 3 Gbit/s of sensor data [25]. On the back-end, many IoT stream applications will run concurrently, consuming these live data streams to quickly derive insights and make decisions. Examples of such applications include peer-to-peer services for traffic control and car-sharing safety and surveillance systems. Note that many of these services cannot be completed on on-board computers within a single car, requiring the cooperation of many computers, edge routers, and gateways with sensors and actuators as sources and sinks. They will involve a large number of cars and components from the road infrastructure.

However, as IoT systems grow in number and complexity, we face significant challenges in building edge stream processing engines that can meet their needs.

The first challenge is: *how to scale to numerous concurrently running IoT stream applications?* Due to the exponential growth of new IoT users, the number of concurrently running IoT stream applications will be significantly large and change dynamically. However, modern stream processing engines such as Storm [7], Flink [32], and Heron [44] and wide-area data analytic systems [39–41, 43, 53, 55, 62, 65, 66] mostly inherit a centralized architecture, in which the monolithic master is responsible for all scheduling activities. They use a first-come, first-serve method, making deployment times accumulate and leading to long-tail latencies. As such, this centralized architecture easily becomes scalability and performance bottlenecks.

The second challenge is: *how to adapt to the edge dynamics and recover from failures to ensure system reliability?* IoT stream applications run in a highly dynamic environment with load spikes and unpredictable occurrences of events. Existing studies on the adaptability in stream processing systems [34, 36, 38, 42, 64] mainly focus on the cloud environment, where the primary sources of dynamics come from workload variability, failures, and stragglers. In this case, a solution typically allocates additional computational resources or re-distributes the workload of the bottleneck execution across multiple nodes within a data center. However, the edge environment imposes additional difficulties: (1) edge nodes leave or fail unexpectedly (e.g., due to signal attenuation, interference, and wireless channel contention); and (2) accordingly, stream operators fail more frequently. Unfortunately, unlike the cloud servers, edge nodes have limited computing resources: few-core processors, little memory, and little permanent storage [37, 59] and they have no backpressure. As such, the previous adaptability techniques by re-allocating resources or buffering data at data sources cannot be applied in edge stream processing systems.

We present DART, a scalable and adaptive edge stream processing engine to address the challenges listed above. The key innovation is that DART re-architects the stream processing system runtime design. In sharp contrast to existing stream

processing systems, there is no monolithic master. Instead, DART involves all peer nodes to participate in operator placement, dataflow path planning, and operator scaling, thereby revolutionarily improving scalability and adaptivity.

We make the following contributions in this paper.

First, we study the software architecture of existing stream processing systems and discuss their limitations in the edge setting. To our best knowledge, we are the first to observe the lack of scalability and adaptivity in stream processing systems for handling a large number of IoT applications (Sec. 2).

Second, we design a novel dynamic dataflow abstraction to automatically place, chain and parallelize stream operators using the distributed hash table (DHT) based peer-to-peer (P2P) overlay networks. The main advantage of a DHT is that it avoids the original monolithic master. All peer nodes jointly make operator-mapping decisions. Nodes can be added or removed with minimal work around re-distributing keys. This design allows our system to scale to extremely large numbers of nodes. To our best knowledge, we are the first to explore DHTs to pursue extreme scalability in edge stream processing (Sec. 3).

Third, using DHTs, we decompose the stream processing system architecture from $1:n$ to $m:n$, which removes the centralized master and ensures that each edge zone can have an independent master for handling applications and operating autonomously without any centralized state (Sec. 4). As a result of our distributed management, DART improves overall query latencies for concurrently executing applications and significantly reduces application deployment times. To the best of our knowledge, we offer the first stream processing engine to make it feasible to operate IoT applications in a DevOps fashion.

Finally, We demonstrate DART’s scalability and latency gains over Apache Storm [7] and EdgeWise [1] on IoT stream benchmarks (Sec. 5).

2 Background

2.1 Stream Processing Programming Model

Data engineers define an IoT stream application as a directed acyclic graph (DAG) that consists of operators (see Figure 1). Operators run user-defined functions such as `map`, `reduce`, `join`, `filter`, and ML algorithms. Data tuples flow through operators along the DAG (topology). In our case, DART supports both stateful batch processing by using *windows* as well as continuously event-based stateless processing. The application’s query latency is defined as the elapsed time since the source operator receives the timestamp signaling the completion of the current window to when the sink operator externalizes the window results.

We consider typical edge environments. The edge compute nodes consist of sensors, routers, and sometimes gateways. They are connected by different connections such as WiFi,

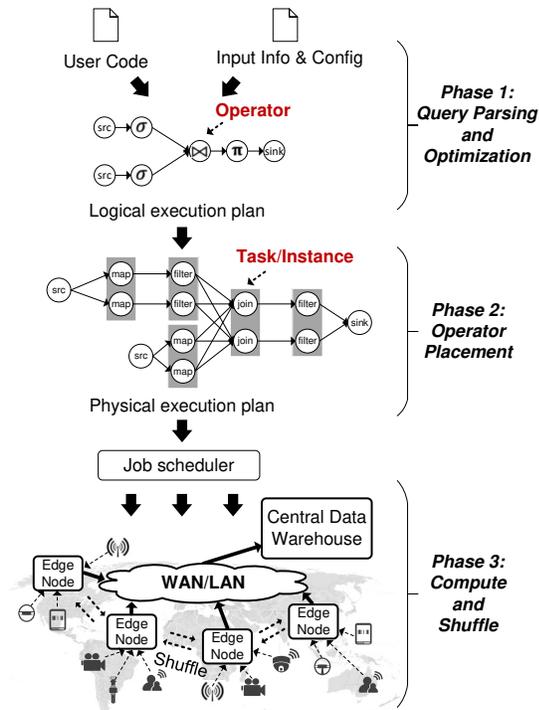

Figure 2: IoT stream applications execution pipeline.

Zigbee, BlueTooth, or LAN with diverse inbound and outbound bandwidths and latency. They have fewer resources compared to the cloud servers, but more resources than embedded sensor networks, and thus can afford reasonably complex operations (e.g., SenML parsers, Kalman filters, linear regressions). As shown in Figure 2, the execution pipeline for processing an IoT stream application has a few key phases:

- **Phase 1: Query parsing and optimization.** When an IoT stream application is submitted by a user, its user code containing transformations and actions is first parsed into a logical execution plan represented using a DAG, where the vertices correspond to stream operators and the edges refer to data flows between operators.
- **Phase 2: Operator placement.** Afterward, the DAG is converted into a physical execution plan, which consists of several execution stages. Each stage can be further broken down into multiple execution instances (tasks) that run in parallel, as determined by the stage’s level of parallelism. This requires the system to place all operators’ instances on distributed edge nodes that can minimize the query latency and maximize the throughput.
- **Phase 3: Compute and shuffle.** Operator instances independently compute their local shard of data and shuffle the intermediate results from one stage to the next stage. This requires the system to adapt to the workload variations, bandwidth variations, node joins and leaves, and failures and stragglers.

2.2 Stream Processing System Architecture

As shown in Figure 3, existing studies [37, 39–41, 43, 50, 53, 55, 62, 65, 66] mostly rely on a master-slave architecture, in which a “single” monolithic master is administering many applications (if any). The responsibilities include accepting new applications, parsing each application’s DAG into stages, determining the number of parallel execution instances (tasks) under each stage, mapping these instances onto edge nodes, and tracking their progress.

This centralized architecture may run well for handling a small number of applications in the cloud. However, when it comes to IoT systems in the edge environment, new IoT users join and exit more frequently and launch a large number of IoT applications running at the same time, which makes the architecture easily become a scalability bottleneck and jeopardize the application’s performance. This is because of (1) **high deployment latency**. These systems use a first-come, first-served approach to deploy applications, which causes applications to wait in a long queue and thus leads to long query latencies; and (2) **lack of flexibility for dataflow path planning**. They limit themselves to a fixed execution model and lack the flexibility to design different dataflow paths for different applications to adapt to the edge dynamics.

The limitation of the centralized architecture has been identified before in data processing frameworks such as YARN [63], Sparrow [51], Apollo [30]. They use two masters for task scheduling (one is the main master and one is the backup master). However, they remain fundamentally centralized [30, 51, 63] and restrict themselves to handle a small number of applications only.

3 Design

This section introduces DART’s dynamic dataflow abstraction and shows how to scale up and down operators and perform failure recovery on top of this abstraction.

3.1 Overview

The DART system aims to achieve the following goals:

- **Low latency.** It achieves low latency for IoT queries.
- **Scalability.** It can process a large number of concurrently running applications at the same time.
- **Adaptivity.** It can adapt to the edge dynamics and recover from failures.

As shown in Figure 4, DART consists of three layers: *the DHT-based consistent ring overlay*, *the dynamic dataflow abstraction*, and *the scaling and failure recovery mechanisms*.

Layer 1: DHT-based consistent ring overlay. All distributed edge “nodes” (e.g., routers, gateways, or powerful sensors) are self-organized into a DHT-based overlay, which has been commonly used Bitcoin [48] and BitTorrent [35].

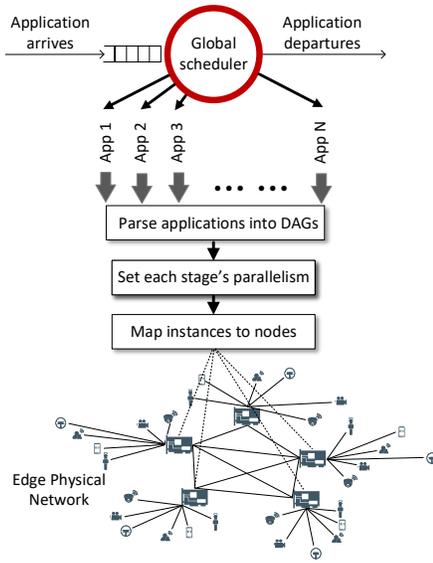

Figure 3: The global scheduler.

Each node is randomly assigned a unique “NodeID” in a large circular NodeID space. NodeIDs are used to identify the nodes and route stream data. *No matter where the data is generated, it is guaranteed that the data can be routed to any destination node within $O(\log N)$ hops.* To do that, each node needs to maintain two data structures: a routing table and a leaf set. The routing table is used for building dynamic dataflows. The leaf set is used for scaling and failure recovery.

Layer 2: Dynamic dataflow abstraction. Built upon the overlay, we introduce a novel dynamic dataflow abstraction. The key innovation is to leverage DHT-based routing protocols to approximate the optimal routes between source nodes and sink nodes, which can automatically place and chain operators to form a dataflow graph for each application.

Layer 3: Scaling and failure recovery mechanisms. Every node has a leaf set that contains physically “closest” nodes to this node. The leaf set provides the elasticity for (1) scaling up and down operators to adapt to the workload variations; (2) re-planning dataflows to adapt to the network variations. As stream data moves along the dataflow graph, the system makes dynamic decisions about the downstream node to send streams to, which increases network path diversity and becomes more resilient to changes in network conditions; and (3) replicating operators to handle failures and stragglers. If any node fails or becomes a straggler, the system can automatically switch over to a replica.

3.2 Dynamic Dataflow Abstraction

In the P2P model (e.g., Pastry [57], Chord [61]), each node is equal to the other nodes, and they have the same rights and duties. The primary purpose of the P2P model is to enable

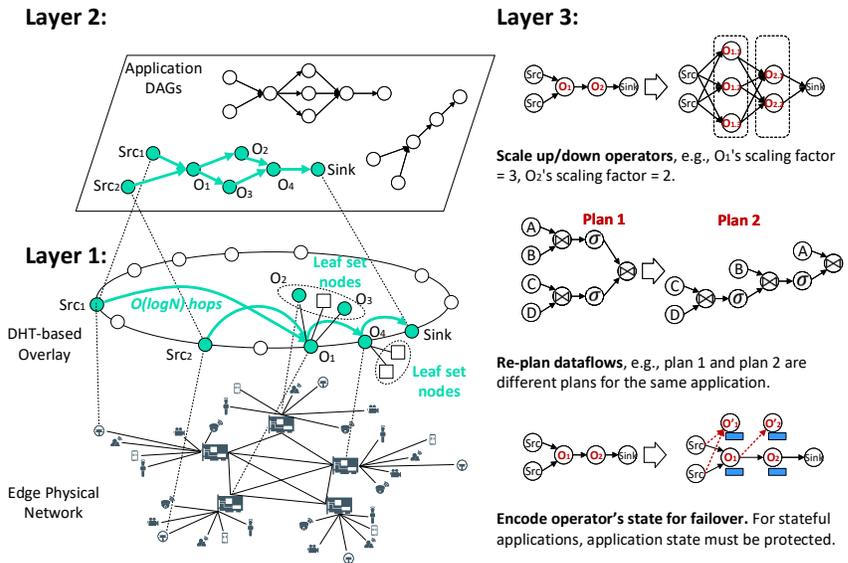

Figure 4: Dynamic dataflow graph abstraction for operator placement.

all nodes to work collaboratively to deliver a specific service. For example, in BitTorrent [35], if someone downloads some file, the file is downloaded to her computer in bits and parts that come from many other computers in the system that already have that file. At the same time, the file is also sent (uploaded) from her computer to others who ask for it. Similar to BitTorrent in which many machines work collaboratively to undertake the duties of downloading and uploading files, we enable all distributed edge nodes to work collaboratively to undertake the duties of the original monolithic master’s.

Figure 5 shows the process of building the dynamic dataflow graph for an IoT stream application. *First*, we organize distributed edge nodes into a P2P overlay network, which is similar to the BitTorrent nodes that use the Kademila DHT [46] for “trackerless” torrents. Each node is randomly assigned a unique identifier known as the “NodeID” in a large circular node ID space (e.g., $0 \sim 2^{128}$). *Second*, given a stream application, we map the source operators to the sensors that generate the data streams. We map the sink operators to IoT actuators or message queues to the Cloud service. *Third*, every source node sends a JOIN message towards a key, where the key is the hash of the sink node’s NodeID. Because all source nodes belonging to the same application have the same key, their messages will be routed to a rendezvous point—the sink node(s). Then we keep a record of the nodes that these messages pass through during routings and link them together to form the dataflow graph for this application.

To achieve low latency, the overlay guarantees that the stream data can be routed from source nodes to sink nodes within $O(\log N)$ hops, thus ensuring the query latency upper bound. To achieve locality, the dynamic dataflow graph covers a set of nodes from sources to sinks. The first hop is always

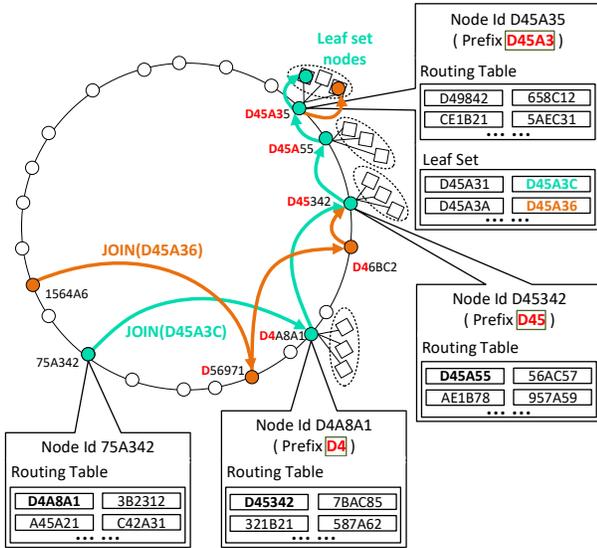

Figure 5: The process of building dynamic dataflow graph.

the node closer to the data source (data locality). Each node in the path has many leaf set nodes, which provides enough heterogeneous candidate nodes with different capacities and increases network path diversity. For example, if there are more operators than nodes, extra operators can map onto leaf set nodes. For that purpose, each node maintains two data structures: a routing table and a leaf set.

- *Routing table*: it consists of node characteristics organized in rows by the length of the common prefix. The routing works based on prefix-based matching. Every node knows m other nodes in the ring and the distance of the nodes it knows increases exponentially. It jumps closer and closer to the destination, like a greedy algorithm, within $\lceil \log_{2b} N \rceil$ hops. We add extra entries in the routing table to incorporate proximity metrics (e.g., hop count, RTT, cross-site link congestion level) in the routing process so as to handle the bandwidth variations.
- *Leaf set*: it contains a fixed number of nodes whose NodeIds are “physically” closest to that node, which assists in rebuilding routing tables and reconstructing the operator’s state when any node fails.

As shown in Figure 5, node 75A342 and node 1564A6 are two source nodes and node D45A3C is the sink node. The source nodes route JOIN messages towards the sink node, and their messages are routed to a rendezvous point (s) — the sink node(s). We choose the forwarder nodes along routing paths based on RTT and node capacity. Afterward, we keep a record of the nodes that their messages pass through during routings (e.g., node D4A8A1, node D45342, node D45A55, node D45A35, node D45A3C), and reversely link them together to build the dataflow graph.

The key to efficiency comes from several factors. First, the application’s instances can be instantly placed without

the intervention of any centralized master, which benefits the time-critical deadline-based IoT application’s queries. Second, because keys are different, the paths and the rendezvous nodes of all application’s dataflow graphs will also be different, distributing operators evenly over the overlay, which significantly improves the scalability. Third, the DHT-based leaf set increases elasticity for handling failures and adapting to the bandwidth and workload variations.

3.3 Elastic Scaling Mechanism

After an application’s operators are mapped onto the nodes along this application’s dataflow graph, *how to auto-scale them to adapt to the edge dynamics?* We need to consider various factors. Scaling up/down is to increase/decrease the parallelism (#instances) of the operator within a node. Scaling out is to instantiate new instances on another node by re-distributing the data streams across extra network links. In general, scaling up/down incurs smaller overhead. However, scaling out can solve the bandwidth bottleneck by increasing network path diversity, while scaling up/down may not.

We design a heuristic approach that adapts execution based on various factors. If there are computational bottlenecks, we scale up the problematic operators. The intuition is that when data queuing increases, automatically adding more instances to the system will avoid the bottleneck. We leverage the Secant root-finding method [29] to automatically calculate the optimal instance number based on the current system’s health value. The policy is pluggable. Let $f(x)$ represent the health score based on the input rate and the queue size ($0 < f(x) < 1$, with 1 being the highest score). Let x_n and x_{n-1} be the number of instances during phases p_n and p_{n-1} . Then the number of instances required for the next phase p_{n+1} such that $f \cong 1$ can be given by:

$$x_{n+1} = x_n + (1 - f(x_n)) \times \frac{x_n - x_{n-1}}{f(x_n) - f(x_{n-1})} \quad (1)$$

For bandwidth bottlenecks, we further consider whether the operator is stateless or stateful. In the case of stateless operators, we simply scale out operators across nodes. For stateful operators, we migrate the operator with its state to a new node in the leaf set that increases the network path diversity. Intuitively, when the original path only achieves low throughput, an operator may achieve higher throughput by sending the data over another network path.

3.4 Failure Recovery Mechanism

Since the overlay is self-organizing and self-repairing, the dataflow graph for each IoT application can be automatically recovered by restarting the failed operator on another node. Here, the challenge is, *how to resume the processing without losing intermediate data (i.e., operator state)?* Examples of operator states include keeping some aggregation or summary

of the received tuples in memory or keeping a state machine for detecting patterns for fraudulent financial transactions in memory. A general approach is checkpointing [7, 8, 54, 64], which periodically checkpoints all operators' states to a persistent storage system (e.g., HDFS) and the failover node retrieves the checkpointed state upon failures. This approach, however, is slow because it must transfer state over the edge networks that typically have very limited bandwidth.

We design a parallel recovery approach by leveraging the robustness of the P2P overlay and our previous experience in stateful stream processing [45]. Periodically, the larger-than-memory state is divided, replicated, and checkpointed to each node's leaf set nodes by using erasure codes [56]. Once any failure happens, the backup node takes over and retrieves state fragments from a subset of leaf set nodes to recompute state and resume processing. By doing that, we do not need a central master. The failure recovery process is fast because many nodes can leverage the dataflow graph to recompute the lost state in parallel upon failures. The replica number, the checkpointing frequency, the number of encoded blocks and the number of raw blocks are tunable parameters. They are determined based on state size, running environment and the application's service-level agreements (SLAs.)

4 Implementation

Instead of implementing another distributed system core, we implement DART on top of Apache Flume [3] (v.1.9.0) and Pastry [16] (v.2.1) software stacks. Flume is a distributed service for collecting and aggregating large amounts of streaming event data, which is widely used with Kafka [4] and the Spark ecosystem. Pastry is an overlay network and routing network for the implementation of a distributed hash table (DHT) similar to Chord [61], which is widely used in applications such as Bitcoin [48], BitTorrent [35], and FAROO [15]. We leverage Flume's excellent runtime system (e.g., basic API, code interpreter, transportation layer) and Pastry's routing substrate and event transport layer to implement the DART system.

We made three major modifications to Flume and Pastry: (1) we implemented the dynamic dataflow abstraction for operator placement and path planning algorithm, which includes a list of operations to track the DHT routing paths for chaining operators and a list of operations to capture the performance metrics of nodes for placing operators; (2) we implemented the scaling mechanism and the failure recovery mechanism by introducing queuing-related metrics (queue length, input rate, and output rate), buffering operator's in-memory state, encoding and replicating state to leaf set nodes; and (3) we implemented the distributed schedulers by using Scribe [33] topic-based trees on top of Pastry.

Figure 6 shows the high-level architecture of the DART system. The system has two components: a set of distributed schedulers that span geographical zones and a set of workers. Unlike traditional stream processing systems that manually

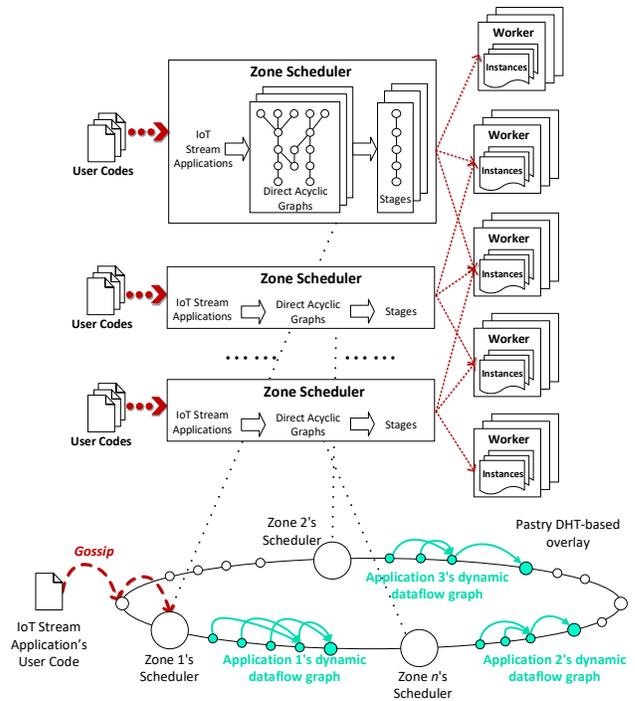

Figure 6: The DART system architecture.

assign nodes as “master” or “workers”, DART dynamically assigns nodes as “schedulers” or “workers”. For the first step, when any new IoT stream application is launched, it looks for a nearby scheduler by using the gossip protocol [31], which is a procedure of P2P communication that is based on the way that epidemics spread. If it successfully finds a scheduler within $\log(N)$ hops, the application registers itself to this scheduler. Otherwise, it votes any random nearby node to be the scheduler and registers itself to that scheduler. For the second step, the scheduler processes this application's queries by parsing the application's user code into a DAG and dividing this DAG into stages. Then the scheduler automatically parallelizes, chains operators, and places the instances on edge nodes using *the proposed dynamic dataflow abstraction*. These nodes are then set as this application's workers. The system automatically scales up and out operators, re-plans, and replicates operators to adapt to the edge dynamics and recover from failures by using *the proposed scaling mechanism and failure recovery mechanism*.

The key to efficiency comes from several factors. First, all nodes in the system are equal peers with the same rights and duties. Each node may act as one application's worker, another application's worker, a zone's scheduler, or any combination of the above, resulting in all load being evenly distributed. Second, the scheduler is no longer any central bottleneck. Third, the system automatically creates more schedulers for application intensive zones and fewer ones for sparse zones, thus scaling to extremely large numbers of nodes and applications.

5 Evaluation

We evaluate DART on a real hardware testbed (using Raspberry Pis) and emulation testbed in a distributed network environment. We explore its performance for real-world IoT stream applications. Our evaluation answers these questions:

- Does DART improve latency when processing a large number of IoT stream applications?
- Does DART scale with the number of concurrently running IoT stream applications?
- Does DART improve adaptivity in the presence of workload changes, transient failures and mobility?
- What is the runtime overhead of DART?

5.1 Setup

Real hardware. Real hardware experiments use an intermediate class computing device representative of IoT edge devices. Specifically, we use 10 Raspberry Pi 4 Model B devices for hosting source operators, each of which has a 1.5GHz 64-bit quad-core ARMv8 CPU with 4GB of RAM and runs Linux raspberrypi 4.19.57. Raspberry Pis are equipped with Gigabit Ethernet Dual-band Wi-Fi. We use 100 Linux virtual machines (VMs) to represent the gateways and routers for hosting internal and sink operators, each of which has a quad-core processor and 1GB of RAM (equivalent to Cisco’s IoT gateway [11]). These VMs are connected through a local-area network. In order to make our experiments closer to real edge network scenarios, we used the TC tool [17] to control link bandwidth differences.

Emulation deployment. Emulation experiments are conducted on a testbed of 100 VMs running Linux 3.10.0, all connected via Gigabit Ethernet. Each VM has 4 cores and 8GB of RAM, and 60GB disk. Specifically, to evaluate DART’s scalability, we use one JVM to emulate one logical edge node and can emulate up to 10,000 edge nodes in our testbed.

Baseline. We used Storm and EdgeWise [37] as the edge stream processing engine baseline. Apache Storm version is 2.0.0 [7] and EdgeWise [37] is downloaded from GitHub [14]. Both of them are configured with 10 TaskManagers, each with 4 slots (maximum parallelism per operator = 36). We run Nimbus and ZooKeeper [9] on the VMs and run supervisors on the Raspberry Pis. We use Pastry 2.1 [57] configured with leaf set size of 24, max open sockets of 5000 and transport buffer size of 6 MB.

Benchmark and applications. We deploy a large number of applications (topologies) simultaneously to demonstrate the scalability of our system. The applications in the mixed set are chosen from a full-stack standard IoT stream processing benchmark [60]. We also implement four IoT stream processing applications that use real-world datasets [12, 13, 24, 47]. They employ various techniques such as predictive analysis, model training, data preprocessing, and statistical summarization. Their operators run functions such as `transform`,

`filter`, `flatmap`, `aggregate`, `duplicate`, and `hash`. For example, we implement the DEBS 2015 application [13] to process spatio-temporal data streams and calculate real-time indicators of the most frequent routes and most profitable areas in New York City. The sensor data consists of taxi trip reports that include start and drop-off points, corresponding timestamps, and payment information. Data are reported at the end of the trip. Although the prediction tasks available in this application do not require real-time responses, it captures the data dissemination and query patterns of more complex upcoming transportation engines. An application that integrates additional data sources – bus, subway, car-for-hire (e.g., Uber), ride-sharing, traffic, and weather conditions – would exhibit the same structural topology and query rates that we use in our experiments while offering decision-making support in the scale of seconds. We implement the Urban sensing application [12] to aggregate pollution, dust, light, sound, temperature, and humidity data across seven cities to understand urban environmental changes in real-time. Since a practical deployment of environmental sensing can easily extend to thousands of such sensors per city, a temporal scaling of 1000× the native input rate can be used to simulate a larger deployment of 90,000 sensors.

Metrics. We focus on the performance metrics of query latency. Query latency is measured by sampling 5% of the tuples, assigning each tuple a unique ID and comparing timestamps at source and the same sink. To evaluate the scalability of DART, we measure how operators are distributed over nodes and how distributed schedulers are distributed over zones. To evaluate the adaptivity of DART, we cause bottlenecks by intentionally adding resource contention and we intentionally disable nodes through human intervention.

5.2 Query Latency

We measure the query latencies for running real-world IoT stream applications on the Raspberry Pis and VMs across a wide range of input rates.

Figure 7a and Figure 7b show the latency comparison of DART vs EdgeWise for (a) DAG queue waiting time and (b) DAG deployment time for an increasing number of concurrently running applications. We choose applications from a pool that contains dataflow topologies (DAGs) including `ExclamationTopology`, `JoinBoltExample`, `LambdaTopology`, `Prefix`, `SingleJoinExample`, `SlidingTupleTsTopology`, `SlidingWindowTopology` and `WordCountTopology`. EdgeWise is built on top of Storm. Both of them rely on a centralized master (Nimbus) to deploy the application’s DAGs, and then process them one by one on a first-come, first-served basis. Therefore, we can see that EdgeWise’s DAG queue waiting time and deployment time increase linearly as the number of applications increases. As such, the centralized master will easily become a scalability bottleneck. In contrast,

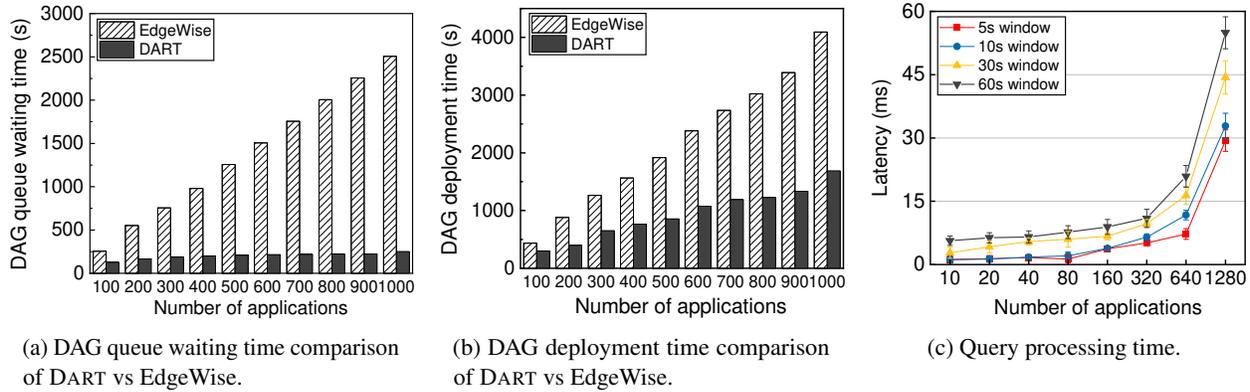

Figure 7: The latency comparison of DART vs EDGEWISE for (a) DAG queue waiting time, (b) DAG deployment time, and (c) query processing time by increasing the number of concurrently running applications.

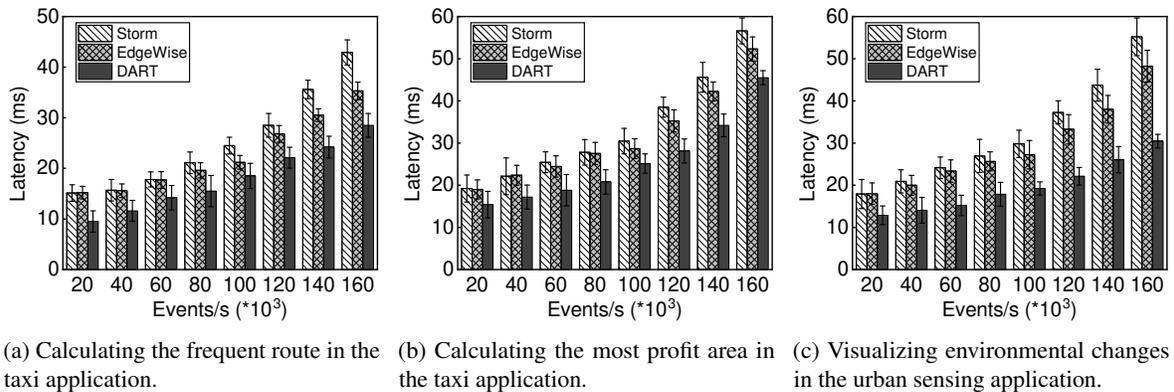

Figure 8: The latency comparison of DART vs Storm vs EdgeWise for (a) frequent route application, (b) profitable area application, and (c) urban sensing application.

DART avoids this scalability bottleneck because DART’s decentralized architecture does not rely on any centralized master to analyze the DAGs and deploy DAGs.

Figure 7c shows the query latency of DART for an increasing number of concurrently running applications. Results show that DART scales well with a large number of concurrently running applications. First, DART’s distributed schedulers can process these applications’ queries independently, thus precluding them from queuing on a single central scheduler which results in large queuing delay. This is similar to the idea that supermarkets add cashiers to reduce the waiting queues when there are many people in supermarkets. Second, DART’s P2P model ensures that every available node in the system can participate in the process of operator mapping, auto-scaling, and failure recovery, which could avoid the central bottleneck, balance the workload, and speed up the process.

The performance comparison results for running the frequent route application, the profitable areas application, and the urban sensing application are shown in Figure 8. In general, DART, Storm and EdgeWise [37] have similar performance when the system is under-utilized (with low input).

When the system is averagely utilized (with relatively high input), DART achieves around 16.7% ~ 52.7% less query latency compared to Storm. DART achieves 9.8 % ~ 45.6% less query latency compared to EdgeWise. This is because DART limits the number of hops between the source operators to sink operators within $\log(N)$ hops by using the DHT-based consistent ring overlay, and DART can dynamically scale operators when input rate changes. DART has better performance in the urban sensing application because this application needs to split data into different channels and aggregate data from these channels, which results in a lot of I/Os and data transfers that can benefit from DART’s dynamic dataflow abstraction. We expect further latency improvement under a limited bandwidth environment since DART selects the path with less traffic for the data flow by using the path planning algorithm.

5.3 Scalability Analysis

We now show scalability: DART decomposes the traditional centralized architecture of stream processing engines into a new decentralized architecture for operator mapping and query scheduling, which dramatically improves the scalability

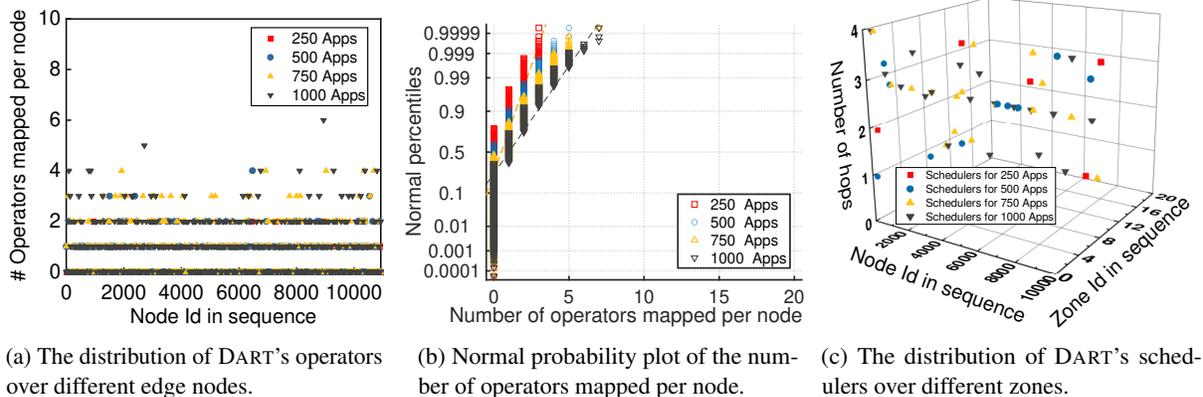

Figure 9: Scalability study of DART for the distribution of operators and schedulers over edge nodes.

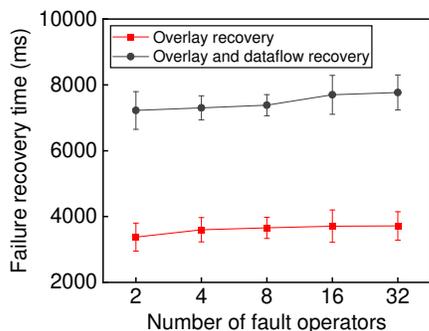

Figure 10: Overlay and dataflow recovery time.

for the system to scale with a large number of concurrently running applications, application's operators, and zones.

Figure 9a shows the mappings of DART's operators on edge nodes for 250, 500, 750, and 1,000 concurrently running applications, respectively. These applications run a mix of topologies with different numbers of operators (an average value of 10). Figure 9b shows the normal probability plot of the number of operators per node. Results show that when deploying 250 and 500 applications, around 96.52% nodes host less than 3 operators; and when deploying 750 and 1000 applications, around 99.84% nodes host less than 4 operators. From Figure 9a and Figure 9b, we can see that these applications' operators are evenly distributed on all edge nodes. This is because DART essentially leverages the DHT routing to map operators on edge nodes. Since the application's dataflow topologies are different, their routing paths and the rendezvous points will also be different, resulting in operators well balanced across all edge nodes.

Figure 9c shows the mappings of DART's distributed schedulers on edge nodes and zones for 250, 500, 750 and 1,000 concurrently running applications, and the average number of hops for these applications to look for a scheduler. For DART, it adds a scheduler for every new 50 applications. According to the P2P's gossip protocol, each application looks for a scheduler in the zone within $\lceil \log_{2^b} N \rceil$ hops, where $b = 4$. If

there is no scheduler in the zone or the number of applications in the zone exceeds a certain threshold, a peer node (usually with powerful computing resources) will be elected as a new scheduler. Results show that as the number of concurrently running applications increases, the number of schedulers over zones increases accordingly. All schedulers are evenly distributed over different zones. Most of the schedulers can be searched within 4 hops.

The above results demonstrate DART's load balance and scalability properties: (1) by using DHT-based consist ring overlay, the IoT stream application's workloads are well distributed over all edge nodes; and (2) DART can scale well with the number of zones and concurrently running applications.

5.4 Failure Recovery Analysis

We next show fault tolerance: in the case of stateless IoT applications, DART simply resumes the whole execution pipeline since there is no need for recovering state. In the case of stateful IoT applications, distributed states in operators are continuously checkpointed to the leaf set nodes in parallel and are reconstructed upon failures. We show that even when many nodes fail or leave the system, DART can achieve a relatively stable time to recover the overlay and dataflow topology.

Figure 10 shows the overlay recovery time and the dataflow topology recovery time for an increasing number of simultaneous operator failures. To cause simultaneous failures, we deliberately remove some working nodes from the overlay and evaluate the time for DART to recover. The time cost includes recomputing the routing table entries, re-planning the dataflow path, synchronizing operators, and resuming the computation. Results show that DART achieves a stable recovery time for an increasing number of simultaneous failures. This is because, in DART, each failed node can be quickly detected and recovered by its neighbors through heartbeat messages without having to talk to a central coordinator, so many simultaneous failures can be repaired in parallel.

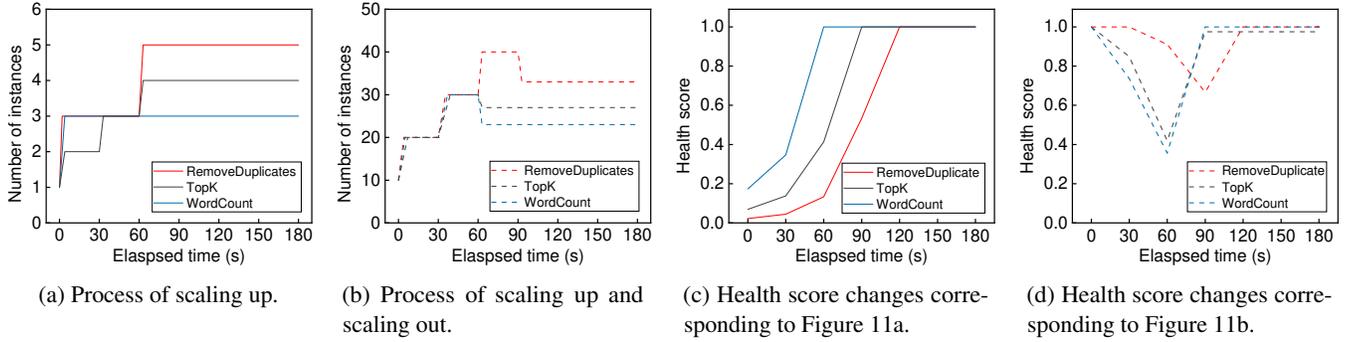

Figure 11: Adaptivity study of DART for the scaling up and the scaling out.

5.5 Elastic Scaling Analysis

Although scaling is a subject that has been studied for a long time, our innovation is that we use the DHT leaf set to select the best candidate nodes for scaling up or scaling out. Therefore, our approach does not need a central master to control, which is fully distributed. If many operators have bottlenecks at the same time, the system can adjust them all together. The periodical maintenance and update of the leaf set ensure that the leaf set nodes are good candidates, which are close to the bottleneck operator with abundant bandwidth, so there is no need for us to search for the appropriate nodes globally.

The auto-scaling process takes the system snapshot collected every 30 seconds for statistical analysis. We deploy three 4-stage topologies (RemoveDuplicates, TopK, WordCount). Figure 11a shows the process of scaling up only. The process starts from the moment of detecting the bottleneck to the moment that the system is stabilized. Figure 11b shows the process of scaling up and then scaling out. For this experiment, we put pressure on the system by gradually increasing the number of instances (tasks) (10 every 30 s) until a bandwidth bottleneck occurs (at 60 s for the blue line and the black line, and at 90 s for the red line). This bottleneck can only be resolved by scaling up. Results show that the system is stabilized by migrating the instance to another node.

Figure 11c shows how the health score changes corresponding to Figure 11a. Figure 11d shows how the health score changes corresponding to Figure 11b. Note that if the goal of pursuing a higher health score conflicts with the goal of improving throughput, we need to strike a balance between health score and system throughput by adjusting the health score function, i.e., aiming at a lower score.

5.6 Overhead Analysis

We evaluate the DART's runtime overhead in terms of the power usage and the CPU overhead. We run the same DEBS 2015 application [13] in Sec. 5.2 to calculate real-time indicators of most frequent routes in New York City with source rate at 100K *events/s*.

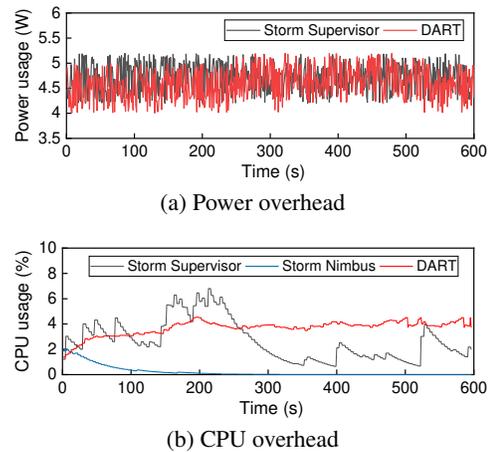

Figure 12: Overhead comparison of DART vs Storm.

Power usage. Most IoT devices rely on batteries or energy harvesters. Given that their energy budget is limited, we want to ensure that the performance gains achieved come with an acceptable cost in terms of power consumption. To evaluate DART's power usage, we use the MakerHawk USB Power Meter Tester [18] to measure the power usage of the Raspberry Pi 4. When plugged into a wall socket, the idle power usage is 3.35 Watt. Figure 12a shows the comparison of the averaged single device per-node power usage of DART node with Storm's supervisor when running the DEBS 2015 application. Results show that DART has less power usage with an average value of 5.24 Watt compared to Storm with an average value of 5.41 Watt, demonstrating that DART efficiently uses energy resources.

CPU overhead. Figure 12b shows the comparison of the CPU overhead of DART with Storm. Results show that DART uses more CPU than Storm Nimbus and Storm supervisor. DART continuously monitors the health status of all operators to make auto-scaling decisions to adapt to workload variations and bandwidth variations in the edge environment, while Storm ignores it. This CPU overhead is an acceptable trade-off for maintaining performance and could be further reduced with a larger auto-scaling interval.

6 Related Work

Existing studies can be divided into four categories: *cluster-based stream processing systems*, *cloud-based IoT data processing systems*, *edge-based data processing systems*, and *wide-area data analytics systems*.

Category 1: Cluster-based stream processing systems. Over the last decade, a bloom of industry stream processing systems has been developed including Flink [2], Samza [5], Spark [6], Storm [7], Millwheel [28], Heron [44], S4 [49]. These systems, however, are designed for low-latency intradatacenter settings that have powerful computing resources and stable high-bandwidth connectivity, making them unsuitable for edge stream processing. Moreover, they mostly inherit MapReduce’s “single master/many workers” architecture that relies on a monolithic scheduler for scheduling all tasks and handling failures and stragglers, suffering significant shortcomings due to the centralized bottleneck. SBONs [52] leverages distributed hash table (DHTs) for service placement. However, it does not support DAG parsing, task scheduling, data shuffling and elastic scaling, which are required for modern stream processing engines.

Category 2: Cloud-based IoT data processing systems. In such a model, most of the data is sent to the cloud for analysis. Today many computationally-intensive IoT applications [22, 23] leverage this model because cloud environments can offer unlimited computational resources. Such solutions, however, cannot be applied to time-critical IoT stream applications because: (1) they cause long delays and strain the backhaul network bandwidth; and (2) offloading sensitive data to third-party cloud providers may cause privacy issues.

Category 3: Edge-based data processing systems. In such a model, data processing is performed at the edge without connectivity to a cloud backend [19, 21, 58]. This requires installing a hub device at the edge to collect data from other IoT devices and perform data processing. These solutions, however, are limited by the computational capabilities of the hub service and cannot support distributed data-parallel processing across many devices and thus have limited throughput. It may also introduce a single point of failure once the hub device fails.

Category 4: Wide-area data analytics systems. Many Apache Spark-based systems (e.g., Flutter [39], Iridium [53], JetStream [55], SAGE [62], and many others [40, 41, 43, 65, 66]) are proposed for enabling geo-distributed stream processing in wide-area networks. They optimize the execution by intelligently assigning individual tasks to the best datacenters (e.g., more data locality) or moving data sets to the best datacenters (e.g., more bandwidth). However, they make certain assumptions based on some theoretical models which do not always hold in practice. For example, Flutter [39], Tetrium [40], Iridium [53], Clarinet [65], and Geode [66] formulate the task scheduling problem as a ILP problem. Pixida [43] formulates the task scheduling problem as a Min

k-Cut problem. They assume that the workload, the inter-DC transfer time, and the WAN bandwidth are known beforehand and do not change, which is rarely the case in practice. Moreover, these systems also suffer significant shortcomings due to the centralized bottleneck.

To our best knowledge, Edgent [1], EdgeWise [37], and Frontier [50] are the only other stream processing engines tailored for the edge. They all point out the criticality of edge stream processing, but no effective solutions were proposed towards scalable and adaptive edge stream processing. Edgent [1] is designed for data processing at individual IoT devices rather than full-fledged distributed stream processing. EdgeWise [37] develops a congestion-aware scheduler to reduce backpressure, but it can not scale well due to the centralized bottleneck. Frontier [50] develops replicated dataflow graphs for fault-tolerance, but it ignores the edge dynamics and heterogeneity.

7 Conclusion

Existing stream processing engines were designed for the cloud environments and may behave poorly in the edge context. In this paper, we present DART, a scalable and adaptive edge stream processing engine that enables fast stream processing for a large number of concurrent running IoT applications in the dynamic edge environment. DART leverages DHT-based P2P overlay networks to create a decentralized architecture and design a dynamic dataflow abstraction to automatically place, chain, scale, and recover stream operators, which significantly improves performance, scalability, and adaptivity for handling large IoT stream applications.

An interesting question for future work is how to optimize data shuffling services for edge stream processing engines like DART. Common operators such as `union` and `join` may require intermediate data to be transmitted over edge networks since their inputs are generated at different locations. Each shard of the shuffle data has to go through a long path of data serialization, disk I/O, edge networks, and data deserialization. Shuffle, if planned poorly, may delay the query processing. We plan to explore a customizable shuffle library that can customize the data shuffling path (e.g., ring shuffle, hierarchical tree shuffle, butterfly wrap shuffle) at runtime to optimize shuffling. We will release DART as open source, together with the data used to produce the results in this paper¹.

CrystalPerf: Learning to Characterize the Performance of Dataflow Computation through Code Analysis

Huangshi Tian¹, Minchen Yu^{1,2}, Wei Wang¹

¹HKUST, ²Huawei Technologies Ltd.

{htianaa,myuaj,weiwa}@cse.ust.hk

Abstract

Dataflow computation dominates the landscape of big data processing, in which a program is structured as a directed acyclic graph (DAG) of operations. As dataflow computation consumes extensive resources in clusters, making sense of its performance becomes critically important. This, however, can be difficult in practice due to the complexity of DAG execution. In this paper, we propose a new approach that *learns* to characterize the performance of dataflow computation based on *code analysis*. Unlike existing performance reasoning techniques, our approach requires *no code instrumentation* and *applies to a wide variety of dataflow frameworks*. Our key insight is that the source code of an operation contains learnable syntactic and semantic patterns that reveal how it uses resources. Our approach establishes a performance-resource model that, given a dataflow program, infers automatically how much time each operation has spent on each resource (e.g., CPU, network, disk) from past execution traces and the program source code, using machine learning techniques. We then use the model to predict the program runtime under varying resource configurations. We have implemented our solution as a CLI tool called CrystalPerf. Extensive evaluations in Spark, Flink, and TensorFlow show that CrystalPerf can predict job performance under configuration changes in multiple resources with high accuracy. Real-world case studies further demonstrate that CrystalPerf can accurately detect runtime bottlenecks of DAG jobs, simplifying performance debugging.

1 Introduction

Dataflow frameworks are deployed widely in the cloud for distributed machine learning (e.g., TensorFlow [2]), processing data streams (e.g., Flink [11]), and analyzing big data (e.g., Spark [81]). Dataflow frameworks provide a library of built-in operations (e.g., map, reduce, and tensor operators), which programmers use to compose a data processing pipeline, structured as a directed acyclic graph (DAG) of operations. Data flows between these operations and is thereby

transformed. The framework schedules DAG executions as parallel tasks on a cluster of machines.

However, dataflow computation routinely faces various performance issues such as resource contention, inefficient configuration, and poor scalability. Due to the complexity of DAG executions, troubleshooting performance issues in dataflow computation usually demands painstaking efforts even for skilled programmers [19, 82, 84].

A leading factor that makes performance debugging difficult is the lack of handy toolchains that can provide useful *performance-resource information* with actionable advices. Existing tools provided by popular frameworks often generate an overwhelming amount of low-level execution traces, which inexperienced developers may find difficult to even make sense of them. Many system solutions have hence been developed recently to simplify performance reasoning, but they either are designed for a specific framework (e.g., [31, 54, 55]) or require modifying the framework's source code with intrusive instrumentation (e.g., [34, 54]). As the codebases of dataflow frameworks are evolving rapidly, the instrumentation code itself needs to be updated frequently, mandating even more, repeated labor.

In this paper, we present CrystalPerf¹, a new performance characterization tool that requires *no code instrumentation* while *generally applicable* to an array of batch dataflow frameworks. Central to our design is a *learning-based performance-resource model* that, for a dataflow job (program), infers from the execution traces and the program source code how much time each operation has spent on different resources (e.g., CPU, network, disk). The model can then predict the program runtime under varying configurations or identify abnormal resource uses in execution.

CrystalPerf builds the performance-resource model for a dataflow job in two stages. In the first stage, it constructs a DAG execution profile (§4.2) from the log traces generated by the built-in profilers, where each node of the DAG repre-

¹Our tool serves as a *crystal sphere* where users can tell the performance of their dataflow jobs, either performance issues in the past execution or performance prediction in what-if scenarios.

sents an operation. For each operation, it extracts the execution details from the log traces, including the start and finish time, and the call trace of the executed functions. It then locates the source code of those functions in the framework’s codebase for further analysis.

In the second stage, CrystalPerf infers the resource use of each operation, characterized by the *resource-time* which measures the time proportion the operation spends on a resource type (e.g., 30% runtime on CPU, 70% on network). However, many frameworks provide no such information in the log traces, nor can it be obtained using common profiling tools. To tackle this challenge, our key insight is that *how an operation uses resources can be largely characterized by analyzing its source code.*² For example, an operation containing many routines for data compression (data transfer) is likely CPU-bound (network-bound). In fact, many dataflow frameworks implement operations using low-level functions provided by standard open-source toolkits and libraries (e.g., Netty [17], Akka [4], Parquet [18]), where experienced developers can clearly identify the bottleneck resources by just reading the source code of those functions. Our approach imitates this process with *neural network classifiers* that learn the resource use by analyzing the syntactic and semantic patterns of the function code (§3.2). The classifiers are trained using the source code of low-level functions (e.g., network and I/O primitives) collected from popular open-source projects with clear indications of resource uses. The trained classifiers can then be used in any framework and language.

Combining the DAG execution profile and the inferred resource-time, CrystalPerf can easily detect the performance bottleneck or abnormal resource uses. CrystalPerf can also predict the job performance in what-if scenarios (e.g., “how would the runtime change if the network is upgraded from 1Gbps to 10Gbps?”) by simulating the DAG execution under the assumed configuration (§5).

We have implemented CrystalPerf as a CLI tool (§6) with support of batch computations of Spark, TensorFlow, and limited cases of Flink [11]. To demonstrate its efficacy (§7), we use CrystalPerf to predict the runtime changes of dataflow jobs under varying configurations. Across six standard benchmarking workloads running in three frameworks, CrystalPerf predicts within an average deviation of 13.47%. Even compared with Monotasks [54], a meticulously architected Spark implementation for performance clarity, CrystalPerf makes runtime predictions with comparable accuracy. We highlight the framework generalizability and performance advantage of CrystalPerf over the existing dataflow characterization approaches in Figure 1. We further show through three real-world case studies that CrystalPerf can help troubleshoot various performance issues that are otherwise difficult to reason about for non-expert programmers.

²The source code includes both the program code *and* the associated documentation such as Javadoc.

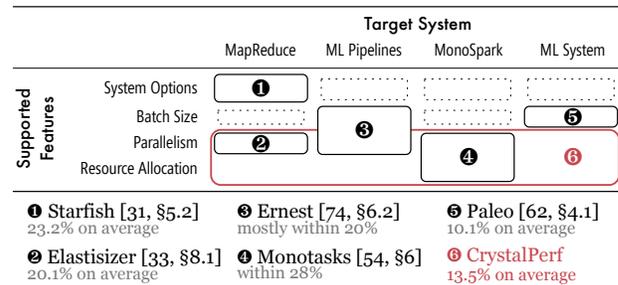

Figure 1: For performance reasoning, we compare CrystalPerf with existing works by answering “On which features can they predict the performance of what systems within how much deviation?”

2 Background and Motivation

In this section, we motivate the need of performance characterization for dataflow programs, where the key is to identify the performance-resource relationship (§2.1). We survey existing solutions and discuss their limitations, which are also the challenges we shall address (§2.2).

2.1 Performance Characterization

Performance characterization plays an indispensable role in the development of dataflow applications. Consider a programmer following the typical development workflow of coding, debugging, and optimizing. If the program runs much slower than expected, she may ask, “Is there any resource malfunctioning [28, 36]?” After fixing those issues, she may want to accelerate its execution, wondering, “What would happen if I put in use more resources [32, 38]?” If the performance remains unsatisfactory, she has to optimize the implementation, typically starting with the question, “What resource is the bottleneck during execution [34]?”

Understanding the performance of dataflow programs also allows cluster operators to better schedule DAG jobs and tune their configurations. State-of-the-art cluster schedulers need to predict how long each task of a DAG job would take if given a certain amount of resources [26, 27, 51, 71]; when deploying a user’s job, the operator also wants to tune the optimal configuration for fast job execution [5, 33].

The key to performance characterization is to identify the *performance-resource relationship*. For example, bottleneck detection and performance debugging can be done by knowing how much time the job spends on each resource; what-if questions, runtime estimation and configuration tuning requires predicting how long a job (or its tasks) would take under a different resource configuration.

However, characterizing the performance-resource relationship for dataflow programs is difficult. During execution, different operations may bottleneck on different resources, e.g., data compression being CPU-intensive, file writing

disk-intensive. For some operations like map in Spark, the actual bottleneck resource depends critically on the input (the map functions applied to an RDD). To make the problem even more complicated, some operations like join and shuffle require cross-machine synchronization and data communication. In practice, even skilled programmers cannot avoid painstakingly reasoning about and troubleshooting performance issues [19, 82, 84].

2.2 Related Work and Challenges

Existing profiling tools provided by popular dataflow frameworks produce an overwhelming amount of low-level traces, in which the relevant performance information is easily drowned out. Take TensorFlow as an example. When training ResNet50, the profiling traces of a single iteration include around 9,500 tensors, 3,000 operators, and 5,600 memory operations [1]. In fact, almost no built-in profilers provide high-level actionable advices for performance debugging. Many performance characterization tools have hence been developed recently for dataflow computation. However, they cannot fully tackle the challenges as summarized below.

Challenge 1: No explicit resource-time information. Though Linux (and other Unix-like systems) provides built-in utilities for time accounting and device monitoring, profiling the program’s resource-time (how long the program spent on each resource type) remains elusive. Linux’s I/O monitoring mechanism is mainly used for throughput tracing. For example, the per-process statistics given in /proc [49] only report the total amounts of read/written characters/bytes or sent/received bytes/packets. Without knowing the effective bandwidth and the data exchange size in execution, the actual I/O time cannot be estimated correctly. The counter-based observability tool perf and the industrial toolchains built on it [63] share the same problem.

The missing resource-time information cannot be uncovered by the recently proposed profiling tools either. Notably, SnailTrail [34] finds the critical path in distributed dataflow, but focuses on coarse-grained activities instead of fine-grained resource use information; Ernest [74] builds the performance model for advanced analytics like machine learning, but only includes input size and cluster scale as parameters. The lack of resource-time information limits their ability in addressing the resource-related issues.

Challenge 2: Heterogeneous hardware behavior. Heterogeneous hardware further complicates the performance model as dataflow operations usually have different resource patterns (e.g., data compression being CPU-intensive, file writing disk-intensive). Two approaches have been proposed in the literature. *Whitebox* approaches such as Starfish [31] build a detailed performance model for MapReduce execution, which cannot be applied to other frameworks. *Blackbox* approaches, such as CherryPick [5] and Ernest [74], con-

Figure 2: When a node (operation) is executing, attached is a sampling profiler for periodically sampling the call stacks. For each node, we build an *execution profile* to organize its resource-time information.

struct statistical machine learning models to correlate the resource allocations with the job performance, but it has to repeat the training process for each job type, making it time-consuming for ad-hoc or non-recurrent jobs.

Challenge 3: Cross-framework support. As dataflow computation prevails in a wide range of frameworks and application domains [2, 11, 12, 42, 47, 48, 79, 81], a general solution with cross-framework support is highly desirable. However, many existing works are tailored to a certain framework, e.g., AROMA [43], ARIA [75], Elastisizer [33] and Starfish [31] building specialized models for MapReduce programs, and DAC [80] designing an algorithm for tuning Spark jobs. Their designs are built on the internal details of the target frameworks and cannot be ported to other systems.

Our Answer In the coming sections, we incrementally develop our solution CrystalPerf to address the three challenges. We start to show in §3 that the time an operation spends on each type of resource can be learned from the source code and its call trace (addressing Challenge 1), using neural network classifiers which, once trained, can be applied to any framework and language (addressing Challenge 3). We then assemble the operation-level resource-time information into a job-level execution profile in §4. In §5, we further construct a performance-resource model to capture the program behaviors with respect to the allocated hardware resources such as CPU, GPU, memory, I/O and network (addressing Challenge 2). Our solution is novel as it requires no code instrumentation and applies to a wide array of dataflow frameworks.

3 Mining Resource-Time from Traces

In this section, we characterize the resource-time of an operation by exploiting the latent information in the call traces (§3.1). The periodic samples of call stacks can tell how long each operation (and its called functions) runs. If we could further obtain the resource use information of each function, then the resource-time of that operation becomes

available. We show that such information can be inferred from the function source code and documentation using neural network classifiers (§3.2–3.3). We validate the feasibility of this approach with a labeled and verified dataset (§3.4).

3.1 Obtaining Call Traces

Standard libraries provide built-in utilities to sample the call stacks, e.g., `backtrace` in GNU C Library and `AsyncGetCallTrace` in Java. CrystalPerf uses the sampling profilers [9] built on these utilities to collect the call traces of a dataflow job and its operation tasks periodically. Figure 2 shows a sample trace of a running `join` task in Spark.

In frameworks like TensorFlow and MXNet, CrystalPerf uses the built-in profiler as it records the start time and the duration of each operation. For JVM-based frameworks like Spark, Flink and Heron, CrystalPerf attaches a lightweight, non-intrusive sampling profiler to the JVM process, and aligns the trace with the time when an operation begins and finishes to extract the called functions. CrystalPerf then locates the implementation of those functions in the framework’s codebase for further analysis. Note that using similar sampling profilers for C# [25], JavaScript [68] and Go [23], the call traces can also be obtained in other frameworks.

3.2 Inferring Resource Use Patterns

With the durations of each operation and its called functions, we derive the resource-time information by analyzing how those functions use resources. As those functions are usually *low-level routines* (e.g., network and I/O primitives), they have clear resource use patterns which can be identified by a skilled programmer by simply examining the source code and its documentation. Following this intuition, we design two neural network classifiers to *infer* the resource patterns from the code and documentation, respectively. This approach requires no instrumentation and is not limited to a specific framework. Figure 3 illustrates how it works. We first embed the source code and documentation into vectors so that they can be processed by neural networks.

Code Embedding The key to code analysis is the *lexical and syntactic information*. The former includes the identifiers of variables, functions, classes and types; the latter refers to the abstract syntax tree (AST). CrystalPerf embeds them with a recursive autoencoder [67] (Figure 3). Following the embedding approach in [76], CrystalPerf parses the function code into an AST and augment it to a binary tree with some artificial nodes. CrystalPerf then constructs a vector representation for each AST node using the autoencoder. It starts by computing a word embedding for each identifier on a leaf node and recursively computes the embedding vector of a parent node from its children’s. Formally, let s_1 and s_2 be the two sibling nodes. The autoencoder computes their parents vector as $p = W[s_1 : s_2] + b$, where W and b are model

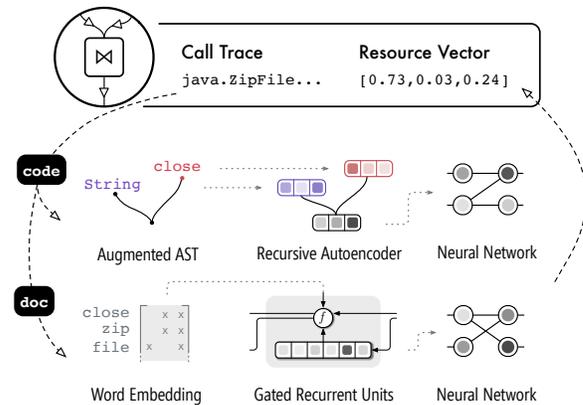

Figure 3: We design two classifiers that can infer the dominant resources for a function from the source code and documentation respectively.

parameters refined by training, and $[:]$ means concatenation. The vector of the root node gives the code embedding.

Documentation Embedding A function may have an associated documentation explaining its performed task and usage, written in natural language. To embed a function documentation, CrystalPerf removes the contained punctuations and hyperlinks and encodes the words into vectors with Flair [3], a language model with state-of-the-art performance. CrystalPerf then encodes the whole document with gated recurrent unit (GRU) [14] which can take an arbitrarily long input sequence. GRU has internal states and works in a recursive manner: it takes an input element, updates state, produces output and repeats. CrystalPerf sequentially feeds the word embeddings to GRU and takes the state from the last iteration as the document embedding.

Inference Procedure With the code and documentation embeddings calculated, CrystalPerf infers the function’s resource uses with two pre-trained neural network models (see §3.3). Both models output a *resource vector*, where each element is the probability of the function using a certain type of resource (e.g., 0.7 in CPU and 0.3 in network), given by the code or documentation analysis. CrystalPerf takes the average of the two predictions as the inferred resource vector³. Our design currently supports three resource types and the output is in the form of $\langle \text{CPU}, \text{Disk}, \text{Network} \rangle$. We next describe the neural network design and training.

3.3 Model Design and Training

Critical to our approach are the two neural network models that learn the resource vector from the function code and documentation. This problem resembles document classifi-

³§B in the supplemental material [70] provides the justification for averaging.

Table 1: The prediction quality of the classifier on the collected dataset. The higher-than-random accuracies imply the learnability of resource information from the source code.

	Accuracy	F1 Score
CPU	77.12% ± 7.39%	0.869 ± 0.046
Disk	82.46% ± 5.63%	0.903 ± 0.034
Network	82.90% ± 5.26%	0.906 ± 0.032
Average	80.83% ± 4.60%	0.893 ± 0.028

cation [78,83], in which a neural network model is trained to predict the probability of a document belonging to a certain class. In our design, we adopt the single-layer neural network (i.e., linear model) because it supports variable lengths in both input and output, allowing us to adjust the dimension of embeddings and incorporate new resources.

To train the two classification models, we collect source code from open-source projects with clean designs and comprehensive documentation. In each project, we choose the source files that have apparent resource uses, such as TCP and UDP services (network-bound), compression and hashing (CPU-bound), file operations (I/O-bound). We extract the selected functions together with their documentation and label their resource patterns. In total, we have collected around 5,000 low-level functions from five popular open-source libraries, including FS2 [22], Twitter Util [72], Play Framework [59], Scalaz [65] and Scala Standard Library.⁴ It took two PhD students 5 hours to manually label those functions.⁵ The labeled resource vectors are in the form of <CPU, Disk, Network>, with the dominant resource set to 1 and the others 0 (one-hot vector). Although some functions use more than one resource, only labeling the dominant one is still feasible as our training dataset only includes low-level libraries where most functions rely on just one type of resource. Admittedly, such labeling inevitably involves subjectiveness and imprecision, but our sensitivity analysis (§7.4) shows that CrystalPerf is robust against the labeling errors.

We have implemented the two classifiers with PyTorch [57].⁶ The classification models, once trained, are *not restricted* to certain frameworks or programming languages. First, our model design accepts arbitrary words as its input because the word embedding techniques, such as Flair [3], work on the level of characters and allow unseen words beyond the training corpus. Second, regardless of the frameworks, their documentation is all written in natural language,

⁴The collected dataset are released at [69].

⁵Manual labeling is feasible as long as the project follows modern design guidelines (e.g., modularity, high cohesion, low coupling). For instance, in a well modularized project, functionally similar codes tend to appear in the same module, so it is feasible to “batch process” them.

⁶The documentation classifier is optimized with stochastic gradient descent (SGD). Its learning rate is set to 0.1 and annealing rate 0.5. For the more complicated code classifier, we choose a more stable optimization algorithm, Limited-memory BFGS, with its step size as 1×10^{-6} .

Table 2: Top 5 words that make the classifier predict a certain category. Most of them appear in *both code and documentation*, except that the underlined ones only in code.

Category	Words
CPU	<u>engine</u> , entry, stream, key, <u>certificate</u>
Disk	file, error, tar, info, name
Network	socket, sock, <u>send</u> , result, address

enabling the reuse of the documentation classifier. Third, many keywords and syntaxes (e.g., condition and repetition) are commonly used in different programming languages, a common ground for our code classifier to exploit. Our evaluation confirms the generalizability of our design: the models trained with Scala code can make accurate predictions in frameworks written in Java and C++ (§7.1).

3.4 Model Validation

We design a model validation test to verify that both the code and documentation contain useful resource information that can be learned correctly by our classifiers. We collect a set of functions from Python standard library and OpenJDK, *manually verify* their resource uses with `strace`, train our classifiers over them, and compute the prediction accuracy. As shown in Table 1, the trained models can identify the dominant resource of a code snippet with accuracy over 77%. The F1 scores⁷ are higher than 0.86, suggesting no possible skewness towards any classes. These results show that our classifiers can accurately identify resource uses from the source code. We believe this also holds true for other codebases as we randomly select the source files from standard libraries.

We next inspect what features learned by our classifiers make major contributions to the prediction results. We turn to LIME [64], a popular framework that can explain what words are the key to making a certain prediction. Table 2 lists the most frequent words that appear in the explanations. As one may expect, the computation of “key” or “certificate” is CPU-intensive and “file” operations involve disk I/O. They indicate that our models have indeed learned meaningful patterns for resource inference. We further compare the predictions made separately by the code and documentation classifiers, and have two major findings: (1) the code and the documentation classifiers have roughly the same level of prediction ability, and (2) they make more accurate predictions on *longer* and *more diverse* code and documentation. We defer the detailed analysis to supplemental materials (§A).

Now that we have the function-level resource information,

⁷F1 score is the harmonic mean of the precision and recall, whose value is within 0 and 1. The larger the value is, the more accurate and the less biased the classifier is.

it remains a challenge to build a job-level profile on top of it, which we address in the next section.

4 Profiling Resource Usage of Job

The previous section infers resource-time for a single function, yet a performance-resource model requires the information about each operation (which may call multiple functions) and the whole job. In this section, we piece together the function resource-time into a resource vector for each operation (§4.1), which unifies the varied resource patterns and captures the time proportion spent on each resource. We then assemble the operation information into a job-level DAG execution profile (§4.2), which forms the basis of performance debugging and prediction.

4.1 Resource Vector

We characterize the resource uses of an operation with a *resource vector*, where each component is the *proportion* of runtime it spent on one resource during execution. For example, the resource vector $\vec{R} = (p_{\text{cpu}}, p_{\text{disk}}, p_{\text{net}}) = (0.15, 0.03, 0.82)$ indicates that the operation mainly uses CPU, disk, and network, with each accounting for 15%, 3% and 82% of the operation execution time. We define resource vectors with *relative* time proportions instead of the absolute scale because the former can be more conveniently handled in machine learning. As the proportions add up to one, our definition implicitly assumes *sequential resource use* during execution. Though this may not be exactly the case (e.g., pipelining in Spark), it serves as a good approximation in many frameworks because operations are typically low-level functions performing simple tasks (e.g., math operation in TensorFlow, primitive operation in Flink). Furthermore, for those operations spending the vast majority of time on one resource, which is usually the case, neglecting concurrent uses on the other resources has a negligible impact to runtime prediction. One piece of empirical evidence is *Monotasks* [54], which rearchitects Spark operators to avoid resource pipelining and merely incurs 9% increase in runtime. Our evaluation also confirms the validity of the sequential resource use model (§7.1).

CrystalPerf infers the resource vector of each operation from its call traces. A stack typically has some system function in the bottom (e.g. `Thread.run`) and the most recently called function at the top. Since the topmost function can be some library or native routine, we scan downwards until we find a function whose source code is available (i.e., some function in the dataflow framework). We then apply the classifiers introduced in §3.2 to infer its resource use, and take the output as its resource vector. As the profiler samples at fixed intervals, we simply assume that the functions in a given stack have remained execution in that interval. We take the average of all the inferred vectors and use it as the

resource vector of the operation in that interval.

4.2 DAG-Based Execution Profile

With the resource vector of operations, we establish the execution profile for a dataflow job in two stages. In the first stage, we organize a DAG to represent the job execution, with necessary modification for certain frameworks (details following next). In the second stage, we annotate each node (operation) with its execution details and the resource-time inferred from its call traces.

Dataflow frameworks expose DAG information through monitoring APIs or runtime logs. In most dataflow frameworks, the job DAG provided in the log trace (e.g., TensorFlow computation graphs and Flink dataflows) can be directly used to represent the internal computation structure, i.e., the operations and their dependencies. Yet a special treatment is needed for Spark, in which a job is decomposed into multiple stages, each containing multiple parallel tasks [81]. We therefore turn to a *hierarchical* DAG representation where a node itself can be a smaller DAG. After constructing the DAG, we associate the profiled execution details to each node, including the start and end time of the operation, the functions it called during execution, the source code of those functions, and the inferred resource vector of the operation. Figure 2 shows a sample profile attached to a join operation in Spark.

The DAG execution profile forms the basis for debugging performance issues. To identify the execution bottleneck, CrystalPerf follows the operation execution on the critical path and sums up the time spent on different resources. The one that takes the longest time is identified as the *bottleneck resource*. The execution profile can also be used to troubleshoot configuration problems by displaying the resource-time breakdown of each operation. For example, in one of our case studies in §7.5, a machine learning job has spent a significant portion of time on I/O. Even though I/O is not the major bottleneck compared with computation, its overuse still suggests a misconfiguration problem for the training job.

5 Performance-Resource Model

The DAG execution profile established in the previous section can be used to characterize the job behaviors in the past execution. In this section, we take a step forward by predicting how the job would perform in what-if scenarios with different resource configurations. We categorize hardware resources into three classes following the von Neumann architecture and model their impacts to the job performance respectively.

Computing Devices such as CPU, GPU or other emerging processors [21, 39] can affect job performance in two ways. (1) Changing the number of devices (e.g., CPU cores) may

Algorithm 1 Predict job runtime under target computing devices.

– N, N' : original and target number of computing devices
– s, s' : original and target computing speed

- 1: **function** PREDICTRUNTIME(s, N, s', N')
- 2: Replay tasks in DAG on N' devices.
- 3: $w \leftarrow$ slowdown of the first-wave tasks due to warm-up
- 4: Scale first-wave task runtime by w \triangleright warm-up effect
- 5: **for** each task in replayed DAG **do**
- 6: $v_{\text{cpu}} \leftarrow$ CPU component of resource vector
- 7: $t_{\text{cpu}} \leftarrow v_{\text{cpu}} \times$ task runtime
- 8: Scale t_{cpu} by s/s'
- 9: Traverse the DAG and compute the updated job runtime

change the degree of parallelism of tasks. (2) Utilizing devices with different processing speeds may change the task runtime. Taking both factors into account, Algorithm 1 estimates the job runtime under a parallelism change from N to N' and a speed change from s to s' . The first part (Line 2-4) reschedules the parallel tasks over N' devices and *simulates* their executions to estimate the runtime.⁸ During the simulation, we distinguish the sequential execution from the parallel, following the insight of Amdahl’s law [6]. As a concrete example, some Spark tasks are executed in a single thread despite the existence of multiple cores, so we keep it sequential in the simulation. We also consider the *warm-up effect*. That is, the first wave of tasks take longer time to complete than the rest, due to various forms of cache (e.g., the instruction cache of CPU, the data cache in distributed storage systems [10, 24] the code cache in JVM [46], etc.). Therefore, if a non-first-wave task is rescheduled to the beginning, we adjust it by a warm-up factor w and vice versa. After the adjustment, the second part (Line 5-8) of the algorithm rescales the compute time of each task by s/s' as CPU time is inversely proportional to the speed [30].⁹

Memory plays a passive role in job execution. Once a job is allocated sufficient memory, more allocation will not make it run faster. Conversely, when a job runs short of memory, frequent garbage collections or paging prolongs its execution. We characterize the relationship between memory and runtime with a *reversed roofline model* [77]—a linearly decreasing function followed by a constant lower limit, where the turning point is chosen by summing up the data size used in the program (e.g., RDD blocks in Spark, tensors in TensorFlow, network buffers in Flink) and the slope is the ratio between the I/O speed of in-memory and on-disk data access. The intuition behind is that the memory is sufficient as long as it can accommodate all data and the delay is primarily

⁸Currently, the replay simulation does not consider the task scheduling but follows the original task order. It is feasible for users to provide a customized scheduler as a plugin (§6).

⁹Approximating speed as a constant follows the precedents in Paleo [62] and Starfish [31].

Algorithm 2 Predict job runtime under target I/O devices.

– B, B' : original and target I/O bandwidth
– S_B : buffer size
– o : overhead of processing buffer for one time

- 1: **function** PREDICTRUNTIME(B, B')
- 2: **for** each task in job DAG **do**
- 3: $v_{\text{I/O}} \leftarrow$ I/O component of resource vector
- 4: $t_{\text{I/O}} \leftarrow v_{\text{I/O}} \times$ task runtime
- 5: $D \leftarrow t_{\text{I/O}} \cdot B$ \triangleright estimated data size
- 6: $t_p \leftarrow (D/S_B) \cdot o$ \triangleright processing overhead
- 7: $t_c \leftarrow t_{\text{I/O}} - t_p$ \triangleright communication time
- 8: Scale t_c by B/B' .
- 9: Traverse the DAG and compute the updated job runtime.

caused by data transfer between memory and disk. We admit that other factors, such as garbage collection, may also affect the runtime, but our evaluation shows that such a simplified model is sufficient to predict the runtime accurately under a wide range of memory changes (§7). We leave it as a future work to model more complicated memory effects on dataflow jobs.

I/O and Network Devices We adopt a buffered I/O model [56] where the data is first placed inside a buffer and then transferred. While other I/O variants do exist, the buffered I/O model remains the most common practice used in Linux API [50] and Java Standard Library [37]. In Algorithm 2, we divide the I/O time into the *buffer processing time* and the *data communication time*. We assume that data are sequentially placed into a buffer and processing a buffer incurs a fixed overhead. The total processing overhead is hence estimated as the number of buffers times the overhead (Line 6). As for the parameters, we set the overhead o the same as the measurement result reported in [58], and buffer size S_B the default values in Linux. The communication time is then rescaled by B/B' to simulate the change in bandwidth.¹⁰

Putting It All Together CrystalPerf combines the execution profile with resource-runtime model to characterize job performance. Figure 4 illustrates the main use cases. For debugging, CrystalPerf generates a detailed report of the time spent on each resource to help users understand the potential issues of the program. For prediction, we consider the scenario where a user profiles a job under a given configuration and wonders how the job completion time would change with a different configuration. CrystalPerf makes the prediction by constructing the DAG execution profile and computing the operation runtime in the new configuration following the aforementioned device models. In both use cases, CrystalPerf requires no code instrumentation nor restricts to a certain framework.

¹⁰Following prior works [31, 62], we assume constant bandwidth in our modelling.

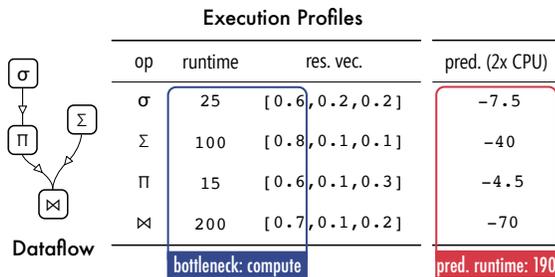

Figure 4: Given an executed job (left), CrystalPerf can either ① analyze resource usage or ② predict its job runtime under another resource configuration (right).

6 Implementation

We have implemented CrystalPerf as a CLI tool in around 4,000 lines of Python and Scala code, which is open-sourced at [69]. Our implementation currently supports three frameworks, Spark, Flink, and TensorFlow.

Pluggable Architecture As a framework-independent tool, CrystalPerf sets to provide a general support for various frameworks, even the future ones. So it has to accommodate different logging conventions, trace formats, DAG representations, etc. We provide plugin mechanisms wherever possible to maximize the usability and generalizability. Our implementation consists of three modules for parsing runtime logs and traces, annotating DAG with resource vectors, and predicting performance based on the given models. The parser accepts plugins that can update with the changing log formats. The annotator supports plugins for locating source code with different directory structure or naming convention. The predictor allows plugins for customized performance models, such as Starfish [31] and Paleo [62]. In our implementation, the supported frameworks (i.e., Spark, Flink and TensorFlow) share the same base modules but all have their specific plugins.

Usage Instructions To use CrystalPerf, users need to enable logging and profiling when executing dataflow jobs. For most JVM-based systems, this can be done by just adding a configuration line and attaching a jar package of an off-the-self profiler.¹¹ Users simply specify the location of the logs and traces in the CLI, and let CrystalPerf extract the runtime information and construct the DAG profile automatically. CrystalPerf provides two modes. (1) For debugging, CrystalPerf outputs the time spent on each resource. (2) To predict the performance under a certain resource configuration, users have to pass that configuration to the CLI, together with the original one. CrystalPerf applies the performance models and outputs the predicted runtime.

¹¹For frameworks such as TensorFlow and MXNet, the log traces already contain the operator names, and there is no need to specify a profiler.

7 Evaluation

In this section, we evaluate CrystalPerf in various scenarios. The highlights of our evaluation are summarized as follows:

- CrystalPerf can predict the job runtime of three frameworks under multiple types of resource variations within an average deviation of 13.47% (§7.1).
- CrystalPerf can predict the performance of a Spark benchmark with accuracy comparable to Monotasks [54], the heavily intrusive state-of-the-art operating on a version of Spark that simplifies performance reasoning (§7.2).
- The neural network classifiers are resistant to the inaccuracy in the labels of training dataset and generalizable to different frameworks (§7.4).
- CrystalPerf can effectively help users identify bottleneck resources and address performance issues (§7.5).

7.1 Performance Prediction

Methodology We evaluate CrystalPerf against six workloads in Spark, Flink, and TensorFlow with different resource variations, as summarized in Table 3. For each workload, we first run it under a baseline configuration and measure its runtime. We then change the resource configuration and use CrystalPerf to predict the new runtime. To measure the accuracy, we rerun the job on a real cluster with the same configuration as in prediction. We report the predicted and the actual runtime in the experimental results. We use *deviation* as a metric to measure accuracy, defined as $|p-a|/a$, where a is the actual runtime and p the prediction.

Spark Figure 5 shows the runtime predictions given by CrystalPerf for two TPC-H queries (see Table 3) under various configurations, where the second bar group in the central graph shows the baseline execution. The average deviation of the predictions is $13.49\% \pm 8.57\%$, demonstrating the effectiveness of CrystalPerf for Spark applications. Note that such deviations are evenly distributed around the actual runtime, an indication that our approach shows no systematic over- or underestimation but mainly suffers from random errors.

Flink For stream processing, we choose two widely used benchmarks [34, 73]. As CrystalPerf does not natively support long-running jobs, we define the *latency* of a streaming application as its runtime because it measures the time of a data batch (i.e., a data buffer in Flink) traversing through the DAG. Therefore, throughout the experimentation of Flink, we run the application for 10 minutes and report the average latency as its runtime. The resource variation includes the change of CPU share and network bandwidth, where CPU share determines the fraction of CPU time granted to a given program.

Figure 6 presents the prediction results of Flink applications, where the average deviation is $12.70\% \pm 10.11\%$.

Table 3: Summary of the workloads used in performance prediction (§7.1).

Framework	Workload	# Instances	Instance Type	Varied Resources
Spark v2.4.3	TPC-H [60] query 6 (short) and 9 (long) with scale factor 100	16	AWS m5.xlarge (4 cores, 16GB mem, 10Gbps)	# cores, memory, network bandwidth
Flink v1.7.2	Yahoo Streaming Benchmark [13] and Dhalion Benchmark [20]	11 (1 master and 10 workers)	AWS m5.xlarge	CPU share, network bandwidth
TensorFlow v1.13	ResNet [29] and VGG [66] on a flower image dataset	8 (1 master, 4 workers and 3 servers)	GCP n1-16-standard (16 CPUs, 60GB mem, Tesla P100 GPU)	computing devices, # cores, memory

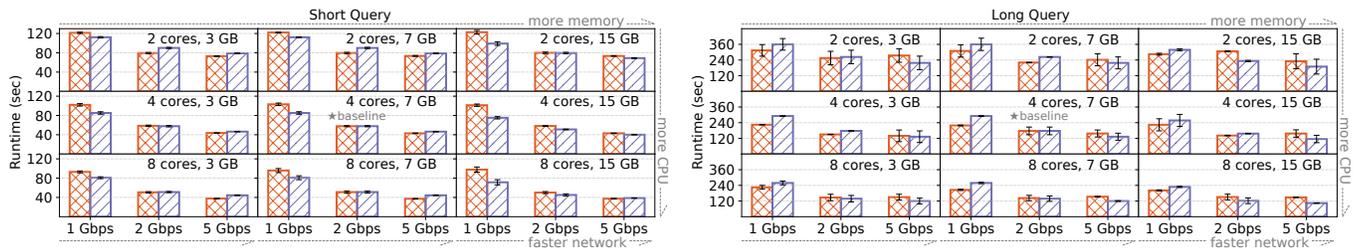

Figure 5: Given the baseline execution (located at the center) of two TPC-H queries, CrystalPerf predicts their runtime under the rest 26 resource configurations. Each bar pair shows one prediction and its corresponding actual runtime (Prediction, Actual).

Again, the deviations are evenly distributed instead of biasing towards over- or underestimation. Moreover, as our classifiers are trained with Scala code (§3.3) whereas Flink is mainly written in Java, the results demonstrate the generalizability of the classification models to other programming languages. Such desirable property results from the fact that programmers tend to use meaningful names [35] and hence those resource-related terminologies are used in different languages.

TensorFlow As for distributed machine learning, we use a managed version of TensorFlow (v1.13) provided by AI Platform [15] in Google Cloud. The training programs adopt the parameter server architecture [45] with asynchronous parallel (ASP) scheme. Because the runtime characteristics of parallel machine learning are highly repetitive across iterations, we report the *average iteration time* as the job completion time. As the iterations in ASP may not be temporally aligned, we take the average of each worker’s iteration time. The resource variation in learning applications include upgrading CPU to GPU, using a different number of virtual CPUs and changing the memory size. Figure 7 shows the prediction results given by CrystalPerf. The average deviation is $14.22\% \pm 11.77\%$. This again confirms the satisfactory prediction accuracy of our approach and the generalizability of our classification models.

7.2 Comparison with Monotasks

As summarized in Figure 1, Monotasks [54] is the most closely related to our work, so we make a comparison to it by predicting the performance of Big Data Benchmark (BDB) [7]. Note that Monotasks has devised its own variant of Spark for performance clarity called *MonoSpark*, which decomposes the pipelined usage of multiple resources so that each compute task only uses one resource. Following the description in §6.2 in [54], we reproduce the experiment in the same settings: first run the BDB workloads on MonoSpark with two disks and let CrystalPerf predict the runtime under the configuration of one disk. As most of MonoSpark’s implementation relies on Spark (including logging), CrystalPerf can reuse its Spark interface.

Figure 8 plots the actual and the predicted runtimes of all queries in the benchmark. CrystalPerf achieves an average deviation of $12.53\% \pm 5.10\%$, while Monotasks reports most errors within 9% and an exception as high as 28% (cf. Figure 12 in [54]). It is worth mentioning that Monotasks uses a whitebox performance model that is specifically tailored to the decomposed design of MonoSpark. In comparison, CrystalPerf requires no such tailoring but still can capture the resource pattern of MonoSpark. This once again confirms that (1) CrystalPerf has comparable prediction ability with the intrusive state of the art, and (2) its effectiveness is not restricted to a particular framework.

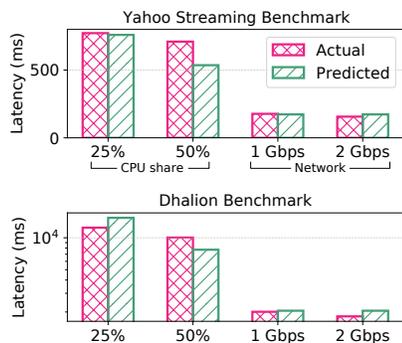

Figure 6: Performance prediction of Flink workloads. The baseline machine uses 100% CPU share and 5Gbps network.

7.3 Microbenchmarking Performance Models

Having shown the predicting ability of CrystalPerf, we need to confirm that the constructed performance models match the real execution. We scrutinize the Dhalion Benchmark running with 100% CPU share (baseline) and 25% (prediction). We choose this case because Flink does not have complicated pipelining so that we could easily check the real resource usage based on the profiling traces. It is worth mentioning that the traces also include the warm-up period (i.e., Java JIT compilation), so we exclude them from the traces and only take samples after the system enters a stable state. The benchmark mainly has two operators, FlatMap and Window. From the latency measurements, we find that they respectively incur 1583.63ms and 2322.50ms latency in the 100% case, and 2961.75ms and 7181.63ms in 25%.

Resource Vector We first verify the CPU entries in the resource vectors of both operators, because they are the key components in prediction. CrystalPerf infers that FlatMap and Window respectively spend 15.13% and 85.05% of the operation time on computation, with an average percentage of 56.70%.¹² We manually examine the profiling traces of the baseline case and find the most dominant computation functions are StreamFlatMap.processElement and WindowOperator.processElement. They appear in 65.46% of the call stack samples, which is close to the inferred percentage of CPU usage.

Performance Model Following our resource-time models (§5), CrystalPerf predicts that FlatMap and Window will take 2296.26ms and 8244.88ms, respectively, if running with 25% CPU share. Again, they are within a tolerable error range when compared with the measured durations. Furthermore, we observe that the occurrences of NioEventLoop.run, a network-related function, increases

¹²It is computed as a weighted average: $(15.13\% \times 1583.63 + 85.05\% \times 2322.50) \div (1583.63 + 2322.50) = 56.70\%$

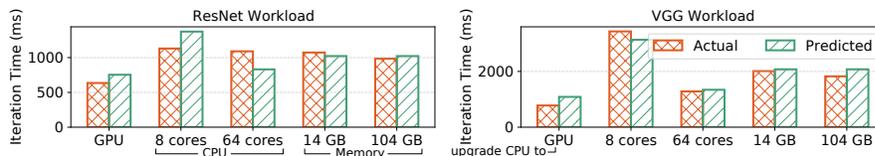

Figure 7: Performance prediction of TensorFlow workloads. The baseline machine uses 16 virtual CPU cores and 60GB memory.

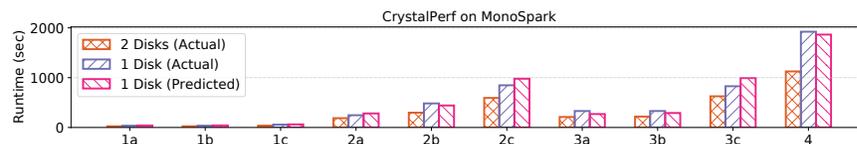

Figure 8: Performance prediction of Big Data Benchmark (BDB) on MonoSpark.

from 3.20% of the samples to 4.10%. This shows how the slowdown of CPU could prolong the processing time of network I/O, confirming our intuition used in modeling resource changes.

7.4 Classifier Sensitivity and Generalizability

Sensitivity to Labeling Quality Recall in §6 that the resource vectors of the low-level functions we collected in the training dataset are manually labeled, and it is difficult to check their accuracy due to the lack of the ground truth. Henceforth, we instead evaluate the robustness of CrystalPerf with respect to the labeling quality. We reuse the training dataset and perturb the labels of 10%/20% data samples. For instance, for the data samples originally labeled as CPU-dominant, we change 1.67% of them to disk and another 1.67% to network, and repeat the process for other two resources to reach the 10% fraction. As shown in Figure 9, the resource classifiers used in CrystalPerf are robust against the labeling errors.

Generalizability Apart from robustness, generalizability is another desirable property because the users don't want to retrain the classifiers for each single framework. Although §7.1 confirms that CrystalPerf can work on different systems with the same classifiers, here we zoom in on the predictions they make on various programming languages. For the test set, we collect 105 low-level functions from Spark (Scala), 194 from Flink (Java), 302 from TensorFlow (Python), and label them in the same way as in §3.3. The prediction results shown in Table 4 indicates that our classifiers, trained on low-level Scala code, predict similarly well across three frameworks, which partially explains the generalizability of CrystalPerf. One noteworthy detail is that sometimes TensorFlow has even higher accuracy than Spark. This is because the tested TensorFlow functions include some example code where they are lengthily documented and thus appear more

Table 4: The classifiers trained with Scala code perform similarly on the chosen systems, implying the generalizability of our approach. (Accuracy/F1 Score)

	Code Cls.	Doc. Cls.
Spark	81.0%/1.797	76.5%/1.673
Flink	73.3%/1.664	74.8%/1.589
TensorFlow	79.9%/1.752	77.8%/1.652

informative to the classifier model.

7.5 CrystalPerf in Action: Case Studies

We further conduct three real-world case studies to demonstrate how CrystalPerf could help users identify resource bottleneck and address performance issues with ease.

Diagnosing Slow Operation A user implemented a Spark program to process a dataset stored in HDFS [8]. However, the program took much longer time than she had expected. We investigated the case by reproducing it with the same configuration as original. We launched a six-node cluster on AWS EC2 with m5.4xlarge instances (16 cores, 64 GB memory, 10 Gbps network), generated dummy data with Sqoop and MySQL, and allocated 5 Spark executors with 3 cores and 15 GB memory each to run the job.

We analyzed the runtime logs using CrystalPerf, and it suggests that CPU is the bottleneck resource. We looked into the DAG execution profile and discovered that most CPU entries in the task resource vectors were around 0.785, indicating that CPU had taken the majority of runtime. For further validation, we inspected the profiling traces and the two most frequently called functions were `Text.decode` and `BuiltInZipDecompressor.decompress`, which appeared in 41.18% and 35.29% of sample stacks. Knowing the CPU dominance of the program, the user could simply allocate more CPUs to accelerate it. According to our measurement, doubling the number of CPU cores reduces the job runtime from 25.89s to 14.76s.

Diagnosing Slow Iteration We then turn to an issue [52] from TensorFlow community, where a user trained a neural network over the MNIST [44] dataset. The user already deployed GPUs but still found the iteration time much longer than she had expected. We reproduced the problem on AWS EC2 using a p2.16xlarge instance (16 NVIDIA K80 GPUs, 64 vCPUs, and 732 GB of memory). After taking in the runtime traces, CrystalPerf suggests that I/O sustains for the longest in the application. We verified the conclusion by manually examining the profiling traces and observed that an operator named `QueueDequeueManyV2` (managing queued

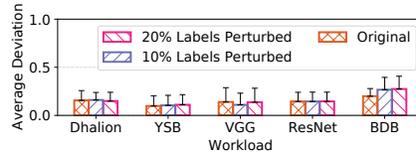

Figure 9: We perturb a portion of the labels used in training two classification models and rerun the prediction experiments on previous workloads. The error bars are *clipped* to show only the upper halves.

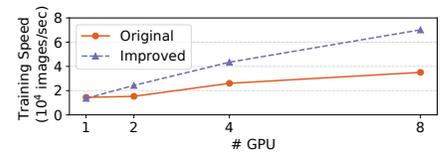

Figure 10: When training models, the user reported the poor multi-GPU scalability in the *original* setting. With CrystalPerf pinpointing the bottleneck as I/O, the user could significantly *improve* it by adopting optimized I/O library.

data in I/O) occupied the majority of iteration time. Such I/O dominance is rare in model training because computation is usually the most time-consuming part, which indicates that the data transfer into and from GPU could be problematic. So we changed GPU to CPU and reran the program. This time, the iteration time dropped from 2 seconds to 80 milliseconds, and the `QueueDequeueManyV2` no longer dominated the traces.

Diagnosing Poor Scalability Next we turn to a question [61] raised in StackOverflow, where a user trained a neural network over the CIFAR-10 [41] dataset. When she increased the number of GPUs, she noticed that the scalability of TensorFlow in the multi-GPU setting was rather poor. We reproduced the user’s problem on AWS EC2, using p3.16xlarge instances (8 Tesla V100 GPUs, 64 vCPUs and 488 GB of memory). After analyzing the traces, CrystalPerf reports that the program is actually I/O bound. Again, we verified this conclusion by checking the traces and noticing that operation `MEMCPYHtD` (copying data from CPU to GPU) took a significant portion of time. As a remedy, we enabled NCCL [53], an optimized library for inter-GPU I/O, and reran the program. Figure 10 shows the increased scalability from the *original* setting to *improved*, demonstrating the effectiveness of CrystalPerf in addressing performance issues.

8 Discussion

Profiling Overhead As runtime logs are enabled by default in many frameworks, the overhead of CrystalPerf mainly comes from the sampling profiler, which we set to sample once per 100ms. We measure Spark applications with and without the profiler and their runtimes differ within 2%, lower than the overhead of instrumentation in SnailTrail [34] (10%). Furthermore, if the framework provides the called functions (e.g., the built-in profiler in TensorFlow), CrystalPerf does not even require profiling.

Extending to New Frameworks In §6 we have introduced the pluggable architecture of our CLI tool, where multiple frameworks can share some common modules such as re-

source inference and basic performance models. When extending it to a new framework, the user has to provide the plugins that parse the generated runtime logs and construct the execution profile. From our experience, it does not involve much labor work. For instance, after implementing the prototype for Spark and TensorFlow, we extend CrystalPerf to Flink with only 172 lines of code.

Advantage over Existing Works As a major improvement, CrystalPerf models dataflow jobs as general DAGs instead of domain-specific structures. For instance, Paleo [62], a performance model for deep learning, is derived from the layer operations of GPUs; Ernest [74] models machine learning pipelines with the common communication patterns specific to machine learning; the stage-by-stage model in Starfish [31] exactly matches the execution of MapReduce jobs. Whereas their model structures limit their applicability scope, CrystalPerf targets a broader array of dataflow computations (e.g., data analytics, stream processing, ML) and exploits commonly available information such as the source code, the execution trace, and the job DAG.

Limitations in Streaming Scenarios Although CrystalPerf is applicable to Flink (§7.1), its ability is restricted by several properties of streaming applications. First, the operators in stream processing can scale up or down as the incoming data fluctuates [40]. Such dynamic parallelism changes the underlying computation graph and thus requires CrystalPerf to update its model accordingly. Second, the processing latency varies with the arrival rate of data [16] as a larger data batch takes a longer time to process. CrystalPerf does not include the rate information for generality. If the users would like to monitor the performance more precisely, we recommend them to record the input rate of data streams and augment the analysis given by CrystalPerf.

9 Conclusion

In this paper, we have presented CrystalPerf, an instrumentation-free, framework-independent approach to performance debugging and reasoning for dataflow computations. For each job, CrystalPerf constructs a DAG execution profile, and infers the resource usage of each operation node from its code and documentation with two machine learning classifiers. We have implemented CrystalPerf as a CLI tool supporting three mainstream frameworks and evaluated it with multiple workloads and use cases. The results show that CrystalPerf can accurately predict the job runtimes under various resource changes and effectively address performance issues.

Acknowledgment

We would like to thank our shepherd, Vasiliki Kalavri, and the anonymous reviewers for their valuable feedback that helps improve the quality of this work. This research was

supported in part by RGC GRF grant 16213120 and ECS grant 26213818. Huangshi Tian and Minchen Yu were supported in part by the Hong Kong PhD Fellowship Scheme and the Huawei PhD Fellowship Scheme, respectively.

Abstract

With growing interest in efficiently analyzing dynamic graphs, streaming graph processing systems rely on stateful iterative models where they track the intermediate state as execution progresses in order to incrementally adjust the results upon graph mutation. We observe that the intermediate state tracked by these stateful iterative models significantly increases the memory footprint of these systems, which limits their scalability on large graphs.

In this paper, we develop memory-efficient stateful iterative models that demand much less memory capacity to efficiently process streaming graphs and deliver the same results as provided by existing stateful iterative models. First, we propose a *Selective Stateful Iterative Model* where the memory footprint is controlled by selecting a small portion of the intermediate state to be maintained throughout execution. Then, we propose a *Minimal Stateful Iterative Model* that further reduces the memory footprint by exploiting key properties of graph algorithms. We develop incremental processing strategies for both of our models in order to correctly compute the effects of graph mutations on the final results even when intermediate states are not available. Evaluation shows our memory-efficient models are effective in limiting the memory footprint while still retaining most of the performance benefits of traditional stateful iterative models, hence being able to scale on larger graphs that could not be handled by the traditional models.

1 Introduction

Streaming graph processing systems [4, 6, 13, 16, 17, 27, 28, 35] aim to deliver real-time results as the graph structure changes via a continuous stream of edge and vertex mutations. These systems are equipped with efficient iterative processing models that are broadly classified into two types: the *stateless iterative model* and the *stateful iterative model*.

Stateless iterative models used in [6, 13, 27, 28] perform regular iterative processing without capturing additional intermediate values that describe the execution history. When the

graph structure mutates (e.g., new edges/vertices get added or old vertices/edges get removed), they either continue the iterative computation without correctly incorporating the impact of mutations on already computed values (i.e., not guaranteeing accuracy of final results) [28]; or, they conservatively deduce the set of values that could be potentially affected due to mutation (using techniques like tag propagation [27]) and recompute those values from scratch.

On the other hand, stateful iterative models used in [16, 17, 35] capture the intermediate state (representing execution history) as computation progresses, often in terms of intermediate values computed for vertices in each iteration. When the graph structure mutates, only the change in values resulting from those mutations are iteratively propagated to correct the intermediate state and compute accurate final results. As expected, stateful iterative models are more efficient in generating correct final results compared to stateless iterative models simply because the stateful models operate on the precise set of intermediate values that get affected by the change. Stateless iterative models, on the other hand, need to be conservative while generating accurate results since they do not capture intermediate values representing the execution history, and hence, they end up demanding much more computation.

While traditional models like [4] maintain the intermediate state in the order of edges for each iteration, recent works [16, 17, 35] capture information in terms of intermediate values computed for vertices, which results in much lesser memory footprint compared to traditional models. In these systems, the amount of intermediate state saved by the stateful iterative models depends on the nature of the graph algorithms they support. For example, models that operate on asynchronous graph analytics algorithms like BFS, shortest paths, connected components, etc. leverage the monotonic relationship of the values in the algorithm to adjust them directly [35], which requires capturing only $O(|V|)$ intermediate state. On the other hand, models that support synchronous graph algorithms like Co-Training Expectation Maximization (CoEM), Collaborative Filtering (CF), etc. capture the

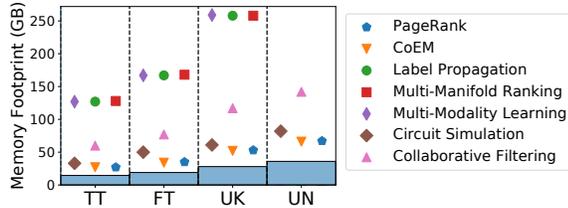

Figure 1: Memory footprint of stateful iterative model across different graph algorithms (shown as different points) and graph datasets (details in Table 2). Solid bars represent the memory consumed by the graph structure.

intermediate state at every iteration in order to incrementally recompute the values iteration-by-iteration and guarantee results equivalent to Bulk Synchronous Parallel (BSP) [32] execution from scratch [16, 17]. Furthermore, the intermediate state in each iteration often contains the aggregation results for vertices along with the vertex values, and their size (in bytes) depends on the graph algorithm being run. For example, CoEM requires 8 bytes per intermediate state of a vertex whereas CF consumes 16 bytes per intermediate state. Other graph algorithms like Multi-Modality Learning (MML) and Label Propagation (LP) have even larger intermediate states depending on the number of labels they operate on.

We profiled GraphBolt [17], a recent state-of-the-art streaming graph processing system, to measure the amount of memory consumed by the intermediate state across different graph algorithms and graph datasets. As shown in Figure 1, the intermediate state consumes at least twice the amount of memory required to hold the input graph itself; for the Collaborative Filtering algorithm this factor increases to over $4\times$ whereas the intermediate state in algorithms like Multi-Manifold Ranking and Label Propagation consumes over an order of magnitude more memory compared to the input graph.

Such high memory footprint significantly limits the scalability of the stateful iterative models on large graphs. For instance we observed that three of the graph algorithms in Figure 1 ran out of memory (with 320GB memory capacity) for the UN graph. With graph datasets growing at a faster rate than memory capacity, it becomes crucial to develop stateful iterative models that do not demand large memory capacities just to hold the intermediate states.

In this paper, we develop novel memory-efficient stateful iterative models that demand much less memory capacity to efficiently process streaming graphs and provide the same BSP guarantees as existing state-of-the-art streaming graph processing systems. First, we propose a *Selective Stateful Iterative Model* where the memory footprint is controlled by selecting a small portion of the intermediate state to be maintained during execution. And then, we propose a *Minimal Stateful Iterative Model* that specializes the incremental processing for certain graph algorithms (depending on their update functions) to drastically reduce the memory footprint.

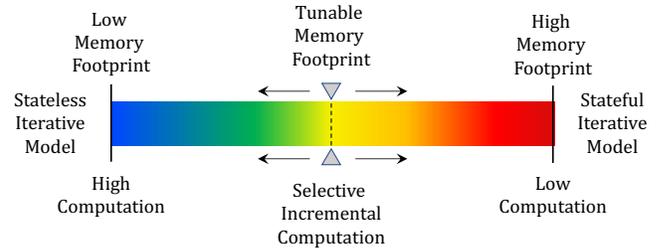

Figure 2: Sliding scale of memory and computation requirements between stateless iterative model and stateful iterative model. By capturing only partial intermediate state (selectively at a fine-grained level), memory consumption can be reduced at the cost of increased computation.

Selective Stateful Iterative Model. The key insight here is that vertex computations within an iteration are independent of each other, and hence, incrementally recomputing the value of a vertex is only dependent on the intermediate state saved for that vertex (i.e., not dependent on the states saved for other vertices). Moreover, the usefulness of different portions of the intermediate state (in terms of the amount of computation pruned out upon graph mutation) is different; this means, intermediate states for certain vertices would end up reducing more computation than those for other vertices.

Based on these insights, our selective stateful iterative model tunes its memory footprint depending on the available main memory by selecting the intermediate vertex states to be captured at a fine-grained level (illustrated in Figure 2). While this enables the model to scale on large streaming graphs, performing incremental computation using the partial intermediate state becomes challenging. This is because the value changes resulting from graph mutations are typically merged with the intermediate vertex states to propagate subsequent (transitive) changes throughout the graph, and how to compute the effects of value changes with missing intermediate states remains unclear. To address this, we develop a *selective incremental processing technique* that correctly computes the effects of changes even when intermediate vertex states are not available. Our strategy captures the nuances of the interaction between vertices with intermediate states and those without intermediate states to ensure that the vertices in the latter set correctly participate in the iteration-by-iteration incremental computation.

Minimal Stateful Iterative Model. In this model, we specialize the incremental processing for certain algorithms. Specifically, algorithms like CoEM and PageRank involve operations that are purely distributive, i.e., outgoing value changes from a given vertex can be directly computed based on the incoming value changes to the vertex. We formalize this characteristic as the novel *distributive update property* to understand the scope of graph computations that are purely distributive. Then, for algorithms that satisfy the distributive

update property, we identify that the effects of graph mutations can be propagated iteration-by-iteration throughout the graph even without using the intermediate states for most of the vertices. Specifically, only the intermediate states for vertices that get directly affected by graph mutation are needed to perform incremental processing over the entire graph.

We use this insight to develop the minimal stateful iterative model, where the amount of intermediate state gets aggressively reduced to a known subset of vertices on which mutations take place, hence consuming a much smaller memory footprint that is dependent on the graph mutations instead of the original graph size. Upon graph mutation, the incremental computation strategy directly operates on changes even for vertices without intermediate states, while also carefully adjusting the available intermediate states for vertices that are directly impacted by mutation.

Results. Our proposed techniques are general, and can be incorporated in any streaming graph processing system to leverage incremental processing without incurring high memory footprint. We implemented both of our proposed memory-efficient models in GraphBolt [17]; since GraphBolt’s existing stateful iterative model maintains intermediate states for all the vertices in the graph, it becomes a natural baseline to demonstrate the effectiveness of our proposed models.

Our evaluation with five real-world graphs and seven synchronous graph algorithms shows that our models demand significantly less memory capacity in comparison to GraphBolt, while still retaining most of its performance benefits. Specifically, the memory footprint of our selective stateful iterative model is dependent on the amount of intermediate state saved; for instance, by selecting only 20% of the intermediate state to be saved, the memory footprint is 35-70% smaller than that for GraphBolt. Furthermore, our minimal stateful iterative model reduces the memory footprint by 28-58% even when it is used for algorithms that have smaller intermediate state to begin with. This allows our memory-efficient stateful iterative models to scale to very large graphs that could not be handled by GraphBolt with the available memory capacity.

2 Background

We briefly review the streaming graph processing model and the stateful iterative processing that performs incremental computation.

Streaming Graph Processing Model. A streaming graph is a graph whose structure keeps on changing via a continuous stream of graph updates (e.g., addition and deletion of vertices and edges). The change in graph structure is also referred to as mutation of graph structure, and each individual update arriving from the stream is also called a mutation. Streaming graph processing systems [4, 16, 17, 27, 28, 35] operate on streaming graphs to continuously produce results consistent with the latest graph structure.

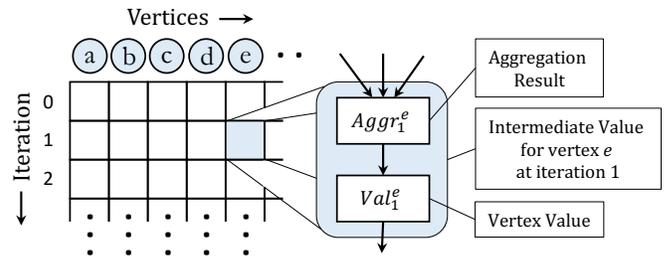

Figure 3: Intermediate state in terms of values relevant for vertices in each iteration. Each intermediate value consists of the aggregation value (to incrementally merge differences) and the vertex value (to compute outgoing differences).

Stateful Iterative Processing Model. *Stateful iterative processing models* used in recent systems like [16, 17, 35] reduce the amount of computation to be performed upon graph mutation using incremental processing. The main idea is to track the intermediate state that captures the necessary details of execution history so that when the graph structure mutates, only the relevant parts of execution history are adjusted or recomputed. To guarantee end results that are same as a Bulk Synchronous Parallel (BSP) execution [32] starting from scratch, GraphBolt employs a *dependency-driven incremental refinement* strategy [17], which incrementally recomputes (or *refines*) intermediate states by propagating changes or *differences* in values resulting due to the graph structure mutation. It propagates the changes in iteration-by-iteration manner, so that correctness guarantees (in form of BSP semantics) are retained for every iteration all the way till the end, hence ensuring that the final result are same as that from a BSP execution from scratch. DZiG [16] (built in GraphBolt) improves the dependency-driven incremental computation by developing a *DelZero-Aware incremental refinement* strategy that retains computation sparsity as iterations progress.

Tracking Intermediate State in Memory. The intermediate state in stateful iterative models is in form of values relevant for vertices at each iteration. As shown in Figure 3, these intermediate values often consist of two components: first, the result of aggregation (also called *aggregation value*) at each vertex that collects values from its incoming edges; and second, the value computed for that vertex. Maintaining both of these values as intermediate state becomes crucial because iterative algorithms often use selective scheduling mechanisms in order to suppress propagation of minor changes (e.g., change less than $1e-2$ threshold). In such cases, the outgoing vertex value for a given iteration may not be based on its aggregation result since the latter can hold multiple minor changes which may not have been propagated to the outgoing neighbors. By explicitly tracking the two values, differences can be correctly computed and propagated based on values visible to the neighbors.

As expected, tracking this intermediate state increases the

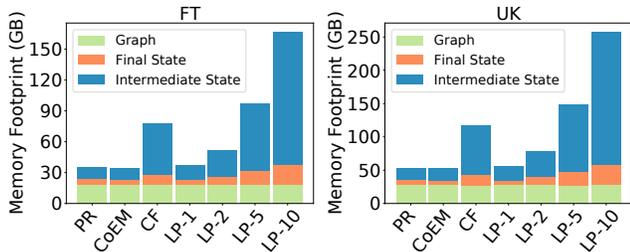

Figure 4: Memory consumption of different components in stateful iterative model: graph structure, final vertex results, and intermediate state. The intermediate state requires different amount of memory across different graph algorithms. On Label Propagation, the memory consumed by intermediate state increases as number of labels increase (indicated by LP- k where k is the number of labels).

memory footprint of such incremental processing techniques. While Figure 1 shows the high memory footprint for different graph algorithms on graph datasets, Figure 4 compares the size of intermediate state relative to the remaining memory consumption of the process (majority of which is taken by the input graph structure and then vertex frontiers). Even though PageRank and CoEM operate on scalar values, their intermediate state and final state consumes nearly as much memory as the remainder of the process. Collaborative Filtering operates on two factors per vertex (i.e., its vertex state is a size-2 vector), and hence, its intermediate state ends up consuming up to 80% additional memory compared to the stateless execution. Finally, Label Propagation operates on feature vectors; as shown in Figure 4, increasing the number of features directly increases the amount of memory consumed by the intermediate state. In fact, maintaining intermediate states with 10 features requires 129GB additional memory for FT and 198GB additional memory for UK, which increases the memory footprint by 3.44 \times and 3.3 \times respectively compared to their stateless executions. Such high amount of memory consumption significantly limits the applicability of the stateful iterative processing model on large graphs.

3 Selective Stateful Iterative Model

3.1 Intuition & Main Idea

Maintaining intermediate state essentially allows incremental processing where the effects of graph mutation are propagated in form of value changes throughout the graph. On the other extreme when intermediate state is not maintained, vertex values that are recomputed in a given iteration have to be pushed out since there is no way to determine whether the new values are different from ones computed prior to graph mutation. We observe that every single vertex computation, either in incremental manner with intermediate state or from scratch without intermediate state, is a local computation. This

means the value for a given vertex can be computed as long as the right values arrive from its in-neighbors (either in form of value differences or actual values). Hence, we selectively trade off the benefits of incremental computation with reduced memory footprint at a fine-grained level.

Our selective stateful iterative model tracks the intermediate states of only a subset of vertices instead of all the vertices in the graph. For vertices whose intermediate states are not tracked, the model reconstructs their states on-the-fly so that changes resulting from graph mutation can be directly propagated. As illustrated in Figure 2, this allows us to limit the memory footprint by directly controlling the subset of vertices whose intermediate values are tracked, at the cost of performing more computation for vertices whose intermediate states are not tracked.

For simplicity, the vertices whose intermediate states are tracked are called *tracked vertices* whereas the remaining vertices are called *untracked vertices*.

3.2 Tracking Useful Vertex States

In order to selectively track intermediate states, we need to answer two main questions: first, how many vertices should be tracked, and second, which specific vertices should be tracked.

A) How many vertices should be tracked? To maximize the benefits of stateful incremental processing, tracking as many vertices as possible becomes an ideal choice. Hence, we can compute the number of tracked vertices based on the memory capacity (or budget) assigned for the process. Specifically, the size of the intermediate vertex states (which is algorithm dependent) can be determined during initialization, which can be used to bound the number of vertices to be tracked using the available memory budget:

$$mem_budget \geq k \times state_size \times t + base_size$$

where k is the number of vertices whose states are tracked, mem_budget is the available memory capacity, $state_size$ is the size of intermediate vertex state, t is the number of iterations for which intermediate state should be captured, and $base_size$ is the memory consumed by other data structures in the system (e.g., input graph structure, vertex frontiers, stream buffers, etc.) along with additional capacity for the graph structure to grow over time. Hence, the above equation can be rewritten to maximize the number of tracked vertices k as:

$$\operatorname{argmin}_k |mem_budget - (k \times state_size \times t + base_size)|$$

Note that the majority of $base_size$ is consumed by the graph data structure, whereas the remaining structures like vertex frontiers (which are simply boolean arrays) often consume less than 10% memory compared to the graph data structure.

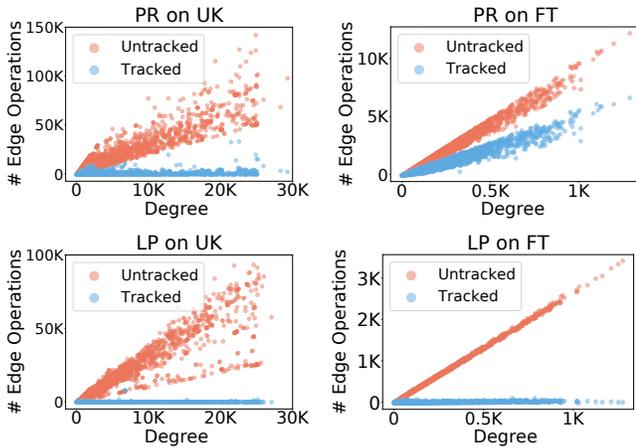

Figure 5: Number of edge operations performed for tracked and untracked vertices based on their in-degrees. Tracking high in-degree vertices reduces more edge operations compared to tracking low in-degree vertices.

B) Which vertices should be tracked? A naive way to select vertices to be tracked can be using random sampling, where tracking of intermediate states can be enabled for a random subset of vertices. While such a strategy easily allows selecting vertices, it remains oblivious of how incremental processing gets performed, and hence it fails to maximize the benefits of incremental processing. Since different vertices require different amount of computation depending on how values get propagated throughout the graph, we must ideally select those vertices that demand high computation so that most of their computation can be effectively eliminated by incremental processing. To do so, we consider the ‘usefulness’ of the intermediate state for each vertex, where the usefulness of an intermediate state is informally defined as the amount of computation it ends up reducing for that vertex. The usefulness of an intermediate state depends on several dynamic factors including the distance (in terms of number of hops) from the vertices where mutations got applied, and the sensitivity of the graph algorithm to changes in graph structure. Since accurately computing such a metric is infeasible for the general case, we approximate the usefulness of an intermediate state using a vertex-local heuristic.

To develop our heuristic, we profiled the amount of computation performed on each vertex when processing a given graph snapshot. The computation for each vertex is measured in terms of the number of edge operations performed for that vertex; this is because edge operations are expensive (often involve atomic writes and random accesses) and they are the primary candidates that incremental processing attempts to reduce [17]. Figure 5 correlates the number of edge operations for different vertices with their in-degrees for two executions: first, the execution where all vertices’ intermediate states are tracked (i.e., GraphBolt’s dependency-driven incremental processing); and second, the execution where computation is started from scratch (i.e., no intermediate state

is tracked). As we can see vertices with higher in-degree demand more computation when their intermediate values are not tracked, and tracking their values reduces their computation requirements. For instance, the top 20% of the high in-degree vertices contribute to up to 34.1-94.9% of the total number of edge operations in Figure 5. Hence, tracking the intermediate states for high in-degree vertices is most useful. On the other hand, the savings for low in-degree vertices are small (visible from the gap between orange points and blue points for low in-degree vertices) since those vertices demand fewer computation even when their intermediate states are not tracked. Therefore, we track the intermediate states for top- k vertices ranked with highest in-degree.

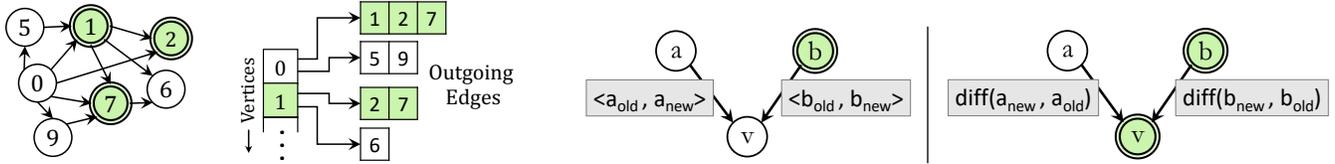

Efficiently Maintaining Tracked Vertex Set. When the graph snapshot gets initialized, a linear pass is performed over the vertices, and the vertex ids are maintained in a degree-ordered max-heap. The vertex ids whose intermediate states must be tracked are then selected in linear time from the heap.

As execution progresses and graph structure mutates, the heap is incrementally adjusted to reflect changes in vertex orderings based on their degree changes. Whenever graph mutations significantly impacts the top- k vertex ranking, the subset of tracked vertices can be refreshed to eliminate certain vertices and add new vertices. As the set of tracked vertices gets updated, the intermediate state for vertices that get newly added to the tracked set needs to become available for subsequent incremental processing. This is achieved during incremental refinement by keeping those newly added vertices active during the iterations so that their intermediate states get incrementally computed, which are then tracked. Vertices that get removed from the tracked set are handled by simply turning off their tracking during the next incremental refinement, and releasing the memory allocated to their tracked state.

3.3 Incremental Processing upon Mutation

With intermediate states available for only a subset of vertices, propagating changes resulting from graph mutations becomes challenging. This is because values during the incremental refinement stage can flow across different vertices regardless of whether their intermediate states are tracked or not. Since we aim to guarantee BSP semantics (similar to systems like [17]), computation of vertex values cannot be deferred as they need to happen in an iteration-by-iteration manner.

We develop a *selective incremental processing* technique that operates on selective intermediate states, i.e., where a selected subset of vertices are tracked. Our technique effectively separates out the interactions between tracked and untracked vertices so that right values get propagated across the edges depending on whether their source and target vertices are tracked or untracked. We first summarize how the graph layout can be optimized when selective intermediate states are maintained, and then discuss the details of our selective incremental processing.

(a) Optimized graph layout. Vertices 1, 2 and 7 are tracked (highlighted), and remaining vertices are not tracked. Each vertex maintains two adjacency lists for outgoing edges: one for tracked neighbors and other for untracked neighbors.

(b) Values propagated based on whether the target vertex is tracked (highlighted) or untracked. Untracked vertices receive the old and new values, whereas tracked vertices directly receive difference in values.

Figure 6

Optimizing Graph Layout. Streaming graph processing systems use efficient dynamic graph representations to handle rapid graph mutation and enable efficient parallel operations on active edges and vertices [6, 7, 15, 17]. Since our selective incremental processing handles the interactions for tracked vertices in a different manner compared to the interactions for untracked vertices, the graph layouts can be improved to avoid expensive checks while propagating values during the refinement process. Specifically, the edges between tracked vertices and untracked vertices can be separated out in the graph layout itself; by doing so, all computations on edges whose target vertices are either tracked or untracked can be performed directly in form of parallel operations without verifying whether every individual target vertex is tracked or untracked.

Since we incorporate our technique in GraphBolt, which uses adjacency lists to hold graph snapshots, such a separation results in the graph layout shown in Figure 6a. Here, each vertex now holds two vectors for its outgoing neighbors: the first vector contains edges whose targets are tracked vertices, and the second vector contains edges whose targets are untracked vertices.

Propagating Differences upon Graph Mutation. When the graph structure mutates, the incremental computation must correctly propagate changes throughout the available intermediate states to compute final results. To retain BSP guarantees at the end of each iteration, our selective incremental processing propagates values iteration-by-iteration.

With only a subset of intermediate states available, processing for different vertices is handled differently. For tracked vertices, the intermediate states are incrementally refined in-place as processing progresses through iterations. Whereas for untracked vertices, a single vector is maintained to hold their latest values as processing progresses through iterations (similar to computing from scratch without intermediate states). In each iteration, the values propagated across edges are based on whether the target vertices are tracked or untracked, as shown in Figure 6b. If the target vertex is tracked, then the difference in value is propagated along its incoming edge similar to the traditional dependency-driven incremental processing [17]. On the other hand, if the target vertex is untracked, then both the old value (from before graph mutation) and the new value (resulting from graph mutation) are propagated along the edge.

This allows the target vertex to compute the necessary differences for its outgoing neighbors in the subsequent iteration.

Algorithm 1 shows how our selective incremental processing propagates values upon graph mutation. In each iteration, the differences directly resulting from graph mutation are propagated (lines 6-13), and then the resulting differences are propagated for the tracked and untracked vertices (line 15-22). The tracked vertices acquire the difference between the previous value change and the new value change. The untracked vertices, on the other hand, receive two values: the previous change and the new change. This allows the untracked vertices to recompute the old aggregation along with the updated aggregation. Once the values arrive at the required active vertices, their vertex values are computed to identify the differences to be propagated in the next iteration (lines 24-33).

As we can see on lines 15 and 19, operations on edges based on their target being tracked or untracked are directly invoked in parallel without any checks per edge, mainly because of the optimized graph layout described above that separates the edges. Moreover, since the selective incremental processing recomputes the vertex values to identify differences, our model tracks only the aggregation values as intermediate states (i.e., it does not track the intermediate vertex values, which is also maintained as part of intermediate state in the traditional dependency-driven incremental refinement [17]).

4 Minimal Stateful Iterative Model

In this model, we aggressively eliminate the tracking of intermediate state by specializing the incremental processing for certain graph algorithms. Specifically, our model will directly operate on value differences without reconstructing the intermediate states so that effects of mutations get propagated only as value differences throughout the iterations.

We first formalize the *distributive update property* that enables this specialization, and then discuss the details of the minimal stateful iterative model.

4.1 Distributive Update Property

Computations in graph algorithms can be modelled as:

$$val(v) = A \left(\bigoplus_{(u,v) \in E} (S(val(u))) \right)$$

Algorithm 1 Selective Incremental Processing

```

1: par for  $e \in E$  s.t.  $\text{target}(e)$  is untracked do
2:   Activate  $\text{source}(e)$  for propagation to untracked targets
3: end par for

4: for  $i \in [1..]$  do
5:   /* Propagate changes directly resulting from mutations */
6:   par for  $e \in$  mutated edges s.t.  $\text{target}(e)$  is tracked do
7:     Propagate old change if  $e$  is added; otherwise retract old change
8:     Activate  $\text{target}(e)$  for vertex computation
9:   end par for
10:  par for  $e \in E$  mutated edges s.t.  $\text{target}(e)$  is untracked do
11:    Propagate old change if  $e$  is removed; otherwise retract old change
12:    Activate  $\text{target}(e)$  for vertex computation
13:  end par for

14:  /* Propagate transitive changes from active vertices */
15:  par for  $e \in E$  s.t.  $\text{target}(e)$  is tracked and ( $\text{source}(e)$  is active or  $e$  is
16:  mutated edge) do
17:    Propagate difference between old change and new change
18:    Activate  $\text{target}(e)$  for vertex computation
19:  end par for
20:  par for  $e \in E$  s.t.  $\text{target}(e)$  is untracked and  $\text{source}(e)$  is active do
21:    Propagate old change and new change
22:    Activate  $\text{target}(e)$  for vertex computation
23:  end par for

23:  /* Compute vertex values and differences to push in next iter */
24:  par for  $v \in$  active tracked vertices do
25:    Merge difference in  $v$ 's intermediate state
26:    Compute  $v$ 's old value and new value
27:    Activate  $v$  for propagation if difference in value changes is not  $\emptyset$ 
28:  end par for
29:  par for  $v \in$  active untracked vertices do
30:    Merge old change in  $v$ 's old value and new change in  $v$ 's new value
31:    Compute  $v$ 's old value and new value
32:    Activate  $v$  for propagation if difference in value changes is not  $\emptyset$ 
33:  end par for
34: end for

```

where \oplus is the aggregation function that combines incoming values to a vertex, S is the function that transforms the source's value to be aggregated (analogous to scatter operation in [8]), and A is the vertex function that computes the vertex value using the aggregation result. For instance, in PageRank \oplus is the *sum* operation, S is the function that divides the rank value with outdegree (i.e., $\text{pr}(u) / \text{out_degree}(u)$), and A is the linear equation that computes rank value using the result of \oplus and damping factor (i.e., $(1-d) + d * \text{sum}$).

The *distributive update property* states that the computation of vertex value can be distributed as sub-computations over its incoming neighbors' values, i.e.,

$$A\left(\bigoplus_{k \in \{w,x,y,z\}} (S(k))\right) = \gamma_{k \in \{w,x\}, \{y,z\}} \left(\alpha\left(\bigoplus_{k' \in k} (S(k'))\right)\right)$$

where γ and α are functions derived from A . This property is important because it allows directly computing the difference in the target value from the difference in the source value without reconstructing $\bigoplus(S(*))$. This allows our minimal stateful iterative model to aggressively reduce the intermediate state by simply not tracking the results from \bigoplus . For instance, in our PageRank example if a source's rank value

Graph Algorithm	Distributive Update Property	Reason for Violation

Multi-Manifold Ranking	✗	
Multi-Modality Learning	✗	

Table 1: Algorithms whose computations satisfy (✓) or violate (✗) the distributive update property.

changes from u_1 to u_2 , then the change in value of the destination vertex v gets directly computed as $d * (u_2 - u_1) / \text{out_degree}(u)$. Note this does not require explicitly reconstructing the sum variable for v .

Applicability. The distributive update property is different from just the aggregation operation being distributive that is studied in static graph processing [39]. While most of the aggregation operations are distributive (which enables edge parallel incremental operations, as well-known in prior research), the distributive update property also requires the vertex functions to be distributive. For instance, the PageRank computation satisfies this property since its linear equation only operates on the aggregation value and constants, and hence, any change in rank value of source vertex can be directly incorporated in the destination value. On the other hand, even though algorithms like Collaborative Filtering [40] and Multi-Modality Learning [31] have *sum* aggregation (which is distributive), their vertex functions are not distributive since they involve operations like *normalization* and *matrix inverse*. Table 1 classifies various graph algorithms based on whether they satisfy or violate the distributive update property.

4.2 Tracking Minimal Vertex State

While the differences can be propagated without computing the intermediate states at each iteration, these differences need to be grounded w.r.t. some basis so that they are meaningful. Hence, we track the earliest intermediate state that initiates the incremental computation when graph structure mutates. These earliest intermediate states correspond to the states of the mutation points (e.g., vertices whose edges got mutated)

Algorithm 2 Incremental Processing with Minimal State

```
1: for  $i \in [1..n]$  do
2:   /* Propagate old values */
3:   par for  $e \in$  mutated edges do
4:     Propagate old value if  $e$  is added; otherwise retract old value
5:     Activate target( $e$ ) for vertex computation
6:   end par for

7:   /* Propagate transitive changes from active vertices */
8:   par for  $e \in E$  s.t. source( $e$ ) is active or  $e$  is mutated edge do
9:     Propagate change
10:  end par for
11:  par for  $v \in$  active vertices do
12:    if  $v$  is tracked then
13:      Merge change in  $v$ 's intermediate state
14:    end if
15:    Activate  $v$  for propagation if change is not  $\emptyset$ 
16:  end par for
17: end for

18: /* Compute final vertex values */
19: par for  $v \in V$  do
20:   Merge change in vertex value with old vertex value
21: end par for
```

since those points start propagating the changes directly based on the specific edge/vertex that gets added/deleted. Apart from the earliest states, no other intermediate state is captured because the computations purely operate on differences to propagate through the rest of the iterations.

Hence, the potential mutation points in the graph are the subset of vertices whose intermediate states are tracked. These vertices are identified based on application-specific insights like mutations occurring at certain important vertices, or what-if queries based on certain regions of the graph. When potential mutation points cannot be identified a priori, high in-degree vertices can be tracked (similar to Section 3.2) in order to increase the chances of mutations getting applied to tracked vertices. As we see next, the incremental processing can automatically handle the case when mutations occur on vertices that are not tracked as well.

4.3 Incremental Processing

With the distributive update property, the impact of mutations on tracked vertices can be computed directly using difference in values. When graph structure mutates, incremental computation is performed in iteration-by-iteration manner by purely operating on differences. Algorithm 2 shows how the differences are identified and propagated. Unlike the selective incremental processing technique, the distributive update property enables straightforward propagation of differences. The mutated edges propagate and retract the old values (lines 3-6), and their target vertices compute the differences. These differences are further propagated in subsequent iterations (line 9). If the target vertex is tracked, the differences are merged in the intermediate state as computation progresses. In the end, the cumulative differences are incorporated with the vertex values to generate the final result (line 20).

When mutation occurs on vertices that are not tracked, the processing can dynamically switch to selective incremental processing (Section 3.3) that correctly propagates value differences based on whether the target vertices are tracked or untracked. This switch happens seamlessly without performing additional computation since the selective incremental processing reconstructs the missing intermediate states on-the-fly as it progresses iteration-by-iteration.

5 Evaluation

We thoroughly evaluate our memory-efficient stateful iterative models and compare their performance with the dependency-driven incremental processing model from GraphBolt [17] (which delivers high performance at the cost of high memory consumption). Specifically, we answer the following questions:

1. How effective is our selective stateful iterative model in controlling the memory footprint?
2. How does the performance of our selective stateful iterative model vary as the number of vertices being tracked changes?
3. How effective is our minimal stateful iterative model in maintaining a small memory footprint while still delivering high performance?
4. How do our memory-efficient stateful iterative models perform when processing a large number of simultaneous graph mutations?

5.1 Implementation Details

We implemented our memory-efficient stateful iterative models in the GraphBolt system for two main reasons: first, it allows our models to utilize the efficient implementation of the underlying framework (e.g., parallelization strategy, atomics, frontiers, etc.); and second, it enables direct performance comparison of our models with GraphBolt's existing execution model.

We implemented the optimized graph layout for the adjacency list representation (discussed in Section 3.3) to replace the existing adjacency list data structure. The intermediate states for selected subset of vertices are tracked in their respective arrays. The state arrays get allocated vertically (per vertex) instead of horizontally (per iteration) so that arrays for untracked vertices are not allocated (hence reducing memory footprint), while at the same time the intermediate states for tracked vertices get addressed without using any hashmap.

5.2 Experimental Setup

We use seven synchronous graph algorithms. PageRank (PR) [23] computes the importance of web-pages based on incoming links to those pages. Collaborative Filtering (CF) [40] is a context-based technique used in recommender systems

Graph	Vertices	Edges	Graph Size	
			Without Final State	With Final State
TwitterMPI (TT)	52.6M	2B	14.2GB	19-30GB
Friendster (FT)	68.3M	2.5B	18.74GB	24-38GB
UK-2007-05 (UK)	105M	3.7B	27.75GB	36-59GB
UK-union (UN)	133M	5.5B	36.2GB	48-80GB
Clueweb (CWB)	978.4M	42.5B	130GB	197-240GB

Table 2: Real-world graphs used in experiments [1, 2, 3]

to classify associated items while Co-Training Expectation Maximization (CoEM) [22] is a semi-supervised learning algorithm for named object identification. Multi-Manifold Ranking (MMR) [37] is a ranking method that uses multiple image manifolds each constructed using a different image features. Multi-Modality Learning (MML) [31] and Label Propagation (LP) [41] are learning algorithms that disperse labels from a subset of vertices to assign label to the rest of the graph. Circuit Simulation (CS) [12] simulates flow in a circuit by solving partial differential equation.

The LP, MMR and MML algorithms compute vector of features for each vertex, whereas the remaining algorithms operate on scalar vertex values except for CF which operates on two factors per vertex. Computations in PageRank and CoEM follow the distributive update property (described in Section 4.1), and hence we evaluate our minimal stateful iterative model with these two benchmarks. Computations in the remaining benchmark do not follow the distributive update due to the complex sub-operations they involve: specifically, LP, MMR and MML normalize the feature vectors in every iteration, CF computes matrix inverse, and CS uses division on its aggregation values.

Table 2 lists the six real-world input graphs used for evaluation. Similar to [17, 28], we obtained an initial fixed point when 50% of edges were loaded, and streamed in the remaining edges to model edge insertions, while randomly sampled edges from the loaded graph were used for edge deletions. To eliminate the effects of locality, we shuffled the edges while forming our edge streams. Starting with 50% of edges is not a requirement for GraphBolt and other systems (i.e., one can start with an empty graph as well), but doing so allows us to evaluate the common scenario where a graph snapshot is already present and mutations are streamed in. For CWB graph which is significantly large, initial fixed point was obtained with 7% of edges so that at least stateless execution could successfully execute. The algorithms that operate on vectors consume high memory, and as expected, the memory footprint increases as the vector size increases. Unless otherwise stated, we use 10 features for LP, MMR and MML so that the GraphBolt baseline could hold the intermediate state without running out of memory, and 2 features are used for CWB graph to ensure that stateless execution could successfully execute. Similar to [17], we run all algorithms for 10 iterations. Unless otherwise stated, we apply 10K edge mutations to evaluate how quickly our models compute the final result; we also vary the mutation batch size from a single mutation

to up to 10 million edge mutations.

All experiments were performed on Oracle Cloud VM.Standard2.24 shape containing Intel(R) Xeon(R) 8167M processor with 24 physical cores (48 threads) and 320GB main memory running 64-bit Ubuntu 18.04.

Throughout the evaluation, we use the following notations for different executions:

- **Selective- $k\%$** : this is our selective stateful iterative model that tracks $k\%$ of total vertices.
- **Minimal**: this is our minimal stateful iterative model.
- **GraphBolt**: this is GraphBolt’s execution [16, 17], which tracks the intermediate state for all vertices.
- **Stateless**: this baseline does not track any intermediate state, and recomputes values from scratch upon graph mutation (same as GB-Reset in [17]).

5.3 Selective Stateful Model Performance

Figure 7 shows the memory footprint and execution time for our selective stateful iterative model when tracking the intermediate state for 20%, 40%, 60% and 80% of the vertices. The figure also compares the performance with GraphBolt and stateless executions. Figure 8 summarizes similar results for CWB graph. As we can see, our selective stateful iterative model is effective in controlling the memory footprint by tracking only the selected subset of vertices. For instance, it consumes 35-70% less memory than GraphBolt when tracking only 20% of vertices, while at the same time delivering 15-83% of the performance gains provided by GraphBolt over the stateless execution. In fact, GraphBolt runs out of memory for certain cases while the selective executions end up successfully executing and delivering high performance.

By tracking more intermediate states the memory footprint increases and the execution time decreases mainly because the intermediate state helps in incremental refinement; this is visible as decreasing number of edge operations in Figure 9 for FT graph as the number of tracked vertices increases from 20% to 80%. Since stateless execution does not track any intermediate state, its memory footprint is the lowest while the execution time is highest; on the other extreme, since GraphBolt tracks intermediate state for all vertices, its memory footprint is the highest while its execution time is the lowest. Our selective stateful iterative model trades off memory footprint for more computation, and hence delivers performance between the two extremes.

We observe that the increase in memory footprint from stateless to selective-20% is higher compared to the increase between consecutive selective variants (e.g., between selective-20% and selective-40%). This is because the selective incremental processing computes both the new value (after mutation) and the old value (prior to mutation) so that differences can be propagated from untracked values; holding

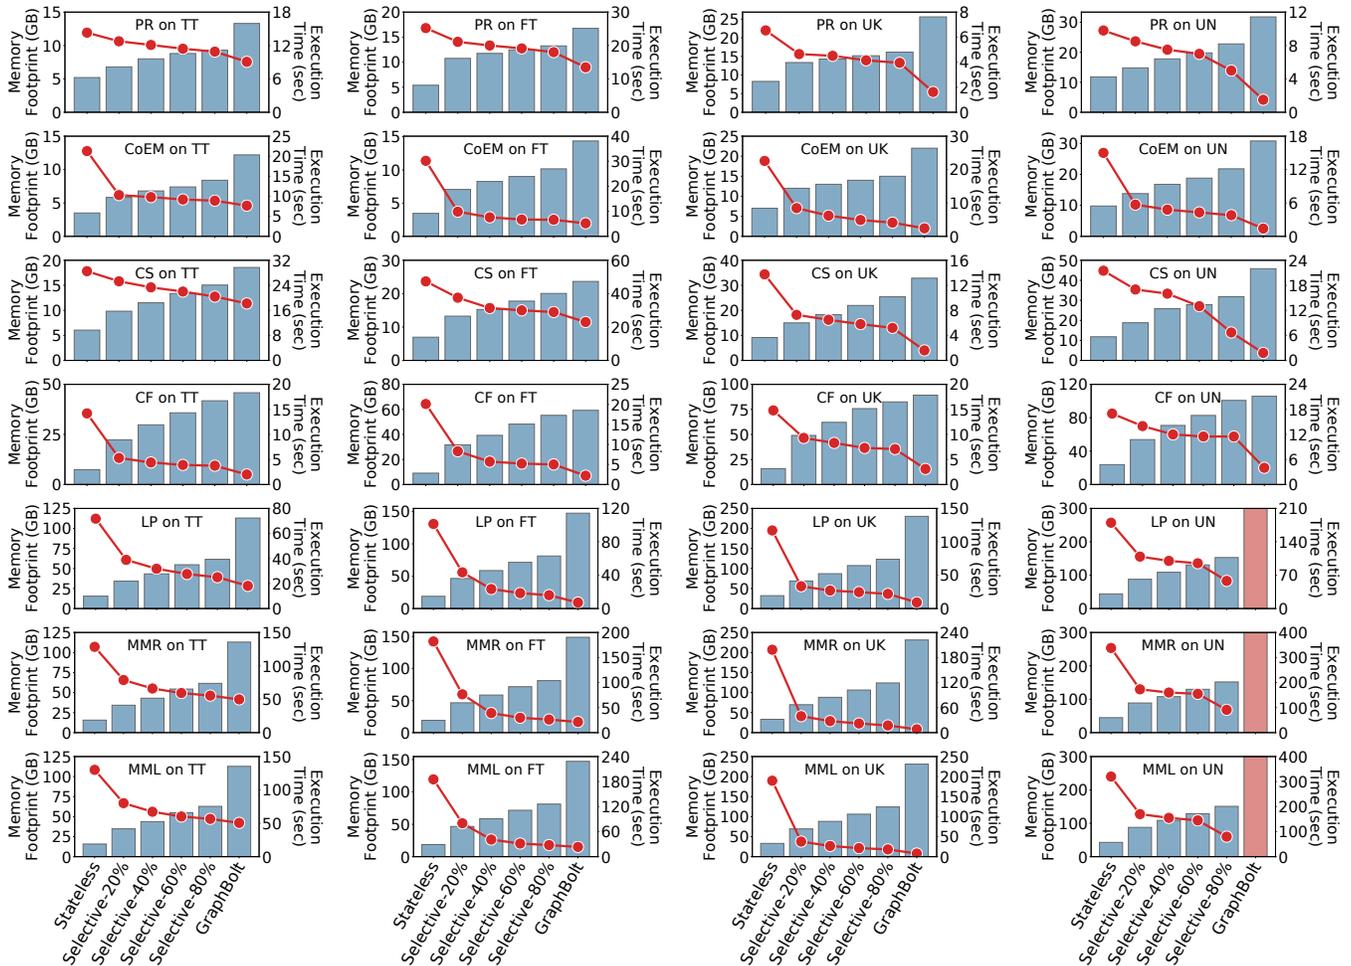

Figure 7: Performance of our selective stateful iterative model compared to the stateless iterative model and the stateful iterative model from GraphBolt. The memory footprints (in GB) are shown as bars (left y-axis) and the execution times (in seconds) are shown as points (right y-axis). Red bar indicates the execution ran out of memory.

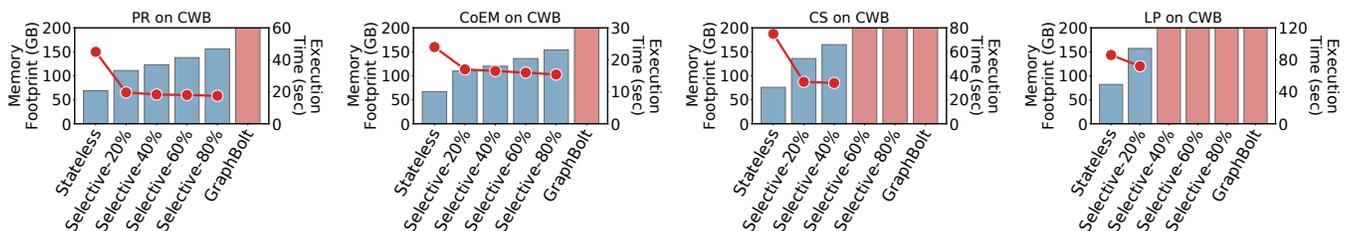

Figure 8: Performance of our selective stateful iterative model on CWB graph compared to the stateless iterative model and the stateful iterative model from GraphBolt. The memory footprints (in GB) are shown as bars (left y-axis) and the execution times (in seconds) are shown as points (right y-axis). Red bar indicates the execution ran out of memory.

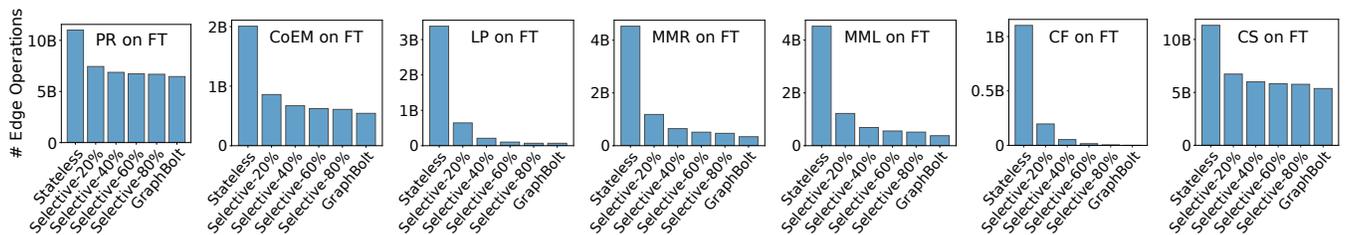

Figure 9: Number of edges operations executed by our selective stateless iterative model, compared to the stateless iterative model and the stateful iterative model from GraphBolt.

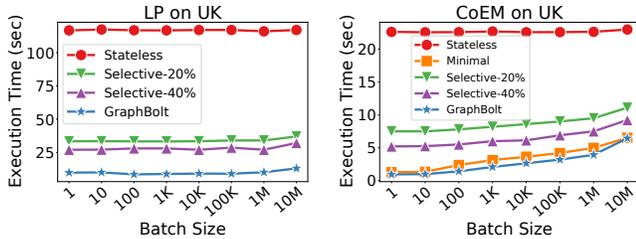

Figure 10: Execution times (in seconds) for different iterative models across varying number of mutations per batch.

these values in memory adds to the memory footprint, which is an overhead that stateless executions do not incur.

For a given graph, the memory footprint depends on the size of intermediate state in the benchmark. Hence, for each graph the memory footprints are lower for PageRank and CoEM since they operate on scalar values, while the footprints are higher for LP, MMR and MML due to their use of feature vectors. This is also the reason why GraphBolt runs out of memory for only LP, MMR and MML on UN graph; whereas on CWB graph only certain executions of selective variants run successfully.

The execution time, on the other hand, is dependent on how the values propagate across iterations which is dependent on the graph algorithm and the structure of input graph. Therefore, the performance benefit with saving selective intermediate state is different for different cases. For instance, selective-20% is $5\times$ faster compared to stateless for MMR on UK, whereas it is only $1.63\times$ faster for MMR on TT. On the other hand, selective-20% is $2.4\times$ faster compared to stateless for CF on FT, but only $1.2\times$ faster for CF on UN.

For most of the cases, we observe that tracking intermediate state for only 20% of vertices achieves 15-83% of performance gains that are achieved by GraphBolt. For instance selective-20% on MMR achieves $1.6-5\times$ compared to stateless executions across different graphs, whereas GraphBolt achieves $2.6-24.4\times$ compared to stateless execution. This is mainly because our model tracks the high-degree vertices that demand more computation if their states are not available, and hence incremental processing for those high-degree vertices ends up achieving high performance benefits. This is a benefit especially for skewed graphs since the memory consumption for selective-20% is much less compared to GraphBolt, while at the same time the performance gains are high. As expected, the performance gains from incremental processing reduce as the number of tracked vertices increases.

Finally, for cases like CF we observe that the difference in execution times between selective-80% and GraphBolt is higher compared to the difference between consecutive selective variants (e.g., between selective-60% and selective-80%). This is again because the selective incremental processing computes both the old values and the new values whereas GraphBolt directly computes the value changes. The effects of these additional computations become more visible for CF

since it has relatively expensive vertex computations (involving a matrix inverse operation).

Scaling with Mutation Batch Sizes. Figure 10 shows the performance of our selective stateful iterative model with 20% and 40% tracked vertices as the mutation batch size increases from a single mutation to up 10 million edge mutations. The memory footprints of the stateful iterative models remain same as in Figure 7 since they are mainly dependent on the number of tracked vertices. However, we observe that the amount of computation performed increases as more mutations get simultaneously applied. Hence, the execution time for both, selective stateful model as well as GraphBolt increases as mutation batch size increases. Since the stateless execution simply recomputes from scratch, its execution time increases very slowly across different mutation batch sizes.

5.4 Minimal Stateful Model Performance

Figure 11 shows the memory footprint and execution times for our minimal stateful iterative model along with GraphBolt and stateless executions on PageRank and CoEM. Since the minimal stateful iterative model only tracks the earliest intermediate states that form the basis for differences, its memory footprint is $1.4-2.4\times$ smaller compared to GraphBolt and only $1.1-1.3\times$ higher than stateless execution. Moreover, the incremental computation in the minimal stateful iterative model purely operates on value differences, and hence, delivers high performance. Our minimal stateful iterative model is $1.1-8.2\times$ faster than stateless executions, which results in 65-90% of the benefits delivered by GraphBolt.

Scaling with Mutation Batch Sizes. Figure 10 shows the performance of the minimal stateful iterative model for CoEM as the mutation batch size increases from a single mutation to up 10 million edge mutations. Similar to selective model, the execution time for the minimal stateful iterative model increases as the number of simultaneous mutations increases; nevertheless, it is $3.5-17.4\times$ faster than the stateless execution.

Unlike the selective model, the memory footprint of our minimal stateful iterative model is sensitive to the number of updates. As the mutation batch size increased from 1 to 10M, the memory footprint of our minimal stateful iterative model increased from 0.5GB ($1.06\times$ higher than stateless, and $2.9\times$ lower than GraphBolt) to 2GB ($1.3\times$ higher than stateless, and $2.4\times$ lower than GraphBolt).

6 Related Work

Several dynamic graph processing systems have been developed in literature. We first discuss the systems with stateful iterative models, and then summarize the works that use stateless models.

Kickstarter [35], GraphBolt [17] and DZiG [16] develop efficient streaming graph processing solutions using stateful iterative models for incremental computation. Upon graph

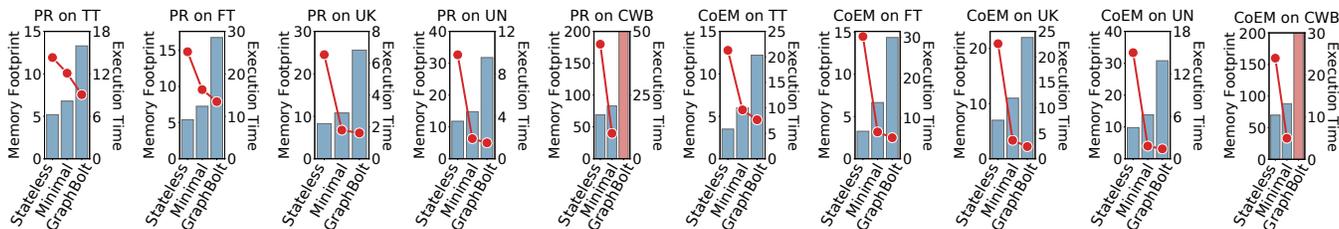

Figure 11: Performance of our minimal stateful iterative model compared to the stateless iterative model and the stateful iterative model form GraphBolt. The memory footprints (in GB) are shown as bars (left y-axis) and the execution times (in seconds) are shown as points (right y-axis). Red bar indicates the execution ran out of memory.

mutation, these systems use the intermediate state to quickly adjust the computed values and deliver final results corresponding to the latest graph version. KickStarter [35] focuses on graph algorithms like BFS and SSSP that use monotonic functions. Its runtime exploits the monotonic relationship between vertex values to capture dependencies between the latest computed values, resulting in only one intermediate state per vertex. Hence, its memory footprint does not drastically increase compared to stateless execution of those algorithms as the input graph consumes the most amount of memory. GraphBolt [17] and DZiG [16] focus on the broader class of graph algorithms that run in BSP manner. They capture the dependency information across intermediate vertex values as computation progresses, and not just across the latest values. DZiG [16] develops a DelZero-Aware incremental refinement strategy to efficiently handle computation sparsity during incremental processing. The intermediate state in both, GraphBolt and DZiG, requires much larger amount of memory compared to KickStarter, which drastically increases their memory footprint. Our memory-efficient stateful iterative models limit the memory footprint by reducing the amount of intermediate state that gets captured for efficient incremental computation.

GraphInc [4] saves all messages across edges along with computed states in order to replay the computation with incremental changes. This ends up demanding much larger memory capacity (intermediate state in the order of edges for each iteration) compared to recent works like GraphBolt. Differential Dataflow [18] is a general-purpose system that enables incremental computation by tracking states at operator level, i.e., for graph computations it also maintains intermediate state in the order of edges per iteration, which results in a much larger memory footprint than KickStarter and GraphBolt. Since our memory-efficient stateful iterative models prune out intermediate state at vertex-level, they can be easily applied to these systems by selectively tracking intermediate edge-level or operator-level states for only a subset of vertices.

Systems like [5, 6, 7, 13, 15, 27, 28, 30] use stateless iterative models which limits their efficiency in delivering accurate results upon graph mutation. Tornado [28], Kineograph [5] and GraphIn [27] perform incremental computation by triggering the user functions based on graph updates and allowing the changes to propagate throughout the graph. Hence, they can-

not guarantee accurate results for BSP algorithms. GraphIn identifies the vertices that could be potentially impacted by graph updates using tag propagation, and restarts computation from scratch for those identified vertices. [30] uses GIM-V (generalized iterative matrix vector multiplication) to perform incremental computation. LLAMA [15], STINGER [7], Aspen [6], GraphOne [13] and LiveGraph [43] focus on designing efficient dynamic graph data structures and storage systems, and their processing models do not support incremental computation. However, incremental computation is crucial in delivering high end-to-end performance, as shown by detailed performance comparison of these systems in [16].

Solutions like [10, 11, 19, 34] operate on evolving graphs that contain a group of temporally-related graph snapshots capturing the evolution of the graph structure over time. These systems do not capture intermediate states and perform incremental computation by directly reusing the results computed for previous graph snapshots, making them suitable for self-fixing graph algorithms but not for general BSP algorithms.

Finally, static graph processing systems [8, 9, 14, 20, 21, 24, 25, 26, 29, 33, 36, 38, 42] focus on processing a given static graph input and do not natively handle dynamic graphs with incremental processing.

7 Conclusion

We presented two memory-efficient stateful iterative models for incremental processing of streaming graphs. The Selective Stateful Iterative Model controls the memory footprint by selecting a small portion of the intermediate state to be maintained throughout execution. The Minimal Stateful Iterative Model further reduces the memory footprint by exploiting the distributive update property in graph algorithms. Our results showed that our models are effective in limiting the memory footprint while still retaining most of the performance benefits of traditional stateful iterative models, hence being able to scale on larger graphs that could not be handled by the traditional models.

Abstract

We introduce AVOCADO, a secure in-memory distributed storage system that provides strong security, fault-tolerance, consistency (linearizability) and performance for untrusted cloud environments. AVOCADO achieves these properties based on TEEs, which, however, are primarily designed for securing limited physical memory (enclave) within a single-node system. AVOCADO overcomes this limitation by extending the trust of a secure single-node enclave to the distributed environment over an untrusted network, while ensuring that replicas are kept consistent and fault-tolerant in a malicious environment.

To achieve these goals, we design and implement AVOCADO underpinning on the cross-layer contributions involving the network stack, the replication protocol, scalable trust establishment, and memory management. AVOCADO is practical: In comparison to BFT, AVOCADO provides confidentiality with fewer replicas and is significantly faster—4.5× to 65× for YCSB read and write heavy workloads, respectively.

1 Introduction

In-memory distributed key-value stores (KVS) [8, 29–31, 40, 44, 45, 61, 66, 88, 106] have been widely adopted as the underlying storage system infrastructure in the cloud because (i) they support latency sensitive applications by keeping data in main memory, and (ii) they are able to accommodate large datasets beyond the memory limits of a single server by adopting a scale-out distributed design.

At the same time, the transition to the cloud has increased the risk of security violations in storage systems [77]. In untrusted environments, an attacker can compromise the security properties of the stored data and query operations. In fact, several studies [36, 37, 83] show that software bugs, configuration errors, and security vulnerabilities pose a serious threat to storage systems. Further, a malicious cloud operator or co-located tenant, presents an additional attack vector [78, 79].

To address these security threats, hardware-assisted trusted execution environments (TEEs), such as Intel SGX [5], ARM Trustzone [12], RISC-V Keystone [53, 76], and AMD-SEV [10] provide an appealing way to build secure systems. In particular, TEEs provide a hardware-protected secure memory region whose residing code and data are isolated from any layers in the software stack including the OS/

hypervisor. Given this promise, TEEs are now commercially offered by major cloud computing providers [23, 34, 60].

Although TEEs provide a promising building block for securing systems against a powerful adversary, they also present significant challenges while designing a *replicated secure distributed storage system*. The fundamental issue is that the TEEs are primarily designed to secure the limited in-memory state of a single-node system, and thus, the security properties of TEEs do not naturally extend to a distributed infrastructure. Therefore we ask the question: *How can we leverage TEEs to design a high-performance, secure, and fault-tolerant in-memory distributed KVS for untrusted cloud environments?*

In this work we introduce AVOCADO, a secure, distributed in-memory KVS based on Intel SGX [5] as the foundational TEE that achieves the following properties: (a) strong *security*, in particular, *confidentiality*—unauthorized reads are prevented, and *integrity*—unauthorized changes to the data are detected, (b) *fault tolerance*—the service continues uninterrupted in the presence of faults, (c) *consistency*—strong consistency semantics for a replicated store (linearizability), while protecting against roll back and forking attacks and (d) *performance*—achieving all of these without compromising performance.

To achieve the aforementioned properties, we need to address the following four design challenges pertaining to the network stack, the replication protocol, trust establishment, and memory management in TEEs.

Firstly, in-memory distributed KVSs are increasingly build on high-performance network stacks, where they bypass the kernel using direct I/O [4, 30, 46]. Unfortunately, the prominent I/O mechanism employed by TEE frameworks [13, 65, 72] is based on asynchronous system calls [85], which exhibit significant overheads [104]. On the other hand, the direct I/O mechanism is fundamentally incompatible with TEEs as the data stored within the protected memory of TEEs cannot be directly accessed via the untrusted DMA connection.

To address this challenge, we design a high-performance network stack for TEEs based on eRPC [46]—it supports the complete transport and session layers, while enabling direct I/O within the protected TEE domain. Our network stack outperforms asynchronous syscall by 66% for iperf (§6.1).

Secondly, in-memory distributed KVSs rely on data replication for fault tolerance. To ensure replicas are consistent in the presence of faults and adversary, a secure replication protocol is deployed. While conventional wisdom requires the employment of BFT protocols [20, 52], they are prohibitively

*Do Le Quoc performed this work at TU Dresden.

expensive for practical systems [22].

To overcome the limitation, we design a secure replication protocol, which builds on top of any high-performance non-Byzantine protocol [56, 98]—our key insight is to leverage TEEs to preserve the integrity of protocol execution, which allows to model Byzantine behavior as a normal crash fault. Our replication protocol offers linearizable reads and writes, and outperforms BFT [87] by a factor of $4.5\times$ – $65\times$, while requiring f fewer replicas and stronger security properties (§ 6.2).

Thirdly, a secure distributed system requires a scalable attestation mechanism to establish trust between the servers and clients. Unfortunately, the remote attestation mechanism in TEEs is designed for establishing root of trust for a single node [68] and it does not provide collective trust establishment across the multiple nodes of a distributed system. Moreover, the attestation itself is based on Intel attestation service (IAS) [3, 11], which suffers from scalability and latency issues.

To address this, we design a configuration and attestation service (CAS) that ensures scalability and flexibility in a distributed environment. Further, it provides configuration management, and improved performance of $18.3\times$ compared to Intel’s IAS attestation (§ 6.3).

And lastly, an in-memory distributed KVS requires fast access to large amount of main memory on each server for single-node KVS. Unfortunately, TEEs provide a limited secure physical memory, and rely on prohibitively expensive paging mechanism to access data beyond the physical limit.

To address this limitation, we design a novel single-node KVS based on a partitioned skip list data structure, which overcomes the memory limitations of TEEs, while supporting lock-free scalable concurrent updates. Our KVS provides fast lookup speed; $1.5\times$ – $9\times$ faster than ShieldStore [48], a state-of-the-art secure KVS for single-node systems (§ 6.4).

Based on these aforementioned four contributions, we build AVOCADO as an end-to-end system from the ground-up, and evaluate it using a real hardware cluster using the YCSB [7, 24] workloads. Our evaluation shows that AVOCADO is scalable and performs similar in read heavy and write heavy workloads: AVOCADO suffers only 50 % slowdown compared to a non-secure distributed KVS (§ 6.5), which is an order of magnitude better than the state-of-the-art secure distributed storage systems providing strong consistency (§ 7).

Limitations: AVOCADO requires a large trusted computing base (TCB) compared to other work using TEE to provided secure replication [18, 25, 26]. While BFT protocols can handle implementation errors, AVOCADO cannot and requires the TCB to be implemented correctly. Further, we do not aim to protect against side-channel attacks and access or network pattern attacks [37, 49, 55, 105]. Protecting against these attacks is outside of the scope of this work.

2 Background

2.1 Trusted computing

Trusted Execution Environments (TEEs) [5, 10, 12, 27, 76] are tamper-resistant processing environments that guarantee the authenticity, the integrity and the confidentiality of their executing code, data and runtime states, e.g. CPU registers, memory and others. Their content remains resistant against all software attacks even from privileged code (OS, hypervisor).

SGX, Intel’s version of a TEE, offers the abstraction of an isolated memory called *enclave*. Enclave pages reside in the enclave page cache (EPC) — a specific memory region (up to 128 MiB for v1 and 256 MiB for v2) which is protected by an on-chip memory encryption engine (MEE). To support applications with larger memory footprint SGX implements a *paging* mechanism. However, the EPC paging mechanism incurs high overheads [16, 65].

This isolation prohibits SGX applications from executing outside-of-the-enclave code directly. Thus, enclave threads need to *exit* the trusted environment and further copy all associated data out of the enclave since kernel code cannot access it. Afterwards, threads have to *enter* the enclave again. We refer to this as *world switch*.

Our AVOCADO project leverages the advancements in shielded execution frameworks; in particular, we use SCONE [13] to build a distributed storage system.

2.2 High-performance networking with eRPC

Traditionally the network stack and the I/O are handled inside the OS kernel where conventional applications perform *system calls* to send/receive messages. However, context switches due to system calls present a bottleneck and might sacrifice performance [2, 38, 43, 86, 101]. Consequently, approaches like RDMA and DPDK [4] are widely favored in high performance networking because they (i) can map a device into the users address space, and (ii) replace the costly context switches with a polling-based approach.

In our work, we build our network stack based on eRPC [46], a state-of-the art general-purpose and asynchronous remote procedure call (RPC) library for high-speed networking for lossy Ethernet or lossless fabrics. eRPC uses a polling-based network I/O along with userspace drivers, eliminating interrupts and system call overheads from the datapath.

Lastly, eRPC provides us with a UDP stack, leverages optimization techniques (e.g. zero-copy reception, congestion control, etc.) while it remains generic; it supports a wide range of transport layers such as RDMA, DPDK, and RoCE.

3 System model

AVOCADO divides the key space into shards. Each shard is replicated over a configurable number of nodes, which are connected over a high speed network. A client issuing a Put, Get, or Delete operation selects the shard associated with the key and chooses a *request coordinator* from the list of nodes. The nodes will coordinate with each other

to provide proof for the success of the operation. For Get operations proofs of integrity, authenticity, consistency and non-/existence need to be provided, too.

Data model. AVOCADO provides confidentiality, integrity, authenticity and strong consistency for the stored data. Specifically, a server only acknowledges a request as long as it can prove the following guarantees: 1) an adversary cannot read or manipulate stored data, without the manipulation being detected, 2) the servers can establish trust with each other and the clients and 3) an operation always observes the latest completed operation on the same key e.g., a Get observes the latest Put.

Threat model. AVOCADO targets an extended threat model beyond the conventional model assumed for single-node shielded execution [17]. In line with the default threat model of SGX, we assume that an adversary has full control over the hardware and software stack of the provided system, including OS and hypervisor. Further, the adversary has the ability to gain full control over the network infrastructure and can drop, delay, or manipulate network traffic. In contrast to BFT protocols, we assume that adversary cannot take advantage of faults in the implementation of SGX or KVS. Moreover, our work does not protect against side-channel attacks [42, 49, 55, 62, 81, 97, 99, 100]. AVOCADO also does not provide mechanisms against access pattern attacks [37, 105]. Lastly, we also do not protect against memory safety vulnerabilities in our implementation [51, 63].

Fault model. We assume an asynchronous model with network and crash-stop failures. The network can be manipulated by the attacker, thus, we assume that message transmission delays can be unbounded, network packets can be reordered, lost or duplicated. We do not assume the existence of synchronized clocks. Individual processes might fail by crashing, but do not operate in a Byzantine manner (because of trusted execution in the nodes). Since the network is controlled by the attacker, AVOCADO cannot provide any availability guarantees. However, as long as there is not a denial-of-service attack on the network, AVOCADO will remain available while a majority of processes remain alive (tolerating f failures).

4 Design

AVOCADO, as a distributed KVS, runs on a set of nodes, each of which has to continuously guarantee the confidentiality, integrity and authenticity of the stored data as well as the sent/received messages. As shown in Figure 1, each node consists of four major components. On the top, a configuration and attestation service (CAS) runs to provide and speed up the trust establishment between the nodes and the clients. Additionally, AVOCADO guarantees fault tolerance as well as consistency between the replicated nodes thanks to an asynchronous replication protocol. We implement this replication protocol using our secure network stack. Further, the network stack securely sends and receives messages, ensuring packet security. Finally, the single-node memory

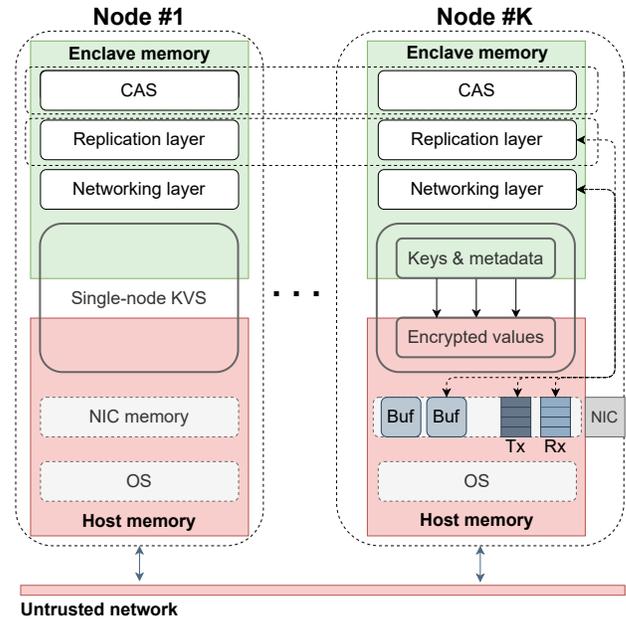

Figure 1: System overview.

KVS stores the dataset, containing all user provided data and ABD’s timestamps.

Following, we will discuss the four major components, i.e. network stack, replication protocol, CAS, and in-memory KVS, in more detail.

4.1 Network stack

Problem. High-performance networking based on direct I/O mechanisms (e.g., RDMA and DPDK) is an essential ingredient to design a distributed in-memory KVS. The networking layer is imperative to support high-performance synchronous replication. Unfortunately, mapping devices into TEEs trusted memory is incompatible to the security guarantees, since the device is untrusted. Direct I/O mechanisms, however, depend on DMA.

Additionally, the synchronous socket syscall I/O is limiting as it requires the expensive world switch in the TEEs (the world switch is around 5.5× more expensive than a kernel context switch; 10,170 cycles compared to 1,800 cycles [104]).

To prevent the expensive world switches, asynchronous syscall mechanisms [85] have been adopted by shielded execution frameworks, such as SCONE [13] or Eleos [65]. Although the asynchronous syscall mechanism helps in mitigating the expensive world switch in TEEs, it is not well-suited for AVOCADO since the system call overhead as well as copying data in/out the enclave memory are not avoided. For example, in our evaluation in Section 6.1 we prove that the exit-less asynchronous socket-based networking is poor choice compared to a userspace approach for AVOCADO.

Solution. To overcome this limitation, we opted for a new network stack based on the userspace direct I/O networking approaches (e.g., RDMA and DPDK), offering a secure implementation of the transport and session layer in the OSI

model. However, we need to tackle the fact that untrusted resources/memory cannot be mapped into the enclave memory. To address this, our network stack maps the DMA, and message buffers into the untrusted host memory, which is accessible by the enclave.

Shielded network stack. For our shielded network stack, we use eRPC [46] on top of DPDK [4]. To strengthen AVOCADO’s security properties and eliminate world switches, we also map all eRPC’s and DPDK’s software stack to the enclave address space by leveraging Scone. Therefore, the logic, i.e. code, *lives* completely within the enclave while the networking buffers (e.g. message buffers, network protocol buffers, Tx and Rx queues) remain in host memory since SGX will not allow registering enclave memory to the NIC. As a result, we map untrusted host memory to both NIC and network buffers required by eRPC and we utilise hugepages memory of 2 MB-pages to boost packet processing (e.g. eliminate page walks, exploit data locality, minimize swapping, and increase TLB hit rate).

As shown in Figure 2, the submission and reception of requests and responses mandate the allocation of message buffers. To transmit the message buffer’s data, eRPC needs to copy the data to a `rte_mbufs` in the Tx queue which is allocated by DPDK library and also resides in hugepages area. However, before that, a header that contains the transport header, and metadata (request handler type, sequence numbers, etc.) is added to the front of the packet. Specifically, eRPC library adds the UDP protocol header while the DPDK library is responsible for the Ethernet protocol header.

Upon a request’s reception, a specific handler for the type of the request is invoked. The Rx queue’s elements are pointers to the address of the received data. In case the packet is smaller than the MTU (1500 B in our case), we perform zero-copy reception by mapping the data address to the message buffer associated for that request. Our networking stack splits big packages (> MTU) into a set of ordered MTU-size smaller messages and delivers them in order—we guarantee to order by unique monotonic sequence ids. The first (sub)-message contains all the necessary metadata (e.g. the size of the original message). That way, if a message is lost, our library identifies the missing part and only the lost message is re-transmitted. Lastly, note that each user thread owns a separate RPC object which owns distinct Tx and Rx queues allowing that way multithreaded concurrent operations.

Encryption and message format. To sum up, AVOCADO efficiently eliminates the world switches, establishes a direct communication with the device bypassing the kernel network stack, attacks the limited enclave memory and promotes parallelism. However, by putting these buffers outside the hardware protected area, AVOCADO has to ensure the integrity and confidentiality for all network data. Towards this direction, we implemented an en-/decryption library (using hardware support for AES-GCM-128). Each call or return from eRPC goes through this en-/decryption layer which also checks the integrity of the transmitted data.

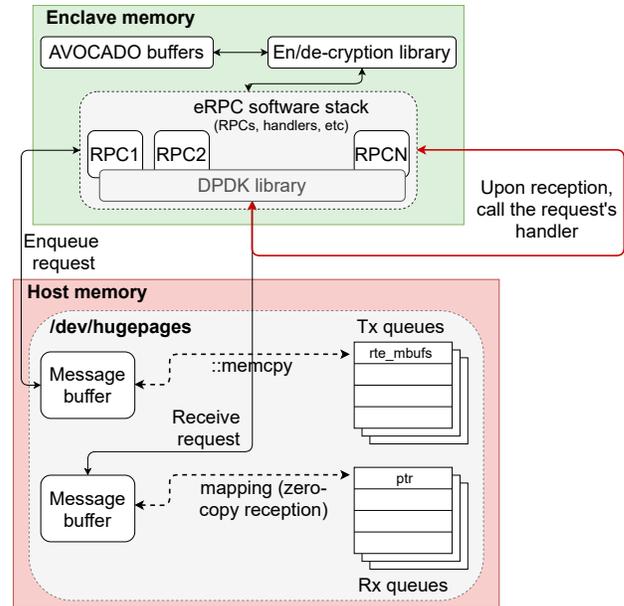

Figure 2: AVOCADO’s network stack.

Figure 3: AVOCADO’s message format.

Figure 3 shows the message format of our AVOCADO-networking layer. For each transmitted packet, the encryption layer builds a payload, which contains a 12 B IV, 8 B operation identifier, 8 B for the key size, 8 B for the size of the entire package then the KV pair with the Lamport clock (§ 4.2). The generated payload is followed by a 16 B MAC which is necessary to prove the authenticity and integrity upon reception in the remote host. The operation identifier also contains a unique id for the current request/response, allowing to detect resend packages by an attacker. Replicas are trusted and all replicas authenticate each other in the boot up step. Further, they make a key exchange, therefore we can use this together with the unique id to authenticate each message. By encrypting and authenticating our packages we can deal with security concerns raised for user space networking [84, 94].

Result. In Section 6.1 we show that our userspace shielded network stack based on eRPC outperforms the kernel approach based on sockets up to 1.66x.

4.2 Replication protocol

Problem. Distributed systems enforce consistency in the face of faults through replication protocols that establish an order of operations in a replicated environment, preventing data corruption and loss. We strive for linearizability [39], the strongest guarantee from a programmability perspective, which mandates that each request appears to take effect globally and instantaneously at some point between its invocation and completion. Additionally, we strive to provide two often contradictory properties: security and

Protocols	Linearizability	Integrity	Confidentiality	Replication factor	Max compromised nodes
Non-Byzantine	✗	✗	✗	$2f+1$	0
BFT	✓	✓	✗	$3f+1$	f
BFT + TEEs	✓	✓	✓	$3f+1$	All
AVOCADO	✓	✓	✓	$2f+1$	All

Table 1: The landscape of replication protocols in the untrusted environment. This table compares theoretical systems with different protocols against AVOCADO. Thereby, all the systems utilize a secure single-node KVS, however only the execution of BFT + TEE is protected. We assume f compromised nodes for linearizability, integrity and confidentiality columns.

performance. Conventional wisdom suggests the use of BFT protocols [20, 52] since they provide a secure consensus protocol in a malicious environment. However, their performance suffers from their overly pessimistic assumptions. On the other hand, non-Byzantine replication protocols, such as ABD [14, 56], chain replication [98] or Raft [64], perform better than BFT, but cannot tolerate a malicious environment.

Solution. Since AVOCADO assumes a malicious environment, BFT [20, 52] protocols could be deployed to deal with malicious responses. Prior work uses trusted components to increase the performance of BFT protocols by detecting equivocation [18, 54]. However, our assumption of the system differs from BFT. In contrast to BFT, we assume that enclaves will respond correctly, preventing equivocation. Furthermore the TEE is able to preserve the integrity of the protocol execution. This allows us to model a Byzantine behavior as a normal crash fault. As a result, we can adopt a non-BFT replication protocol, which deals with crash faults. Thereby, our design greatly increases the performance by avoiding the additional broadcast rounds required by BFT, while also reducing the required nodes to tolerate f failures. In Table 1 we compare security guarantees of different protocols with and without TEEs.

In AVOCADO we build our replication protocol on the well established multi-writer ABD [56] protocol. (From now on “ABD”.) By choosing ABD, we can also guarantee protection against forking and rollback attacks. ABD requires a majority of nodes to acknowledge each operation, guaranteeing that at least one replica involved in the operation has observed the most recent operation on the same key. This further guarantees liveness in case of network partitioning as long as a majority of nodes are in the same partition. While we do not change the replication-related behavior of the original ABD protocol, we design a secure replication protocol based on our network stack (§ 4.1). In the following we describe the important operations of AVOCADO.

#I: Put. In a Put operation the client will determine, by hashing the key and looking up the nodes, the set of nodes responsible for the key. They, then, send the Put to a randomly selected replica, which will act as the Put’s coordinator.

The chosen request’s coordinator will prepare it’s own KVS by preparing the local put operation, however it will not make the local put visible for other operations until the replicated Put operation is completed. This reduces EPC pressure, since the value doesn’t have to be cached in enclave memory before

it can be inserted into the nodes KVS. An example of the AVOCADO’s Put request is shown in Figure 4. The coordinator, first, executes the first of two broadcast rounds. All replicas store the key-value along with its Lamport clock to determine an order of operations. The Lamport clock consists of a logical counter and a machine id. This id guarantees that only one machine can generate a specific clock value. In the first broadcast round, the coordinator requests the timestamps that are stored in the replicas for that key. All replicas lookup the key in their in-memory KVS, to find their stored timestamp. Crucially, the replicas do not have to make an authenticity and integrity check on the timestamp, as the Lamport clock is stored as part of the metadata in enclave memory. Upon receiving a majority of the remote timestamps (including its own locally stored timestamp), the coordinator creates the timestamp of the new Put, by incrementing the highest of the received timestamps and concatenating its own node-id. Finally, it broadcasts the new KV pair along with its new timestamp to all replicas, which insert the KV pair into their in-memory KVS. Since the put operation does not return the value to the user, and the meta data is protected by the enclave AVOCADO does not have to check the authenticity and integrity of the old value. Upon gathering a majority of acknowledgements it reports completion to the client.

#II: Get. The Get operation is similar to Put; the client sends its request to a randomly selected server, which coordinates it. The server then looks up the KV-pair in its local store.

The chosen request coordinator executes one broadcast round. In certain cases a second, optional broadcast round is required. Similarly, to the first round of a Put, the first round of a Get finds out the highest timestamp for that key when the majority of replicas has responded. This action guarantees that the Get will observe any completed Put (recall that a Put only completes if it reaches a majority of replicas). The replicas will respond with their locally stored value and corresponding Lamport timestamp to the coordinator, this involves a lookup in the local KVS and decryption together with integrity and authenticity checks of the value. The Get always returns to the client the value that corresponds to the highest timestamp found in its first round. However, the coordinator can reply to the client iff, based on the replies it received on its first round, it can guarantee that a majority of replicas are aware of this value. Otherwise it must perform a second broadcast round.

The second broadcast round is identical to the second write of a Put: it shares the KV-pair along with its timestamp

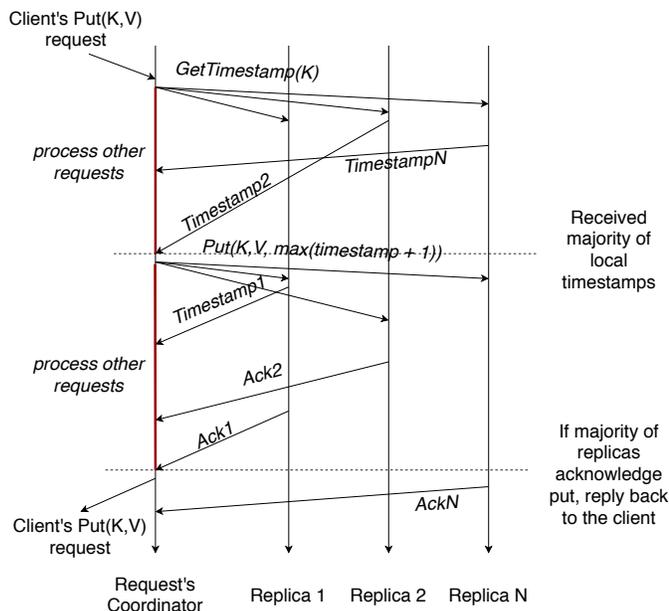

Figure 4: Example of Put request in AVOCADO protocol.

with all replicas. Completion of the Get is reported to the client only after gathering a majority of acks. The second round of the Get, ensures that a Get not only observes the latest completed Put, but also guaranteeing that the Put will be visible to all subsequent Gets.

#III Delete. Delete is supported by issuing a Put operation with an empty value. This will remove the value from the KVS, but importantly it will not remove the key. We need to keep the key and the corresponding Lamport clock, to be able to establish an order of operation if a future Put operation accesses the same key.

#IV: Fault tolerance. AVOCADO remains highly available in the face of machine failures. However, as nodes fail, new nodes must be added, to ensure that the deployment always includes a majority of live nodes. In order to ensure that machines can safely join the configuration, we deploy a recovery algorithm inspired by Hermes [47].

Specifically, when adding a new node all other live replicas are notified of the new node’s intention to join the replica group. The new node starts operating as a *shadow replica* that participates in all Put-related broadcast rounds (of remote replicas), but it cannot yet become the coordinator of a client request. Furthermore, the shadow replica does not take part in the Get quorum. In the meantime, the shadow replica reads chunks (multiple keys) from other replicas to fetch the latest values and reconstruct the KVS. To archive this the shadow replica is using the first broadcast round of ABD, but it never executes the second round, because it does not need to notify other replicas of what it read. After reading the entire KVS, the shadow replica is up-to-date and transitions to operational state, whereby it is able to serve client requests.

Result. We compare AVOCADO against BFT and Raft in

Section 6.2. Our evaluation shows that AVOCADO is between 4.5 and 65× faster than BFT-Smart [87].

4.3 Configuration and attestation service

Problem. To ensure the integrity of the code and data deployed in the remote hosts with TEEs, TEEs, such as Intel SGX, provide attestation mechanisms. Secrets (e.g. certificates, encryption keys, etc.) are provided only after the attestation. Once an enclave is initialized, an attestation process can be launched to verify the integrity of code and data inside the enclave and proves the enclaves identity to a remote party.

Intel SGX uses an architecture Platform Service Enclave (PSE) called *Quoting Enclave* to sign the report of the loaded enclave [11, 27]. The remote verifier forwards this signed report to the Intel Attestation Service (IAS). Thereafter, IAS confirms or refuses the authenticity of the report to the verifier.

This conventional attestation mechanism using IAS incurs significant overhead in a distributed setting, especially for elastic computing or fault tolerance. The reason is that every time a distributed system (e.g. a distributed KVS) spawns a new enclave, it needs to perform the remote attestation via IAS which is not necessarily hosted in the same data center, incurring high latency. Lastly, and importantly, cloud providers usually do not want to disclosure their hardware or cluster information, as this information might be confidential.

Solution. In AVOCADO, we overcome this challenge by designing a decentralized configuration and attestation management system (CAS) for distributed SGX-based applications.

By consolidating and expanding the traditional attestation mechanism of Intel to build our CAS, we automatically and transparently perform the attestation for each node. The key idea behind our design is that we replace the Quoting Enclave in the Intel attestation mechanism by the LAS. The CAS first attests the LAS using the Intel attestation mechanism, thereafter the LAS will operate as the root of trust in our remote attestation mechanism. Note, that we can launch as many LAS instances as required for availability. The LAS performs the local attestation for AVOCADO nodes and provides attestation quotes that can be verified by the CAS. Thus, our mechanism does not need to interact with IAS after the LAS is trusted, this reduces significantly the overhead of the traditional attestation. We achieve the *transparent and automatic properties* by deeply embedding the remote attestation into the AVOCADO runtime. In addition, our CAS only provisions a configuration and secrets to execute AVOCADO once it ensures that all nodes were not manipulated. Each node of AVOCADO can only communicate with others if it can provide a valid certificate provided by our CAS. Therefore, users can just rely on the CAS to control and operate other components of AVOCADO. They only have to attest our CAS before providing secrets to it. The CAS itself also runs inside an enclave, thus users can use the traditional attestation method of Intel to validate it.

Result. As shown in 6.3 our CAS achieves 18.2× lower end-to-end latency in AVOCADO when comparing with IAS.

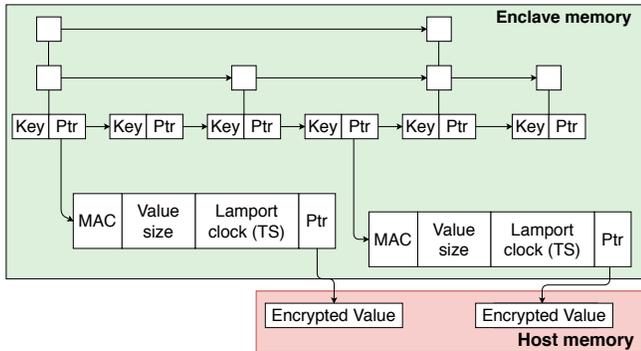

Figure 5: AVOCADO’s single-node KVS.

4.4 Single-node KVS

Problem. Enclave’s memory limitation is in stark contrast to the requirements of designing an in-memory KVS, which requires fast access to large amounts of in-memory data. Unfortunately, enclaves provide only limited physical memory (94 MiB) and incur high overheads due to the EPC paging mechanism (2–2000× [51]) beyond it.

To overcome the limitations of the strawman design, ShieldStore [48], a state-of-the-art secure in-memory KVS for a single-node system, proposed a MerkleTree-like data structure design where the entire KVS resides in the untrusted host memory, except for the security metadata (hash buckets heads). The metadata stored in the enclave memory is used to speed up the look up and to perform authenticity and integrity checks on the KV pairs. However, in our experience, the ShieldStore design suffers from continuous integrity re-calculations. Furthermore, the memory layout prohibits efficient concurrent operations.

Compared to Speicher [16], which also introduced the KV pair separation scheme for enclaves, our KVS is optimized for paging by encountering locality.

Solution. To overcome these limitations, we designed and propose our own in-memory concurrent data structure for the single-node KVS. Our KVS is based on a authenticated and confidentiality-preserving skip list [74] which supports secure and fast updates and lookups. We have chosen skip list as our fundamental data structure because it maintains the best features of a sorted array for searching ($O(\log n)$) and of a linked list-like structure for insertion ($O(\log n)$). Our design carefully partitions the key and value space by placing the keys along with metadata inside the enclave memory, while storing the bulk of data encrypted and integrity and authenticity protected in the untrusted host memory. Our partitioned data structure (keys and values) allow for faster lookups than ShieldStore’s hash buckets, while it also reduces the amount of necessary calculations to guarantee the integrity and authenticity. Furthermore, our lock-free data structure supports concurrent operations and it is well-suited for increased parallelism.

As shown in Figure 5 the nodes of the skip list reside

inside the enclave and contain the key and a pointer to metadata structure. This structure contains the 16 B MAC, for guaranteeing the integrity and authenticity of the value. Furthermore, the data structure also includes the size of the value, which makes checks on the value easier, since we do not need to read any information from the untrusted host memory, to retrieve how many bytes should be read. AVOCADO’s consistency protocol uses logical clocks, i.e. Lamport clocks, to establish an order of operations on each key (§ 4.2). Therefore, we also store the Lamport clock in the corresponding metadata block, to prevent costly decryptions on the timestamp queries. Lastly, the metadata structure also stores the pointer to the value in the untrusted host memory.

Importantly, separating the metadata and the bulk data (i.e. values) from the skip list allows us to update the skip list *lock free*. Further, it also decreases the EPC pressure when doing a lookup, as nodes can be stored more compact and the metadata can be stored on a different page. However, looking up a value mandates an additional indirection due to keys and metadata separation. Nevertheless, we believe that updating the KVS without acquiring any locks is worth this additional indirection as it allows better multi-threaded scalability. Therefore, in contrast to a HashBucket design like ShieldStore, we never need to stall. In contrast to ShieldStore our approach seems to be limited by the enclave memory, however, assuming we have 1 KiB values and 16 B keys, we achieve a space reduction for enclave memory of 92.8 % compared to a naive implementation. Further, SGX provides a paging mechanism significantly increasing the available trusted memory, therefore increasing the possible size of the KVS. While SGX-paging incurs a high overhead, often accessed keys will eventually resided in EPC.

Result. Our evaluation in Section 6.4 confirms that our AVOCADO single-node KVS is scalable and more performant; the speedup of AVOCADO single-node KVS compared to ShieldStore increases from 1.6× in a single threaded benchmark to 5× when utilizing all 8 available CPU threads.

5 Implementation

5.1 System components

AVOCADO network stack. The AVOCADO network stack is based on eRPC [46] and DPDK [4]. In particular, we leverage SCONE to build both eRPC and DPDK. We also assure that the device DMA mappings resides in the host memory. The changes to implement the mappings amount to 154 new LoC and 81 removed LoC.

To run eRPC inside the enclave, we accordingly modify the hugepages allocation mechanism (a) to ensure that all network buffers reside in the host memory, (b) to fix a bug regarding the hugepages’ detection, and (c) to alter how the address of the memory region is calculated. We also replace eRPC’s allocation algorithm with our own allocator. We notice that the eRPC’s native allocation algorithm, which allocates double the space of the previous allocation, quickly reserves all available memory in AVOCADO. Our memory

allocator is less aggressive and allows us to use our servers' limited huge page memory more efficiently. In total, 80 LoC are added to eRPC, while 28 LoC are removed.

eRPC provides us with its own implementation of the UDP protocol. To secure the network communication, on top of the layer protocol, we use a modified OpenSSL [6] version. These changes allow us to randomly access the encrypted data. We added 55 LoC to OpenSSL. Further, we added another 287 LoC for a shared en-/decryption layer for the AVOCADO single-node KVS store and networking. Lastly, we further extend the shared layer to well-fit with the message format. This adds another 205 LoC.

AVOCADO replication layer. We implement AVOCADO replication layer in C++ on top of the AVOCADO network stack (2,743 LoC). We implement the protocol from scratch using the eRPC networking library across AVOCADO's different layers, i.e., replication and networking layer.

Configuration and attestation service. We implement AVOCADO CAS in Rust [59] for better memory safety (22,730 LoC). To run the CAS inside the Intel SGX, we use SCONE since it transparently supports Rust applications. We make use of an encrypted embedded SQLite [9] to maintain configurations and secrets of AVOCADO inside AVOCADO CAS. To setup the configuration and bootstrap process, we provide configurations scripts, in Bash and Python 3, in total these bootstrap scripts require 709 LoC.

AVOCADO single-node KVS. We implement the AVOCADO single-node KVS based on a skip list based partitioned data structure. Particularly, AVOCADO single-node KVS extends Folly's ConcurrentSkipList [32]. We ported the Folly library to SCONE, which resulted to 167 new LoC and 40,394 removed LoC. In addition, the implementation requires another 190 LoC for the integration of the Boost library [19] to SCONE. Further, we implement an efficient host memory allocator (388 LoC) for our skip list. We share en-/decryption layer based on OpenSSL [6] with the network stack.

5.2 Optimizations

[O1] Remove duplicated en-/decryptions. In AVOCADO, we use a shared encryption key between all replicas for the network operations. This allows us to replace some encryption calls with memory copies, as we can send the same packets to all replicas without costly re-encrypting the messages. However, this optimization is an optional trade-off between security and performance since one compromised enclave would compromise the entire system.

[O2] Remove locks. Separating the metadata from the key allows us to make atomic updates to the skip list, avoiding expensive locks. However, it also allows us to retire values earlier to the host memory; thereby reducing the EPC pressure since the metadata can already be written without being visible to other calls. Further, our host memory allocator supports lock-free operations on our skip list by providing similar atomic allocation and de-allocation primitives.

[O3] Limited number of message buffers. We design a rate limiter to allow all current running requests to finish without having to wait for the available resources. While we mostly implement it to prevent eRPC from running out of hugepages memory, we also find that it also reduces the stalls between accepting and completing a request.

6 Evaluation

Our evaluation answers the following questions.

- How does the AVOCADO network stack perform compared to the alternative networking approaches? (§ 6.1)
- How does the AVOCADO replication layer compare with alternative protocols (Raft [64] & BFT [87])? (§ 6.2)
- What are the performance overheads of AVOCADO CAS and how it compares with Intel's IAS [3]? (§ 6.3)
- How does the AVOCADO single-node KVS perform compared to ShieldStore [48]? (§ 6.4)
- What are the overall performance overheads of AVOCADO KVS? (§ 6.5)
- How does AVOCADO scale with increasing number of nodes? (§ 6.6)

Testbed. We perform all of our experiments on real hardware using a cluster of 5 SGX server machines with CPU: Intel(R) Core(TM) i9-9900K each with 8 cores (16 HT), memory: 64 GiB, caches: 32 KiB (L1 data and code), 256 KiB (L2) and 16 MiB (L3), NIC: Intel Corporation Ethernet Controller XL710 for 40GbE QSFP+ (rev 02). They are connected over a 40GbE QSFP+ network switch.

Benchmarks. For the evaluation, we use the YCSB benchmark [7, 24] with different read/write ratios. Client-server communication over the network is prohibitively expensive from within an enclave (see § 4.1). Therefore, we stress-test the performance of AVOCADO by generating the workload within the enclave. This is the worst-case scenario for our system, since a client-server setting will show negligible latency/throughput overheads, due to client-server communication being the bottleneck. We configured AVOCADO to use a shared network key between the replicas (§ 5.2[O1]). For evaluating the network stack, we use iperf [41].

6.1 Network stack

Baselines and setup. We evaluate the performance of the AVOCADO network stack against three competitive baselines: eRPC-native, sockets-native, and sockets-SCONE. Note that SCONE uses asynchronous syscalls [85] for performance improvements. Further, note that the native (eRPC and sockets) versions do not provide any security.

For the sockets (native and SCONE), we use iperf to measure the throughput. For eRPC-native and AVOCADO network stack, we implement a simple server-client model on top of eRPC to simulate iperf's behavior.

In our experiments, we compare the performance with different number of packet sizes, while keeping the number of threads fixed to 4. Note that eRPC supports only UDP while

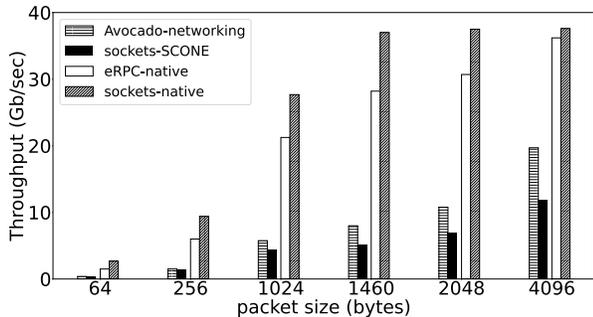

Figure 6: Performance comparison of AVOCADO network stack, eRPC-native, sockets-native, and sockets-SCONE for different packet sizes.

iperf supports both TCP and UDP. In our servers, we found that TCP performs better than UDP, so we report iperf’s TCP measurements since a designer could always benchmark both protocols and choose the most performant one.

Results. Figure 6 shows that eRPC-native is comparable to sockets-native. The reason is that TCP is optimized for high speed bulk transfers while UDP is optimized for low latency in the Linux kernel. This has an impact on buffer sizes and how data is polled and handed over. In addition to this, processing of the entire TCP/IP stack is frequently offloaded to the network controller.

Based on Figure 6 we deduce two core conclusions; (a) SCONE’s overhead is not negligible—SCONE performance degrades $\sim 4\times$ and $\sim 8\times$ compared to AVOCADO network stack and sockets-SCONE, respectively; and (b), due to the number of system calls the sockets’ layer is executing, AVOCADO network stack in the context of the secure enclave performs up to $1.66\times$ faster than socket s-SCONE. As discussed, enclave exits and data copies in and out of the enclave deteriorate sockets’ performance. This is further supported by the fact that the bigger the packet size is, the worse the performance becomes. Therefore, sockets-SCONE is a poor design choice as far as our requirement is concerned, and it justifies our design of the AVOCADO network stack.

6.2 Replication protocol

Baselines and setup. We show our system’s end-to-end performance in comparison with two state-of-the-art protocols: (a) BFT (BFT-Smart [87]) for the Byzantine setting, and (b) Raft (eRPC-Raft [1]) for the non-Byzantine setting. To the best of our knowledge, there is no secure distributed in-memory KVS; BFT-Smart KVS is the closest baseline in terms of security properties for Byzantine environments, but BFT protocols (or BFT-Smart) still do not preserve confidentiality. Additionally, we compare AVOCADO against eRPC-Raft since it is also built on top of eRPC. This comparison aims to demonstrate the efficacy of eRPC. We compare them with a native version of AVOCADO, AVOCADO-native, which runs without TEEs. We compare AVOCADO and BFT along three parameters, as shown in Figure 7; (i) different

	kOp/s	Speedup
AVOCADO	96	5.05 \times
eRPC-Raft	19	

Table 2: Performance comparison between AVOCADO and eRPC-Raft under a 100% W workload and a single client.

read/write ratios, (ii) different value sizes and (iii) different workload threads per machine. We evaluate using the YCSB benchmark [7, 24]. Similarly, we compare AVOCADO against Raft implemented with eRPC. Note that eRPC-Raft is limited to only PUT requests and 1 workload thread in total.

Results. Our evaluation shows that AVOCADO can achieve $4.5\times$ to $65\times$ more operations per second compared to BFT. Our AVOCADO presents similar performance to all four workloads, deducting that it is equivalently performant to both read and write heavy workloads. In addition, we notice that striving for the strictest security guarantees can decrease the performance to half compared to a native, unsecure version of AVOCADO.

Furthermore, we observe that the value size has great impact in the end-to-end performance. For instance, even in a read-heavy workload with value size to be equal to 256 B, the performance of AVOCADO is $6\times$ higher compared to BFT and $1.83\times$ lower than the native version. However, for value size to be equal to 1024 B, AVOCADO is 20% slower than BFT and $9\times$ slower than AVOCADO-native. Similarly, for value size to be equal to 4096 B, AVOCADO is $1.25\times$ faster than BFT and $3.65\times$ slower than AVOCADO-native. We discuss the effects of value size on AVOCADO further in section § 6.5. Lastly, AVOCADO scales up with the number of threads; AVOCADO achieves 38% more operations when the number of threads is increased from 4 to 8 threads. Due to the limitation with the amount of threads inside the enclave, AVOCADO cannot be executed with 16 threads.

Lastly, we compare eRPC-Raft against AVOCADO. AVOCADO under the same settings outperforms eRPC-Raft for $4.8\times$ as shown in Table 2. The reason is that eRPC-Raft does process requests asynchronously while in AVOCADO the time required for the necessary replicas to respond overlaps with processing any outstanding requests.

6.3 Configuration and attestation service

Baseline and setup. To evaluate the advantage of the attestation mechanism using AVOCADO CAS in comparison to the traditional attestation mechanism of Intel using IAS, we conduct an experiment to measure the end-to-end latency of the attestation process using both mechanisms.

Results. The attestation using AVOCADO CAS achieves a speedup of $18.2\times$ compared to the traditional mechanism using IAS (see Table 3). The mechanism using AVOCADO CAS performs the attestation via LAN connections, since AVOCADO CAS is deployed in the same cluster as AVOCADO instances. Meanwhile, the mechanism using IAS performs the attestation via WAN connections since it requires to verify the quotes using IAS that is deployed at Intel. Furthermore, AVOCADO CAS

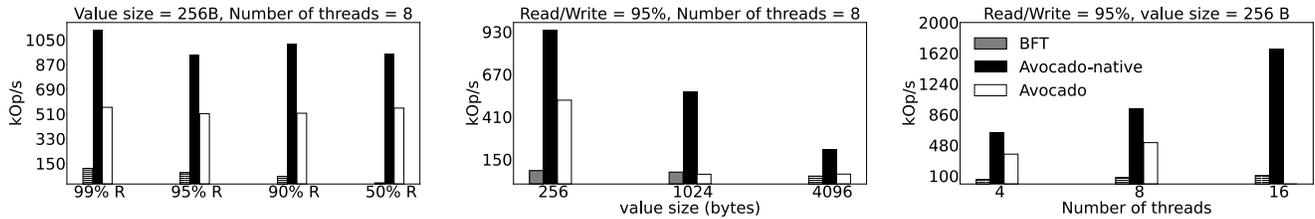

Figure 7: End-to-end performance comparison between AVOCADO, AVOCADO-native and BFT for different types of workloads, value sizes and number of threads.

	Mean / s	SD / s	Speedup
AVOCADO CAS	0.169	0.0195	18.2×
IAS	2.913	0.177	

Table 3: The end-to-end latency comparison between the attestation mechanisms using AVOCADO CAS and IAS.

provides transparently provides configuration management features to operate in an distributed environment.

6.4 Single-node KVS

Baselines and setup. We compare our AVOCADO single-node KVS against ShieldStore [48], a state-of-the-art secure in-memory KVS for a single-node system. For the single-node system evaluation, we use Intel(R) Core(TM) i7-8565U CPU of 8 logical threads and 16 GiB memory. This is due to ShieldStore’s dependencies on specific versions of OS, linux-SGX [82] and tcmlloc [58], we are not able to run it on our servers. We evaluate AVOCADO single-node KVS and ShieldStore across three dimensions using the YCSB workload: threads (Figure 8), value size and read-write ratios (Figure 9).

Results. Figure 8 shows the scaling capabilities of our AVOCADO single-node KVS vs. ShieldStore for two different value sizes. Our AVOCADO single-node KVS, for all number of threads, is 1.6× to 9.5× faster than ShieldStore. Regarding the value size, we observe that ShieldStore’s performance is highly affected when the value size is increased. For example, with 2 threads, ShieldStore presents a performance degradation of 7.3× from 16 B to 1024 B while the same scenario deteriorates AVOCADO single-node KVS’s performance only by 1.23×. We deduct this to the fact that Shieldstore searches require decrypting the concatenated entry of the key and the value in each visited bucket. As a result, bigger value sizes increase the cipher text that needs to be decrypted leading to higher performance costs. In contrast, AVOCADO stores keys inside protected area and search time is not affected by value sizes and decryption cost.

We observe similar behavior as the number of threads increases. ShieldStore is designed to avoid synchronization costs between threads that are matched to different KVS’s areas. However, to achieve this, ShieldStore requires to sort and distribute (through hashing) requests across threads which adds overheads compared to AVOCADO single-node KVS. Specifically, we show that for value size equal to 16 B AVOCADO single-node KVS is 1.6×, 3× and 5× faster than ShieldStore when using

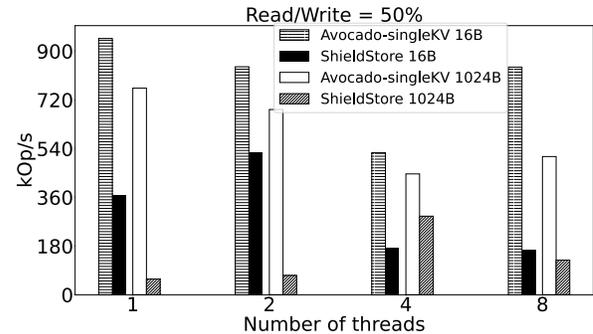

Figure 8: Performance comparison between AVOCADO single-node KVS and ShieldStore under a 50R-50W workload for varying number of threads.

2, 4 and 8 threads, respectively. Additionally, for value size equal to 1024 B, AVOCADO single-node KVS is 9.5×, 1.5× and 4× faster than ShieldStore with 2, 4 and 8 threads, respectively.

However, we find that both AVOCADO single-node KVS and ShieldStore have a performance drop, when the number of threads is increased. This trend is visible until the number of threads exceeds the number of physical cores. We attribute this behavior to two main reasons. Firstly, the CPU we are running this experiment on, is a lower power CPU, with a low base frequency (1.8 GHz) but a relatively high turbo frequency (4.8 GHz). This high turbo frequency cannot be reached with a high number of threads running, giving a performance boost to low thread numbers, compared to higher thread numbers. Secondly, increasing the number of threads results in a higher rate of cache misses, due to other cores having requested different memory, or having to invalidate the cache lines in lower level caches i.e. L1 and L2. This effect is especially pronounced in a write heavy workload, as presented in Figure 8. Increasing the number of threads further, from number of physical cores to logical cores, allows the CPU to schedule a different thread, while it is waiting for a memory access to complete, explaining the increase of performance with 8 threads.

Secondly, we also study how AVOCADO single-node KVS and ShieldStore perform under different value sizes and different read-write ratios. In particular, Figure 9 compares the two Key-Value (KV) stores against three different workloads and varying value sizes, where we fix the number of threads across the experiments to 4. For all three workloads as shown in Figure 9, AVOCADO single-node KVS achieves better performance than ShieldStore; 3.63× to 2.97× faster when value size is equal

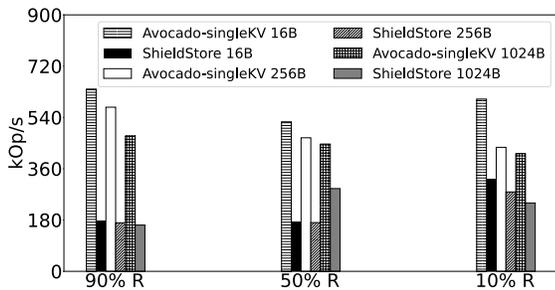

Figure 9: Performance comparison between AVOCADO single-node KVS and Shieldstore under three different workloads for varying value sizes.

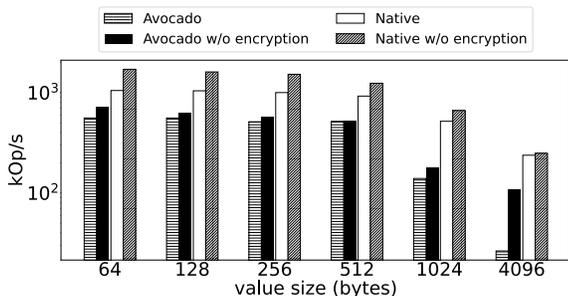

Figure 10: Performance comparison of AVOCADO with and without network and KVS encryption, inside and outside of the enclave, with different value sizes with 95% reads and 8 threads per machine.

to 16 B, $3\times$ to $1.53\times$ faster when value size is equal to 256 B and $1.87\times$ to $1.56\times$ faster when value size is equal to 1024 B.

Lastly, we conclude that AVOCADO single-node KVS is better in read-dominant workload (90% reads) than in write-heavy workload (90% writes), since AVOCADO single-node KVS achieves $\sim 5\%$ to $\sim 30\%$ better performance.

6.5 Distributed KVS

Baselines and setup. We evaluate the overhead AVOCADO incurs from running inside an enclave, against running AVOCADO natively, i.e. without SGX. Furthermore, we also evaluate the encryption overheads for in-memory KVS and network traffic. Thus, we compare AVOCADO with encryption activated and deactivated against the native KVS. Both with encryption for the KVS and network enabled and disabled. We run the YCSB benchmark with 95% reads with 5 machines and 8 threads per machine, with different value sizes.

Results. Figure 10 shows the performance influence of SGX and encryption on AVOCADO. The value size comparison shows that for small values, i.e. values under <1 KiB, AVOCADO reaches around half, between 51.2 and 56.0% of the performance compared to the native KVS. However, with bigger value sizes the difference becomes greater with a slowdown of $3.7\times$ and $9.0\times$, for 1 or 4 KiB respectively. The sudden drop in performance compared to the native case is mainly due to two reasons: firstly, eRPC has to acquire a lock

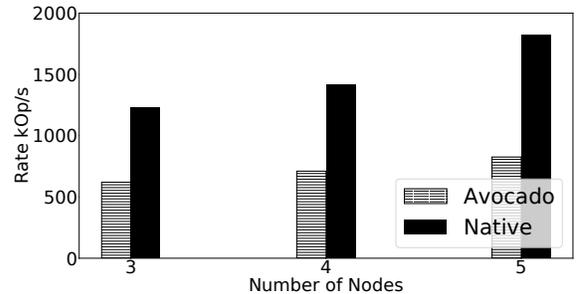

Figure 11: Performance of AVOCADO inside and outside of the enclave running on different number of nodes with a value size of 256 B, 95% reads and 8 threads per machine.

when allocating DMA for bigger packages size than the MTU, which is configured in our case to 1 KiB. While this penalizes native and AVOCADO, it is worse for AVOCADO, since this could result in an enclave exit for yielding. Additionally, with bigger value sizes, it gets more likely that we have to evict a page from the EPC, when inspecting the network traffic. This might be addressed with a memory buffer, which is reused for all data transfer between untrusted host memory and EPC memory. Due to constant accessing of this buffer, it should rarely get paged out the enclave.

The comparison also shows that encrypting the in-memory KVS and network traffic adds up to 62% overhead for small values and 4.6% for large values in the native case. However, we observe a different behavior for AVOCADO. The overhead for small values is more moderate compared to native with around 25%. However, the overhead does not get smaller with bigger values sizes. In contrast, it peaked with a values size of 4 KiB with $4.1\times$, which is due to EPC paging.

In these experiment we also observed a mean latency of $66\ \mu\text{s}$. This latency was reached in a fully stressed system. Due to SGX requiring us to make a syscall for taking a timestamp detailed latency analysis was impractical, as the syscall overhead together with the world switch would have easily dominated the benchmark.

6.6 Scalability

Baselines and setup. We evaluated the scalability of AVOCADO by running it inside and outside (natively) the enclave on a varying number of nodes. We run the YCSB benchmark with 95% reads on 3, 4 and 5 machines and 8 threads per machine, with a fixed value size of 256 B.

Results. Figure 11 shows the scalability numbers for different number of nodes. We are limited in our cluster to 5 nodes. The evaluation shows that replicating the KVS over 5 nodes instead of 3 increases the throughput of the native solution by 49% and 33% for AVOCADO.

6.7 Number of keys

Baselines and setup. We measure the performance of AVOCADO with increasing number of distinct keys. We run the YCSB benchmark with two different distributions, i.e.

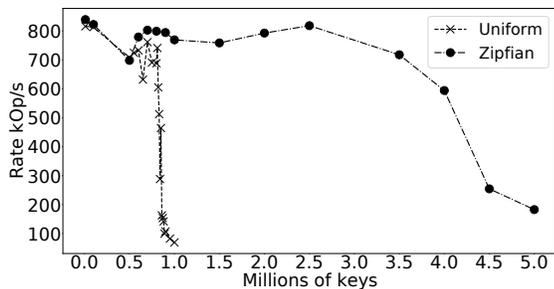

Figure 12: Performance of AVOCADO inside the enclave running with different number of distinct keys, with a uniform and Zipfian ($\alpha = 1.0$) distribution with a value size of 256 B, 95% reads and 8 threads per machine

uniform and Zipfian, on 5 machines with 8 threads and 95% reads and a fixed value size of 256 B.

Results. Figure 12 shows the throughput of AVOCADO with different distribution. Both distributions have a similar performance until 700k keys, where the performance of the uniform distribution starts to suffer greatly, due to SGX paging overheads. The uniform distribution prevents efficient caching from SGX in the EPC, since it does not generate any hot keys. In a uniform distribution, AVOCADO is therefore restricted by the EPC size. However, this could be alleviated with a multi-level lookup, which stores the lower levels in the host memory.

On the other hand, if the data set is not uniformly distributed AVOCADO can take advantage of the caching of EPC and extend the number of supported keys. In our experiments AVOCADO throughput was stable until 3.5M keys in the Zipfian distribution before it starts to suffer from the paging overheads. Similar to the uniform distribution, a multi-level lookup could reduce the paging overheads.

7 Related work

Shielded execution. With the adoption of TEEs in the cloud, shielded execution frameworks are being adopted to provide strong security properties for unmodified/legacy applications running in the untrusted environment [13, 17, 35, 93]. These frameworks promote portability, programmability and good performance. As a result, they have been used to implement a wide-range of secure systems for storage [16, 50], data analytics [80], databases [73], distributed systems [90], FaaS [92], network functions [91], machine learning [75], profilers [15], etc. Our AVOCADO project leverages the advancements in shielded execution frameworks; in particular, we use SCONE [13] to build a distributed storage system.

Networking for shielded execution. Shielded execution frameworks, like SCONE [13] and Eleos [65] provide an asynchronous system call API [85]. However, the asynchronous syscall mechanism incurs high overheads (due to data copies) and latency. ShieldBox [91] alleviates the issue of asynchronous syscalls by using DPDK [4] as polling user mode driver for a secure middlebox. Unfortunately, Shieldbox network stack targets only layer 2 in the OSI model, and

therefore, it is incompatible with the RPC layer required for a distributed KVS. rkt-io provides a library OS in the enclave, and can therefore provide a full network stack [89].

Secure storage systems. Secure storage is an important theme for cloud computing systems. A wide-range of systems have been proposed in the community based on different hardware with varying security guarantees and storage interfaces: KVS [16, 48, 50], filesystems [33, 96, 103], databases [28, 67, 70, 73, 95], etc. In contrast to these existing systems, AVOCADO proposes a scalable distributed in-memory KV store instead of a single-node system.

For distributed storage system design, Depot [57] and Salus [102] propose secure distributed storages, which provide consistency, durability, availability and integrity. A2M [21] is also robust against Byzantine faults. On top of those properties, AVOCADO also offers confidentiality. CloudProof [69] completely distrusts the cloud provider. However, CloudProof requires the client to guarantee these security properties, which requires major changes to the client, which isn't required by AVOCADO. Furthermore, since our work leverages hardware-assisted shielded execution as the root of trust, we do not need a trusted proxy, which limits the scalability of the system.

8 Conclusion

We present an approach to build a secure, high-performance in-memory distributed KVS system for untrusted cloud environments using TEEs. Our design includes four core contributions involving TEEs in a distributed environment: (a) the first direct I/O RPC network stack for TEEs based on eRPC with the complete support for transport and session layers; (b) a secure replication protocol based on hardening of a non-Byzantine protocol, where we transform a Byzantine behavior to a faulty behavior using TEEs; (c) a configuration and attestation service to seamlessly extend the trust from a single-node TEE to the distributed environment; (d) a secure in-memory single-node KVS based on a novel partitioned Skiplist data structure, and show that it is well-suited to overcome the memory limitations and support lock-free scalable concurrent updates in the TEEs.

Importantly, we set out to build a practical system without compromising performance—the literature distinctly shows that BFT protocols are typically not adopted in practice due to their high overheads [22, 71]. In contrast to BFT, our system provides stronger security properties (also preserves confidentiality) and improved performance (4.5× to 65×), while using f fewer replicas.

Accelerating Encrypted Deduplication via SGX

Yanjing Ren[†], Jingwei Li^{†*}, Zuoru Yang[‡], Patrick P. C. Lee[‡], and Xiaosong Zhang[†]

[†]University of Electronic Science and Technology of China [‡]The Chinese University of Hong Kong

Abstract

Encrypted deduplication preserves the deduplication effectiveness on encrypted data and is attractive for outsourced storage. However, existing encrypted deduplication approaches build on expensive cryptographic primitives that incur substantial performance slowdown. We present SGXDedup, which leverages Intel SGX to speed up encrypted deduplication based on server-aided message-locked encryption (MLE), while preserving security via SGX. SGXDedup implements a suite of secure interfaces to execute MLE key generation and proof-of-ownership operations in SGX enclaves. It also proposes various designs to support secure and efficient enclave operations. Evaluation on synthetic and real-world workloads shows that SGXDedup achieves significant speedups and maintains high bandwidth and storage savings.

1 Introduction

Outsourcing storage management to the cloud is a common practice for clients (enterprises or individuals) to save the overhead of self-managing massive data, and *security* and *storage efficiency* are two major goals for practical outsourced storage. To satisfy both goals, we explore *encrypted deduplication*, a paradigm that combines encryption and deduplication by always encrypting duplicate plaintext chunks (from the same or different clients) into duplicate ciphertext chunks with a key derived from the chunk content itself; for example, the key can be the cryptographic hash of the corresponding chunk [25]. Thus, any duplicate ciphertext chunk can be eliminated via deduplication for storage efficiency, while all outsourced chunks are encrypted against unauthorized access. Encrypted deduplication is particularly suitable for backup applications, which carry high content redundancy [59] and are attractive use cases for outsourced storage [35, 38, 58].

Existing encrypted deduplication approaches often incur high performance overhead to achieve security guarantees. We use DupLESS [14], a state-of-the-art encrypted deduplication system, as a representative example to explain the performance concerns (see §2.1 for elaboration). First, to prevent adversaries from inferring the content-derived keys, DupLESS employs *server-aided key management*, in which it deploys a dedicated key server to manage key generation requests from clients. However, server-aided key management requires expensive cryptographic operations to prevent the key server from knowing the plaintext chunks and the keys during key generation. Second, to prevent adversaries

from obtaining unauthorized access to ciphertext chunks by inferring the deduplication pattern (a.k.a. side-channel attacks [32, 33]), DupLESS can take one of the following approaches: it either (i) performs *target-based deduplication* (i.e., uploading all ciphertext chunks and letting the cloud remove any duplicate ciphertext chunks) so that the deduplication pattern is protected from any (malicious) client, or (ii) performs *source-based deduplication* (i.e., removing all duplicate ciphertext chunks on the client side without being uploaded to the cloud) and additionally proves to the cloud that it is indeed the owner of the ciphertext chunks (i.e., has access to the full contents of the corresponding plaintext chunks) and is authorized to perform deduplication on the ciphertext chunks. The former incurs extra communication bandwidth for uploading duplicate ciphertext chunks, while the latter incurs expensive cryptographic operations for proving that the client is the owner of the ciphertext chunks. Although various protocol designs have been proposed to address the performance issues of encrypted deduplication, they often weaken security [23, 41, 60], add bandwidth overhead [33, 42], or degrade storage efficiency [41, 51, 62] (see §6 for details).

The advances of hardware-assisted trusted execution [1–3, 57] provide new opportunities to improve the performance of encrypted deduplication. In particular, we focus on Intel Software Guarded Extensions (SGX), which provides a *trusted execution environment (TEE)*, called an *enclave*, for processing code and data with confidentiality and integrity guarantees [13]. Given that SGX achieves reasonably high performance with proper configurations [34], we are motivated to offload the expensive cryptographic operations of encrypted deduplication by directly running sensitive operations in enclaves, so as to improve the performance of encrypted deduplication, while maintaining its security, bandwidth efficiency, and storage efficiency.

We propose SGXDedup, a high-performance SGX-based encrypted deduplication system. SGXDedup builds on server-aided key management as in DupLESS [14], but executes efficient cryptographic operations inside enclaves. Realizing the design of SGXDedup has non-trivial challenges. First, it is critical to securely bootstrap enclaves for hosting trusted code and data, yet attesting the authenticity of enclaves incurs significant delays. Second, each client needs to communicate via a secure channel with the enclave inside the key server, yet the management overhead of the secure channels increases with the number of clients. Finally, clients may renew or revoke cloud service subscriptions, so allowing dynamic client authentication is critical. To this end, we implement three

*Corresponding author: Jingwei Li (jwli@uestc.edu.cn)

major building blocks for SGXDedup:

- *Secure and efficient enclave management*: It protects against the compromise of the key server and allows a client to quickly bootstrap an enclave after a restart.
- *Renewable blinded key management*: It generates a blinded key for protecting the communication between the enclave inside the key server and each of the clients based on key regression [30], such that the blinded key is renewable for dynamic client authentication.
- *SGX-based speculative encryption*: It offloads the online encryption/decryption overhead of secure channel management via speculative encryption [27].

We evaluate our SGXDedup prototype using synthetic and real-world [5, 45] workloads. It achieves significant speedups by offloading cryptographic operations to enclaves (e.g., a $131.9\times$ key generation speedup over the original key generation scheme in DupLESS [14]). It also achieves $8.1\times$ and $9.6\times$ speedups over DupLESS [14] for the uploads of non-duplicate and duplicate data, respectively, and has up to 99.2% of bandwidth/storage savings in real-world workloads.

We release the source code of our SGXDedup prototype at: <http://adslab.cse.cuhk.edu.hk/software/sgxdedup>.

2 Background and Problem

We present background details and formal definitions for encrypted deduplication (§2.1) and Intel SGX (§2.2). We also present the threat model addressed in this paper (§2.3).

2.1 Encrypted Deduplication

Basics. We consider *chunk-based deduplication* [45, 59, 63], which is widely deployed in modern storage systems to eliminate content redundancy. It works by partitioning an input file into non-overlapping *chunks*. For each chunk, it computes the cryptographic hash of the chunk content (called the *fingerprint*). It tracks the fingerprints of all currently stored chunks in a *fingerprint index*. It only stores a physical copy of the chunk if the fingerprint is new to the fingerprint index, or treats the chunk as a duplicate if the fingerprint has been tracked, assuming that fingerprint collisions are highly unlikely in practice [17].

Encrypted deduplication extends chunk-based deduplication with encryption to provide both data confidentiality and storage efficiency for outsourced cloud storage. A *client* encrypts each *plaintext chunk* of the input file with some symmetric secret key into a *ciphertext chunk* and stores all ciphertext chunks in the *cloud* (or any remote storage site), which manages deduplicated storage for ciphertext chunks. To support file reconstruction, the client creates a *file recipe* that lists the fingerprints, sizes, and keys of the ciphertext chunks. It encrypts the file recipe with its own master secret key and stores the encrypted file recipe in the cloud.

Message-locked encryption (MLE) [15] formalizes a cryptographic primitive for encrypted deduplication. It specifies

how the symmetric secret key (called the *MLE key*) is derived from the *content* of a plaintext chunk (e.g., its popular instantiation *convergent encryption (CE)* [25] uses the cryptographic hash of a plaintext chunk as the MLE key). Thus, it encrypts duplicate plaintext chunks into duplicate ciphertext chunks, so that deduplication remains viable on ciphertext chunks.

Server-aided MLE. CE is vulnerable to *offline brute-force attacks*, as its MLE key (i.e., the hash of a plaintext chunk) can be publicly derived. Specifically, an adversary infers the input plaintext chunk from a target ciphertext chunk (without knowing the MLE key) by enumerating the MLE keys of all possible plaintext chunks to check if any plaintext chunk is encrypted to the target ciphertext chunk.

Server-aided MLE [14] is a state-of-the-art cryptographic primitive that strengthens the security of encrypted deduplication against offline brute-force attacks. It deploys a dedicated *key server* for MLE key generation. To encrypt a plaintext chunk, a client first sends the fingerprint of the plaintext chunk to the key server, which returns the MLE key via both the fingerprint and a *global secret* maintained by the key server. If the global secret is secure, an adversary cannot feasibly launch offline brute-force attacks; otherwise, if the global secret is compromised, the security reduces to that of the original MLE. Server-aided MLE further builds on two security mechanisms. First, it uses the *oblivious pseudorandom function (OPRF)* [47] to allow a client send “blinded” fingerprints of the plaintext chunks, such that the key server can still return the same MLE keys for identical fingerprints without learning the original fingerprints. Second, it rate-limits the key generation requests from the clients to protect against *online brute-force attacks*, in which malicious clients issue many key generation requests to the key server, in order to find a target MLE key.

Proof-of-ownership. For bandwidth savings, encrypted deduplication can apply source-based deduplication, instead of target-based deduplication, to remove duplicate ciphertext chunks on the client side without being uploaded to the cloud (§1). The client sends the fingerprints of ciphertext chunks to the cloud, which checks if the fingerprints are tracked by the fingerprint index (i.e., the corresponding ciphertext chunks have been stored). The client then uploads only the non-duplicate ciphertext chunks to the cloud. However, source-based deduplication is vulnerable to *side-channel attacks* [32, 33] when some clients are compromised. One side-channel attack is that a compromised client can query the existence of any target ciphertext chunk (e.g., if the ciphertext chunk corresponds to some possible password [33]) by sending the fingerprint of the ciphertext chunk to the cloud, so as to identify the sensitive information from other clients. Another side-channel attack is that a compromised client can obtain unauthorized access to the stored chunks of other clients. Specifically, it can use the fingerprint of any target ciphertext chunk to convince the cloud that it is the owner of the corresponding ciphertext chunk with full access rights [32].

Proof-of-ownership (PoW) [32] is a cryptographic approach that augments source-based deduplication with protection against side-channel attacks, while maintaining the bandwidth savings of source-based deduplication. Its idea is to let the cloud verify that a client is indeed the owner of a ciphertext chunk and is authorized with the full access to the ciphertext chunk. This ensures that a compromised client cannot query for the existence of other clients' chunks. Specifically, in PoW-based source-based deduplication, a client attaches each fingerprint being sent to the cloud with a *PoW proof*, through which the cloud can verify if the client is the real owner of the corresponding ciphertext chunk. The cloud only responds upon the successful proof verification, thereby preventing any compromised client from identifying the ciphertext chunks owned by other clients.

Limitations. Recall from §1 that existing encrypted deduplication implementations require expensive cryptographic protection. Server-aided MLE necessitates the OPRF protocol [47] to protect the fingerprint information against the key server, yet the OPRF protocol involves expensive public-key cryptographic operations. For example, our evaluation (§5.1) shows that the OPRF-based MLE key generation achieves only up to 25 MB/s (Exp#1) and limits the overall encrypted deduplication performance to 20 MB/s (Exp#4). Also, the existing PoW implementation is based on the Merkle-tree protocol [32], which achieves only 37 MB/s (Exp#3) due to frequent hash computations for chunk-level PoW. In a 1 GbE LAN environment, the computational overhead of PoW even *negates* the performance gain of eliminating the uploads of duplicate data in source-based deduplication. Although we can mitigate PoW computations by applying PoW on a per-file basis (i.e., a client proves its ownership of a file), the cloud cannot verify if a chunk belongs to a file under chunk-based deduplication. Existing solutions that improve the performance of server-aided MLE or PoW often sacrifice security [23, 41, 60], bandwidth efficiency [33, 42], or storage efficiency [41, 51, 62] (§6).

2.2 Intel SGX

We explore hardware-assisted trusted execution to mitigate the performance overhead of encrypted deduplication, while preserving security, bandwidth efficiency, and storage efficiency. In this work, we focus on Intel SGX [3], a suite of security-related instructions built into modern Intel CPUs. SGX shields the execution of code and data in a hardware-protected environment called an *enclave*. In the following, we highlight three security features of an enclave related to our work: isolation, attestation, and sealing.

Isolation. An enclave resides in a hardware-guarded memory region called the *enclave page cache (EPC)* for hosting any protected code and data. An EPC comprises 4KB pages, and any in-enclave application can take up to 96 MB [34]. If an enclave has a larger size than the EPC, it encrypts unused pages and evicts them to the unprotected memory. In this

work, we deploy enclaves in each client and the key server to protect sensitive operations (§3.1). We also limit the size of in-enclave contents to mitigate the paging overhead (§3.4).

An enclave provides an interface, namely *enclave call (ECall)*, such that an outside application can issue ECalls to securely access in-enclave contents. Note that ECalls incur context switching overhead for accessing the enclave memory [34]. We reduce the number of ECalls by batching contents for processing (§4).

Attestation. SGX supports *remote attestation* to authenticate a target enclave via a remote entity (e.g., the cloud). In the remote attestation process (see [3] for elaboration), the remote entity needs to contact the attestation service operated by Intel to check the integrity of the enclave information provided by the target enclave. Then the remote entity verifies the target enclave by comparing its enclave information with the trusted configuration expected in the target enclave. We use remote attestation to ensure that the correct code and data are loaded into each enclave in the first bootstrap.

Sealing. SGX protects enclave contents when they are stored outside an enclave via sealing. It uses a secret *sealing key* to encrypt the data before being evicted. The sealing key can be derived from either the *measurement hash* (i.e., a SHA256 hash on the enclave contents) or the author identity of the enclave, so that only the corresponding enclave can access the sealing key and decrypt the sealed data. Since remote attestation incurs significant delays (Exp#7), we use sealing to eliminate remote attestation after the first bootstrap of an enclave (§3.2).

Remarks. We do not consider memory encryption-based TEEs (e.g., AMD SEV [1] and MK-TME [2]), since they need a large trusted computing base and expose a broad attack surface [46]. Also, AMD SEV [1] does not protect memory integrity, and is vulnerable to the attack that a privileged adversary can manipulate encrypted memory pages [46].

2.3 Threat Model

Adversarial capabilities. We start with the server-aided MLE architecture [14] with multiple clients, the key server, and the cloud. Our major security goal is to achieve data confidentiality for outsourced cloud storage [14] against a *semi-honest* adversary that infers the original plaintext chunks via the following malicious actions:

- The adversary can compromise the key server and learn the MLE key generation requests issued by each client. It can also access the global secret to infer the original chunks in outsourced storage via offline brute-force attacks [14].
- The adversary can compromise one or multiple clients and send arbitrary MLE key generation requests to query the MLE keys of some target chunks [14]. It can also launch side-channel attacks against some target chunks [33] (§2.1), so as to infer the original plaintext chunks owned by other non-compromised clients.

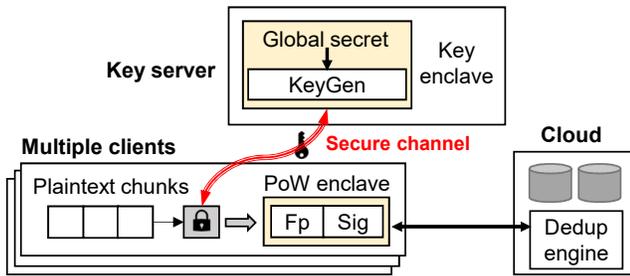

Figure 1: Overview of SGXDedup architecture: a key enclave and a PoW enclave are deployed in the key server and each client, respectively.

Assumptions. We make the following threat assumptions. (i) All communications among the clients, the key server, and the cloud are protected against tampering (e.g., via SSL/TLS). (ii) SGX is trusted and reliable; denial-of-service or side-channel attacks against SGX [18, 48] are beyond our scope. (iii) We can achieve both *integrity* via remote auditing [11, 36] and *fault tolerance* via a multi-cloud approach [42]. (iv) We do not consider traffic analysis [64], frequency analysis [41] and chunk size leakage [54], while the related defenses [41, 54, 64] are compatible to our design.

3 SGXDedup Design

SGXDedup is a high-performance SGX-based encrypted deduplication system designed for outsourced storage, particularly for backup workloads with high content redundancy. It aims for the following design goals: (i) *confidentiality*, which protects the outsourced chunks and keys against unauthorized access even when the key server or any client are compromised, as in server-aided MLE in DupLESS [14] and source-based deduplication with PoW [32]; (ii) *bandwidth/storage efficiency*, which removes all duplicate chunks across multiple clients before uploads, as in source-based deduplication. (iii) *computational efficiency*, which mitigates the computational overhead of the cryptographic operations and achieves significantly higher performance than existing software-based encrypted deduplication designs.

3.1 Overview

Architecture. Figure 1 presents the architecture of SGXDedup, which introduces two enclaves: the *key enclave* and the *PoW enclave*. SGXDedup deploys a key enclave in the key server to manage and protect the global secret of server-aided MLE against a compromised key server. To perform MLE key generation, both the key enclave and a client first establish a secure channel based on a shared *blinded key* (see §3.3 for details how a blinded key is formed). The client then submits the fingerprint of a plaintext chunk via the secure channel. The key enclave computes the MLE key as the cryptographic hash of both the global secret and the fingerprint. It returns the MLE key via the secure channel.

The key enclave benefits both performance and security.

It avoids the expensive OPRF protocol [14] of server-aided MLE during MLE key generation. Also, it protects the fingerprints and MLE keys via a secure channel based on a shared blinded key, such that the key server cannot learn any information from the MLE key generation process. Furthermore, it protects the global secret in the enclave memory, and preserves security even if the key server is compromised (note that the security of the original server-aided MLE degrades when the key server is compromised; see §2.1).

SGXDedup deploys a PoW enclave in each client to prove the authenticity of the ciphertext chunks in source-based deduplication. The PoW enclave first sets up a shared *PoW key* with the cloud (we currently implement the key agreement using Diffie-Hellman key exchange (DHKE); see §4). After MLE key generation, the client encrypts each plaintext chunk into a ciphertext chunk. The PoW enclave takes the ciphertext chunk as input, computes the corresponding fingerprint, and creates a signature of the fingerprint using the shared PoW key with the cloud. The client then uploads both the fingerprint and the signature to the cloud. The cloud verifies the authenticity of the fingerprint based on the corresponding signature and the PoW key. Only when the fingerprint is authenticated, the cloud proceeds to check if the fingerprint corresponds to any already stored duplicate ciphertext chunk. Note that we verify the client’s ownership of ciphertext chunks rather than that of plaintexts (e.g., [32]), so as to protect the original information from the cloud. Ensuring the ownership of ciphertext chunks is enough for security, since MLE applies one-to-one mappings and the ownership of a ciphertext chunk is consistent with that of the corresponding plaintext chunk.

The PoW enclave again benefits both performance and security. It avoids the computational overhead for the cryptographic PoW constructions. It also protects the deduplication patterns against malicious clients, as the patterns are only returned given the authenticated fingerprints.

Note that prior studies [24, 31, 37] perform key generation and encryption inside an enclave, while we opt to perform encryption in unprotected memory. The main reason is that both the original plaintext chunks and the encryption process are co-located within a client. Moving the encryption process to the enclave does not improve the security, as compromising the client can also access its plaintext chunks, yet it adds significant computational overhead to the enclave.

Questions. Realizing SGX-based encrypted deduplication efficiently is non-trivial, since we need to mitigate the potential performance overhead of SGX that would otherwise negate the overall performance benefits. Here, we pose three questions, which we address based on a suite of ECalls for the key enclave and the PoW enclave (Table 1).

- How should the enclaves be securely and efficiently bootstrapped? (§3.2)
- How should the key enclave and each client establish a secure channel? (§3.3)

ECall Name	Description
Key enclave	
<i>Secret generation</i>	Generate a global secret (§3.2)
<i>Rekeying</i>	Renew a blinded key (§3.3)
<i>Nonce checking</i>	Check the uniqueness of a nonce (§3.4)
<i>Key generation</i>	Return the MLE keys (§3.4)
<i>Mask generation</i>	Pre-compute masks (§3.4)
PoW enclave	
<i>Key unsealing</i>	Unseal a PoW key (§3.2)
<i>Key sealing</i>	Seal a PoW key into disk (§3.2)
<i>Proof generation</i>	Sign the ciphertext chunk fingerprints (§4)

Table 1: Major ECalls in SGXDedup.

- How should the key enclave reduce its computational overhead of managing the secure channels of clients? (§3.4)

3.2 Enclave Management

SGXDedup establishes trust in all enclaves via the cloud when it is first initialized. Before SGXDedup is deployed, we first compile the enclave code into shared objects [3], append each shared object with a signature (for integrity verification), and distribute the shared objects to the key server and each of the clients. The cloud also hosts the shared objects for subsequent verification. The key server creates the key enclave, while each client creates its own PoW enclave by loading the corresponding shared object. The cloud authenticates each enclave via remote attestation (§2.2) to ensure that the correct code is loaded. Here, we address two specific management issues: (i) how the global secret (§3.1) is securely bootstrapped into the key enclave; and (ii) how each client efficiently bootstraps its PoW enclave after a restart.

Key enclave management. Instead of bootstrapping the global secret in entirety, SGXDedup generates the global secret in the key enclave based on two *sub-secrets* respectively owned by the cloud and the key server, so as to prevent either of them from learning the whole global secret.

To generate the global secret, we hard-code the cloud’s sub-secret into the key enclave code, and deliver the code (as a shared object) to the key server during SGXDedup’s initialization. We also implement a *secret generation ECall* for the key enclave, so as to allow the key server to provide its own sub-secret. The ECall can only be issued by the key server after the cloud’s sub-secret is included into the key enclave. It takes the key server’s sub-secret as its single input, and hashes the concatenation of the key server’s sub-secret and the cloud’s sub-secret to form the global secret. Note that the key server cannot access the enclave code and hence cannot learn the cloud’s sub-secret hard-coded inside the enclave (assuming that reverse engineering is impossible). Thus, even if the key server is compromised, the global secret remains secure, so the security of server-aided MLE is preserved. If both the key server and the cloud are simultaneously compromised, the security of SGXDedup reduces to that of the original MLE (§2.1).

PoW enclave management. When a client bootstraps its PoW enclave, it needs to attest the authenticity of the PoW enclave. However, remote attestation generally incurs a very large latency (e.g., about 9 s; see §5.1) to connect to the Intel service. Unlike the key enclave, whose remote attestation is only done once during initialization, the client needs to bootstrap and terminate the PoW enclave each time it joins and leaves SGXDedup, respectively. If remote attestation were used each time when the client joins, its substantial overhead will hurt usability.

SGXDedup leverages sealing to avoid remote attestation after the first bootstrap of the PoW enclave. Recall that the PoW enclave shares a PoW key with the cloud, such that the cloud can verify the authenticity of fingerprints (§3.1). Our idea is to seal the PoW key based on the measurement hash of the PoW enclave. Thus, when the client bootstraps again its PoW enclave, it unseals the PoW key into the bootstrapped PoW enclave. As long as the PoW key is recovered successfully, the authenticity of the bootstrapped PoW enclave is verified.

Specifically, the client first checks whether any sealed PoW key is locally available in its physical machine. If a sealed PoW key is not available (the first bootstrap), the client attests the PoW enclave via remote attestation and exchanges a PoW key with the cloud; otherwise if a sealed PoW key is available (after the first bootstrap), the client creates a new PoW enclave by loading the shared object, and calls the *key unsealing ECall* of the new PoW enclave to unseal the PoW key. The key unsealing ECall takes the address of the sealed PoW key as input. It derives a sealing key based on the measurement hash of the new PoW enclave, decrypts the sealed PoW key, and keeps it in the new PoW enclave.

When the client leaves SGXDedup, its PoW enclave needs to be terminated. The client issues the *key sealing ECall* to seal the PoW key. The key sealing ECall encrypts the PoW key based on the measurement hash of the PoW enclave, and stores the result in the address provided by the client.

3.3 Renewable Blinded Key Management

Each client securely communicates with the key enclave via a shared *blinded key* to prevent the eavesdropping by the key server (§3.1). To form the blinded key, a straightforward approach is to directly implement a key agreement protocol between the key enclave and each client. However, the key enclave needs to authenticate the client on-the-fly (e.g., a client may renew or revoke its cloud service subscription). Such dynamic authentication puts performance burdens on the key enclave.

SGXDedup manages blinded keys with the help of the cloud. During initialization, the cloud hard-codes a blinded secret κ into the key enclave code. Each client downloads a *key state* (derived from κ ; see below) from the cloud, and generates its blinded key (based on the key state) for the secure communication with the key enclave. Our rationales are two-fold. First, when the client issues any download request

from the cloud, the cloud can check if the client is authorized. Second, we can derive a sequence of renewable blinded keys from κ (instead of directly using κ), so as to prevent the revoked/compromised clients from persistently accessing the key enclave. As a side benefit, the renewable key management also prevents online brute-force attacks (§2.1) without actively slowing down the key generation rate [14].

SGXDedup uses *key regression* [30] to derive renewable blinded keys, while ensuring that the blinded keys in each client and the key enclave are consistent. Specifically, key regression works on a sequence of key states $S[1], S[2], \dots, S[m]$, each of which can be used to derive a key (e.g., via hashing). It allows the key enclave and the cloud to perform *rekeying* to derive a new state from an old state (e.g., deriving $S[2]$ from $S[1]$) using a *key regression secret*, such that the client cannot learn any information about new states without knowing the key regression secret. It also allows each client to derive any old state from the new state (e.g., deriving $S[1]$ from $S[2]$).

To realize key regression in SGXDedup, we use κ as the key regression secret shared between the cloud and the key enclave for deriving the new states and keys. In each upload, the client first downloads the up-to-date key state $S[i]$ from the cloud, and requests the current version number j of the blinded key accepted by the key enclave. Given that the key enclave may not renew the blinded key in time (e.g., it is busy with serving key generation exactly in the scheduled rekeying time), j is typically smaller than i (i.e., $S[j]$ is prior to $S[i]$). Then the client derives $S[j]$ from $S[i]$ and the corresponding blinded key $K[j]$, and communicates with the key enclave based on the same $K[j]$. Note that the cloud can derive $K[j]$, but it cannot eavesdrop the communication between each client and the key enclave, since the communication is additionally protected via the SSL/TLS-based channel between the client and the key server (see our assumptions in §2.3).

SGXDedup renews blinded keys in both the cloud and the key enclave. The cloud implements a timer to trigger rekeying over periodic time intervals. The key server issues the *rekeying ECall* to trigger rekeying when a scheduled rekeying time is reached.

Currently, we implement the hash-based key regression scheme [30] for high key derivation performance. Specifically, we define a parameter n (now set as 2^{20} [30]) to indicate the maximum number of affordable rekeying times. The cloud and the key enclave compute the i -th key state as $S[i] = \mathbf{H}^{n-i+1}(\kappa)$, and each client derives the corresponding blinded key as $K[i] = \mathbf{H}(S[i]||0^8)$, where $\mathbf{H}^{n-i+1}()$ iteratively calls the cryptographic hash function $\mathbf{H}()$ by $n-i+1$ times, and $||$ is the concatenation operator. To derive old states, the client downloads $S[i]$ and recovers $S[i-1] = \mathbf{H}(S[i])$.

3.4 SGX-Based Speculative Encryption

Given the shared blinded key (§3.3), the key enclave manages a secure channel with each client to protect the transferred fingerprints/keys during MLE key generation (§3.1). How-

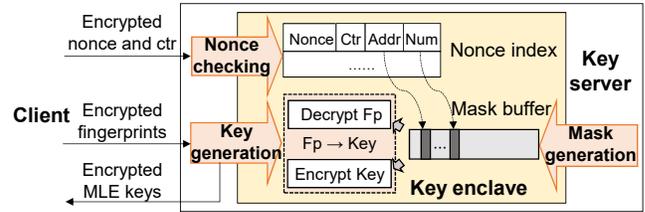

Figure 2: Overview of SGX-based speculative encryption.

ever, managing the secure channels, particularly with many clients, incurs high encryption/decryption costs in the key enclave. SGXDedup augments the secure communication channel management using *speculative encryption* [27] in the context of SGX, so as to offload the encryption/decryption overhead of the key enclave.

Speculative encryption. Speculative encryption [27] adopts encryption/decryption in *counter mode* [6] and pre-computes partial encryption/decryption results in an offline procedure, so as to reduce the online computational overhead in standalone cryptographic file systems. To encrypt a plaintext M , we first partition M into a sequence of plaintext blocks b_1, b_2, \dots, b_m (e.g., each block has a fixed size of 16 bytes). For each client, we pick a unique *nonce* θ that can be used only once by the encryption with the same key. We then compute the *mask* for the i -th plaintext block as $e_i = \mathbf{E}(K, \theta||i)$, where $\mathbf{E}()$ is a symmetric encryption function, K is the key, i is the *counter* (for counter-mode encryption), and $||$ is the concatenation operator. Finally, we compute each ciphertext block $c_i = e_i \oplus b_i$, where \oplus is the bitwise XOR operator, and form the whole ciphertext $C = c_1 || c_2 || \dots || c_m$. To decrypt the ciphertext, we generate the mask e_i for each block like above, recover the corresponding plaintext block $b_i = e_i \oplus c_i$ and hence the original plaintext M . Since the mask generation step is independent of each target plaintext/ciphertext, we can pre-compute the masks offline, followed by applying the lightweight XOR operation for online encryption/decryption.

Integration. To realize speculative encryption in SGXDedup, we need to address the nonce management issue. A unique nonce serves as an unpredictable “one-time-pad” that makes each counter-mode encryption output look random [6]. If counter-mode encryption is used by multiple clients, we need to associate each client with a unique nonce in its encryption/decryption operations. However, since different clients are isolated, it is challenging to ensure that the nonces associated with the clients are unique.

To ensure the uniqueness of a nonce, SGXDedup manages a centralized key-value store, called the *nonce index*, in the key enclave. Each entry of the nonce index maps a stored nonce (12 bytes) to three fields: its counter (4 bytes), the starting address (8 bytes) of the corresponding mask, and the number (4 bytes) of its available masks. Also, SGXDedup implements a *nonce checking ECall* (Figure 2) that can be called by the key server to compare the nonce submitted by

each client with the previously stored nonces in the nonce index and inform the client to re-pick a new one if a duplicate nonce is found. Note that the in-enclave nonce index can be effectively managed, since it can serve up to 112,000 clients (assuming one nonce per client) with only 3 MB EPC space (default configuration of SGXDedup).

SGXDedup applies speculative encryption to establish a secure channel between a client and the key enclave for the protection of MLE key generation. To initialize the secure channel, the client synchronizes its self-picked nonce θ and the corresponding counter i with the key enclave, where i is initialized as zero if θ has not been used for any encryption/decryption by the client. Specifically, it encrypts θ and i with the up-to-date blinded key (§3.3), computes a message authentication code (MAC) based on the resulting ciphertexts, and submits both the ciphertexts and the MAC to the key server. Here, we adopt *encrypt-then-MAC* [16] to detect any outdated blinded key by checking the MAC for any information transferred between the client and the key enclave.

The key server issues the nonce checking ECall, which takes the client's uploads as input, decrypts θ and i , and checks the decrypted θ and i with the nonce index:

- Case I: If θ is duplicate and $i = 0$, this indicates the re-use of an existing nonce, and the ECall returns a signal to inform the client to re-pick a new nonce.
- Case II: If θ is duplicate and $i \neq 0$, this implies that the nonce has been stored. The ECall updates the stored counter and marks the corresponding pre-computed masks (to be used for follow-up processing, as elaborated below).
- Case III: If θ is unique, this implies that the nonce is new, and the ECall adds θ into the nonce index.

For Cases II and III, the ECall accepts the communication and asks the client to transfer fingerprints for MLE key generation (§3.1). The client encrypts the fingerprints based on θ and i , and uploads the results; after encrypting each fingerprint block, the client increments i by one to prevent replay attacks. As shown in Figure 2, the key server issues the *key generation ECall* to process the encrypted fingerprints. The ECall checks if some masks are marked for the current client. If found (i.e., Case II), it uses the marked masks to decrypt the fingerprints and encrypt the generated MLE keys. Otherwise (i.e., Case III), it computes the masks online for decryption and encryption.

Mask pre-computation. To speed up encryption/decryption, the key enclave performs mask pre-computation when a new blinded key is applied (i.e., all existing masks are invalid) or a client has connected again after the last mask generation (i.e., some of its masks have been consumed). The key enclave calls the *mask generation ECall* (Figure 2), which pre-computes the masks for a number (e.g., three in our case) of most-recently-used nonces and writes the results into a *mask buffer*. By default, we configure the mask buffer with up to 90 MB. Suppose that each mask takes 16 bytes and the

average chunk size is 8 KB. The MLE key generation of a fingerprint consumes four masks: two are for decrypting the 32-byte fingerprint and the other two are for encrypting the resulting 32-byte MLE key. Thus, the pre-computed masks in the mask buffer can be used to process the fingerprints of up to 11.25 GB of data.

4 Implementation

We build an SGXDedup prototype in C++ using OpenSSL 1.1.1g [49], Intel SGX SDK 2.7 [3] and Intel SGX SSL [7]. Our prototype implements fingerprinting operations for plaintext and ciphertext chunks via SHA256, and chunk-based encryption via AES256. It contains about 14.2 K LoC.

Setup. To bootstrap the key enclave, the cloud hard-codes both the cloud's sub-secret (§3.2) and the blinded secret (§3.3) into the key enclave code. Alternatively, SGXDedup can also provision both secrets (using the secret provisioning functionality of SGX [3]) after authenticating the key enclave, at the expense of incurring extra bootstrapping overhead. The key enclave uses SHA256 to generate the global secret and implement the hash function in key regression. Each PoW enclave implements DHKE in NIST P-256 elliptic curve to share a PoW key with the cloud.

Key generation. Each client implements Rabin fingerprinting [52] for content-defined chunking. We fix the minimum, average, and maximum chunk sizes in Rabin fingerprinting at 4 KB, 8 KB, and 16 KB, respectively. To implement SGX-based speculative encryption (§3.4), we fix the nonce and the counter at 12 bytes and 4 bytes, respectively, and implement MACs using HMAC-SHA256. The key enclave generates the MLE key of each plaintext chunk via SHA256.

Deduplication. SGXDedup realizes source-based deduplication coupled with PoW. The PoW enclave implements a *proof generation ECall* to compute the fingerprints of ciphertext chunks and generate a signature based on the resulting fingerprints using AES-CMAC. The cloud implements the fingerprint index (§2.1) as a key-value store based on LevelDB [4]. To mitigate network and disk I/O costs, we store (non-duplicate) ciphertext chunks in 8 MB containers as units of transfers and storage [43].

Optimization. To reduce context switching and SGX memory encryption/decryption overhead, each client batches multiple fingerprints (4,096 by default) to transfer in the secure communication channel with the key enclave (§3.4). The key enclave processes each received batch of fingerprints. It accesses the batch via a pointer without copying the contents into the enclave [34]. Similarly, the PoW enclave processes the ciphertext chunks on a per-batch basis (4,096 by default) without content copy. We also use multi-threading to boost performance. Each client parallelizes the processing of chunking, fingerprinting of plaintext chunks, encryption, PoW, and uploads via multi-threading, while the key enclave and the cloud serve multiple connections in different threads.

5 Evaluation

We configure a LAN cluster of machines for multiple clients, the key server, and the cloud. Each machine has a quad-core 3.0 GHz Intel Core i5-7400 CPU, a 1 TB 7200 RPM SATA hard disk, and 8 GB RAM. All machines run Ubuntu 18.04 and are connected with 10 GbE. We evaluate SGXDedup using both synthetic (§5.1) and real-world (§5.2) workloads. We summarize the main results as follows.

- SGXDedup achieves high MLE key generation performance in both single-client (Exp#1) and multi-client (Exp#2) cases. For example, it achieves a $131.9\times$ speedup over OPRF-RSA adopted by DupLESS’s MLE key generation [14] in the single-client case.
- SGXDedup has $2.2\times$ and $8.2\times$ computational PoW speedups over universal hash-based PoW [60] (that only achieves weaker security) and Merkle-tree-based PoW [32] (Exp#3).
- SGXDedup has high overall performance in single-client (Exp#4 and Exp#5) and multi-client (Exp#6) cases. We also provide a time breakdown of SGXDedup in uploads (Exp#7). For example, in a 10 GbE LAN testbed, SGXDedup incurs only a slowdown of 17.5% in uploads compared to a plain deduplication system without any security protection; in real-cloud deployment (Exp#5), SGXDedup incurs a slowdown of 13.2% and its performance is bounded by the Internet bandwidth.
- SGXDedup is efficient for processing real-world workloads (Exp#8 and Exp#9). For example, its upload performance overhead over plain deduplication (without security protection) is within 22.0%; it also achieves high bandwidth savings over existing approaches [33, 42], by an absolute difference of up to 91.4%.

5.1 Evaluation on Synthetic Workloads

We generate a synthetic dataset with a set of files, each of which comprises globally non-duplicate chunks. By default, we set the file size as 2 GB (except for Exp#2, in which we stress-test the MLE key generation performance). A client uploads or downloads a file via the cloud. To avoid the performance impact of disk I/O, we store the file data in memory rather than on disk (except for Exp#5, in which we process on-disk files in real-cloud deployment). We plot the average results over 10 runs. We also include the 95% confidence intervals from *Student’s t-Distribution* into bar charts (for brevity, we exclude them from line charts).

Exp#1 (Single-client MLE key generation). We evaluate MLE key generation in two rounds. First, a client creates the plaintext chunks of a 2 GB file via Rabin fingerprinting (§4) and issues MLE key generation requests. It then repeats the MLE key generation process for the chunks of a different 2 GB file. The difference is that the second round uses the pre-computed masks for MLE key generation (§3.4).

We compare the single-client MLE key generation speed of SGXDedup with state-of-the-arts. We consider two OPRF-

based key generation approaches, namely *OPRF-BLS* [10] and *OPRF-RSA* [14], which implement the OPRF primitive (§2.1) based on blind BLS and blind RSA signatures, respectively. We also consider two relaxed key generation approaches, namely *MinHash encryption* [51] and *TED* [41], which trade storage efficiency and security for performance. Specifically, MinHash encryption generates MLE keys using OPRF-RSA on a per-segment basis, where the average segment size is configured as 1 MB. TED generates the MLE key for each chunk based on the sketch-based frequency counting of the short hashes of the chunk (c.f. §3.3 in [41]).

Figure 3 shows the results. SGXDedup outperforms all baseline approaches, by avoiding the expensive cryptographic primitives in OPRF-BLS, OPRF-RSA, and MinHash encryption and the frequency counting computations in TED. Its first round achieves $1,583\times$ and $131.9\times$ speedups over OPRF-BLS and OPRF-RSA, respectively. The speedups are $9.4\times$ and $3.7\times$ over MinHash encryption and TED, respectively, even though the latter two sacrifice storage efficiency and security. Speculative encryption in the second round improves the MLE key generation speed of the first round by 67.8%.

Exp#2 (Multi-client MLE key generation). We evaluate multi-client MLE key generation. For stress-testing, we configure a single machine that runs multiple threads, each of which simulates a client, to simultaneously issue MLE key generation requests to the key server (which runs on a different machine). Recall that the pre-computed masks in the key enclave can be used to efficiently process at most 11.25 GB of data (§3.4). To enable speculative encryption for each simulated client in the second round, we configure each thread to generate 40,960 fingerprints (i.e., 320 MB of raw data for 8 KB chunks) and configure the key enclave to equally pre-compute masks for each simulated client after the first round of key generation. We measure the *aggregate* MLE key generation speed on processing all MLE key generation requests from all simulated clients.

Figure 4 shows the results. The aggregate key generation speeds of both rounds initially increase with the number of simulated clients. At peak, the first and second rounds achieve 8.5×10^5 keys/s and 29×10^5 keys/s for five and ten simulated clients, respectively. After ten clients, the aggregate speeds drop due to aggravated context switching overhead. On average, speculative encryption in the second round achieves $4.4\times$ aggregate key generation speedup over the first round.

Exp#3 (Computational PoW). We evaluate the PoW performance. We consider a single client that performs PoW on a 2 GB file. The client creates plaintext chunks from the file, encrypts each plaintext chunk, and issues PoW requests to the cloud. We measure the *computational PoW speed* based on the total computational time of all chunks in both the client (where the PoW enclave performs fingerprinting on the ciphertext chunks and signs the resulting fingerprints) and the cloud (which verifies the authenticity of the fingerprints); note that we exclude the network transfer time between the

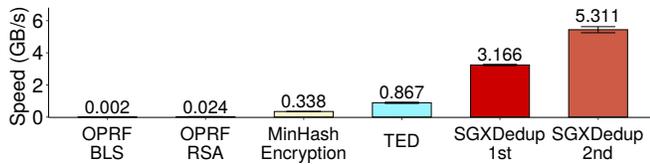

Figure 3: (Exp#1) Single-client MLE key generation.

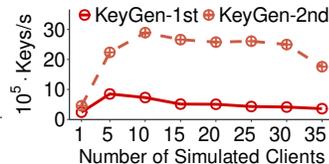

Figure 4: (Exp#2) Multi-client MLE key generation.

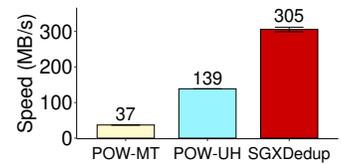

Figure 5: (Exp#3) Computational PoW.

client and the cloud in our speed calculation (we consider the network transfer time in Exp#11 in Appendix).

We compare SGXDedup with two state-of-the-art PoW approaches: (i) *PoW-MT* [32] (a.k.a. the basic version in [32]), a Merkle-tree-based PoW approach that encodes the chunks with erasure coding and builds a Merkle tree over the encoded content for PoW; and (ii) *PoW-UH* [60], which builds on universal hashing but trades security for performance. For fair comparisons, we implement both PoW-MT and PoW-UH in C++ by ourselves. Note that there are improved PoW approaches [32], but they incur even higher performance overhead for low memory usage.

Figure 5 shows the results. SGXDedup dramatically outperforms PoW-MT, since it avoids erasure coding and Merkle tree construction in the client, as well as Merkle-tree-based verification in the cloud. It achieves an 8.2× speedup over PoW-MT. It also achieves a 2.2× speedup over PoW-UH.

Exp#4 (Single-client uploads and downloads). We consider a single client, and compare the upload and download performance of SGXDedup with two baseline systems: (i) *PlainDedup*, which disables the key generation, encryption and PoW operations of SGXDedup, and hence realizes source-based deduplication without any security protection; and (ii) *DupLESS* [14], which generates per-chunk MLE keys via OPRF-RSA, performs encryption and uploads all ciphertext chunks to the cloud for deduplication. Since the original implementation of DupLESS does not provide a deduplicated storage backend (it assumes that Dropbox is used), we implement DupLESS in C++ based on the design described in [14] by ourselves. Note that PlainDedup retrieves files based on file recipes that are not encrypted, and differs from the two-round downloads in encrypted deduplication systems (i.e., both SGXDedup and DupLESS); in the latter, the client first downloads and decrypts the file recipe, followed by downloading the chunks to reconstruct the file (§2.1).

We evaluate the upload and download speeds in three steps: (i) a client first uploads a 2 GB file; (ii) the client restarts and then uploads another 2 GB file that is identical to the previous one; and (iii) the client downloads the file. Note that the second upload performs source-based deduplication (for both PlainDedup and SGXDedup), and leverages the pre-computed masks to accelerate key generation (only for SGXDedup).

Figure 6(a) shows the upload speeds for different network bandwidths controlled by *trickle* [28]. For the first upload, when the network bandwidth is 1 Gbps, the upload speeds of both SGXDedup (106.6 MB/s) and PlainDedup (106.2 MB/s)

are bound by the network speed, while the performance bottleneck of DupLESS (20.1 MB/s) is the OPRF-RSA-based key generation (Exp#1). When the network bandwidth increases to 10 Gbps (the default), the upload speeds of SGXDedup and PlainDedup achieve 193.6 MB/s and 242.0 MB/s, respectively, while that of DupLESS keeps stable at 20.0 MB/s. For the second upload, DupLESS achieves the same speed as the first upload due to its key generation performance bottleneck. The upload speeds of both SGXDedup and PlainDedup are less influenced by the network bandwidth since they do not need to transfer data. On average, SGXDedup achieves 8.1× and 9.6× speedups over DupLESS in the first and the second uploads, respectively. Even compared with the insecure PlainDedup, SGXDedup only incurs about 17.5% and 21.4% drops of the corresponding upload speeds. The overhead comes from the security mechanisms of SGXDedup, including key generation, encryption, and PoW.

Figure 6(b) shows the download speeds. As the network bandwidth increases to 10 Gbps, both SGXDedup and DupLESS achieve 323.1 MB/s, a 44.2% drop from PlainDedup. The reason is that they serially retrieves and decrypts the file recipe, followed by downloading the ciphertext chunks.

Exp#5 (Real-cloud uploads and downloads). We now extend Exp#4 and evaluate the upload and download speeds in a real-cloud deployment. Specifically, we deploy the client and the key server in our LAN testbed (§5), and connect the client via the Internet to the *Alibaba Cloud*, in which we rent a virtual machine *ecs.c6e.xlarge* to run the cloud. The cloud machine is equipped with a quad-core 3.2 GHz CPU (Intel Xeon Cascade Lake Platinum 8269CY in its host platform), 8 GB memory. We mount the cloud with *Alibaba General Purpose NAS* as the storage backend. The NAS can achieve up to 20000 IOPS for 4 K random reads and writes.

We use on-disk data files for uploads (as opposed to Exp#4, which loads files into client’s memory before uploads), and allow the cloud to store the received data files in NAS. We also use *scp* to upload the whole data file (i.e., 2 GB) from the client to the cloud, so as to provide a data transfer benchmark in the Internet environment.

Table 2 shows the results. In the first upload, the performance of all systems (11.4 MB/s for SGXDedup, 11.6 MB/s for PlainDedup and 10.8 MB/s for DupLESS) is bounded by Internet bandwidth (11.9 MB/s). In the second upload, SGXDedup achieves 104.3 MB/s, 9.7× speedup over DupLESS and 13.2% drop compared to PlainDedup. Note that the performance differences are smaller than those in Exp#4, since

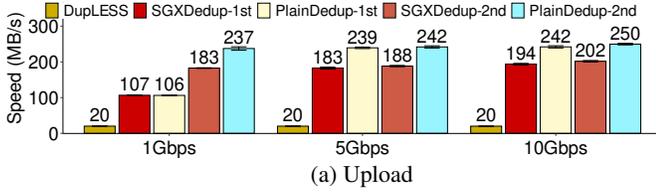

Figure 6: (Exp#4) Single-client uploads and downloads. We exclude the second upload speed of DupLESS (which has the same performance in two uploads) and the download speed of DupLESS (which is identical to that of SGXDedup).

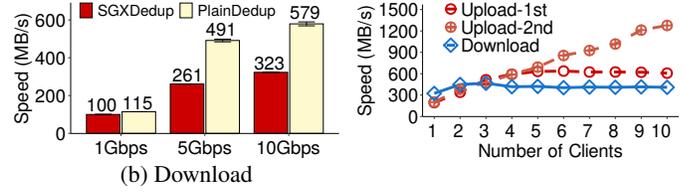

Figure 7: (Exp#6) Multi-client uploads and downloads.

Approach	First Upload	Second Upload	Download
Transfer	11.9 ± 0.03		
SGXDedup	11.4 ± 0.3	104.3 ± 1.2	10.1 ± 0.1
PlainDedup	11.6 ± 0.1	120.1 ± 1.4	11.3 ± 0.3
DupLESS	10.8 ± 0.2		10.1 ± 0.1

Table 2: (Exp#5) Real-cloud upload and download (unit: MB/s).

SGXDedup and PlainDedup are now bounded by client-side disk I/Os. In download, the performance of all three systems is bounded by Internet bandwidth again, while SGXDedup and DupLESS degrade the download speed of PlainDedup by 10.6% due to their serial retrieval and decryption (Exp#4).

Exp#6 (Multi-client uploads and downloads). We now consider multiple clients that issue uploads/downloads concurrently. We focus on SGXDedup, and configure the key enclave to equally pre-compute masks for each client after the first upload. We fix the network bandwidth at 10 Gbps, and evaluate the *aggregate* upload and download speeds for all clients to complete the uploads/downloads.

Figure 7 shows the results with up to ten clients. The aggregate upload speed in the second round increases with the number of clients, and reaches 1277.1 MB/s. On the other hand, the aggregate upload speed in the first round increases to 637.0 MB/s for seven clients, followed by dropping to 620.3 MB/s for ten clients due to the write contention across clients. Similarly, the aggregate download speed finally drops to 408.8 MB/s for the read contention of multiple clients.

Exp#7 (Time breakdown). We present a time breakdown of SGXDedup to study the performance of different steps. Suppose that the key enclave has been started and we focus on the initialization and the upload procedures of a single client. The initialization procedure bootstraps the PoW enclave of the client. The upload procedure includes the following steps: (i) *chunking*, which partitions an input file into plaintext chunks; (ii) *fingerprinting-p*, which computes the fingerprints of plaintext chunks; (iii) *key generation*, which generates MLE keys from the key enclave; (iv) *encryption*, which encrypts the plaintext chunks; (v) *fingerprinting-c*, in which the PoW enclave computes the fingerprints of ciphertext chunks; (vi) *signing*, in which the PoW enclave computes the signature of the fingerprints; (vii) *verification*, in which the cloud verifies the authenticity of received fingerprints; (viii) *deduplication*, in which the cloud detects duplicate ciphertext chunks and informs the client; and (ix) *transfer*, which uploads the non-

Procedure/Step	First Upload	Second Upload
Initialization	9.38 ± 2.72 s	0.80 ± 0.004 s
Chunking	3.77 ± 0.15 ms	
Fingerprinting-p	3.24 ± 0.28 ms	
Key generation	0.31 ± 0.01 ms	0.18 ± 0.01 ms
Encryption	2.47 ± 0.10 ms	
PoW	Fingerprinting-c	3.28 ± 0.01 ms
	Signing	0.01 ± 0.00004 ms
	Verification	0.005 ± 0.00003 ms
Deduplication	0.38 ± 0.03 ms	0.48 ± 0.03 ms
Transfer	1.29 ± 0.09 ms	0.05 ± 0.01 ms

Table 3: (Exp#7) Time breakdown per 1 MB of file data processed: fingerprinting-p and fingerprinting-c are operated on plaintext and ciphertext chunks, respectively.

duplicate ciphertext chunks and the file recipe.

Table 3 presents the results (per 1 MB of file data processed). The initialization procedure is time-consuming in the first upload since it needs to contact the Intel attestation service for checking the integrity of the PoW enclave. When the client restarts again, it no longer needs to execute remote attestation and reduces the setup time of the first round by 91.5%. Note that the time overhead of the initialization procedure can be amortized across multiple uploads and downloads.

The key generation step is efficient, and takes up to 2.1% of the overall upload time. With speculative encryption, SGXDedup further reduces the key generation time of the first upload by 41.9%. Also, the overall PoW step takes up to 24.4% of the overall upload time, and the dominant computation in PoW is the fingerprinting of ciphertext chunks, which is necessary for finding duplicates in encrypted deduplication. With the lightweight signing and verification steps (that take up to 0.1% of the overall upload time), we protect source-based deduplication against side-channel attacks, while reducing the transfer time of the first upload by 96.1%.

Additional experiments. In our technical report [53], we study the impact of batch size on key generation and PoW performance, as well as the rekeying latency.

5.2 Evaluation on Real-world Workloads

We evaluate SGXDedup using real-world workloads (which contain duplicates). We consider two real-world datasets in our evaluation.

- The first dataset, called *FSL*, contains the backup snap-

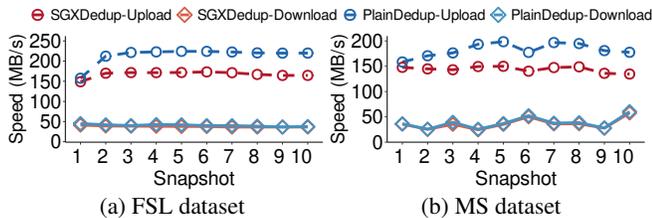

Figure 8: (Exp#8) Trace-driven upload and download performance.

shots of user home directories from a shared file system at the File systems and Storage Lab (FSL) [5, 56]. Each snapshot lists the 48-bit fingerprints of the chunks of an average chunk size of 8 KB. We select all snapshots (under `fs1homes`) from January 22 to June 17, 2013, covering a total of 56.2 TB of pre-deduplicated data. The dataset reduces to 431.9 GB after deduplication (i.e., a 133.2× deduplication ratio).

- The second dataset, called *MS*, contains the Windows file system snapshots from Microsoft [45]. Each snapshot lists the 40-bit fingerprints of the chunks of an average chunk size of 8 KB. We sample 140 snapshots from the original 857 snapshots, such that each snapshot has a size of about 100 GB. Our dataset contains 14.4 TB of pre-deduplicated data. It reduces to 2.4 TB after deduplication (i.e., a 6× deduplication ratio).

Exp#8 (Trace-driven performance). We conduct trace-driven evaluation on the upload and download performance of SGXDedup. We choose ten snapshots from FSL and MS each as follows. For FSL, we pick the snapshots from the same user to have high cross-snapshot redundancies; for MS, we pick the snapshots that have the most intra-snapshot redundancies. The chosen FSL and MS snapshots take 1.3 TB and 1.0 TB of pre-deduplicated data, respectively. Since our snapshots only contain fingerprints without actual data, we reconstruct each plaintext chunk by repeatedly writing its fingerprints into a spare chunk until reaching the specified chunk size, so the same (distinct) fingerprint returns the same (distinct) chunk. We use a single client to upload the snapshots one by one, followed by downloading them in the same order of uploads. We compare SGXDedup with PlainDedup (Exp#4).

Figure 8(a) shows the upload and download speeds across FSL snapshots. Both SGXDedup and PlainDedup achieve high upload speeds, especially when uploading the subsequent snapshots (e.g., at least 164.5 MB/s for SGXDedup and 212.2 MB/s for PlainDedup) after the first snapshot (e.g., 148.8 MB/s for SGXDedup and 157.5 MB/s for PlainDedup). The reason is that the FSL dataset has high redundancies across snapshots, and both systems can upload less data for subsequent snapshots. On average, SGXDedup incurs an upload performance drop of 22.0% compared to PlainDedup. Note that the overhead is slightly larger than that (17.5-21.4%) in our performance evaluation (Exp#4) using synthetic workloads. The reason is that chunking is now

disabled in trace-driven evaluation, and the bottleneck for SGXDedup switches to PoW (see Table 3), while the bottleneck for PlainDedup is fingerprinting. The download speed decreases from 41.3 MB/s to 36.4 MB/s for SGXDedup, and from 45.0 MB/s to 37.9 MB/s for PlainDedup, mainly due to chunk fragmentation [43]. We can mitigate chunk fragmentation via re-writing and caching [19, 43].

Figure 8(b) shows the upload and download speeds across MS snapshots. Both systems have lower upload speeds than in the FSL dataset, since the MS dataset has more non-duplicate chunks (e.g., 28.7 M for MS versus 18.3 M for FSL) and aggravates the access overhead of the fingerprint index. On average, SGXDedup incurs an upload slowdown of 21% compared to PlainDedup. Note that the download speeds fluctuate (e.g., 24.3-57.5 MB/s for SGXDedup and 25.6-60.3 MB/s for PlainDedup), since some MS snapshots have more non-duplicate chunks and are likely to be stored in consecutive regions that can be accessed quickly via sequential reads (i.e., less chunk fragmentation [43]).

Exp#9 (Bandwidth savings). We evaluate the bandwidth efficiency of SGXDedup. We consider two existing approaches that defend against side-channel attacks using both source-based deduplication (i.e., the client performs deduplication and uploads only non-duplicate ciphertext chunks to the cloud) and target-based deduplication (i.e., the client uploads all ciphertext chunks to the cloud, which performs deduplication on the received ciphertext chunks): (i) *two-stage deduplication* [42], which applies source-based deduplication on individual users, followed by target-based deduplication across users; and (ii) *randomized-threshold deduplication* [33], which performs either source-based deduplication or target-based deduplication based on a randomly chosen threshold. We choose the upper and lower bounds of the threshold in randomized-threshold deduplication as 20 and 2, respectively, as in [33]. For FSL, we aggregate the same-day snapshots of different users, and add each aggregate snapshot into the storage in the order of its creation time. For MS, we add each snapshot based on its snapshot ID (we assume that each MS snapshot is from a distinct user). We measure the *bandwidth savings* as the fraction of data reduction in transmission compared to the pre-deduplicated data. Here, we do not consider the bandwidth overhead due to metadata.

Figure 9 shows the cumulative bandwidth saving after uploading each snapshot. After uploading all snapshots, SGXDedup achieves 99.2% and 83.2% of bandwidth savings in FSL and MS, respectively. Since SGXDedup performs source-based deduplication, its bandwidth savings are also translated to the storage savings. Two-stage deduplication has almost identical bandwidth savings to SGXDedup in FSL, since the FSL dataset includes a large volume of intra-user redundancies. On the other hand, in MS, two-stage deduplication only has 47.9% of bandwidth savings (less than SGXDedup by an absolute difference of 35.3%). Randomized-threshold deduplication has varying bandwidth savings, with 48.5% in MS

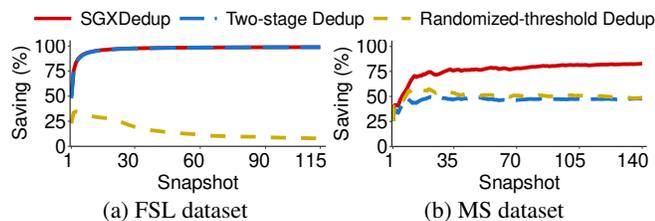

Figure 9: (Exp#9) Cumulative bandwidth savings after each snapshot is stored.

but only 7.8% in FSL (less than SGXDedup by an absolute difference of 34.7% and 91.4%, respectively).

6 Related Work

MLE key management. Traditional MLE-based [15] encrypted deduplication systems (e.g., [8, 20, 55]) are vulnerable to offline brute-force attacks [14]. DupLESS [14] proposes server-aided MLE to perform MLE key generation in a dedicated key server. Follow-up studies on server-aided MLE focus on deduplication pattern attestation [10], cross-user deduplication [62], and MLE key renewal [51].

Some studies mitigate the overhead of chunk-based MLE key generation at the expense of degrading deduplication effectiveness [51, 62] or weakening security [40]. SGXDedup outperforms these approaches in performance, while preserving both deduplication effectiveness and security (§5.1). Some other MLE key generation approaches include threshold-based key management [26] and decentralized key management [44], but they build on the cryptographic primitives (e.g., threshold signature [26] and password-authenticated key exchange [44]) that are theoretically proven but not readily implemented.

Defenses against side-channel attacks. Source-based deduplication is bandwidth-efficient but vulnerable to side-channel attacks [33]. Prior studies [33, 42] combine source-based deduplication and target-based deduplication to defend against side-channel attacks, while SGXDedup achieves significantly more bandwidth savings by purely performing source-based deduplication (§5.2) and using PoW to protect against side-channel attacks. Also, SGXDedup is much more efficient than Merkle-tree-based PoW (§5.1). Some other studies make PoW efficient by relaxing security (e.g., [23, 60]), while SGXDedup uses client-side SGX to preserve the security of PoW.

SGX-based storage. SGX [3] has been widely used for securing storage systems. PESOS [39] enforces the access policies of object storage with SGX. OBLIVIATE [9] enhances the security of SGX-based file systems against privileged side-channel attacks. EnclaveDB [50] and OblIDB [29] protect outsourced databases against information leakage via SGX. NEXUS [24] enables fine-grained access control with SGX over untrusted cloud storage. On the performance side, Harnik *et al.* [34] propose guidelines on mitigating the perfor-

mance overhead of SGX implementations. ShieldStore [37] implements application-specific data management to limit the enclave memory usage. SPEICHER [12] is an SGX-based LSM-based key-value store with efficient I/O operations.

All the above studies do not consider deduplication. Dang *et al.* [22] propose proxy-based protocols for bandwidth-efficient encrypted deduplication, but the protocols do not address the key generation performance overhead and have no implementation. SPEED [21] leverages deduplication to make SGX computations efficient, but SGXDedup improves the performance of encrypted deduplication with SGX. Other studies use a cloud-side enclave for PoW verification [61] and secure file-based deduplication [31], while SGXDedup uses a client-side enclave for efficient PoW proof generation and supports more fine-grained chunk-based deduplication.

7 Conclusion

This paper addresses the performance overhead of encrypted deduplication via SGX. We present SGXDedup, which implements a set of ECalls to run sensitive operations in SGX enclaves, so as to accelerate encrypted deduplication while preserving security. SGXDedup incorporates three key designs: (i) the secure and efficient enclave management, (ii) the renewable blinded key management, and (iii) the design of SGX-based speculative encryption for lightweight computations. Evaluation on our SGXDedup prototype demonstrates its high performance in synthetic and real-world workloads.

ICARUS: Attacking low Earth orbit satellite networks

Giacomo Giuliani, Tommaso Ciussani, Adrian Perrig, Ankit Singla
Department of Computer Science, ETH Zürich

Abstract

Internet service based on low Earth orbit satellites is generating immense excitement in the networking community due to its potential for global low-latency connectivity. Despite the promise of LEO satellite networks, the security of their operation has so far been largely neglected. In this context, we present ICARUS, a new class of denial of service attacks on LEO networks. ICARUS turns these networks' key benefits into vulnerabilities: an adversary can leverage the direct global accessibility to launch an attack from numerous locations, while the quest for low latency constrains routing, and provides predictability to the adversary. We explore how the adversary can exploit other unique features, including the path structure of such networks, and the public knowledge of the locations and connectivity of the satellite-routers. We find that a small amount of attack bandwidth can hamper communications between large terrestrial areas. Finally, we lay out open problems in this direction, and provide a framework to enable further research on attacks and defenses in this context.

1 Introduction

SpaceX Starlink [60,61], Amazon Kuiper [35], and others are deploying hundreds to thousands of satellites, each carrying high-capacity networking equipment. These low Earth orbit (LEO) satellite networks (LSNs) aim to provide global broadband Internet service. While global access would itself be a huge leap in connectivity, these networks also promise low-latency communications between otherwise well-connected regions. For instance, recent work [9] shows that for long-distance communication beyond a few thousand kilometers, such networks could provide lower latency than not only today's fiber Internet, but also specialized free-space radio networking used in the high-frequency trading industry.

Driven by the exciting potential of global low-latency networking, researchers are exploring many interesting problems related to LSNs, such as estimating their latency improvements [9, 28], and network topology design [10] and new routing strategies [25, 29, 33].

However, prior work has thus far largely ignored the aspect of the secure operation of these networks in the face of adversaries. We hence explore the resilience of LSNs to a large-scale volumetric distributed denial-of-service (DDoS) attack, carried out by a botnet of compromised satellite-enabled hosts. This threat has been extensively studied in terrestrial networks, but as we detail later (§ 3.4), an LSN is an extremely different environment: an adversary can leverage its global footprint to flexibly inject traffic into the network; knowledge about node (satellite) locations and network structure, far from be-

ing closely guarded, is easily available public information; and the low-latency objective both limits path diversity and reduces uncertainty about routing for the adversary.

With these unique opportunities for the adversary, also come new challenges: unlike a terrestrial transit network, the LSN connects directly to the clients injecting traffic into it, and can more easily detect and stop malicious behavior; at least initially, the client population will be much smaller than the Internet, limiting the adversary's resources; and the sparse structure of the inter-satellite network creates a risk for attack traffic flows to congest each other instead of the target(s).

Leveraging the unique opportunities and addressing the new challenges, we present ICARUS, a DDoS attack on LSNs. ICARUS draws on Coremelt [64] and Crossfire [31], and other DDoS work, but is customized for LSNs — the adversary carefully plans attack traffic using an LSN's structure, with the objective of congesting a target link or set of target links. The adversary hopes to do so at low *cost*, in terms of attack traffic volume, and with low *detectability*, in terms of change in the ingress bandwidth at individual satellites.

To help develop intuition in this new setting, we first analyze ICARUS in the scenario where the LSN uses single shortest-path routing. By simulating the attack on the LSN with the largest deployment to date, Starlink, we find that the adversary can successfully target the majority of its links, congesting both ground-to-satellite links and inter-satellite links (ISLs). Somewhat surprisingly, multi-target attacks that hamper connectivity between large regions are also feasible, at somewhat higher cost, but *without* increasing detectability compared to the single-target case.

In practice, LSNs may leverage multipath routing, potentially with randomized load balancing. We thus introduce a probabilistic version of ICARUS, that allows them to congest the target(s) with high probability, despite the uncertainty of routing. We analyze this attack against four intuitive routing schemes. Unfortunately, our experiments show that ICARUS is still able to attack targets at some additional cost compared to the single shortest-path scenario. The routing scheme that is most effective at increasing the attack cost—by 385% for the median target, *if* the adversary desires to minimize risk of detection—incurs a large latency increase on its paths, $1.32\times$ in the median and up to $2.04\times$ in more extreme cases. Despite this latency inflation, in the absolute, this increased attack cost still translates to less than 80 Gbps of attack traffic, and with a few tens of Mbps of bandwidth per bot, as promised by LSNs, translates to a few thousand bots. This is also the most pessimistic scenario for the attacker: there is no benign network traffic to lower the bar for congesting targets, the

LSN is willing to accept a large latency degradation, and the attacker seeks to minimize detectability rather than cost. In many settings, a few hundred bots will suffice instead.

Lastly, we briefly analyze additional attack opportunities that may arise from the dynamic nature of LSNs — as satellites move and paths change, there is natural flux in both the latencies of end-end paths, and in the traffic carried by each ISL. An adversary could potentially leverage latency changes to double the bandwidth of attack flows for a short period, in a manner similar to temporal lensing [55]. However, early results indicate little additional utility from this seemingly promising method. Further, an adversary may also time their attack flows to coincide with natural surges in link utilization from path changes. Our preliminary analysis indicates promise for this latter strategy, but a packet-level analysis is necessary to ascertain its impact.

Our main contributions are:

- We draw out the unique features of LSNs that introduce a vulnerability to DDoS, motivating a new analysis of a problem well-studied in terrestrial networks.
- We present the ICARUS attack, which exploits these unique features to successfully congest target links in an LSN. ICARUS addresses the new challenges the LSN setting poses for the adversary in terms of cost and detectability.
- We use the simple single shortest-path routing setting to develop intuition, and to show how connectivity between large regions may be hampered by ICARUS.
- We extend ICARUS to a randomized multipath routing scenario, and evaluate it against four intuitive routing schemes, showing that the attack still succeeds with high probability.

To the best of our knowledge, ICARUS is the first volumetric DDoS attack on upcoming LSNs. Beyond our particular attack methods and results, we hope that our analysis framework will aid further work on the vulnerability of LSNs to DDoS attacks, and on developing and evaluating mitigation strategies, e.g., routing that optimizes the latency-resilience tradeoff. Our framework is available on [GitHub](#).

2 Background & related work

Our contributions lie at the intersection of the nascent research on large upcoming LSNs, and well-studied (for terrestrial networks) denial-of-service (DoS) attacks. We introduce the relevant background for both.

2.1 LEO satellite networks

In the proposed and under-deployment LSNs, hundreds to thousands of satellites will be arranged in equally-spaced *orbital planes*, each containing the same number of satellites. Satellites connect to terminal units (TUs) on the ground with radio links. At the same time, satellites may connect to each other by laser ISLs. Each orbit has a fixed *height* above sea level; under 2000 km is considered LEO. This relative closeness to the ground provides a great advantage in terms of communication latency, as the signal has to travel a much

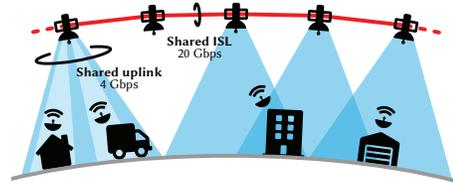

Figure 1: Satellite forwarding. Satellite-enabled hosts communicate with the satellites overhead using radio up- and downlinks. Traffic is routed from satellite to satellite via ISLs.

shorter distance to reach the satellite than, for example, to reach Geostationary satellites at 35,786 km.

In most proposed constellations, the orbital planes do not intersect the Equatorial plane at a 90° angle, and thus do not transit over the Earth’s poles. Instead, a lower *inclination angle* is used to allow the satellites to spend more time at lower latitudes, thus improving coverage above more populous areas, whilst avoiding the polar regions.

Our analysis throughout uses the first shell of the SpaceX Starlink constellation, for which the above parameters are: 72 orbital planes, each with 22 satellites, a height of 550 km, and an orbital inclination of 53° [60, 61, 63].

Satellite-ground connectivity. Figure 1 shows a typical LSN communication scenario. Terminal units (TUs) are installed at the clients on the ground. Each satellite can simultaneously connect with multiple TUs, thanks to their multi-beam antennas [17]. We call the aggregate capacity incoming to and outgoing from a satellite its *uplink* and *downlink* respectively. Based on recent FCC filings [60, 61], our analysis assumes both up- and downlink capacities to be 4 Gbps.

TUs can communicate with overhead satellites that are above a *minimum elevation angle* over the horizon. The angle varies from constellation to constellation, and expresses a trade-off between the size of the coverage area or *footprint* of a satellite, and the rate of communication achievable. Greater elevation angles translate to smaller footprints, but also force shorter paths inside the atmosphere and allow for better frequency reuse, thus increasing capacity. For Starlink’s shell I, the minimum elevation angle is planned to be 40°.

Inter-satellite connectivity. A key feature of the proposed constellations is the use of laser inter-satellite links (ISLs) on each satellite.¹ A typical approach is to have 4 ISLs per satellite, two connected to fore and aft satellites in the same orbital plane, and two to satellites in adjacent orbital planes [69]. The resulting ISL topology is used to transit traffic between TUs. As shown in Fig. 1, traffic can be forwarded from a TU to a satellite in view through an uplink, then across multiple ISLs, and finally to the destination via a downlink.

Some constellations, particularly during early stages of deployment, may forego ISLs, instead transiting data through a series of up and down transmissions between ground stations

¹SpaceX recently launched ISL-capable satellites [59], and Telesat has started producing them [65].

and satellites; this is, for instance, the case for Starlink in its first stages of deployment. However, ISLs are expected to be a key component of future LSNs, including more mature deployments of Starlink, and are crucial to achieving many of their benefits [10, 28, 29]. We therefore focus our analysis on the setting with ISLs; no-ISL LSNs are a strictly easier attack target: ground–satellite links will have a much lower capacity than ISLs, with each satellite supporting a few Gbps of uplink at most, simplifying the adversary’s goal of creating congestion. On the other hand, previous work [17] and laser equipment vendors’ offerings [47] suggest that ISLs will be able transfer up to 20 Gbps full-duplex, greatly increasing the capacity of the network.

Benefits: global low-latency broadband. With their hundreds to thousands of satellites, each providing multi-gigabit connectivity, LSNs can blanket the globe with broadband Internet. Besides their potential to extend the Internet’s coverage to under-served regions, LSNs are also generating excitement due to their potential for low-latency connectivity even in already well-connected areas. Prior work [10] estimates that LSNs could reduce latency for long-distance routes by more than $2\times$ compared to today’s Internet. Two factors contribute to this reduced latency: first, the speed of light in vacuum is roughly 50% higher than the speed of light in the glass medium of optical fiber. Second, a series of ISLs can often provide a more direct path between TUs than what fiber can achieve on the ground.

2.2 Denial of service

The term *denial of service* encompasses a large class of attacks. DoS attacks can target different resources at different layers in the network. We are interested in discovering and analyzing the threats to communication that are peculiar to LSNs, and that arise from the characteristics we have presented in the previous section. During a volumetric DDoS attack, a *botmaster* directs the traffic of thousands to millions of *bots* [3], i.e., compromised hosts, towards a target element in the network, overwhelming it. The *botnet* is usually composed of bots distributed across the globe; and targets can be servers, end-hosts, routers, etc. Traditional DDoS attacks send traffic to a target end-point. Newer attacks like Coremelt and Crossfire are designed to congest in-network elements instead—their approach to send traffic between bots or to initiate connections to a variety of public servers defies traditional methods to classify traffic into legitimate and unwanted.

Coremelt & Crossfire. In Coremelt [64], the adversary tries to congest a target inter-domain *link* by making use of legitimate-looking flows generated between the N bots of a botnet. Given the knowledge of the $\binom{N}{2}$ paths between the bots, the adversary can initiate flows that will cross the target link. With sufficient resources, the adversary can successfully congest any link in the network.

Crossfire [31] expands on this idea. With Crossfire, the adversary is able to hinder communication between entire

regions of a network, as bots simultaneously connect to strategically selected servers, thus creating overload on the links leading into the region under attack.

Both attacks have been notoriously hard to mitigate, since the adversary uses indistinguishable, legitimate traffic. In § 7 we argue that ICARUS poses an even larger threat, as the few mitigations available against Coremelt and Crossfire cannot be directly employed.

3 ICARUS adversary model

The ICARUS adversary controls a botnet of compromised hosts equipped with TUs that connect to the LSN. These bots are exploited by the adversary to send traffic over the LSN to congest links and disrupt communications between other TUs controlled by benign users.

3.1 The adversary’s objective

The adversary seeks to generate legitimate-looking traffic that, by careful selection of source and destination bots, disrupts target communications by exhausting the capacity of certain LSN links. More concretely, the adversary may target:

- *A satellite uplink or downlink.* This is the easiest attack, as these are the lowest bandwidth links in an LSN.
- *An ISL.* Congesting ISLs is a potentially more disruptive attack, as they carry traffic for more source-destination pairs. However, they are also more difficult to attack than uplinks and downlinks, as they have higher capacity.
- *Multiple links.* We also consider multi-link attacks, in which the adversary selects a combination of target ISLs and/or up/downlinks to achieve a broader attack effect. For example, the adversary could try to congest *all* the links in the load-balancing set for a target source-destination communication, or to target all links connecting two large terrestrial areas.

Our simulations label a link *congested* when aggregate traffic demand across it exceeds its capacity. In practice, degradation of communication starts before this threshold.

3.2 Metrics of attack success

For any of the above targets, the adversary is interested in causing disruption at *low cost* and while *avoiding detection*.

Cost. Attack cost measures the resources an adversary has to deploy to successfully achieve their attack’s goals. We express cost as the traffic volume (in Gbps) the adversary has to generate to be successful. With each bot generating tens of Mbps of attack traffic, as seen in initial measurements from Starlink [5, 11], an ISL’s 20 Gbps worth of capacity translates to, e.g., 500 bots each sending 40 Mbps.

Detectability and maxUp. If the LSN operator sees large changes in how much traffic a certain satellite receives on its uplink, the operator could potentially localize and identify the compromised bots. Thus, to reduce detectability, the adversary would distribute attack traffic across numerous uplinks. To characterize detectability, we use the *maximum absolute*

bandwidth increase caused by the attack traffic across the uplinks of the LSN (maxUp). We use the absolute increase, rather than relative, to obtain comparable results from simulations with different baseline traffic models.

3.3 The adversary’s capabilities & constraints

Unlike terrestrial networks, many aspects of an LSN’s operations are public knowledge or can be inferred.

LSN topology. Satellite orbits are public-domain information constantly updated and published by NORAD [12]. From these, an adversary can precisely compute the positions of the satellites for a chosen attack time; the error in such computations is at most a few kilometers per day into the future [32]. As noted earlier (§2), the ISL interconnect is expected to be a typical cross pattern. The design capacity of all links is also known through public regulatory filings. Thus, we assume full advance knowledge of the LSN topology. Moreover, changes in the shortest paths happen on timescales of seconds. As the maximum forwarding latency in the network is about 125 ms, the adversary can look at the LSN in snapshots [10], and compute the attacks for successions of snapshots. They can thus avoid the complexity of continuous satellite motion.

Routing. The topology is known, as is the propagation delay across each link at all times. Therefore, given frequent measurements of latency between a large set of bots, the adversary can determine how routes are being chosen. This is a much simpler setting for network tomography than one where the topology and forwarding latencies are unknown.

If routing is deterministic, e.g., shortest-path routing, the adversary can compute the full forwarding path for any source-destination pair ahead of time. If routing is randomized, e.g., for load balancing across near-shortest paths, we assume the adversary knows the algorithm with which the *load-balancing set* is constructed. The adversary therefore knows in advance the possible paths traffic will take, but not the actual path selected for forwarding a particular flow.

Bot locations & availability. A key promise of LSNs is global coverage, thus providing diverse locations for potential bots. Even if terminals themselves are secure, it suffices to compromise the user devices connected through them, and therefore exploits used today to create botnets directly apply in the case of a satellite-enabled botnet. We thus assume that the adversary can compromise TUs at any location on land. Given that such TUs, even today [66], feature GNSS²-based self-location to aid signal acquisition from satellites, the adversary accurately knows the locations of their bots.

Regarding the size of the botnet, we do not constrain the number of compromised TUs at any location beyond the limits imposed by the capacity of uplinks. We will later show that successful attacks only require hundreds to thousands of compromised TUs—a very small fraction of the tens of millions of TUs expected to be available globally (SpaceX has sought permits for 5 million TUs in the US alone [62]).

²Global Navigation Satellite System.

Attack control channel. We assume that the adversary can coordinate the bot army through a command-and-control channel, which is typical for modern botnets. As we show later, the advance knowledge of the topology, the routing algorithm, and the bot locations, allows the adversary to pre-compute and disseminate to the bots their attack traffic commands ahead of time. Fine-grained time-synchronization across bots would only be needed if the adversary sought to create extremely short-term congestion (e.g., for tens of milliseconds) [36, 55]. This would easily be possible through GNSS.

3.4 Unique attack opportunities & challenges

The above discussion highlights that an adversary targeting LSNs has several advantages compared to one targeting traditional terrestrial networks.

- An adversary has full access to the network topology. The positions of the satellites are published regularly [12], and can be predicted with high accuracy into the future [32]. The design detail of the interconnections, moreover, can be deduced from the FCC requests that the satellite operators are mandated to file. In contrast, the topology of terrestrial networks is concealed, and may even be obfuscated [44].
- Given the LSN’s global exposure, the adversary can recruit bots in diverse locations for generating attack traffic.
- The low-latency goal of LSNs leads to routing predictability, as shortest or near-shortest paths must be used.
- For already well-connected regions, the primary value of an LSN is low latency, as terrestrial fiber routes will be cheaper. This lowers an adversary’s burden: between a target source-destination pair, the adversary must only deteriorate a small set of desirable (low-latency) paths, instead of needing to congest a cut in the network graph.
- Our analysis of the topology and path structure of an LSN shows that certain links are more vulnerable than others, providing easy targets for an adversary.
- Exploiting the system’s predictability, communication with the bots can be asynchronous, making traditional detection of the command and control traffic difficult.

However, some aspects of the LSN setting also pose challenges to the adversary:

- Each bot has limited resources, and the pool of bots available is only a small fraction of Internet-connected hosts that could otherwise be purposed as bots. It is thus even more crucial for an adversary to keep attack cost low.
- The adversary needs to ensure that their limited attack resources are not wasted by self-congestion, whereby traffic from its bots congests links before reaching the target links.
- Congesting some satellite’s uplink exploiting a large number of bots directly underneath is counter to the adversary’s need to avoid detection. The LSN is a centrally-managed, intra-domain network, and therefore has better monitoring and policing capabilities than terrestrial transit networks.

Thus, the adversary has to be especially stealthy, and employ more distant and diffuse collections of bots.

- If the LSN uses randomized load balancing across multiple paths, this results in routing unpredictability for the adversary, requiring a probabilistic approach that would potentially consume more resources.

Our attack methods exploit the aforementioned unique opportunities, while addressing the new challenges.

4 ICARUS attack: shortest-path routing

We first discuss our ICARUS denial-of-service attack against an LSN in the simpler setting, where the LSN uses single shortest-path routing. While this provides low latency, the deterministic routing aids the adversary.

4.1 Attack mechanism

Paths in an LSN are typically stable on the order of seconds (§ 3.3). Thus, the adversary can compute the flows the bots must send on a static snapshot of the network, and use the same flow assignment for seconds before issuing a new one. Note that the adversary is also aware of the times when paths will change, and can plan their flow assignments for change-free periods. The assignments can be sent asynchronously to the bots for several periods in advance, as the entire system is fully predictable on a much longer timescale. For a particular system snapshot, the set of attack flows is computed as follows, similarly to Crossfire [31]:

- A1** *Link and path discovery.* The adversary uses the known inter-satellite topology to create a connectivity graph. They compute all the satellite in view of each bot, and add an uplink and a downlink for each reachable satellite to the connectivity graph. Finally, the adversary runs Dijkstra’s algorithm for all the $N(N - 1)/2$ pairs of bots to find the forwarding paths.
- A2** *Path filtering.* For a given target link or links, the adversary finds all bot-pairs whose shortest path traverses the target(s). The adversary retains only the paths that traverse the target(s) in the desired (attacked) direction.
- A3a** *Feasible attack flow computation.* The adversary must decide how much traffic to send on the chosen attack paths between its bot-pairs. The adversary checks if there exists a flow assignment such that (i) the target links are just above capacity, and (ii) no other links are congested. Satisfying these constraints ensures that the target(s) can be congested without the attack traffic self-congesting, i.e., being bottlenecked before reaching them. This approach minimizes cost in terms of attack bandwidth.
- A3b** *Reducing maxUp.* If **A3a** produces a feasible attack flow, the adversary iteratively optimizes maxUp. Recall that maxUp, D , is the maximum attack traffic volume across the uplinks. At each iteration i , the adversary lowers the permissible attack traffic volume on all uplinks, D_i ; then they perform the feasibility check again. This process

is repeated until the minimum value, D_{min} , is found, for which the attack is still feasible.

4.2 Evaluation setup

We evaluate the above attack strategy in terms of how its cost and maxUp depend on the attack scenario. The attack scenario varies the targets, i.e., either individual links or sets of links, and what type of benign traffic already uses the LSN.

Throughout, we use simulations on the SpaceX Starlink shell I constellation (§2) with a total of 1584 satellites. Note however, that our evaluation framework supports arbitrary constellations; an example set of results for a different configuration is included in §D in the Supplemental materials. We assume that bots and benign TUs can be located at any point on land. To keep the simulations tractable, we discretize the continuous space of geolocations to a regular geodesic grid. This is done in the form of a triangular tiling of the planet that, when restricted to land areas, amounts to a total of 1761 possible positions. (The restriction to land areas is driven by our below models of benign traffic, which are based on population and economic activity.) Each of the triangular tiles represents an area of 100,000 km². Since a single Starlink satellite covers an area ten times this size, this grid suffices to capture the nuances of different TU placement relative to the same satellite.

We test three traffic scenarios for benign traffic on the LSN:

- *Empty network:* This case, with no benign traffic, serves as a baseline, comparing against which, we can understand the impact of existing traffic.
- *GDP traffic:* A “gravity” sampling model, where probability of adding 10 Mbps of benign traffic between two locations is proportional to the product of their Gross Domestic Product (GDP) [48]. Each tile’s centroid serves as a traffic source/sink location, with the aggregate GDP for the tile’s area being this location’s GDP weight. We then sample 250k times, discarding the samples that, if added, would exceed 90% of the capacity on the links. This process results in a utilization of 28% of the on-land uplink capacity. This model treats traffic as proportional to economic activity, representing the view that the biggest economic centers will drive traffic and revenue.
- *Pop traffic:* Another gravity model similar to the above, except the population is used as the weight instead of GDP [13]. This model represents the scenario where the LSN’s primary role is improving coverage in regions that are populous but still poorly connected. For this model, we get 34% utilization.

All the simulations in the following are executed by our [LSN simulation framework](#) (~5000 lines of Python code).

4.3 Single link target scenarios

Attacking an uplink. The outcome of the attack on an uplink is easy to determine: either the adversary has enough bots in the area of coverage of the victim satellite uplink, or

the attack cannot succeed. This attack has therefore maximum maxUp in our model, as the adversary has to completely fill the uplink with attack traffic.

Downlinks. Unlike uplinks, downlinks can be reached from arbitrarily afar, and therefore the adversary can more easily find bots to congest them. In theory, the attack flows can self-congest: as the attack traffic flows towards the target downlink, more and more flows join paths, filling the ISLs leading up to the target. While this can violate constraint ii) in A3a (§ 4.1), it is unlikely for an attack on a downlink — all the ISLs preceding the target downlink can carry $5\times$ the bandwidth needed to congest the downlink. As a result, our simulations reveal that *all* downlinks from satellites located over land are attackable in this manner. As our model does not allow TUs in the seas, there is no way to congest downlinks for the remaining satellites. We also verified that this result remains the same regardless of our three traffic models, as even with benign traffic, there is always enough leftover capacity in the network for the relatively small amount of attack traffic bandwidth required.

ISLs. ISLs have higher bandwidth than up-/down-links, making an attack more complicated and more costly to achieve. Not only is more attack traffic needed to cause congestion on an ISL compared to a downlink, but also self-congestion *does* often occur in practice for attack flows headed to a target ISL. This often results in there being no feasible attack flow. Consequently, of the 6336 possible ISL target links (1584 satellites, each with 4 ISLs, counting both directions), we find that in an empty network scenario, 5470 (86%) are feasible. With GDP or Pop traffic, this drops to 72% and 71% respectively. This is along expected lines: benign traffic reduces the available capacity on the attack flow paths, limiting the attack traffic that reaches the target.

An interesting finding from our simulations is that with all three models, of the end-to-end paths with at least one ISL, fewer than 0.6% do not contain at least one ISL the adversary can congest. Therefore, this attack can disrupt >99.4% of all communications that rely on an ISL.

Cost and maxUp. In the above, we have only discussed feasibility for each individual targeted link: for uplinks, feasibility depends simply on having enough bots under the target uplink; all downlinks over land are feasible to attack; and for ISLs, self-congestion limits feasibility, with the details dependent on the benign traffic. For the feasible attacks, we can also analyze attack cost and maxUp.

Figure 2 shows the cost and maxUp of attacks against all links that are feasible to attack (downlinks and ISLs together; uplinks are uninteresting as discussed, and thus omitted) for all three traffic models. From the cost graphic (top), we see that for the empty network, there are only two modes in the CDF — all downlinks cost 0.2 and all ISLs cost 1 to attack. (We present costs normalized to one ISL’s bandwidth, i.e., 20 Gbps; recall that downlinks have one-fifth the capacity of an ISL.) This is as expected: in an otherwise empty network,

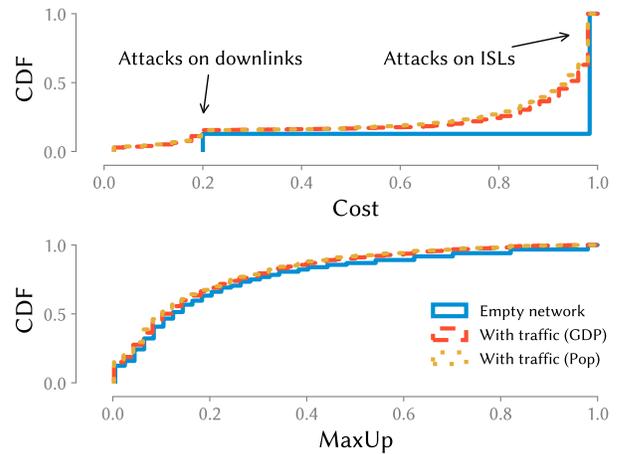

Figure 2: Cost and maxUp of single-target attacks. While maxUp is similarly distributed either with or without baseline traffic, attack cost decreases significantly.

congesting any link requires sending the target link’s capacity worth of traffic. In the presence of benign traffic, for both traffic models, the attack cost is lower, as the adversary needs to add a smaller amount of traffic to the existing benign traffic. In terms of number of bots, a cost of 1 translates to a few hundred bots sending tens of Mbps each (§ 3.2). The maxUp plot (Fig. 2, below) shows the distribution of maxUp across attacks on different target links. We normalize maxUp to one uplink’s bandwidth, such that needing to fully saturate a satellite’s uplink is the worst case for the adversary, and means that maxUp is 1. The maxUp of an attack on the median target link is below 0.13 in the empty network scenario. Thus, the *maximum* satellite uplink bandwidth consumed across attack flows sent towards these target links comprises roughly one-eighth of an uplink’s bandwidth. Adding benign traffic to the network with either traffic model further lowers the adversary’s risk of detection.

While adding benign traffic decreases attack cost and lowers maxUp for those target links that are feasible to attack, it actually decreases the fraction of feasible target links. However, closer inspection shows that this is not a particularly severe problem for the adversary: the links that become less vulnerable when benign traffic is present are mostly above the oceans, and not the higher-value ones over the more populous regions (further analysis is presented in §A.1 in the Supplemental materials).

4.4 Multi-link region disconnection scenarios

Beyond attacking individual links and communications that traverse them, an adversary may seek to hamper all communication between two large geographic areas. To do so, they must congest *all* paths connecting the two regions simultaneously. This makes the attack more challenging: the adversary now has to carefully select the set of target links to congest, such that hampering region-region connectivity incurs low cost and has low maxUp. Figure 3 shows an example in which

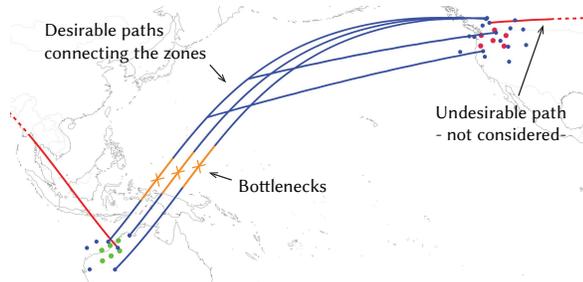

Figure 3: Example of region disconnection. Although 12 distinct shortest paths are available between North-western America and North-western Australia, just 3 bottlenecks suffice to prevent communication between these large zones.

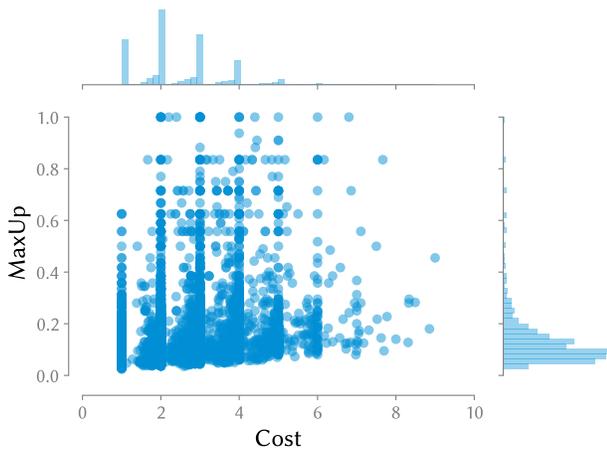

Figure 4: Cost and maxUp of zone disconnection attacks. As shown by the marginals, maxUp is low for most attacks. The peaks shown in the cost marginal correspond to the number of bottlenecks in the paths between the zones.

the adversary intelligently selects 3 bottlenecks shared across the 12 different paths, greatly reducing the attack cost. In many cases, however, the choice is not as obvious.

The adversary has to select the minimum set of links *it is able to attack simultaneously*, among the ones in the paths connecting the zones, such that their congestion results in a complete disconnection. Unfortunately, this problem is equivalent to the minimum set cover problem (we prove equivalence in §B in the Supplemental materials), which is NP-hard [34]. To avoid exponential explosion, we use a heuristic which computes a good approximation of the set of links to attack in polynomial time. Each link in the paths to congest is assigned a score, equal to the ratio between the maxUp of the attack on the link, and the number of paths that share the link. The lower this score, the stealthier it is to attack such a link. We therefore add the link with the lowest score to the attack set, we remove it from the network alongside all the paths it congests, and finally recompute the scores for all remaining links. We continue this procedure until all paths are congested. We run this heuristic three times, slightly varying the order in which links are removed, and keep the lowest maxUp result.

Simulation results. We iteratively sample 5000 pairs of regions, each comprising six points on the geodesic grid (§ 4.2). For each pair, we run the attack twice, inverting source and destination region, for a total of 9658 viable attack cases (some are discarded because the zones are overlapping). The results are shown in Fig. 4.

We find that 9208 of these zone pairs (95%) can be successfully attacked. The median maxUp of these attacks is 0.10, implying that attacking large regions does not expose the adversary more than the single-link attacks (where the maxUp was 0.13). The minor difference in maxUp arises because the zone construction algorithm prevents some of the corner cases that increase the median maxUp in the single-link attacks. Since zones are composed by multiple grid points, they have to be located farther away from the edges of satellite connectivity (high latitudes, or narrow corners of continents), thus giving the adversary more uplinks on which to distribute the attack traffic. Finally, the overall cost is mainly driven by the number of bottlenecks found (characterized by the spikes in the marginal in Fig. 4), which is consistently below 4.

5 ICARUS against more sophisticated routing

We use the single shortest path routing setting discussed thus far primarily to develop intuition about the vulnerabilities of an LSN, and to broadly understand an adversary’s tradeoffs. In practice, the more likely scenario entails the LSN load-balancing traffic across multiple paths. We therefore consider several candidate routing schemes for such load balancing, and then formulate and evaluate a modified attack strategy suited for this more complex setting.

5.1 Candidate routing schemes

Developing, evaluating, and comparing new routing strategies is not our objective, and has been tackled in some depth in prior work (§ 8). However, to understand how load balancing across multiple paths impacts an adversary, we must frame some suitable routing methods. Here, we use one guiding constraint: the chosen non-shortest paths must still be “near shortest”, i.e., not increase latency by a large amount. In the extreme, any path’s latency must not exceed that of a terrestrial fiber route.³ We thus evaluate the following multi-path routing variants:

- k*-SP** *Shortest paths:* This strategy load-balances traffic among the *k*-shortest source–destination paths.
- k*-DG** *Ground-to-ground disjoint paths:* This strategy only considers the *k* shortest paths that are node-disjoint, i.e., without shared uplinks, downlinks, or ISLs.
- k*-DS** *Satellite-to-satellite disjoint paths:* This strategy is similar to the above, with the exception that overlap is allowed on uplinks and downlinks. Disjointness is enforced exclusively on the ISLs.

³This fiber latency is estimated, based on past measurement work [58], by multiplying the great-circle distance by a path-stretch factor of 1.53, and then dividing by the speed of light in fiber, $\approx 2c/3$.

***k*-LO** *Limited-overlap shortest paths*: we implement the ESX algorithm by Chondrogiannis et al. [15], a heuristic that finds the shortest k paths with a *similarity score* of no more than 50%.

Note that sometimes these algorithms yield fewer than k paths because of the faster-than-fiber and path disjointness constraints. (For k -SP, only the former applies, and is only limiting for nearby end-points.) Each algorithm considers different types of near-shortest paths, varying the degree to which paths overlap. k -SP, which does not limit overlap, typically offers multiple paths with nearly the same latency as the shortest, but risks the shared links across these paths becoming the bottleneck. On the other extreme, the most restrictive scheme, k -DG, typically does not even provide more than 4 paths. Further analysis of the path structure of these algorithms is in §C in the Supplement. For each scheme, we assume that the LSN uses randomized load balancing (similar to ECMP) across the chosen path. Note that uniform random load balancing is the worst case for the adversary; any deterministic adaptive scheme will strictly reduce uncertainty for the adversary.

5.2 Probabilistic ICARUS

The use of load-balanced, uniformly randomized routing introduces uncertainty in the *link discovery* phase. As the network chooses the end-to-end path only at forwarding time, from a set of k pre-computed paths, the adversary cannot know in advance which specific path will be taken by their attack traffic. We therefore present a probabilistic variation of ICARUS that accounts for this uncertainty. This attack performs attack-flow assignment in such a way that the target link will be flooded with high probability, while avoiding self-congestion among attack flows, and lowering maxUp.

Congesting the target. The adversary pre-computes all the load-balancing paths for all its bot source-destination pairs, and considers those (s, d) -pairs for which *at least* one path contains the target link. Consider an (s, d) -pair connected by $n \leq k$ paths, with m of them crossing the target link. Then the event “the forwarding path chosen for this (s, d) -pair uses the target link” can be described as a Bernoulli random variable $X_{(s,d)}$ with probability of success $p_{(s,d)} = m/n$. Suppose the adversary uses an attack-flow set \mathbb{A} , comprising many (s, d) -pairs. Then the sum $Y = \sum_{s,d \in \mathbb{A}} X_{s,d}$, is a random variable describing the number of attack flows that are forwarded across the target link. The X variables are independent but *not* identically distributed, with different m and n across (s, d) -pairs, therefore Y follows a Poisson binomial distribution.

The adversary’s goal is for the attack-flow set, \mathbb{A} , to be such that at least T attack flows use the target link with high probability. Here, T is determined by each attack flow’s bandwidth, and the target link’s capacity; in our model, for example, an ISL has a capacity of 20 Gbps; if a single (s, d) -pair can transmit 40 Mbps (3.2), T is 500.

The target link is congested if $Y \geq T$. The adversary wants to bound their probability of failure to at most a small

value, β , i.e., $P[Y < T] \leq \beta$. The adversary can get more certainty, i.e., lower β , at the expense of more resources.

The computation of $P[Y < T]$ is infeasible for non-trivial settings, but we can approximate it via the Chernoff (lower tail) bound [46]:

$$P[Y < (1 - \delta)\mu] \leq \exp(-\mu\delta^2/2) \quad (1)$$

where $\mu = E[Y]$. By setting $\delta = 1 - \frac{T}{\mu}$ in eq. (1), we get:

$$P[Y < T] \leq \exp(-\mu(1 - T/\mu)^2/2)$$

Note that $\mu = E[Y] = \sum_{(s,d) \in \mathbb{A}} p_{(s,d)}$ by the linearity of expectation. The adversary can easily calculate μ for any attack-flow set, \mathbb{A} . To ensure that $P[Y < T] \leq \beta$, the adversary can pick \mathbb{A} ’s constituent (s, d) -pairs such that they satisfy:

$$\exp(-\mu(1 - T/\mu)^2/2) \leq \beta$$

For $0 < \beta < 1$ and $1 \leq T < \mu$, this is equivalent to:

$$\mu > \sqrt{\ln \beta \cdot (\ln \beta - 2T)} + T - \ln \beta = \mu_{min} \quad (2)$$

Avoiding self-congestion. The adversary must also ensure that the attack flows do not cause self-congestion, i.e., congest other links before reaching the target. This problem, of *not* congesting non-target links, requires the same machinery as that above for congesting the target. For every non-target link, l , we simply need to repeat analysis similar to the above, except towards ensuring we *do not* congest l , i.e., $W_l < C_l$, where W_l is a random variable describing the number of attack flows that traverse l , and C_l is l ’s capacity.

Say γ is a parameter analogous to β above, indicating the maximum acceptable risk of self-congestion. For any non-target link, l , μ_l (analogous to μ above) is the expected number of attack flows crossing l , such that $\mu_l = \sum_{(s,d)} p_{(s,d)}$ for (s, d) -pairs that traverse link l . Analysis similar to the above—but considering the upper tail—yields, the following condition:

$$\mu_l < \frac{1}{2} \left(-\sqrt{\ln \gamma \cdot (\ln \gamma - 8C_l)} - \ln \gamma + 2C_l \right) = \mu_{l,max} \quad (3)$$

Probability of attack success. An attack is successful if the target is congested without congesting any other link. We combine the probabilities computed so far as follows:

$$P[\text{success}] = 1 - P[\text{failure}] \quad (4)$$

$$= 1 - P[Y < T \vee W_1 \geq C_1 \vee \dots \vee W_N \geq C_N] \quad (5)$$

$$\stackrel{\text{u.B.}}{\geq} 1 - \left(P[Y < T] + \sum_{l=1}^N P[W_l \geq C_l] \right) \quad (6)$$

$$\geq 1 - (\beta + N \cdot \gamma) \quad (7)$$

$$= 1 - \alpha \quad (8)$$

where eq. (6) is given by the union bound, and N is the number of non-target links. For a high probability of success, α has to be small. In our setting, N is in the range 1500–2000. We therefore choose $\gamma = 1/N^2 = 1/2000^2$ and $\beta = 0.1$, which gives $P[\text{success}] \approx 0.9$. Empirically, we find that the Chernoff bound is quite loose, and for these values of β and γ the success probability is higher ($\geq 95\%$).

Attack set construction. The adversary must construct the attack-flow set, \mathbb{A} , such that it simultaneously satisfies the constraints on μ , and for every non-target link l , μ_l :

$$\mu = \sum_{(s,d) \in \mathbb{A}} p_{(s,d)} > \mu_{min} \quad \text{and} \quad (9a)$$

$$\mu_l = \sum_{(s,d) \in W_l} p_{(s,d)} < \mu_{l,max} \quad \forall \text{ non-target links } l \quad (9b)$$

Since μ is additive, we use a greedy approach:

- We sort the (s,d) -pairs by decreasing value of $p_{(s,d)}$.
- Iteratively, we add an (s,d) -pair to \mathbb{A} , checking that eq. (9b) holds. Otherwise, we discard the pair and move on to the next one.
- We repeat this until either eq. (9a) is satisfied—in which case the attack succeeds with probability $\geq 1 - \alpha$, or there are no more (s,d) -pairs, and the algorithm fails to guarantee this probability of success.

The above approach yields the attack set with the minimum number of (s,d) pairs. However, maxUp is not minimized, and is (nearly) μ_{max}/C_{uplink} . If the adversary wants to minimize maxUp before cost, they can iteratively lower $\mu_{l,max}$ for the uplinks to the minimum value such that the construction of \mathbb{A} still succeeds.

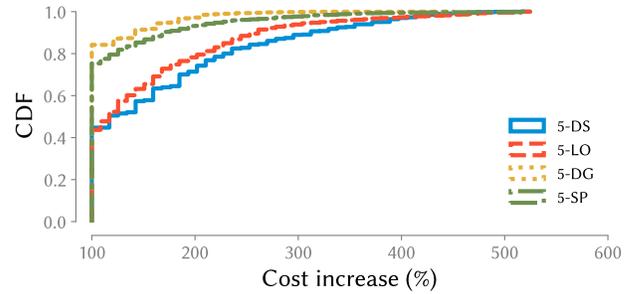

Further optimization. Due to the structure of the topology and the routing schemes, for each target link, there are certain (s,d) -pairs for which $p_{(s,d)} = 1$. In the above probabilistic analysis, such (s,d) -pairs needlessly contribute to making the probability bounds loose. Instead, they can be considered separately, and the above analysis done after accounting for those (s,d) -pairs.

5.3 Evaluation

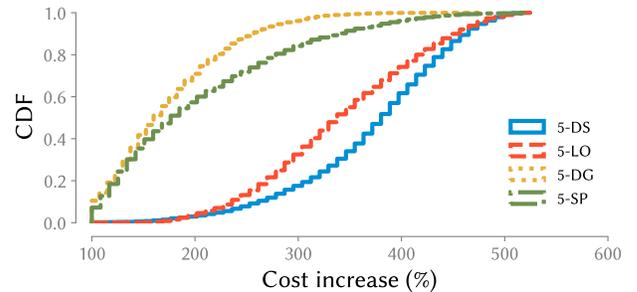

We evaluate probabilistic ICARUS using the same constellation, Starlink shell I, under the 4 routing schemes from § 5.1, with $k = 5$ paths, and uniform randomization across the paths. We present results for the empty network scenario, without any benign traffic, as it is the costliest for the adversary.

We target a maximum attack failure probability α of 10%, and measure the cost for the adversary in terms of the size of the attack set. A resilient routing scheme will force the adversary to incur higher attack cost for the same α , while vulnerable routing schemes will incur cost closer to the single shortest-path routing case. Following this intuition, we present attack costs for different routing schemes in comparison to the latter.

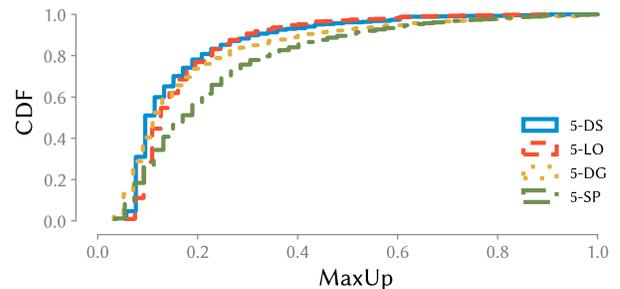

Fig. 5a and 5b show the attack cost for all 4 routing schemes, when the attacker optimizes for cost and for maxUp, respectively. Surprisingly, 5-DG and 5-SP perform similarly, even though they are very different: the former does not allow any overlap between paths for the same (s,d) -pair, while in the latter, path overlaps are not restricted at all. The commonality, however, is that the uncertainty in the forwarding path is low for both. In 5-SP, this is due to the lack of separation between the 5 absolute-shortest paths in the SN. In

(a) Cost CDF for the attacks, when executed with cost minimization. For maxUp, please refer to text in § 5.2.

(b) Cost CDF for the attacks, when executed with maxUp minimization. The cost increases significantly compared to the previous figure, to the benefit of maxUp (below).

(c) MaxUp CDF for the attacks, when executed for maxUp minimization.

Figure 5: Cost and maxUp of the attacks on all ISLs assuming different load-balancing strategies.

5-DG, on the other hand, the low uncertainty comes from the lack of alternatives: between many (s,d) -pairs, this scheme is overly restrictive and does not provide 5 paths. The adversary can use such (s,d) -pairs in the attack-flow set, effectively side-stepping routing uncertainty.

The most resilient scheme in terms of increasing the adversary's cost, is 5-DS. This scheme strikes a balance between avoiding path overlap and being flexible enough to maintain enough path options: enforcing disjointness between satellites is less limiting than ground-to-ground disjointness. The median cost increase compared to single shortest-path routing is 385% with 5-DS. The price of this resilience is increased latency — paths often incur more than $1.5 \times$ latency compared to the shortest path (Fig. 4 in the Supplemental materials).

Unfortunately, despite incurring a high latency cost, while

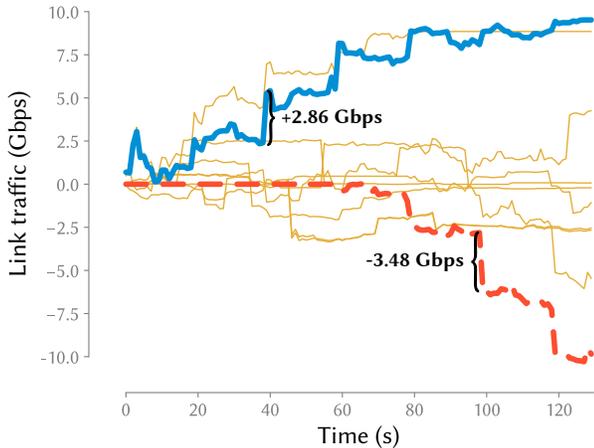

Figure 6: Load surges. The figure shows the link traffic over time of the 10 links with the largest load surges. The biggest positive (—) and negative (--) surges are also highlighted.

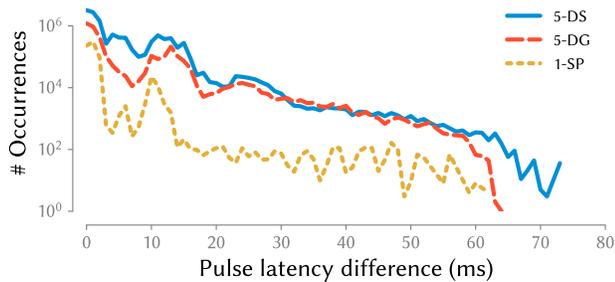

Figure 7: Feasibility of pulsing attacks.

the percent-increase in cost seems large (385%), in the absolute, this is still under 80 Gbps of attack traffic, and botnets with a few thousand bots (depending on per bot bandwidth) can still congest the median LSN link. Note also that this cost is in the most difficult setting, i.e., without any benign traffic, with the LSN accepting a large latency deterioration, and with the attacker seeking to absolutely minimize maxUp. Further, valuable links above land are easier to attack. Figure 2 in the Supplemental materials shows *where* the cost of the attack is highest across the network’s ISLs, with 5-DS. Attacking ISLs that are above land is easier because the adversary can always find a source-destination bot-pair for which there are few, or greatly overlapping paths (reducing uncertainty).

For maxUp, shown in Fig. 5c, 5-SP is the outlier, with higher maxUp than the other three schemes, for which results are similar. This is because other algorithms often have multiple uplinks available in the same load-balancing set, thus spreading the attack traffic and reducing its maxUp. In 5-SP, paths mostly overlap, and especially on the uplinks, preventing this effect.

6 Open problem: exploiting LSN dynamics

Thus far, the attacks we have presented consider only snapshots of the SN’s state, with the adversary drawing on the relative stability of the network on the timescale of seconds to

pre-compute attack flows. It is worth considering how/if the adversary may exploit the LSN’s dynamics as an additional opportunity, rather than a minor hindrance that requires per-computed, albeit frequent, changes in the attack-flow set. We discuss two potential opportunities of this type.

Load surges. The motion of satellites naturally moves ISLs across low- and high-utilization areas. As a result, the network’s links see large fluctuations in their utilization over time. Figure 6 shows how the load changes in time across the links with the biggest surges and drops over 130 seconds of simulation for the GDP traffic model. An adversary that knows or can reasonably guess the traffic matrix of the LSN can use these load surges to increase the effectiveness of low-volume attacks: well-timed bursts that coincide with the natural surges can cause high congestion, at a fraction of the cost. The effectiveness of such an attack depends on the the LSN’s protocol stack, e.g., how long does congestion control take to detect such short, transient congestion, and how does it react and recover? Addressing this requires packet-level analysis, and is left to future work.

Pulsing attacks. Another dynamic feature of an LSN is the time-varying latency of paths. Consider a bot that has a path to a destination, d , across a target link. Over time, this bot’s path to d changes, with some of these changes still traversing the target, but potentially over a higher- or lower-latency path, resulting from satellite motion. When the path changes from a higher latency one to a lower latency one, the adversary can potentially double the effective attack bandwidth of the bot: traffic sent on the first and the second path will traverse the target link *simultaneously* for a short time interval. This “pulsing attack” bears similarities to *temporal lensing* [55], with the important difference that temporal lensing uses *external* infrastructure like DNS to create a time difference between the forwarding paths, while in LSNs this is provided by the network’s inherent dynamics.

We briefly test the feasibility of pulsing attacks by running the following experiment:

1. At each time-step, we consider a target link, and compute all the paths across it.
2. We identify paths that will not be valid in the next time-step, and compute their replacement paths.
3. For each changed path, we compute the difference in latency from the source to the target link, between the original path and its replacement.

We run this procedure for all 6336 target links in a 130-sec simulation, and a time-step of 1 sec for evaluating changes. Figure 7 shows the results for a few routing schemes. For single shortest-path routing, achieving latency differences of tens of milliseconds across the path change is possible less than once per simulation second across the *entire* constellation. The multipath schemes increase this opportunity, but it is nevertheless small: even for the most favorable algorithm, 5-DS, there are only 8133 pulses with a duration above

50 ms. Since there are 6336 target ISLs, the adversary can benefit from little more than 1 pulse per ISL, on average, over the entire 130 sec of the simulation. Thus, while pulsing is possible in principle, its utility for an adversary is limited to occasionally impacting a small number of targets.

Future outlook. Our above analysis indicates positive potential for load surges, and a largely negative result for pulsing. Exploring other methods for an adversary to leverage LSN dynamism, as well as a deeper understanding of the impact of load surges, are left to future work.

7 Mitigations

We find that several traditional methods of addressing DDoS attacks are not applicable against ICARUS:

- *Overprovisioning* to absorb more than expected traffic is difficult: our model already accounts for ISLs having higher capacity than access links, and increasing ISL capacity or number will push against the cost, weight and power constraints of the satellites.
- *In-network filtering* [4, 26, 39, 42, 45, 54] requires computational resources, which are lacking at both the satellites and the TUs (TUs often need to be portable). More fundamentally, like Coremelt and Crossfire, attack traffic is indistinguishable from benign traffic. Therefore, even if satellites or TUs have the computational capabilities for filtering, it is unclear how they would distinguish malicious and benign traffic.
- *Capabilities* in the form of cryptographic tokens that provide access rights [2, 37, 38, 40, 52, 72] are not useful here either — the adversary compromises legitimate satellite-connected users to gain access to the LSN; thus inheriting these users' capabilities.
- *Cloud-based mitigations* [1, 16, 21, 24, 41, 51] offload the filtering of adversarial traffic to the cloud. Since TUs will often use the LSN as their last-mile provider, the burden of passing traffic through a cloud provider falls on the LSN, incurring additional bandwidth and latency overheads.

Thus, effective defenses against Coremelt and Crossfire—such as upgrading capacity or re-routing traffic to more capable networks—cannot be used to alleviate ICARUS' impact. In light of the above, we discuss two avenues that show promise towards neutralizing ICARUS.

Resilient routing and network design. Our experiments in § 5.2 show that resilient routing can greatly increase the attack's cost. While for our tested routing schemes, this comes at the expense of increased latency, we have only scratched the surface in exploring resilient routing; identifying routing schemes with the most favorable tradeoff curve remains an interesting direction for future work. Another possibility is to attack the problem using network topology design — Bhattacharjee et al. [10] have recently proposed to re-arrange ISLs, deviating from the traditional “cross” pattern, to improve forwarding latency. A similar strategy can be used in an

adversarial setting: altering the structure of the network can improve resilience to attacks with minimal impact on latency.

Traffic separation and differential pricing. In this work, we assume that all TUs are equally capable, and optimized for low-latency communication. It is foreseeable, however, that not all hosts will require such an optimization. This consideration opens up the opportunity of creating different classes of service, with a premium service offering the lowest latency and highest resilience, at the expense of shifting other traffic to longer, less predictable paths. It remains to be seen, however, whether this introduces enough randomness in forwarding to make the attacks too costly to perform, or if, instead, the higher resource usage caused by more circuitous paths *increases* vulnerability.

8 Other related work

We discuss related work not already covered in § 2 or § 7.

Attacks on satellite systems. The most commonly recognized threat to satellite communications on the physical layer is *jamming* [30, 49, 56]: the adversary uses high-power antennas to induce noise on up- and downlinks, preventing the endpoints from reaching the ingress satellite. ICARUS is however beyond detection by a jamming analyzer as it uses protocol-compliant traffic from authorized (albeit compromised) sources. GNSS spoofing is another well-understood threat, with a long list of attacks and mitigations [57]. More recently, the attention has shifted towards the security of cryptographic standards used in satellite communications [18], and lack thereof [50].

Network-layer denial of service on LSNs has been addressed, to the best of our knowledge, only recently by Usman et al. [67]. However, their focus is on traditional geostationary orbit satellite networks, using only bent-pipe connectivity through satellites, without any notion of ISLs. The authors thus focus on ping flooding to exhaust control plane resources at GS network devices. In contrast, our work examines a completely different setting with modern LSNs, analyzing an entirely different breed of attacks: congestion-causing volumetric DDoS attacks from distributed bots. To the best of our knowledge, we are the first to frame and study this problem.

Routing in satellite constellations. Given the dynamic nature of links in LSNs, many works focus on the challenges of discovering and disseminating network status information, and optimizing forwarding latency [14, 19, 20, 22, 23, 27, 43, 53, 68–71, 73]. Barrit et al. [6–8] bring software-defined networking (SDN) to LSNs, and introduce the Temporospatial-SDN. The SDN controller uses the predictability of satellite orbits to maintain an accurate view of the LSN's topology, and aid routing decisions. Despite this past work, the subject of optimizing routing for resilience against an ICARUS-like attacker remains an open question.

9 Conclusion

We present ICARUS, the first volumetric DDoS attack against next-generation LSNs. We demonstrate ICARUS's disruptive potential across a variety of scenarios, with different LSN routing schemes, and different attack targets. ICARUS's potency stems from leveraging several unique characteristics of LSNs, whereby the adversary operates with greater information than available for terrestrial networks, and exploits the topology and path structure of LSNs. ICARUS also turns the low-latency and global coverage objectives of LSNs into vulnerabilities. Nevertheless, successful attacks of such networks require careful limitation of cost and detectability (characterized with the maxUp metric), as ICARUS does. In addition, randomized multipath routing increases an adversary's cost, but as we experimentally show, ICARUS also succeeds in that setting. We hope that our first steps in understanding the vulnerability of LSNs to DDoS will seed the ground for further research on this topic. To this end, we release our simulation framework, which is the first tool for analyzing DDoS attacks and defences on LSNs. It allows easy testing of the resilience of arbitrary constellation configurations and novel path-selection algorithms.

Abstract

We present RAINBLOCK, a public blockchain that achieves high transaction throughput without modifying the proof-of-work consensus. The chief insight behind RAINBLOCK is that while consensus controls the rate at which new blocks are added to the blockchain, the number of transactions in each block is limited by I/O bottlenecks. Public blockchains like Ethereum keep the number of transactions in each block low so that all participating servers (miners) have enough time to process a block before the next block is created. By removing the I/O bottlenecks in transaction processing, RAINBLOCK allows miners to process more transactions in the same amount of time. RAINBLOCK makes two novel contributions: the RAINBLOCK architecture that removes I/O from the critical path of processing transactions (txs), and the distributed, multi-versioned DSM-TREE data structure that stores the system state efficiently. We evaluate RAINBLOCK using workloads based on public Ethereum traces (including smart contracts). We show that a single RAINBLOCK miner processes 27.4K txs per second (27× higher than a single Ethereum miner). In a geo-distributed setting with four regions spread across three continents, RAINBLOCK miners process 20K txs per second.

1 Introduction

Blockchains maintain the history of transactions as an immutable chain of blocks; each block has an ordered list of transactions, and is processed after its parent or previous block. Blockchains can be public, allowing untrusted servers to process transactions [1,2], or private, allowing only a few specific servers [17]. With their decentralized nature, fault tolerance, transparency, and auditability, public blockchains have led to several applications in a wide range of domains like cryptocurrencies [1,2,19], games [29], and healthcare [43].

In general, public blockchains work in the following manner. Servers participating in the blockchain, termed miners, receive transactions from users. Miners execute the transactions and package them up into blocks. A consensus protocol, like proof-of-work (PoW) [34], decides the next block to be added to the blockchain. With PoW, miners release a new block at a regular cadence (*e.g.*, every 10–12 seconds in Ethereum [2]).

Problem: Low throughput. Public blockchains suffer from low transaction throughput. Two popular public blockchains,

Metric	No state	State: 10M	Ratio
Time taken to mine txs (s)	1047	6340	6× ↑
# Tx per block	2150	833	2.5× ↓
Tx throughput (txs/s)	28.6	4.7	6× ↓

Table 1: Impact of system state on blockchain throughput. This table shows the throughput of Ethereum with proof-of-work consensus when 30K txs are mined using three miners, in two scenarios: first, there are no accounts on the blockchain, and in the second, 10M accounts have been added. Despite no other difference, tx throughput is 6× lower in the second scenario; we trace this to the I/O involved in processing txs.

Bitcoin [1] and Ethereum, process only tens of transactions per second, limiting their applications [33,65].

Prior work traces back the low throughput of blockchains to their proof-of-work (PoW) consensus. PoW limits the block creation rate so that miners have enough time to receive and process the previous block before the next block is created [59]. This ensures that most of the miners are building on the same previous block, preventing forks in the blockchain. Researchers have proposed new consensus protocols [5,30,31,42,46] to increase the transaction throughput.

Insight. We observe that while PoW limits the block creation rate, it *does not* limit the block size (number of transactions in each block). The block size is limited by the rate at which miners can process transactions (§2). Processing transactions involves executing a transaction and modifying the system state accordingly; this becomes more expensive as the state grows. Table 1 experimentally shows that when the number of accounts increases, block size reduces in Ethereum even with PoW consensus (only among three miners). The chief insight in this paper is that *if we could increase the rate at which transactions are processed, we could increase the block size safely, without modifying the PoW consensus protocol.*

How can we increase the block size safely? Miners will continue to release a block every 10–12s after proof-of-work; however, miners can pack more transactions into each block due to faster processing. Typically, increasing the block size increases the time taken to transmit that block, and time taken by miners to process the block. Previously, when Ethereum

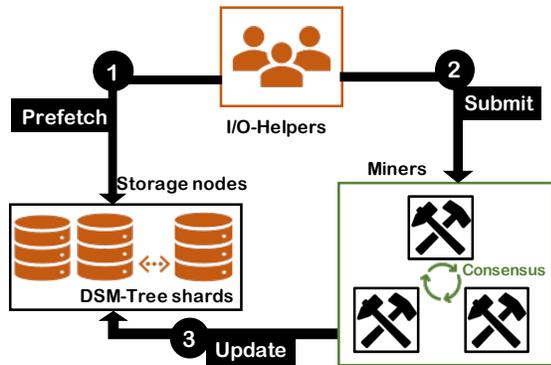

Figure 1: **RAINBLOCK architecture.** I/O-Helpers read data from in-memory storage nodes (out of the critical path) on behalf of the miners. Miners execute txs without performing I/O; storage nodes are updated asynchronously.

increased the maximum block size [21], it was observed that the time taken to propagate the block increased marginally, while the time taken to process transactions saw a significant increase [22]. Thus, if we can increase the rate at which transactions are processed, miners can pack more transactions into each block. Note that as proof-of-work is not modified, the safety properties will continue to hold. The block creation rate, and the transaction confirmation latency will remain the same. However, the rate at which transactions are confirmed will increase as there will be more transactions in each block.

Approach: reducing I/O bottlenecks in tx processing. This work takes the novel approach of increasing tx throughput by tackling I/O bottlenecks in tx processing. Processing a transaction involves executing the transaction and verifying that the execution result is valid. In Ethereum, both execution and verification require reading and writing system state that is stored in a Merkle tree [11,44] on local storage. Tx processing is bottlenecked by I/O: for example, processing a single block of 100 txs in Ethereum requires performing more than 10K random I/O operations (100× higher) and takes hundreds of milliseconds even on a datacenter-grade NVMe SSD (§2).

These I/O bottlenecks arise from two sources. First, the Merkle tree is serialized and stored in a RocksDB [10] key-value store. As a result, traversing the Merkle tree requires multiple, expensive RocksDB reads [53]. Second, Ethereum miners process txs one by one in the critical path; this reduces parallelism and allows I/O bottlenecks to limit the tx throughput. These I/O bottlenecks are an intrinsic part of how Ethereum (and more generally, public blockchains that use Merkle trees) are designed [54]; merely upgrading to faster storage (or even holding all state in memory) will not resolve these problems. By removing these I/O bottlenecks, this work accelerates tx processing, and allows miners to pack more txs in each block, and thereby increases the overall throughput.

This work. This paper presents RAINBLOCK, a new architec-

ture for building public blockchains, that increases the overall throughput with faster transaction processing. RAINBLOCK tackles I/O bottlenecks by designing a custom storage solution for blockchains; at the heart of this storage is a novel data structure, the Distributed, Sharded Merkle Tree (DSM-TREE). The DSM-TREE stores data in a multi-versioned fashion across shards, and allows concurrent reads and writes. DSM-TREE eliminates the inherent serialization from using key-value stores like RocksDB. RAINBLOCK deconstructs miners into three entities: storage nodes that store data, miners that process txs, and I/O-Helpers that fetch data and proofs from storage nodes and provide them to miners, as shown in Figure 1. By having I/O-Helpers prefetch data on behalf of miners, I/O is removed from the critical path of tx processing; moreover, multiple I/O-Helpers can prefetch data at the same time.

Challenges. The RAINBLOCK architecture has to solve several challenges to be effective. For example, Ethereum considered using stateless clients [24] with separate storage nodes; proofs that validate the data sent (termed witnesses) are included in the blocks. The size of these blocks that must be sent over the network made the scheme impractical [25,27], and the proposal was abandoned [57]. RAINBLOCK handles this by co-designing the storage nodes and caches at the miners, minimizing the data sent over the network. A second challenge is prefetching data for Turing-complete smart contracts [56]. As smart contracts can execute arbitrary code, it is not straightforward for the I/O-Helpers to prefetch all the required data. RAINBLOCK solves this by having I/O-Helpers *speculatively pre-execute* the transaction to obtain data and proofs. A third related challenge is that I/O-Helpers may submit stale proofs to the miners (miners may update storage after I/O-Helpers finish reading). RAINBLOCK handles this by having miners tolerate stale proofs whenever possible, via *witness revision*, allowing transactions that would otherwise abort to execute.

Implementation. We implement the RAINBLOCK prototype using Ethereum. We chose Ethereum as our implementation base and comparison point for two reasons. First, Ethereum has been operating as a public blockchain for nearly six years, providing large amounts of data to test our assumptions. Second, Ethereum supports Turing-complete smart contracts, allowing the codification of complex decentralized applications.

Security and Trust. Ethereum has increased the block size in the past [14], without triggering any negative events such as increased forks [16]. RAINBLOCK does the exact same thing, without changing the PoW consensus or block creation rate; as a result, RAINBLOCK inherits the security guarantees of Ethereum. RAINBLOCK introduces storage nodes and I/O-Helpers; however, neither storage nodes, nor I/O-Helpers, nor miners, trust each other. All data exchanged between these entities is authenticated using Merkle trees and can be verified. As a result, the new architecture of RAINBLOCK, while certainly increasing the complexity of the system, does not change its core security or trust assumptions (§3.6).

Evaluation. To evaluate RAINBLOCK, we generate synthetic workloads that mirror transactions on Ethereum mainnet. We analyzed Ethereum transactions and observed that user accounts involved in transactions have a Zipfian distribution: 90% of transactions involve the same 10% of user accounts. We observed that only 10–15% of Ethereum transactions invoke smart contracts. We build a workload generator that faithfully reproduces these distributions. We evaluate RAINBLOCK using these workloads and observe that a single RAINBLOCK miner processes $27\times$ more transactions than an Ethereum miner; we provide a breakdown of the performance difference (§6). When the RAINBLOCK miners are geo-distributed across three continents (thus incurring significant network latency), RAINBLOCK throughput reduces only by 20% compared to a single miner, achieving 20K transactions per second. Since RAINBLOCK has the same proof-of-work consensus and block creation rate as Ethereum, RAINBLOCK finalizes $20\times$ more transactions (with the same latency) as Ethereum. In summary, this paper makes the following contributions:

- The novel RAINBLOCK architecture (§3)
- The novel DSM-TREE authenticated data structure (§4)
- Empirical evidence that throughput in public blockchains can be increased without modifying PoW consensus (§6)

2 Background and Motivation

We provide some background on public blockchains and detail the I/O bottlenecks in transaction processing.

2.1 Public Blockchains and Ethereum

Blockchains are decentralized databases with support for transactions (txs). Blockchains log these txs as a chain of blocks; every block stores an ordered list of txs along with the cryptographic hash of its previous block (parent). Private blockchains allow specific servers to extend the blockchains, while public blockchains allow anyone to participate. As a result, all participating servers in public blockchains are untrusted; any of them can be malicious. Public blockchains depend on the non-malicious majority for correct behavior.

How do public blockchains work? We use Ethereum, a popular public blockchain, as reference. Servers that attempt to add a new block to the blockchain are termed *miners*. Miners receive txs submitted by users, execute these txs, and group them into a block. We term executing txs and grouping into a block as *processing txs*. Several miners compete to add a block to the blockchain. Each miner tries to solve a proof-of-work (PoW) puzzle; the miner that solves the puzzle attaches the solution and broadcasts its block to other miners. Other miners verify the PoW solution and the txs in the block, and build on top of the block. A tx is *confirmed* or *finalized* once ten blocks are built on top of the block containing the tx.

Typically, a miner has two threads as shown in Figure 2. The worker thread executes and groups txs into a partial block.

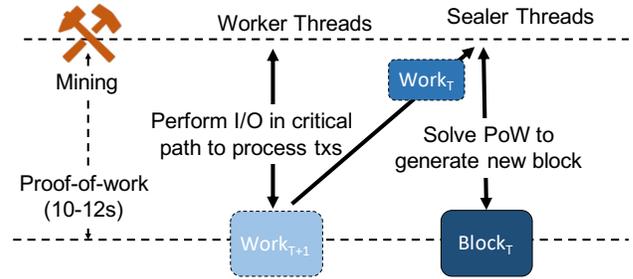

Figure 2: **How Ethereum miners work.** The worker thread processes txs, packages them into a future/partial block, and hands them to the sealer thread. The sealer thread solves the PoW puzzle (in 10–12s), and propose a new block; the worker thread must process txs in this time-frame. I/O bottlenecks result in worker threads packing fewer txs into each block.

The sealer thread obtains the partial block from the worker, and then tries to solve the PoW puzzle; PoW consensus has miners emitting a block every 10–12s, for example. While the sealer thread is working on one block, the worker thread tries to get the next block ready. Thus, the worker has about 10–12s to process txs; if it can process txs faster, it can pack more txs into the partial block that it passes to the sealer.

2.2 Problem: Low throughput

Ethereum and other public blockchains suffer from low throughput: only tens of txs are added to the blockchain per second. The low throughput comes from two factors. First, the PoW consensus limits the block creation rate to one block every 10–12s so that a majority of miners can receive and process a block before a new one is released; this ensures that every miner is building on the same previous block, preventing forks in the blockchain. Note that while PoW consensus limits the block creation rate, it doesn’t directly limit the size of the block. The factor limiting the block size is tx processing time: the rate at which the worker thread can process txs limits the maximum size of the block, as shown in Figure 2.

Tx processing. Processing a tx involves executing the tx and modifying the system state like account values. Since miners do not trust each other in a public blockchain, miners *authenticate data* and can prove that the data they provide is correct. This is done by maintaining a Merkle tree [44] over the data and publishing the latest Merkle root in the blocks; another miner is able to independently execute txs in a block and verify that its local Merkle root matches the root in the block. An account value and its vertical path in the Merkle tree (termed a *witness*) are sufficient to verify the correctness of that value.

Unfortunately, *accessing and authenticating data becomes more expensive as the total size of the data increases* [64]. As a result, tx processing increasingly becomes bottlenecked on I/O. We demonstrate this with an experiment. We create two private Ethereum networks using the Geth client [13];

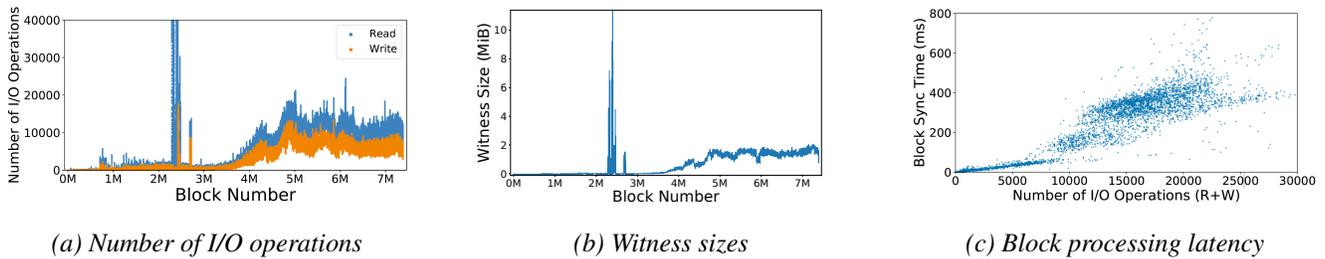

Figure 3: **I/O bottlenecks in processing Ethereum txs.** The increasing system state increases (a) the number of I/O operations performed per block, and (b) the amount of authenticated data accessed (Merkle witnesses) per block. Further, (c) the direct correlation between the block processing time and the number of I/O operations highlights the I/O bottleneck. Spikes in (a) I/O operations and (b) witness sizes are due to a DDOS attack that targeted the system state [64] by creating dummy user accounts.

each network has three miners, 30K txs to mine, and the same proof-of-work (PoW) configurations. While the first network has only 3 miner accounts (total size: 220 MB), the second has 10M additional accounts (total size: 4 GB). Note that Ethereum currently has $\approx 130M$ accounts (total size: > 400 GB [12, 15]) in its blockchain state. Overall, the second network takes $6\times$ more time and $2.5\times$ more blocks to mine all txs using PoW consensus (Table 1). Using profilers, we see that in the second scenario, the time spent solving the PoW puzzle has increased proportionately; however, the worker thread takes $6\times$ more time to process txs, and 69% of this time is spent in accessing and updating the authenticated system state. Thus, miner’s tx processing rate depends on the system state; this impacts the block size and overall throughput. Ethereum uses the modified Merkle Patricia Trie [11] to authenticate the state, we refer to it as the Merkle tree.

Empirical Study. We now study the I/O overheads observed on the Ethereum public blockchain. We use the Parity 2.2.11 client [8] to initialize a new server that joins the Ethereum network, and replays the blockchain (until 7.3 million blocks) to measure various costs. Since we want to observe the historical I/O cost, we do not mine new blocks; rather, we replay the blockchain and execute transactions in blocks that have already been added, termed syncing. The I/O cost remains the same as when mining the block for the first time.

Reading Eth. accounts results in multiple I/O operations. For processing a single block with around 100 transactions, Ethereum performs more than 10K random I/O operations (two orders of difference). Most of these I/O operations are performed for reading and updating user accounts in the Merkle tree. Figure 3(a) shows the number of I/O operations incurred in each block while processing txs, till 7.3 M blocks.

Data authentication causes significant I/O overhead. A witness is the vertical path in the Merkle tree required to verify a data item. Witness sizes represent the amount of data read and modified per block while reading and updating paths in the Merkle tree. In Ethereum, which uses secure 256-bit cryptographic hashes, the witness size of a single 100 byte

user account (or value) can be above 4 KB, resulting in $40\text{--}60\times$ overhead. The witness size also increases as the total data in the Ethereum state increases, as shown in Figure 3(b).

Tx processing is bottlenecked by I/O. We measure the time taken to process (or sync) each block: executing the txs in that block, and verifying if the resultant local Merkle root matches with the Merkle root in that block. Processing an Ethereum block with about 100 txs takes hundreds of milliseconds even on a datacenter-grade NVMe SSD. Figure 3(c) shows the direct correlation between the time taken to process Ethereum blocks and the number of I/O operations performed, indicating that tx processing in Ethereum has I/O bottlenecks.

Summary. The I/O bottlenecks stem from storing the Merkle tree in an LSM-based [49] key-value store like RocksDB [10] that has inherent I/O amplification [52, 53]; Merkle nodes are indexed with their hash, randomizing node locations on disk.

2.3 Straw-man solutions

We consider some straw-man solutions and discuss why they are not suitable for handling I/O bottlenecks in tx processing.

Storing entire system state in memory. Public blockchains like Ethereum do not want to place restrictions on the hardware specifications of miners. If every miner is required to hold the entire authenticated state in memory, only machines with large amounts of DRAM would be able to process transactions. This solution breaks one of the central tenets of Ethereum that contributes to the decentralization of its miners.

Increasing block size. Increasing the block size is the goal of this work; however, doing this naively would not work. If we simply increased the number of txs in each block, miners receiving the block would need more time to process the large block and build on top of it. As a result, the block creation rate would have to be lowered to ensure that previous block is processed by a majority of the miners before a new block is released. Overall, tx throughput would not increase though the block size increased. Over time, I/O bottlenecks exacerbate with the increasing state size, and new servers will take longer to sync and participate in mining. This weakens decen-

tralization. Thus, tackling I/O bottlenecks is crucial to safely increasing block size, and maintaining decentralization.

Alternative consensus protocols. Faster consensus protocols would result in blocks being released quicker, increasing the overall throughput. The goal in this work is to increase throughput *without* changing the consensus, and thus is orthogonal to the work on new consensus protocols. Researchers have noticed that even with faster consensus, blockchains ultimately run into the I/O bottlenecks in tx processing [67].

Thus, we need a mechanism to reduce the I/O bottlenecks in transaction processing. RAINBLOCK achieves this goal with a new architecture and a novel authenticated data structure, the DSM-TREE. With faster transaction processing, RAINBLOCK enables larger blocks and maintains decentralization, *without* changing the PoW consensus or the block creation rate.

3 RainBlock

RAINBLOCK is a public blockchain based on Ethereum that increases overall throughput with faster transaction processing. RAINBLOCK minimizes the I/O bottlenecks in transaction processing, allows miners to safely pack more transactions into each block, and thereby increases the overall throughput.

3.1 Overview

RAINBLOCK minimizes I/O bottlenecks using two techniques. First, it makes each I/O operation cheaper by storing system state in the novel DSM-TREE. In contrast to Ethereum, which accesses data from the RocksDB key-value store on SSDs (where each RocksDB get operation takes between a few hundred microseconds to a few milliseconds), RAINBLOCK stores the system state in memory using the DSM-TREE. DSM-TREE is a sharded, multi-versioned, in-memory authenticated data structure. Second, RAINBLOCK introduces a new architecture that removes I/O from the critical path. RAINBLOCK deconstructs miners into three entities: storage nodes, miners, and I/O-Helpers that read data from storage and submit to miners. In the common case, miners can process txs without performing I/O. Neither miners, nor storage nodes, nor I/O-Helpers trust each other: all data supplied by other entities is verified using Merkle witnesses before use.

RAINBLOCK differs from Ethereum in exactly two aspects: 1) miners are replaced by storage nodes, miners, and I/O-Helpers, and 2) the RocksDB-based storage is replaced with DSM-Tree. Everything else, like the proof-of-work consensus and the block creation rate, remains the same.

3.2 Building up the design step by step

In this section, we start with the problems that our study on Ethereum highlights. We discuss how RAINBLOCK solves these problems and addresses the resulting challenges.

Problem-I: storing authenticated state in key-value stores leads to expensive I/O. Ethereum stores system state in a Merkle tree [11], which is stored in the RocksDB [10] key-value store. Traversing such a Merkle tree requires looking

up nodes using their hashes. Hashing is computationally expensive and results in the nodes of the tree being distributed to random locations on storage. As a result, traversing the Merkle tree to read a leaf value requires several random read operations. Further, the log-structured merge tree [47] that underlies RocksDB results in high I/O amplification [52, 53].

Solution: store state in an optimized in-memory representation. RAINBLOCK introduces an in-memory version of the Merkle tree. Persisting the data is done via a write-ahead log and checkpoints. Traversing the Merkle tree is *decoupled* from hashing; obtaining the next node in the tree is a simple pointer dereference (§4). Note that simply running RocksDB in memory would not be effective, as serializing and hashing Merkle nodes would still add significant overhead.

Resulting challenge: scalability and decentralization. As the blockchain grows, the amount of state in the Merkle tree will increase; soon, a single server's DRAM will not be sufficient. Furthermore, for maintaining decentralization, we cannot require miners participating in the blockchain to have significant amounts of DRAM.

Solution: decouple storage from miners and shard the state. RAINBLOCK solves this problem using separate storage nodes, each of which is a commodity server. RAINBLOCK shards the Merkle tree into subtrees such that each subtree fits in the memory of a storage node. As the amount of data in the state increases, RAINBLOCK increases the number of shards. In this manner, RAINBLOCK scales with commodity miners and storage nodes without reducing the decentralization.

Problem-II: Miners perform slow I/O in the critical path. Transaction processing in Ethereum includes performing slow I/O operations in the critical path, and these transactions are processed one at a time.

Solution: decouple I/O and transaction execution. RAINBLOCK solves this problem by removing the burden of doing I/O from the miners. RAINBLOCK introduces I/O-Helpers that prefetch data and witnesses from the storage nodes and submit them to the miners. Miners use this information to execute transactions without performing I/O and asynchronously update the storage nodes. This architecture also increases parallelism as multiple I/O-Helpers can be prefetching data for different transactions at the same time.

Resulting challenge: Prefetching I/O for smart contracts. One challenge with I/O-Helpers prefetching data is that some transactions invoke smart contracts. Smart contracts are Turing-complete programs that may execute arbitrary code. Thus, how does the I/O-Helper know what data to prefetch?

Solution: pre-execute transactions to get their read and write sets. RAINBLOCK solves this problem by having the I/O-Helpers pre-execute txs. As part of this pre-execution, I/O-Helpers read data and witnesses from the storage nodes. One challenge is that the pre-execution may have different results than when the miner executes the tx (*e.g.*, the smart contract

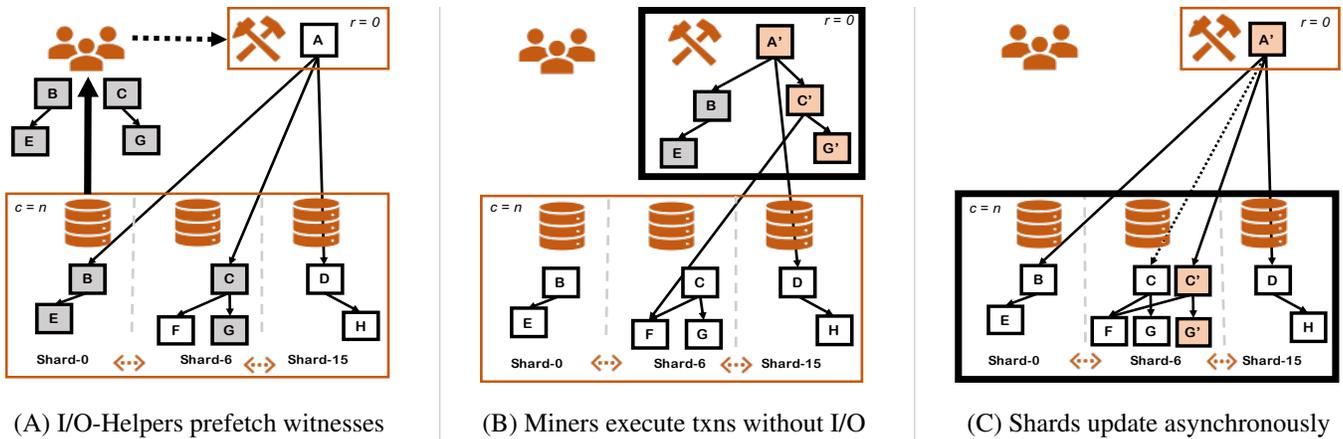

Figure 4: **RAINBLOCK architecture.** This figure shows how RAINBLOCK processes a transaction that reads and updates accounts in two different shards that are along the paths ABE and ACG . (A) I/O-Helpers prefetch witnesses BE and CG from storage nodes and submit them to the miners. (B) Miners verify the witnesses and use them to execute the transaction against their top layer of the DSM-TREE. Then, miners update the storage nodes. (C) Storage nodes verify updates from miners and asynchronously update their bottom layer, creating a new version of the modified Merkle nodes $A'C'G'$. Here, miners retain only the root node of the DSM-TREE ($r = 0$), and the storage nodes send full un-compacted witnesses ($c = n$ or $c = \infty$).

may execute different code based on the block it appears in). We will describe how I/O-Helpers handle smart contracts correctly despite stale data from pre-execution (§3.4).

Resulting challenge: Consistency in the face of concurrency. Another challenge that arises from decoupling I/O from transaction execution is consistency. Multiple I/O-Helpers are reading from the storage nodes, and multiple miners are updating them in parallel. Using locks or other similar mechanisms will reduce concurrency and throughput.

Solution: using the two-layered, multi-versioned DSM-TREE. RAINBLOCK uses DSM-TREE to store the system state. The DSM-TREE has two layers: the *bottom layer* is sharded across the storage nodes and contains multiple versions. Every write causes a new version to be created in a copy-on-write manner; there are no in-place updates. As a result, concurrent updates from miners simply create new versions and do not conflict with each other. Further, each miner uses a DSM-TREE *top layer*: a private, writeable, consistent snapshot of the data, that reflects the miner’s latest version.

Resulting challenge: RAINBLOCK has higher network traffic. Finally, the architecture of RAINBLOCK trades local disk I/O for remote network I/O. As a result, RAINBLOCK results in more network utilization, and the network bandwidth may become the bottleneck.

Solution: RAINBLOCK reduces network I/O via deduplication and the synergy between the DSM-TREE layers. RAINBLOCK uses multiple optimizations to reduce network I/O. First, the bottom and top layer of DSM-TREE collaborate with each other to reduce network traffic. Second, when any component of RAINBLOCK sends witnesses over the network, it

will batch witnesses and perform deduplication to ensure only a single copy of each Merkle tree node is sent. Finally, miners send logical updates to storage nodes rather than physical updates as logical updates are smaller in size.

3.3 Architecture

RAINBLOCK introduces three kinds of participating entities: I/O-Helpers, miners, and storage nodes. Users send txs to I/O-Helpers, which pre-execute these txs and prefetch data and witnesses from storage nodes. Figure 4(a) shows how I/O-Helpers submit txs and the prefetched information to miners. Miners are responsible for creating new blocks of transactions and extending the blockchain; each miner maintains a private DSM-TREE top layer. Figure 4(b) shows how miners use the submitted information to execute these transactions without performing I/O. Finally, miners create a new block, gossip it to other miners, and update the storage nodes. Storage nodes are responsible for maintaining and serving the system state. They use the multi-versioned bottom layer of the DSM-TREE to provide consistent data to I/O-Helpers while handling concurrent updates from miners. Figure 4(c) shows how the miners asynchronously update the bottom layer of the DSM-TREE at the storage nodes.

3.4 Speculative Pre-Execution

I/O-Helpers read all the witnesses required for executing a tx from storage nodes. While this is straight-forward for simple txs, how do I/O-Helpers handle Turing-complete smart contracts that may access arbitrary locations? I/O-Helpers handle this by *speculatively* pre-executing the smart contract to obtain the read and write set.

However, smart contracts can use the timestamp, or block

number of the block in which they appear, during their execution at the miner. These values are not yet known during their pre-execution at the I/O-Helpers. I/O-Helpers speculatively return an estimated value while pre-executing the contract.

Our analysis of Ethereum contracts shows that despite providing estimated values, I/O-Helpers still successfully prefetch the correct witnesses and node bags. For example, the `CryptoKitties mixGenes` function references the current block number and its hash. Since these numbers only affect written values (and not the read set), substituting approximate values does not affect the witnesses that are prefetched.

We observe that I/O-Helpers can pre-execute with *stale* data and still prefetch the correct witnesses. For example, many contracts are *fixed-address* contracts: their behavior depends only on call inputs. To deal with rare *variable-address* contracts, the miner may asynchronously read from storage nodes after the transaction is submitted. Even in these cases, the I/O-Helper will have retrieved some of the correct witnesses required for the tx (e.g., the `to` and `from` accounts).

3.5 Life of a Transaction in RAINBLOCK

We outline the various actions that take place from the time a tx is submitted, to when it becomes a part of the blockchain.

1. I/O-Helper pre-executes the transaction by fetching data and witnesses from the storage nodes
2. I/O-Helper batches and deduplicates Merkle nodes across multiple witnesses and sends these optimized witnesses (termed node bags), txs, and data, to the miner
3. Miner verifies the node bags and advertises them to others.
4. Miner executes the tx using its top layer and the node bags, without any I/O; miner caches all Merkle nodes it reads or revises from these node bags in its top layer
5. Miner, on solving PoW, creates and advertises a new block to other miners; miner also sends the block (with a new Merkle root) and the logical updates to the storage nodes
6. Storage nodes first validate the block (check if PoW solution in the block solves the puzzle), and then persist the logical updates and return successful to the miner.
7. Storage nodes apply the updates asynchronously, and check if their Merkle root matches the root in the block
8. Other miners validate the block and gossip it to others. Then miners execute its txs using node bags, and accept the block by mining new blocks on top of this block
9. Once a majority of the miners receive, validate, and accept the block, the tx becomes part of the blockchain
10. Once ten or more blocks are mined on this block, the tx is confirmed; storage nodes garbage collect the associated versions from the unconfirmed, competing blocks

3.6 Discussion

We note that RAINBLOCK differs from Ethereum in only two aspects: its architecture and its storage. We discuss how these affect trust, incentives, and security, and discuss the trade-offs.

Trust assumptions. RAINBLOCK does not require trust between any of its components. Miners operate without trusting I/O-Helpers or the storage nodes, as miners re-execute transactions and verify the data they receive from I/O-Helpers; I/O-Helpers verify the data they read from storage nodes; and storage nodes verify new blocks and updates from miners.

Incentives. RAINBLOCK shares elements of its architecture with the Ethereum stateless clients proposal [24] that received community support. The central question is how are the storage nodes incentivized to store and serve the latest system state? We propose a model where I/O-Helpers or users pay storage nodes; stateless clients proposal had a similar solution where users pay storage nodes for access to state via state channels. I/O-Helpers or users can always detect if the data served by storage nodes is incorrect or stale, and penalize any malicious shards. We also believe an ecosystem will develop around RAINBLOCK architecture, with commercial entities offering active storage backups; market economics drives these backups to provide and maintain the latest system state with high availability. Note that I/O-Helpers are an optimization and users can prefetch data themselves if required, or pay the I/O-Helpers. Finally, RAINBLOCK miners behave similar to the miners in Ethereum, and are incentivized to process txs via block rewards. Miners are incentivized to broadcast correct updates to storage nodes to aid the acceptance of their fork. Thus, we outline a few ways to incentivize RAINBLOCK components and leave the full solution to future work.

Security. RAINBLOCK provides similar security guarantees as Ethereum, as it does not change the proof-of-work consensus or trust assumptions between participating servers. RAINBLOCK does not impact the block creation rate, as it packs more transactions per block without changing the total time taken to process a block of transactions.

Availability and DDoS attacks. RAINBLOCK decouples storage from miners and has separate storage nodes. RAINBLOCK requires only one replica of each storage shard to be available for making progress. While DDoS attacks can be mounted on storage nodes in RAINBLOCK, they are not new, cannot tamper with the data, and do not impact the correctness of RAINBLOCK; DDoS attacks are also possible on Ethereum and have been successfully executed in the past [60, 64].

Trade-offs. RAINBLOCK introduces new storage nodes and I/O-Helpers; while this adds more complexity into the system, Ethereum was already considering adding storage nodes and stateless clients. Thus, we believe the additional complexity of RAINBLOCK is a good trade-off for its scalability and performance benefits. RAINBLOCK trades off local storage I/O for accessing memory over network, so the network may be

come a bottleneck. RAINBLOCK recognizes this risk and uses multiple techniques like utilizing the memory available at the miners to cache the top layer of the DSM-TREE, and performing witness compaction and deduplication to reduce network traffic (§4.3). Although RAINBLOCK uses extra resources for separate storage nodes, storage nodes are shared across miners, amortizing the costs. I/O-Helpers also use extra resources; however, they are a performance optimization and can execute read-only txs without involving the miners. If users judge I/O-Helpers not useful, users can prefetch from storage nodes, or turn off prefetching, causing miners to perform I/O.

RAINBLOCK adoption. RAINBLOCK can be deployed incrementally in principle. While RAINBLOCK miners rely on storage nodes and I/O-helpers, other miners can use their local RocksDB-based storage, as the two would be compatible.

4 DSM-Tree

RAINBLOCK stores the system state in the DSM-TREE data structure. The Distributed, Sharded Merkle Tree (DSM-TREE) is an in-memory, multi-versioned, sharded, two-layer variant of the Merkle tree. We first present the in-memory representation of the two layers, then describe each layer in detail, and then discuss how the layers collaborate and their trade-offs in different configurations.

In-Memory Representation. DSM-TREE builds the Merkle tree in memory using pointers. Tree traversal is decoupled from hashing and node serializations: traversing the DSM-TREE requires dereferencing pointers to the next Merkle node; in contrast, Ethereum’s Merkle tree reads a Merkle node from RocksDB using its hash, and then deserializes the node to find the cryptographic hash of the next node. DSM-TREE uses periodic checkpoints for persisting the data. The checkpoints are only used to reconstruct the in-memory data structure in case of failures; reads are always served from memory.

Lazy Hash Resolution. When a leaf node in a Merkle tree is updated, hashes of nodes from the leaf to the root need to be recomputed. Recomputing hashes is expensive as nodes have to be serialized before being hashed. DSM-TREE defers this recomputation; on writes, only the leaf nodes are updated; on a subsequent read, all the modified nodes are rehashed exactly once. Thus, lazy hash resolution improves performance significantly by reducing the number of expensive node hashes and RLP (Recursive Length Prefix) serializations [9].

4.1 Bottom Layer

The bottom layer consists of a number of shards. Each shard is a vertical subtree of the Merkle tree, stored in DRAM. The bottom layer supports multiple versions to allow concurrent updates, as shown in Figure 5. The bottom layer has a write-ahead log to persist logical updates.

Multi-versioning. Each write to the bottom layer creates a new logical version of the tree, in a copy-on-write manner. There are no in-place updates. This versioning is required as

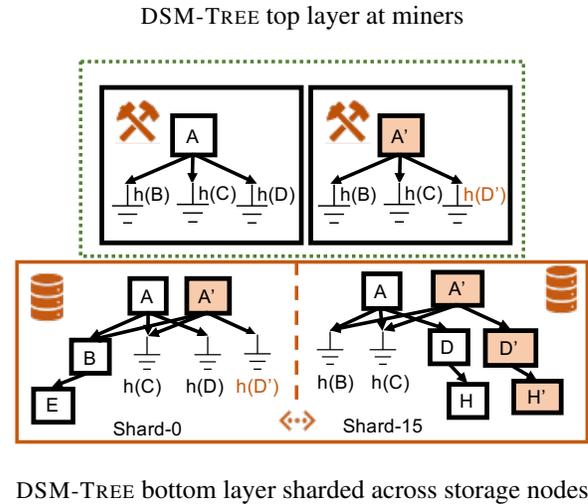

Figure 5: **DSM-TREE design in RAINBLOCK.** This figure shows the two-layered DSM-TREE where miners have their private copy of the top layer for consistency and the bottom layer is sharded for scalability. $h(C)$ is a hash node for C .

miners may submit multiple blocks concurrently that potentially conflict with each other; the bottom layer creates a new version for each write. Thus, writes never conflict with each other, and DSM-TREE does not require locking or additional coordination among miners or I/O-Helpers.

Sharding. Each subtree at the root node of the Merkle tree is a shard; root node in the modified Merkle Patricia Trie has 16 children, so DSM-TREE has 16 shards by default. Moreover, individual subtrees in each shard can further be partitioned, allowing shards to increase with the increasing system state.

Garbage collection. Garbage collection of versions is driven by the higher-level blockchain semantics. When multiple miners are working on competing forks of the blockchain, multiple versions are maintained. Eventually, one of the forks is confirmed and accepted as the mainline fork, and the others are discarded; associated versions from discarded blocks are garbage collected by the bottom layer of the DSM-TREE.

4.2 Top Layer

Given that the bottom layer maintains multiple versions across multiple shards, what data should be read by the miners? To resolve this question, miners use the top layer. Each miner has a private top layer, that represents a consistent, writeable snapshot of the system state; it contains the first few levels of the Merkle tree, till a configurable retention level (r), and has the Merkle root node that summarizes a consistent snapshot of the entire system state. When a miner executes transactions, all reads return values from this snapshot of the system.

As a miner executes txs, their top layer is updated, switching to another consistent view of the state as shown in Figure 5. The miner asynchronously updates the bottom layer’s shards.

Caching and Pruning. The top layer acts as an in-memory cache of witnesses for the miner. By design, the top layer stores the recently used and the frequently changing parts of the Merkle tree. When the miner receives witness from I/O-Helpers, the top layer uses the witnesses to reconstruct a *partial* Merkle tree that allows miners to execute transactions, typically without performing I/O. The top layer also supports pruning the partial Merkle tree to help miners reclaim memory. Pruning replaces the nodes at the retention level ($r + 1$) with *Hash nodes*. Hash nodes are placeholders that help miners to identify the DSM-TREE shard which has the pruned nodes.

Witness Revision. The bottom layer of the DSM-TREE is updated asynchronously by miners. As a result, the top layer (miner) may receive stale witnesses from the bottom layer (via I/O-Helpers). We introduce a new technique termed *witness revision* to tolerate stale witnesses. A witness is determined to be stale or incorrect because the Merkle root in the witness doesn't match the top layer's Merkle root. However, this could happen because of an *unrelated update* to another part of the Merkle tree. For example, the top layer might contain one vertical path; a different vertical path might have been updated. The top layer detects when this happens, and *revises* the witness to make it current by applying updates to the witness that are known to the miner. If the Merkle root matches now, then the witness is accepted. Witness revision is similar to doing `git push` (trying to upload your changes), finding out something else in the repository has changed, doing a `git pull` (obtaining the changes in the repository) to merge changes, and then doing a `git push`. With witness revision, the top layer tolerates stale data from the bottom layer and allows miners to execute non-conflicting transactions that would otherwise get rejected. Note that, witness revision cannot revise every potential stale witnesses. If the top layers are pruned aggressively, they may have insufficient information to detect if the changes are from an unrelated part of the Merkle tree.

4.3 Synergy between the layers

The top and bottom layers collaborate to reduce network traffic. We also briefly discuss the potential DSM-TREE configurations with r (retention at the top layer) and c (compaction level at the bottom layer), and the tradeoffs involved.

Witness compaction. As the top layer of the DSM-TREE stores the top levels of the Merkle tree, the storage nodes need not send a full witness. Like the configurable retention level at the top layer r , the bottom layer has a configurable compaction level, c . If witnesses are larger than c , witnesses are compacted by removing the top few Merkle nodes, and are sent over the network. In addition, multiple witnesses are batched and Merkle nodes are deduplicated (node bagging), further reducing the network burden of transmitting witnesses.

Configurations. The DSM-TREE can be configured to operate entirely from local memory without any network overhead, or just from remote memory with high network utilization. For

example, if the top layer of the DSM-TREE has $r = \infty$, then the top layer caches the entire Merkle tree and is fully served from local memory. Similarly, if the bottom layer has $c = n$ or $c = \infty$, then un-compacted witnesses are sent over the network and accessed entirely from remote memory, as shown in the Figure 4. These parameters (r and c) can be tuned based on the available memory and network capacity.

Tradeoffs. In a Merkle tree that has n levels, any DSM-TREE configuration that satisfies $c \geq (n - r)$ allows the top layer to use compacted witnesses from the bottom layer. Note that having a higher r results in a lower number of transaction aborts, as the top layer has more information to detect non-conflicting updates and perform witness revision. The top layers should therefore set r based on the amount of memory available. Pruning the top layer should only be done under memory pressure.

4.4 Summary

The DSM-TREE is a novel variant of the Merkle tree, modified for faster transaction processing in public blockchains. DSM-TREE presents a new point in the design space of authenticated data structures. DSM-TREE highlights the benefits of in-memory pointer-based tree traversals in comparison to using node hashes and RocksDB lookups. The top layer exploits the cache-friendliness of the Merkle tree (top nodes are frequently read and updated), while the sharded bottom layer relies on the fact that witness creation only requires a vertical slice of the tree. DSM-TREE top layer uses witness revision to handle stale data from concurrent updates. While the DSM-TREE supports transactions and is exclusively used with RAINBLOCK in this paper, it can be easily modified to work with other blockchains and applications.

5 Implementation

We implement RAINBLOCK and DSM-TREE in Typescript, targeting `node.js`. Miners and storage nodes use the DSM-TREE library¹. The performance critical portions of the code, such as `secp256k1` key functions for signing transactions and generating `keccak` hashes, are written as C++ `node.js` bindings. To execute smart contracts, we implement bindings for the Ethereum Virtual Machine Connector interface (EVMC) and use Hera (v0.2.2). Hera can run contracts implemented using Ethereum flavored WebAssembly (ewasm) or EVMC1 bytecode through transcompilation. The I/O-Helper is implemented in C++. DSM-TREE and RAINBLOCK, together 15K lines of code, are open source and available on Github². RAINBLOCK assumes 16 shards by default; this is configurable.

6 Evaluation

We seek to answer the following questions:

- What is the performance of a single miner? (§6.1)

¹www.npmjs.com/package/@rainblock/merkle-patricia-tree

²<https://github.com/RainBlock>

System/optimization	Get	Put
In-memory Ethereum MPT	1x	1x
Pointer-based traversal	2.7x	2.3x
Batching and Lazy hash resolution	56x	69x
All optimizations	150x	160x

Table 2: **Performance breakdown.** The table shows the throughput of DSM-TREE (relative to in-memory Ethereum merkle tree) on gets and puts with different optimizations.

- What is the end-to-end performance of RAINBLOCK in a geo-distributed setting? (§6.2)
- How is performance affected by tunable parameters? (§6.3)
- What are the overheads of RAINBLOCK? (§6.4)

Our technical report [50] contains more details for these experiments, along with additional experimental results.

Experimental setup. We run the experiments in a cloud environment on instances which are similar to the `m4.2xlarge` instance available on Amazon EC2 with 32GB of RAM and 48 threads per node. We use Ubuntu 18.04.02 LTS, and `node.js` v11.14.0. For the end-to-end benchmarks, each storage node, miner, and I/O-Helper is deployed on its own instance.

Workloads. We evaluate the performance of RAINBLOCK against synthetically generated workloads that mirror transactions on the Ethereum public *mainnet* blockchain. Since Ethereum transactions are signed, they cannot be used in experiments: we cannot change transaction data or the source accounts, because we do not have the `secp256k1` private key. To tackle this challenge, we analyze the public blockchain to extract salient features, and develop a *synthetic workload generator* which generates accounts with private keys we control so our I/O-Helpers can run and submit signed transactions.

Synthetic Workload Generator. We analyze the transactions in the Ethereum *mainnet* blockchain to build a synthetic workload generator. We analyzed 100K recent (since block 7M) and 100K older blocks (between blocks 4M and 5M) in the Ethereum blockchain to determine: 1) the distribution of accounts involved in transactions, and 2) the fraction of all transactions that invoke smart contracts. We observe that 10-15% of Ethereum transactions are contract calls and the rest are simple transactions. This is true of both recent blocks and older blocks. It is also the case that a small percentage of accounts are involved in most of the transactions. Based on the analyzed data, we generate workloads where 90% of accounts are called 10% of the time, and 10% of the accounts are called 90% of the time. Smart contracts are invoked 15% of the time.

6.1 Performance of a single miner

The performance of a single miner depends on three things: the DSM-TREE data structure, the I/O-Helpers, and the top-

layer cache at the miner. We first evaluate the performance of the DSM-TREE data structure, and then measure overall tx processing performance on a single node varying the number of I/O-Helpers. We then show the performance of the miner when varying the retention level of the top-layer cache.

DSM-TREE performance. For a fair comparison, we configure Ethereum to use an in-memory key-value store for storage. Ethereum uses the in-memory Merkle Patricia-Trie (MPT) [6] implemented using the `memdown` red-black tree [7]. We use `put` operations to recreate the system state corresponding to four million blocks on the Ethereum public chain. This results in 1.19M accounts. We read all accounts sequentially using `get` operations. `Put` operation creates or updates user account with 160-bit Ethereum address; `get` operation returns the RLP-encoded [9] Ethereum account at the address, along with its witness containing RLP-encoded Merkle nodes. We also compare the memory used.

Performance breakdown. DSM-TREE outperforms Ethereum’s in-memory Merkle tree significantly in both gets and puts, as shown in Table 2. Note that both data structures are in memory, so the performance difference comes from other optimizations. Eth MPT has to use node hashes to traverse the Merkle Tree; in contrast, DSM-TREE uses pointers for constructing the tree, and eliminates hashing. This feature improves performance by 2.7x. Eth MPT has to hash and serialize, or deserialize each node in the Merkle tree while writing or reading them; DSM-TREE optimizes this with memoization and batching. Memoization allows remembering the hashes and RLP-encodings of unmodified Merkle nodes. Memoizing RLP-encoded nodes in DSM-TREE increases `get` performance by reducing redundant node de-serializations. Further, with batching, common nodes in the upper part of the Merkle Tree are only deserialized once, increasing the `get` performance by 56x relative to MPT, bringing the overall performance difference between DSM-TREE and Eth MPT to be 150x. A good overall intuition for these performance improvements is the difference between a linked list in memory versus a linked list where each node is serialized and stored in an in-memory key-value store using the node’s hash as its key.

The performance difference for puts is similar (160x). The efficient memory representation of DSM-TREE contributes to 2.3x of this performance difference; the rest of the difference is due to lazy hash resolution. Lazy hash resolution defers recomputing the hashes of inner tree nodes until they are read. As a result, only the leaf nodes are updated in the critical path. If we force all the Merkle nodes to be updated and rehashed after every thousand updates, the performance difference with Eth MPT drops to 5x overall for puts.

Memory consumption. For the same system state with 1.19M accounts, DSM-TREE consumes 34x lower memory (775 MB) than Ethereum MPT (25 GB). This results from Eth MPT storing each node as a key-value pair. The reduced memory consumption of DSM-TREE is important since we

Optimizations	Config	Txs/s
Baseline	Ethereum, 1 miner	1K (1×)
RAINBLOCK	1 miner, 1 helper, $r=0$	2.6 K (2.6×)
Prefetch in parallel	1 miner; 4 helpers, $r=0$	7.7K (7×)
DSM-TREE tuning	1 miner; 4 helpers, $r=7$	27.4 K (27×)
Geo-distributed	4 miners; 16 helpers, $r=8$	20K (20×)

Table 3: **Performance breakdown.** The table shows the throughput of RAINBLOCK with different optimizations. All configs use 16 storage shards. Helpers indicate I/O-Helpers. While parallel prefetching increases RAINBLOCK throughput by 2.9× from 2.6K to 7.7K tps, the DSM-TREE top layer caching and witness compaction further increase throughput by 3.5×, from 7.7K to 27.4K tps.

want each shard to fit in the memory of a commodity server.

Overall performance. An Ethereum miner can process 1000 txs per second, if its system state is stored in an in-memory key-value store. We measured the performance of a single RAINBLOCK miner with one I/O-Helper when the top-layer caching is disabled; the miner is accessing system state from remote in-memory shards. In this setting, RAINBLOCK processes 2600 txs per second (2.6× higher than Ethereum).

Performance with multiple I/O-Helpers. Increasing the number of I/O-Helpers, increases the performance of RAINBLOCK, till up to four I/O-Helpers per miner. With four I/O-Helpers, parallel prefetching increases performance to 7700 txs per second (2.9× higher). Thus, RAINBLOCK miner (with four I/O-Helpers) outperforms an Ethereum miner by 7.7×.

Performance with DSM-TREE tuning. When we configure the top layer of the DSM-TREE to retain the first seven levels ($r = 7$, $c = n - 7$), the miner can process 27400 tps (3.5× higher than when top layer caching and witness compaction was disabled, and 27× higher than a single Ethereum miner).

6.2 End-to-End Geo-distributed Experiment

We run a geo-distributed experiment, with varying numbers of regions across three continents. Each region has four I/O-Helpers, one miner, and 16 storage nodes, caching eight levels of the DSM-TREE tree ($r = 8$, $c = n - 8$).

RAINBLOCK in a single region has a throughput of 25000 txs per second; this is slightly reduced from the 27400 tps in the previous section since the storage nodes are being accessed over a wide-area network. When we scale to four regions, the throughput drops to 20000 txs per second, thus retaining 80% of the single-region performance. When we ran a workload consisting purely of smart contracts (OmiseGO Token), RAINBLOCK achieved 17900 tps. Table 3 captures RAINBLOCK performance in various settings, from a single miner with one I/O-Helper to the geo-distributed experiment.

Tx confirmation latency remains the same as in Ethereum,

as RAINBLOCK and Ethereum share the same block creation and confirmation logic (confirmed after ten blocks build on the block containing the tx). As more txs are present in each block, more txs are confirmed per second. These experiments use the same PoW consensus in Ethereum, thus demonstrating that RAINBLOCK achieves higher tx throughput without modifying the consensus protocol.

6.3 Perf impact of tunable parameters

We discuss the impact of varying two configuration parameters: the retention level r (number of Merkle tree levels stored at the top layer), and the compaction level c (bottom c levels of the witnesses are sent over the network by the shards).

Impact of tuning retention level. Increasing the retention level at miners increases overall tx throughput, but also increases the memory requirements at the miners. Pruning the cache to a certain retention level (r) helps reclaim the memory consumed by miners. For the Merkle tree constructed in the geo-distributed experiment described previously, miners caching till a tree depth of five ($r = 5$) consumes only 40% of the memory consumed by storing the full DSM-TREE in memory. As we increase the number of I/O-Helpers, the impact of higher r decreases. For example, in the geo-distributed experiment in a single region, there was no performance difference between $r = 7$ and $r = 8$ with four I/O-Helpers, but performance improved by 35% between $r = 7$ and $r = 8$ with two I/O-Helpers.

Retention Level and Tx Abort rate. If the top layer doesn't cache enough levels, stale witnesses cannot be revised, leading to tx aborts. We evaluate RAINBLOCK with 16 storage shards, 1 miner, and 4 clients, with various r and c configurations to measure the transaction abort rate. Increasing r reduces the transaction abort rate. Further, when there are a large number of accounts, the contention on Merkle tree nodes reduces, increasing the number of witnesses that can be revised and thus, reducing the abort rate for a fixed r . With 1M accounts and $r=6$, RAINBLOCK aborts less than two txs per second. In cases where the txs get aborted, I/O-Helpers or users themselves can fetch up-to-date witnesses from storage nodes and resubmit transactions to miners.

Tuning compaction level. A lower compaction level c increases the DSM-TREE shard throughput for I/O-Helpers (as it reduces the size of witnesses transmitted over network); with 10M accounts in state and $c = n$, shards process account reads at 1.36K ops/sec and with $c = n - 6$, they process 9.4K ops/sec (7× increase in throughput per shard). The compaction level should be tuned alongside the retention level, with $c \geq (n - r)$ for a Merkle tree with n levels.

6.4 Overheads

RAINBLOCK has two main sources of overhead. First, it trades local storage I/O for network I/O, hence resulting in more network traffic. Second, it requires the participation of more

commodity servers as I/O-Helpers and storage nodes. We discuss these overheads and how RAINBLOCK mitigates them.

Network bandwidth requirements. RAINBLOCK can be configured to produce blocks of a given size. For example, if the network can only handle 1 MB blocks, RAINBLOCK can be configured to produce blocks of this size. In our experiments, we do not constrain RAINBLOCK, and see that RAINBLOCK can pack about 240K transactions into each block ($480\times$ higher than Ethereum), on average, with the same proof-of-work consensus and block creation time. RAINBLOCK blocks are about 24MB in size, compared to the recent Ethereum blocks that are 40-60 KB. Our geo-distributed experiment used 24 MB blocks over the wide-area-network without running into network bottlenecks. The second source of network traffic is gossiping witnesses between miners. Using witness compaction, and node bagging (batching and deduplication), RAINBLOCK reduces witness sizes by 95%, allowing miners to advertise witnesses with commodity network bandwidths. Our witnesses sent over the network were a few KB in size.

Additional resources. RAINBLOCK requires I/O-Helpers and storage nodes. While storage nodes keep all state in memory, the state is sharded so that each shard fits in the DRAM of a commodity server. Storage nodes are shared among all miners, and hence they do not significantly increase the overall cluster requirements; I/O-Helpers can also be shared by miners.

7 Related Work

In this section, we place our contributions RAINBLOCK and DSM-TREE in the context of prior research.

Stateless Clients. The Stateless Clients [24] proposal seeks to insert witnesses into blocks, allowing miners to process a block without I/O. Despite active discussions [3, 25, 27], this proposal has not been implemented due to large witness sizes [57]; a single, simple transaction can have 4-6KB witness sizes, resulting in $40\text{-}60\times$ the network overhead. In contrast, DSM-TREE reduces witness sizes by 95%; RAINBLOCK does not insert witnesses in blocks, and uses I/O-Helpers to reduce the I/O burden on miners.

Hyperledger Fabric. Fabric [17] is private while RAINBLOCK is public, resulting in significant differences. Fabric introduces a new execute-order-validate architecture where txs are executed only on a subset of servers. In RAINBLOCK all miners execute every transaction. While Fabric relies on signatures from trusted nodes (which can become the bottleneck), RAINBLOCK uses witnesses from untrusted servers to authenticate data. Peers in Fabric store the entire state, while RAINBLOCK storage nodes store partitions of the system state. RAINBLOCK improves performance with I/O-efficient transaction processing, while Fabric derives high performance from optimistic execution and efficient consensus.

Sharding. Sharding the blockchain into independent parallel chains that operate on subsets of state [36, 39, 41, 61, 62, 70]

reduces I/O overheads; however, requires syncing the independent chains for consistency, is less resilient to failures or attacks [51, 55, 69], and require complex cross-shard transactions protocols. In contrast, RAINBLOCK does not shard the blockchain; the storage is sharded, but all miners add to a single chain. RAINBLOCK does not require locking or additional communication for executing transactions across multiple storage shards. Payment channels [4, 32, 35, 38, 40, 45] that offload work to side chains are complementary to our work.

Dynamic accumulators. Merkle trees belong to a general family of dynamic accumulators [20, 26]. Merkle trees, allow fast processing but, proofs grow with the underlying state. Constant-size dynamic accumulators based on RSA signatures [20, 26] have fixed size proofs but, have low processing rates; improving their performance is an ongoing effort [23]. DSM-TREE provides a practical solution to achieve high processing rates and small witness sizes. Recent work has proposed many new authenticated data structures [18, 28, 37, 53, 54, 58, 66, 68]. In contrast to these works, DSM-TREE scales Ethereum's Merkle Patricia trie [11] without changing its core structure, or how proofs are generated.

Transaction execution. RAINBLOCK adopts a design similar to Solar [71] and vCorfu [63], where transactions are executed based on data from sharded storage. RAINBLOCK modifies the design for decentralized applications and authenticated data structures. This allows RAINBLOCK to execute transactions on sharded state without requiring locking or additional coordination among miners. Similar to RAMCloud [48], the DSM-TREE design argues that large random-access data structures can get higher throughput and scalability when served from memory over the network.

8 Conclusion

We have presented RAINBLOCK, a public blockchain architecture that increases transaction throughput without changing the proof-of-work consensus protocol. RAINBLOCK achieves this by tackling the I/O bottleneck in transaction processing, allowing miners to pack more transactions into each block. RAINBLOCK introduces a novel architecture that moves I/O off the critical path, and the DSM-TREE, a new authenticated data structure that provides cheap access to system state. Please refer to our technical report [50] for more details about RAINBLOCK and the DSM-TREE. The RAINBLOCK prototype is publicly available at <https://github.com/RainBlock> and we welcome working with the community on its adoption.

An Off-The-Chain Execution Environment for Scalable Testing and Profiling of Smart Contracts

Yeonsoo Kim[†], Seongho Jeong[†], Kamil Jezek[‡], Bernd Burgstaller[†], and Bernhard Scholz[‡]
[†]*Yonsei University* [‡]*The University of Sydney*

Abstract

Smart contracts in Ethereum are executable programs deployed on the blockchain, which require a client for their execution. When a client executes a smart contract, a world state containing contract storage and account details is changed in a consistent fashion. Hence, the execution of smart contracts must be sequential to ensure a deterministic representation of the world state. Due to recent growth, the world state has been bloated, making testing and profiling of Ethereum transactions at scale very difficult.

In this work, we introduce a novel off-the-chain execution environment for scalable testing and profiling of smart contracts. We disconnect transactions from the world state by using substates to execute the transactions in isolation and in parallel. Compared to an Ethereum client, our execution environment reduces the space required to replay the transactions of the initial 9 M blocks from 700.11 GB to 285.39 GB. We increased throughput from 620.62 tx/s to 2,817.98 tx/s (single-threaded) and 30,168.76 tx/s (scaled to 44 cores). We demonstrate the scalability of our off-the-chain execution environment for hard-fork testing, metric evaluations of smart contracts, and contract fuzzing.

1 Introduction

Ethereum is a permissionless blockchain capable of executing smart contracts. Since its inception in 2015, a total of 964 M transactions deployed in 11.6 M blocks have been processed. The number of unique Ethereum accounts soared from 20 M in 2018 to more than 131 M by January 2021. The rapid adoption has been fueled by applications in trade [34], banking [27, 37], governance, and supply chain. This trend has been amplified by a growing interest in decentralized finance¹, with a total value of 4 billion USD and a recent peak of 3.1 M contract calls in a single day [10].

¹Decentralized finance (DeFi) refers to an alternative, peer-to-peer financial infrastructure built on the blockchain.

Because smart contracts control large monetary values, blockchain designers and developers have a strong incentive in building tools that improve the correctness, efficiency, and security of their smart contracts. Developers typically write smart contracts in the Solidity language [17]. The Solidity compiler translates smart contracts into an immutable bytecode representation for the Ethereum virtual machine (EVM). Bytecode is persistently deployed on the blockchain where it can be invoked for execution on the EVM in a transaction.

The execution of smart contracts and Ethereum itself is a protocol defined formally in the Yellow paper [44] and practically implemented in Ethereum clients. Ethereum clients function as peers on the Ethereum network. They keep the ledger of the Ethereum blockchain consistent, fetch its updates, and integrate the EVM to execute smart contracts. The two most popular clients are Geth [18]² and Parity [39]³. When a client executes a smart contract, it constructs its input state from the blockchain's ledger and writes its state changes back onto the ledger. Hence, a smart contract's state evolves continuously on the ledger, where the history of all state changes of a smart contract is kept.

For testing, the state of a smart contract must be retrieved before it can be validated and analyzed. However, due to the ledger's cryptographically secured data structures and due to its sequential representation of the ledger as a blockchain, the retrieval of a smart contract's state is prohibitively slow [35, 46]. This problem is exacerbated for testing and debugging tools that process large quantities of blocks (or even all blocks) on the blockchain.

It has been acknowledged by the community that the testing of smart contracts at scale is a long-standing problem. It affects the development of the entire blockchain-oriented software (BOS) ecosystem, i.e., all software systems that work with a blockchain implementation. There have been calls for research into mocking blockchains [40] for enhancing testing

²Geth is the most widespread open source Ethereum client officially maintained by the Ethereum community, with a market share of 80%, according to <https://ethernodes.org/>.

³In Jan. 2020, Parity has been renamed to OpenEthereum.

and debugging in isolation. A recent survey [50] conducted among practitioners, GitHub developers, and industry professionals working on Ethereum smart contracts revealed the concern that the “*EVM is a single-threaded machine that cannot run transactions in parallel*”, which may affect “*people who have a higher requirement on the timely reaction and verification of their transactions*”. A survey [5] among 156 developers of popular blockchain projects on GitHub shows that backward compatibility (the ability to validate earlier transactions) and the difficulty of setting up testnets⁴ are pressing issues for BOS developers, and that the distributed environment currently cannot be adequately simulated on development machines.

To mitigate the above problems and enable testing and profiling of smart contracts at scale, we introduce a *transaction record and replay* mechanism that enables the fast re-execution of individual transactions for testing purposes. Our mechanism records the historical Ethereum state that was used when a transaction was originally executed. The transaction can then be replayed in isolation for testing purposes. Our recorder reorganizes the Ethereum world state into transaction-relevant substates. Replay is conducted off-the-chain to avoid the overhead of the distributed system. The replayer mocks the distributed blockchain environment so that a transaction has the same execution behavior as if it was executed by an Ethereum client. Our approach facilitates the efficient replay of all transactions of the blockchain because transactions can be replayed in parallel (unlike testnets) and in isolation. We demonstrate that our novel *off-the-chain* execution environment enables applications such as hard-fork testing (i.e., a regression test checking whether the newly introduced policies of a hard fork do not hamper the execution of legacy smart contracts), metric evaluations of smart contracts (e.g., measuring the number of wasteful instructions in a smart contract), and contract fuzzing for detecting execution anomalies in smart contracts.

The contributions of this work are as follows:

- We present a new off-the-chain execution environment for blockchain transactions using a recorder and replayer so that transactions can run in isolation showing unprecedented performance improvements in comparison with state-of-the-art approaches.
- We introduce a new substate representation for transactions that captures the substate of the world state which is relevant for their execution.
- We show the efficiency and effectiveness of our approach using a regression tester for hard forks, a dead-code analysis, and a program fuzzer.

⁴A testnet is a blockchain that is used for testing of smart contracts in a production-like environment, but without spending cryptocurrency of real value.

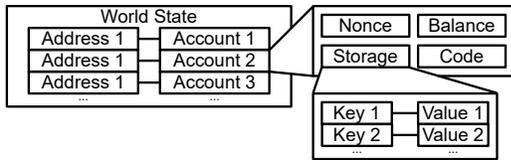

2 Background and Motivation

Ethereum Blockchain: A blockchain is a ledger shared among peers on a peer-to-peer (P2P) network. The Ethereum blockchain is fully described in its specification, the Yellow paper [44]. A *blockchain* is implemented as a chain of blocks that has been accepted by participants in the network following a consensus protocol. A *block* consists of a block header and a block body. The block header contains the reference to the parent block and metadata for the block verification. The block body holds a sequence of transactions created by participants and added in the block by miners. Transactions may either transfer funds or invoke smart contracts.

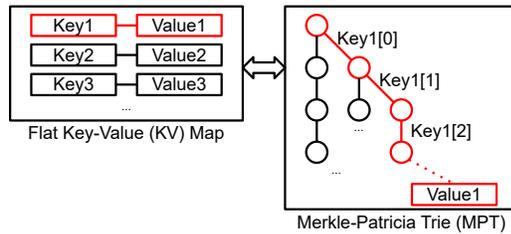

A *transaction* in the blockchain is signed by its sender and contains input data that are propagated into the global state. The execution of a transaction can be perceived as a state transition where a global state is transformed. The global state encompasses the state of smart contracts, accounts, and other aspects such as transaction receipts or smart-contract execution logs. Accounts are addressed by public keys generated by the private keys of the account owners. The sender issuing a transaction has to sign the transaction with the account’s private key. Peers can verify the transaction by computing the sender’s account address from the signatures. It is important to note that the state transition must be deterministic among all peers in the blockchain network for the sake of consistency. Without deterministic state transitions of a transaction, it is impossible to find consensus.

The Ethereum blockchain provides the following three types of transactions. A *transfer* transaction takes assets from a sender and transfers them to a recipient. A transaction for *contract creation* conveys the initial endowment of the newly created account and a smart contract in the form of EVM bytecode to initialize the created account. The created account is associated with contract code, and it has an account storage to maintain its state across contract invocations. A *contract invocation* transaction sends a message to an account to execute the associated contract code. The message contains input data and gas converted from cryptocurrency to fuel the EVM bytecode execution. The EVM will execute the contract code with the input data, consuming the gas metered based on executed instructions. If the gas consumption reaches the provided gas limit, the contract is terminated prematurely.

Ethereum World State: The Ethereum world state is the global state information of Ethereum that maps between account addresses and the data associated with an account. Each account has its own key-value storage in which only the owner has the authority to load and store values via `SLOAD` and `SSTORE` instructions of EVM bytecode. For state verification and as input to the next block, Ethereum clients are required to maintain a local copy of the entire global state after processing a particular block. As depicted in Figure 1a, Ethereum employs key-value (KV) maps to maintain (1) accounts and

(a) Ethereum world state and account storage.

(b) Flat KV map and corresponding MPT.

Figure 1: Ethereum world state and account storage (a), corresponding MPT as the underlying representation of a flat KV map (b).

(2) the data stored in each account. Data is encoded in recursive length prefix (RLP) format [44]. For cryptographic verification, the flat KV maps are encoded as Merkle Patricia tries (MPTs, [16]), depicted in Figure 1b. State verification in Ethereum relies on the property of MPTs that if two MPTs are *identical*, the hash values of their root nodes are identical [33].

The EVM bytecode interface provides the view of the flat KV map from Figure 1a to the application. Only after transaction execution will a client employ the RLP and MPT encoding depicted in Figure 1b, verify states, and store the MPT nodes in an on-disk key-value database (KVDB). A client may use a data representation different from MPTs to improve database performance [1]. Nevertheless, MPTs must still be constructed for state verification as mandated by the ledger protocol. The specification of the EVM and the world state are provided in the Ethereum Yellow paper [44].

3 Limitations of Smart Contract Testing

Testing smart contracts requires an Ethereum world state and a transaction execution environment. We refer to *transaction replay* as the execution of a transaction at the historical Ethereum state that the transaction was originally executed on at a given block height on the blockchain. Note that, in principle, it is not necessary to have the Ethereum network and blockchain available for testing. In this section, we consider different test environments currently available to blockchain designers and developers for replaying transactions. None of them facilitate replay on transaction granularity—only block granularity is supported. We highlight the impracticality of the test environments and conclude with the observed scalability problems. Unless otherwise specified, our evaluations were conducted on the server platform shown in Table 1.

Server	Geth full node	Substate replayer	Geth archive node
CPU	Intel Xeon E5-2699 v4, 2.2 GHz to 3.6 GHz, 22 cores × 2 sockets		
RAM	512 GB DDR4 RAM @ 2,400 MHz		
SSDs (PCIe)	Intel Optane 900P 480 GB Intel Optane DC P3700 800 GB	Samsung PM1725b 6.4 TB	
OS	CentOS Linux release 7.9.2009 (core), kernel version 4.11.3-1.el7.elrepo.x86_64		
Filesystem	ZFS pool (1.2 TB total size)	XFS	

Table 1: Evaluation platform specification.

3.1 Transaction Replay Delegation

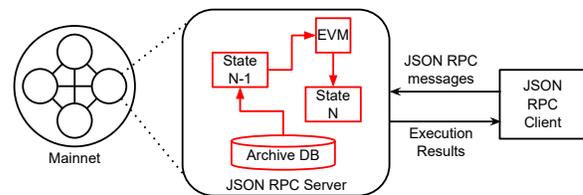

Figure 2: JSON RPC server (archive node) replaying transactions in block N on behalf of a client. State N is the state after executing all transactions in block N . The client sends request messages via the JSON RPC interface; messages include RPC method names and their arguments.

Ethereum clients can be configured as Ethereum *archive nodes*. They keep the entire history of world states in their database and can thus be used to retrieve historical state information. Geth provides a JSON RPC API⁵ for this purpose. Via the JSON RPC API, a Geth client can delegate the replay of a transaction to an archive node. Figure 2 illustrates this scenario.

Unfortunately, delegation suffers from significant overhead incurred by the JSON RPC API and the fact that transaction throughput of archive nodes is seriously constrained by the considerable database size for storing all historical world states (6 TB of disk space for blocks up to 11 M [20]). An Ethereum client can be configured as an archive node that generates execution traces during transaction replay. In a small experiment, we observed that a query to replay traces of ten blocks at blocks after 9 M using `traceBlockByNumber` timed out running for an entire hour (at that stage we stopped the replay attempt). After disabling the EVM stack, memory, and storage tracing, the archive node achieved a replay throughput of 19.4 tx/s for 100 blocks at block 9 M and after. Hence, a test environment that uses transaction replay delegation is not a viable solution for testing—even for a small number of replay queries.

⁵<https://geth.ethereum.org/docs/rpc/ns-debug>

3.2 Transaction Replay in a Client

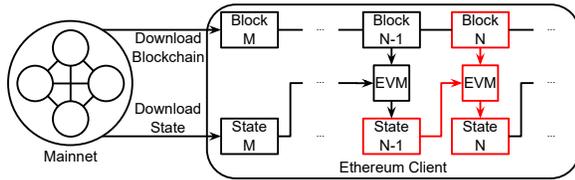

Figure 3: Full node to replay transactions in block N . State N is the state after block N has been imported, and block M is any block prior to block N on the blockchain.

When Ethereum clients are configured as Ethereum *full nodes*, they replay transactions for verification and synchronization with peers on the network. Figure 3 illustrates how Ethereum clients replay transactions during synchronization. To replay transactions in block N , a client requires the state at block $N - 1$. A full node can download the state after block M directly from trusted peers using a fast synchronization protocol instead of processing all M blocks from the genesis block by itself. The fast synchronization protocol is a trade-off to save transaction processing time at the cost of the higher network bandwidth required for downloading the state. The community refers to fast synchronization as *fast-sync* mode and it represents the default configuration of Geth clients. At block 11.5 M, a Geth full node consumes more than 600 GB of disk space [21].

Transaction replay in full nodes suffers from severe drawbacks: If the desired block for replay is located far behind the tip of the chain, no peer will be available to provide the state for synchronizing in fast-sync mode. In the absence of a downloadable state, the client must process (import) all blocks itself, commencing from the genesis block, to produce state $N - 1$ for replaying block N . In our experiment, the Geth client on an AWS `i3.2xlarge` instance took 8.13 h to fast-sync the state at block 11.5 M. When the Geth client imported blocks from the genesis block, it took 227 h (i.e., 9.5 d) to produce the state at block 8 M. Similarly to replay delegation, transaction replay throughput is very low: At block height 9 M the observed throughput of our archive node was 19.4 tx/s while our full node achieved 447.7 tx/s. Therefore, replaying millions of transactions with an archive node is not viable in practice, and a full node will take several weeks to accomplish such a testing task.

3.3 Testnets

The Ethereum main network (mainnet) is the only P2P network for real-world trading of Ethereum cryptocurrency. For testing purposes, the Ethereum community maintains public and private testnets where new protocols are activated and tested before they are deployed on the mainnet. Blockchain designers and developers deploy and test contracts on a test-

net using clients that synchronize with recent blocks from the testnet like the nodes on the mainnet. The major limitation of testing with testnets is that its state can only be configured via side effects of smart contracts that are executed through transactions. This requires considerable effort from a developer to build a test fixture. In particular, the developer must deploy and execute the following transactions to test a smart contract on a testnet: (1) transactions to initialize the target contract and other participating accounts, (2) transactions to set up the complete world state and environment parameters for the input, and (3) a transaction to invoke the target contract with the prepared input state.

3.4 Lack of Scalability on Multicores

Testing smart contracts by replaying transactions on a full node does not scale on a multicore server because of two reasons: First, execution of transactions on the blockchain is inherently sequential. To replay transactions in blocks later than the current state, a node must import all intermediate blocks on the chain between the current block and the block to be replayed. Second, it takes a considerable amount of disk space to maintain a complete world state in MPT format. Running multiple Ethereum nodes with different ranges of blocks has the potential to increase the overall throughput on a multicore server. However, each node will require hundreds of GBs to maintain multiple world state instances. E.g., running nine full nodes for segments of 1 M blocks as stated in Table 2 requires 2.8 TB of disk space. One may expect an archive node to scale on multicores because it does not have to import blocks prior to replaying a transaction. But practically, as observed in our experiments, a single archive node requires 6 TB of disk space and exhibits very low transaction replay throughput. (Note that our evaluation platform from Table 1 uses PCIe SSDs and thus can be considered an advantageous case, performance-wise.) Testing smart contracts on a testnet has the same limitations as replaying of transactions on a full node because it executes transactions in order and has to encode a complete state in MPT format for verification.

4 Off-The-Chain Testing

Our new *off-the-chain* testing environment is based on a transaction record and replay mechanism. The record mechanism records the historical state from before and after a transaction on the chain. The recorder is an augmented Ethereum client that produces the historical state as a side effect while importing blocks from the blockchain. For a transaction, the recorder captures *substates*, which contain only relevant parts of the world-state and environment parameters that contain enough information to replay a transaction with no dependency on earlier transactions. The recorder stores the substates in the *substate database*, which is a flat key-value map.

The replay mechanism mocks the Ethereum protocol of a client such that transactions can be executed without the peer-to-peer network of Ethereum and the cryptographic verification tasks of a client. We use EVM binaries for building the replay mechanism, which are stand-alone clients and have been implemented for checking the correctness of the EVM only. Our replay mechanism operates directly on the substate database. It executes transactions off-the-chain, in parallel, and in isolation achieving unprecedented scalability for testing smart contracts.

4.1 Transaction Substate

Key to our record/replay mechanism is the substate, which contains a subset of the world-state trie to faithfully replay a transaction. The subset contains all the entries represented as a key-value pair (not as an MPT) for executing the transaction in full isolation. The substate is enhanced with meta information that is required for the execution of the transaction including (1) the values of the input arguments of the transaction, (2) the cryptographic hashes needed for the execution, and (3) the expected return values. In the following, we summarize the information stored in substates.

1. **Alloc:** information about each accessed account, i.e., account address, nonce, balance, code hash, and storage values from the world state accessed by the transaction.
2. **Block:** block number, block creation timestamp, block hashes, coinbase, difficulty, and block gas limit.
3. **Message:** nonce, gas price, provided gas, sender account address, recipient account address, input value, and input data of the transaction to initiate the message call.
4. **Result:** status code, transaction gas usage, logs and their Bloom filter from the output of the transaction execution.

The substate representing the historical Ethereum world state before executing a transaction is called the *input substate*. It consists of three parts: input alloc, block, and message. The substate representing the historical Ethereum world state after executing a transaction is called the *output substate*. It consists of two parts: output alloc and the transaction result. Together, the input and output substates contain all information required to faithfully replay and validate the respective transaction. Note that accounts and storage values that are not accessed by a transaction can be omitted from a substate because they have no effect on the transaction’s execution and hence cannot affect the transaction’s output.

4.2 Substate Recorder

Our substate recorder is an extended Ethereum client that collects and stores transactions’ substates while importing blocks as depicted in Figure 4. Our recorder collects the substates from before and after a transaction on the chain. We refer

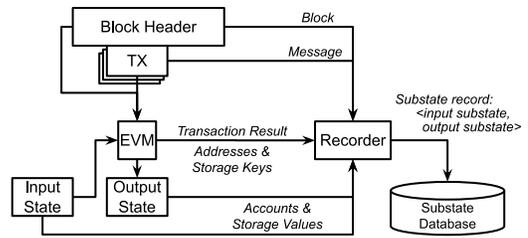

Figure 4: Substate recorder.

to these substates as the input and output substates, respectively, and the recorder stores them as a substate record in the substate database.

Throughout the execution of a transaction, the recorder collects the set of *indices* accessed in the world state. An index is represented by a tuple $\langle \text{Address}, \text{Key} \rangle$, where *Address* denotes an account/wallet address, and *Key* represents the storage key to the account’s accessed storage location (as illustrated in Figure 1a). After the transaction’s completion, the recorder collects for each index the corresponding value from the world state prior to the start of the transaction (for the input substate), and the value from the world state after the transaction terminated (for the output substate). The collected *input* and *output tuples* are of the shape $\langle \langle \text{Address}, \text{Key} \rangle, \text{Value} \rangle$. Collectively, the input/output tuples contain the complete set of storage locations and associated values read and written by a transaction.

As an example, we assume a *token transfer* of 10 units from account 1 at *address1* to account 2 at *address2*. Account 1 and account 2 are endowed with 25 units and 80 units before transaction commencement, and both accounts maintain their token values at storage key *key2*. Recording this transaction will result in the following input/output tuples, which signify the drop of funds in account 1 from 25 to 15 units, and the increase in account 2 from 80 to 90 units.

Input tuples:	Output tuples:
(1) $\langle \langle \text{address1}, \text{key2} \rangle, 25 \rangle$	$\langle \langle \text{address1}, \text{key2} \rangle, 15 \rangle$
$\langle \langle \text{address2}, \text{key2} \rangle, 80 \rangle$	$\langle \langle \text{address2}, \text{key2} \rangle, 90 \rangle$

The recorded input/output tuples do not include storage locations where accounts keep information that has not been accessed as part of a given transaction. In practice, a transaction involves only a few accounts. The recorded input/output tuples thus constitute a small subset of the world state’s account storage before and after a transaction, which facilitates space-efficient transaction replay.

We record input/output tuples for nested transactions, which occur with calls across smart contracts. Tuple collection includes reverted transactions, which are transactions that do not take effect on the world state, e.g., because the transaction runs out of gas. Even such invalid transaction termination requires the input/output tuples to ensure the faithful replay of the reverted transaction.

Consider as an example the aforementioned token-transfer contract. The contract has a runtime check for reverting a transaction if there are insufficient funds available. Assume that the initial endowment of account 1 is zero, hence, the runtime check will fail and make the transaction revert. In this case, the input substate will have the tuple $\langle\langle\text{address1}, \text{key2}\rangle, 0\rangle$ only. This tuple is nevertheless necessary for reproducing the failed runtime check during replay.

As depicted in Figure 4, our recorder creates a *substate record* from the input/output substates (including the transaction’s environment parameters, i.e., block, message, and transaction result), and stores the substate record in the substate database. Records in the substate database are indexed by the key $\langle\text{block}, \text{tx}\rangle$, where *block* is the block number and *tx* is the index of the transaction within the block. Each substate record can thereby be accessed by a single database lookup, which eliminates dependencies on earlier transactions and provides our replayer with instant access to the historical state of any recorded transaction.

Because our recorder collects substates during on-chain operations, it requires as much time and space as the synchronization of a Geth full node. However, the recording has to be performed only once. As soon as the substate database is created, all historical transactions can be replayed an arbitrary number of times with our replay mechanism.

4.3 Substate Replayer

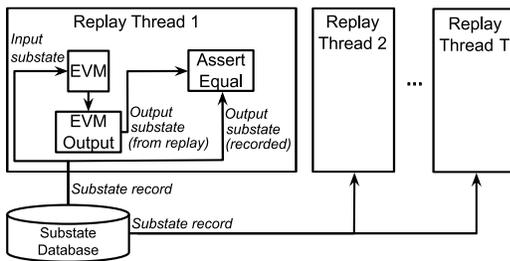

Figure 5: Substate replayer.

The replay mechanism is based on the EVM binaries that we extended for replaying transactions arbitrarily and in parallel from our substate database. Figure 5 illustrates the design of our multi-threaded replayer. It receives the number of replay threads T and an inclusive block range $[N_{\text{first}}, N_{\text{last}}]$ as input. The replayer creates a thread pool of T replay threads and pushes the designated block numbers from N_{first} to N_{last} into a channel on which all replay threads wait⁶. We employ a dynamic work partitioning scheme where replay threads repeatedly dequeue a block number, load the block’s substate records, and replay its transactions.

⁶The EVM binaries and hence our extensions are implemented in the Go programming language.

For each transaction, a replay thread invokes a fresh EVM instance, for which it copies input alloc, block, and message from the input substate to an in-memory context that the EVM instance can read and modify off-the-chain. This in-memory context simulates on-chain features such as hard forks, gas costs, block environment, precompiled contracts, and database snapshots for reverted transactions.

The EVM instance executes the corresponding smart contract code in isolation on the in-memory context. The replay thread thereafter collects the output tuples and the transaction result from the modified context and validates them against the recorded output substate. If a thread successfully replayed all transactions in a block, it sends the block number back to the main thread. The main thread maintains the processed block total and triggers the termination of the replay threads once all blocks have been processed.

Replay threads collect the set of indices accessed in the world state in the same manner as the recorder. Because transaction replay must be deterministic (running the same transaction with the same input must produce the same output), the replayed transaction must access the same storage locations as the recorder, and the accessed indices must coincide.

For example, considering the token transfer example (1) on the previous page. If during replay the transaction accesses index $\langle\text{address1}, \text{key1}\rangle$ instead of $\langle\text{address1}, \text{key2}\rangle$, the replayer will detect this index mismatch (cf. “Assert Equal” in Figure 5).

In general, if any of the accessed indices, output values, or the transaction result differ from the recorded historical information, the replayer will raise an exception, report the substate record’s key and the difference between the EVM output and the expected output, and terminate.

4.3.1 Replay Performance and Accuracy

We evaluated the runtime and storage improvements of our replayer compared to a Geth full node, and we validated its replay accuracy. All experiments were conducted on the platform specified in Table 1. Tables 2 and 3 compare the disk space and execution-time requirements of a Geth full node and our substate replayer to replay all 590 million transactions of the initial 9 M blocks of the Ethereum mainnet. We imported blocks from files to replay transactions with the Geth full node. The size of Geth’s database in Table 2 increases drastically as it contains all accounts existing in the previous blocks. The substate database requires less space than Geth because Geth must maintain a complete world state with all accounts and storage values in MPTs for on-chain synchronization, while our off-the-chain test environment selectively recorded accounts that are accessed during transaction execution.

Table 3 compares time and throughput of transaction replay between Geth and our substate replayer with a single thread. Both took more time in later blocks because the number of transactions per block increased. Blocks in range 2–

Blocks (M)	Geth full node (GB)	Substate replayer (GB)	Space savings (%)
0-1	0.96	0.68	29.17
1-2	3.00	1.83	39.00
2-3	29.30	16.91	42.29
3-4	37.76	6.58	82.57
4-5	124.57	39.55	68.25
5-6	272.06	51.58	81.04
6-7	407.48	50.30	87.66
7-8	551.04	55.96	89.84
8-9	700.11	62.00	91.14
0-9	700.11	285.39	59.24

Table 2: Disk space requirements and space savings of our substate replayer over a Geth full node. The space required by Geth is the size of its database at the last block of the stated range. Ranges 8-9 M and 0-9 M require the same space because the Geth full node maintains a complete world state at 9 M regardless of the number of blocks it replays.

Blocks (M)	Geth full node		Substate replayer		Speed-up (×)
	Time (s)	tx/s	Time (s)	tx/s	
0-1	1184	1414.07	526	3183.01	2.25
1-2	2879	2217.13	1517	4207.73	1.90
2-3	28906	252.73	24125	302.82	1.20
3-4	10775	1946.33	5222	4016.03	2.06
4-5	94868	1196.67	28873	3931.90	3.29
5-6	165673	748.71	35390	3504.97	4.68
6-7	173503	552.82	33672	2848.55	5.15
7-8	224426	485.51	38060	2862.87	5.90
8-9	248519	447.70	41999	2649.17	5.92
0-9	950733	620.62	209384	2817.98	4.54

Table 3: Total execution time (s) and throughput in transactions per second (tx/s) of Geth block import and substate replay with a single thread.

3 M showed lower performance because of denial-of-service (DoS) attacks described in [3]. In later blocks, the Geth full node was substantially slower than our substate replayer because Geth needs multiple LevelDB lookups to read MPT nodes leading to a single MPT leaf value. As the blockchain grows, the number of MPT nodes and the size of the Geth database increases, which increases both the total number of lookups and the time per lookup. In contrast, our substate recorder packages all values required to replay a transaction into a single substate record. Therefore, one LevelDB lookup is sufficient to load all data required to replay a transaction. Overall, our substate replayer is 4.54 times faster than the Geth full node. Because transaction replay from a substate record is an isolated execution on the EVM, it can be parallelized. Figure 6 shows the speedup when using multiple replay threads for the initial 9 M blocks of the Ethereum mainnet.

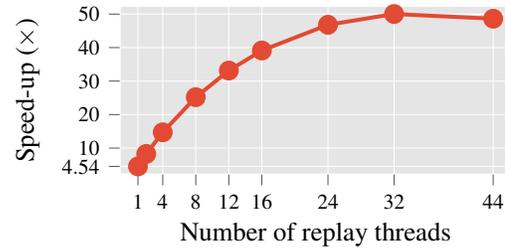

Figure 6: Speedup of parallel transaction replay by the multi-threaded substate replayer with 9 M blocks compared to a Geth full node.

As discussed in Section 4.3, our replayer will raise an exception if the execution of a replayed transaction deviates from the recorded historical information. When replaying the 590 million transactions on the Ethereum mainnet from the genesis block up to block 9 M, our replayer finished without raising an exception, which confirms that all transactions were replayed faithfully and that our off-the-chain testing environment achieved a replay accuracy [26] of 100%.

5 Use Cases

In this section we introduce three use cases for our substate replayer: (1) a metric use case based on transaction replay, (2) a fuzzer use case based on testnets, (3) a method to assess hard forks using off-the-chain execution.

5.1 Metric Use Case

Program analysis techniques have been widely adopted for smart contracts. A 2019 survey of 27 Ethereum contract analysis tools [11] found that most tools concentrate on security issues and employ static analyses. But pressing efficiency and scalability limits of blockchains have become another major concern [13, 30, 41, 49]. We argue that because of the inherent limitations of static analyses, in particular precision and cost [7, 14], dynamic analysis techniques will gain further momentum. Specific metrics aimed at measuring the complexity, communication capability, gas-usage and performance have already been instigated in [40]. A set of metrics that includes contract execution time and the time to update the Ethereum world state has been proposed in [49]. Novel program metrics in smart contracts will be required to guide future design decisions for infrastructure and language implementation, e.g., to determine the profitability of speculative parallelization [12].

To demonstrate the effectiveness of our record/replay infrastructure for comprehensive dynamic analyses of transactions on the Ethereum mainnet, we implement a metric for *wasteful instructions*. A wasteful instruction is an instruction whose side effect does not lead to a lasting side effect on the

Nr.	Opcode	Nr.	Opcode
1	PUSH 0x80	13	DUP
2	PUSH 0x40	14	REVERT
3	MSTORE	15	JUMPDEST
4	PUSH 0x00	16	POP
5	PUSH 0x01	17	PUSH 0x3797
6	SSTORE	18	DUP
7	CALLVALUE	19	PUSH 0x25
8	DUP	20	PUSH 0x00
9	ISZERO	21	CODECOPY
10	PUSH 0x15	22	PUSH 0x00
11	JUMPI	23	RETURN
12	PUSH 0x00		

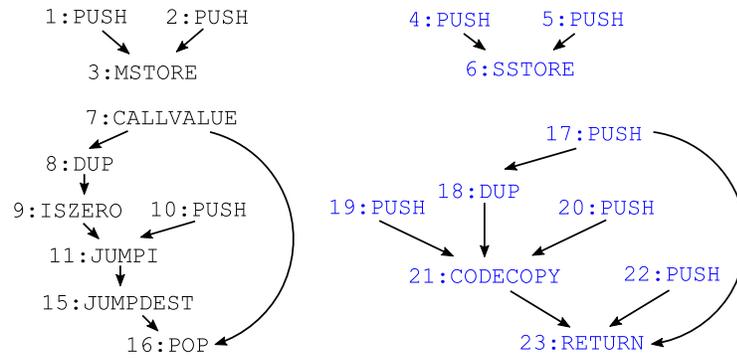

Figure 7: A bytecode of a smart contract and its value graph. Necessary instructions are colored in blue.

blockchain. Because each instruction needs to be paid for by gas, wasteful instructions are costly and should be avoided.

To determine wasteful instructions at runtime, we construct a value graph $G(V, E)$ for each smart contract execution. During the EVM execution, each instruction becomes a node in the value graph, and edges between nodes denote data flow among instructions. We define *necessary* instructions as instructions that contribute towards side effects on the blockchain or results to users. We categorize the list of necessary instructions as follows.

- SSTORE, SELFDESTRUCT, CREATE, and CREATE2 cause side effects on the blockchain by changing the world state trie or the account storage trie.
- RETURN produces a result of the smart contract and delivers it to the user.
- LOG0, LOG1, LOG2, LOG3, and LOG4 generate log records.
- CALL, CALLCODE, and DELEGATECALL execute another smart contract. Although these instructions do not have a side effect themselves, the callee contract might have a side effect. Investigating such a relationship is beyond this paper's scope, so we simplified and considered call-related instructions as necessary instructions. However, STATICCALL, which cannot have any side effect by its definition, is excluded.

A sample bytecode and its value graph are depicted in Figure 7. Each node in the graph represents an instruction with the attached number specifying the execution order. If instruction x depends on instruction y , we add a directed edge from instruction y to instruction x . For example, 3:MSTORE receives two stack values as its arguments to store the value from 1:PUSH at the memory address from 2:PUSH. Dependencies are not restricted to values from the EVM stack but may extend to memory references. Instruction 23:RETURN is such a case: it pops two arguments from the stack, which represent the address and length of data in memory to return. The third dependency (on 21:CODECOPY) encodes the memory reference itself. Instructions 12–14 from the bytecode do

not occur in the value graph because the underlying execution took the jump from instruction 11 to instruction 15 at runtime.

We built an algorithm that propagates the necessity of instructions in the value graph in a backward fashion, based on the introduced necessary instruction list. Necessary instructions are colored in blue in Figure 7. All instructions connected to 6.SSTORE and 23.RETURN are considered necessary. We obtain the set of wasteful instructions as the complement set of the necessary instructions.

To analyze the wastage characteristics of the Ethereum blockchain, we computed value graphs for the initial 9M blocks on the replayer, which took 75 h to complete. A box plot and the average ratios of wasteful instructions are shown in Figure 8 and Figure 9.

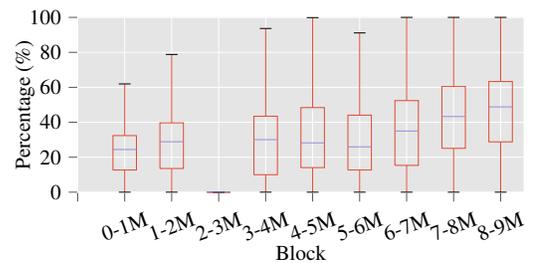

Figure 8: Box plots of wasteful instruction ratios for ranges of 1 M blocks.

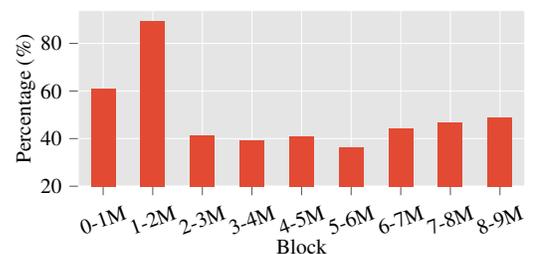

Figure 9: Average ratios of wasteful instructions for ranges of 1 M blocks.

The median and average of the wasteful instruction ratios are gradually increasing from block 5 M. As a consequence, wasteful instructions constitute nearly 50% of the total instructions in range 8–9 M. The irregularity in range 2–3 M in Figure 8 is due to DoS attacks in the year 2016 (cf. [3]). As a result, the box and whiskers in this range stick to zero, while the average ratio is not affected. Another irregularity shows in range 1–2 M in Figure 9, because it contains smart contracts with a high total number of instructions but a negligible number of necessary instructions. This skewed the average ratio of wasteful instructions, although this was not caught in the box plot.

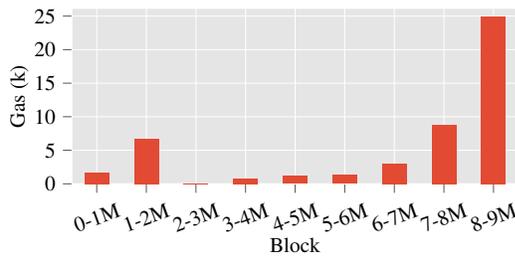

Figure 10: The average of wasted gas per transaction for ranges of 1 M blocks.

We calculated the gas consumed by wasteful instructions. As illustrated in Figure 10, recent transactions tend to waste more gas. We found a single transaction to waste nearly 25,000 gas in range 8–9 M.

5.2 Fuzzer Use Case

Fuzzing is a popular means to assess software quality [32] and exercise a program under test with many randomized inputs. A fuzzer aims to execute as many program paths as possible by varying input values, and, hence, fuzzers incur a large runtime overhead as they repeatedly execute the program under test. Some approaches reduce the environment overhead [47] or improve path coverage [36] for alleviating the fuzzing overheads. There is a variety of fuzzers available for Ethereum such as Echidna [24] and Harvey [45], which require user annotations in the Solidity source code for guiding the fuzzing process. Other fuzzing tools [31, 42] do not require annotations but still require the source code (not the EVM bytecode).

Low-performing fuzzers limit the effectiveness of a fuzzing campaign and may result in many false negatives [29]. Parallelizing fuzzers improve the performance but cannot be directly used for the blockchain testing due to its sequential execution. A parallel fuzzer for blockchains would require to replicate the blockchain for each parallel instance, which is not a viable approach.

We adapt our replay mechanism introduced in Section 4.3 for parallel fuzzing as a showcase. The aim of this showcase

is to demonstrate the efficiency of the ContractFuzzer [29] using our parallel replay mechanism. The ContractFuzzer dynamically analyzes compiled bytecode, which is most suitable for third-party auditing of binaries that does not require user annotations for fuzzing. The ContractFuzzer cannot audit third-party contracts efficiently without our replay mechanism because contracts will be fuzzed on the testnet where all smart contracts undergoing the fuzzing campaign must be deployed (as described in Section 3.3). For each input variation of a fuzzing campaign, the contracts must be redeployed on the testnet slowing down the campaign.

For fuzzing, the ContractFuzzer tool needs an Ethereum smart contract application binary interface [19, ABI], which describes input parameters and the message type of a smart contract. Most re-usable contracts/services have their ABIs publicly available, e.g., via the Etherscan web service [22].

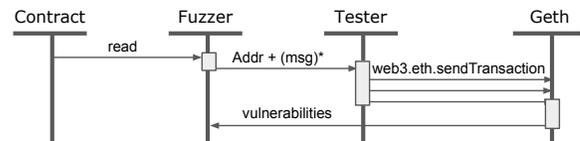

Figure 11: ContractFuzzer workflow.

Figure 11 depicts a sequence diagram of the ContractFuzzer workflow without our replay mechanism. The bytecode of a *contract* is read by the *fuzzer*, which analyzes the contract’s ABI and generates a set of random messages that execute the contract and comply with its ABI. The *tester* sends the messages one-by-one to *Geth*, for execution on the EVM, which contains specific monitoring hooks for discovering vulnerabilities that occur during bytecode execution. The results from the bytecode execution are sent back to the *fuzzer*, which generates a vulnerability report.

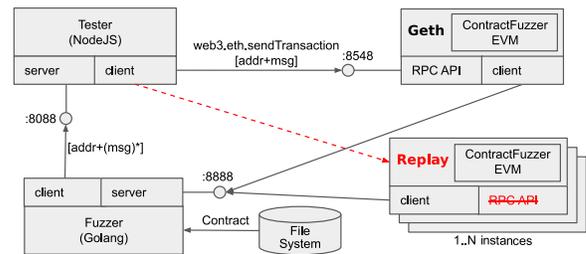

Figure 12: Extended ContractFuzzer architecture.

We extended the ContractFuzzer with our *replay* mechanism for parallel fuzzing as depicted in Figure 12. Our parallel fuzzing mechanism directly reads the input substate from the substate database (as indicated by the dashed arrow in Figure 12) such that fuzzing can be performed in parallel and without the need of deployment on the testnet.

The input variations generated by the ContractFuzzer in the form of random messages (see Figure 11) differ from the

Number of threads	Throughput (contracts/min)	Speedup (\times) over original	Speedup (\times) replay
Original	1	0.46	n/a
Replayer	1	3.28	7.07
	4	4.65	10.01
	8	6.25	13.46
	16	10.05	21.65
	32	15.99	34.44

Table 4: ContractFuzzer performance improvements.

recorded, historical *message* data of the input substate from Section 4.1. For each input variation, the replayer replaces the historical message data of the input substate by the information provided in the corresponding message from the ContractFuzzer. This modification of the transaction input obviates the need to validate the transaction (“Assert Equal” in Figure 5) because fuzzing does not attempt a faithful replay. Rather, the purpose of the input variation in the fuzzer is to execute untested program paths and uncover previously unobserved behavior in the smart contract under test. We used several of ContractFuzzer’s sample contracts [28] to validate the integration of ContractFuzzer and its modified Geth EVM with our replayer. The integration produced the expected result, i.e., the same vulnerabilities as the original ContractFuzzer.

Our focus with this use case was to determine the achievable performance from off-the-chain fuzzing. For this experiment, we used our recording of the Ethereum mainnet. We created a simple NodeJS client for the Etherscan web service [22] to obtain the ABI of contracts. We used this client to get the first several hundred contracts from the mainnet that provide their ABI. Because ContractFuzzer supports contract analysis in batches, we divided this group into batches of ten contracts each. We have executed an analysis of this dataset using various combinations of batches running in parallel. We have measured the throughput of contracts (i.e., the number of analyzed contracts/min) as shown in Table 4. The first row lists the performance of the original ContractFuzzer, while the following rows list the throughput with increasing parallelism—i.e., the number of contract batches analyzed in parallel. The middle column provides the speedup over the original ContractFuzzer (w.r.t. the first row).

It follows from the second row that the ContractFuzzer with replay executing all batches in sequence is faster than the original ContractFuzzer. We attribute this to the fact that Geth adds more overhead compared to our light-weight substate. The speedup grows proportionally in the number of threads. The last column shows the relative speedup of multi-threaded over single-threaded replay.

Our fuzzing method has three key benefits: Firstly, our replayer provides smart contracts instantly and without prior deployment on a testnet, making the fuzzing configuration

straightforward. Secondly, our database has no dependencies between substate records and enables parallel fuzzing. This allows fuzzing campaigns on smart contracts where an arbitrary number of threads can be utilized. Thirdly, the substate database always provides the same initial data, while fuzzing against the testnet requires repeated redeployment to start from the same initial state.

5.3 Hard Fork Assessment

The Ethereum specification has been updated over the years because of several reasons such as the introduction of new EVM instructions and the protection from DoS attacks. Peers willing to accept the update have participated by accepting a blockchain forked from the existing blockchain, or hard fork. A hard fork is first proposed via a meta Ethereum improvement proposal (meta EIP), which includes other EIPs. When the Ethereum community agrees on the hard fork, a certain block number is pre-determined after which the hard fork becomes effective.

At the time of writing there have been nine hard forks on the Ethereum blockchain that changed gas costs of existing instructions or introduced new instructions. Such updates of the EVM specification can cause problems on already-deployed smart contracts which—then—depend on an outdated specification. For example, Ethereum suffered from breaks of backward compatibility by EIP-1884 [15] during the Istanbul hard fork. The EIP changed the gas cost of several opcodes and it was expected that a few contracts will fail to operate. Indeed, Ethereum frameworks such as Aragon and Kyber found function calls in their smart contracts to fail with out-of-gas errors [6, 43]. Aragon expected that EIP-1884 would break 680 smart contracts in their framework [9], and had to release new smart contracts to replace them [43].

Therefore, it is essential to assess a hard fork on existing contracts before it is activated on the network. The Ethereum community maintains testnets where hard forks are activated and tested before being deployed on the mainnet. However, testnets have their own state databases which differ from the mainnet, and developers must execute transactions on a testnet to deploy contracts and predict possible impacts from a hard fork. This approach is merely a new execution of transactions and cannot reproduce the historical contexts with a new hard fork specification.

We propose the use of our replayer to assess new hard forks on already deployed smart contracts on the mainnet. Our replayer efficiently replays transactions in the same context except the protocols changed by the new hard fork. Hence, the effect of the hard fork on existing contracts can be observed, which helps decision making and hard-fork analysis.

For demonstration purposes we conducted an assessment of the historical hard forks on the Ethereum mainnet. Table 5 enumerates the history of the Ethereum hard forks at the time of writing. Out of nine hard forks, the *DAO Fork* and

Hard fork	Assessed transactions (M)	EVM runtime exception (%)			Output changed (%)	Gas usage changed (%)			Unaffected (%)
		Invalid JUMP	Invalid opcode	Reverted		Out-of-gas	Increased	Decreased	
Homestead	0.416	0.000	0.000	0.000	0.000	0.002	0.000	0.000	99.998
Tangerine Whistle	2.508	0.585	0.000	0.000	3.667	2.761	75.125	0.003	17.859
Spurious Dragon	3.055	0.530	0.000	0.000	9.407	2.549	71.182	0.001	16.331
Byzantium	26.014	0.062	0.000	0.000	2.560	0.299	8.359	0.001	88.718
Constantinople / Petersburg	193.668	0.008	0.000	0.000	0.344	0.040	1.123	0.000	98.485
Istanbul	303.300	0.064	0.198	1.009	3.804	7.884	68.494	18.547	0.000

Table 5: Hard fork assessment: percentage of affected and unaffected contract invocations and the share of each effect. Column “Assessed transactions” indicates the number of contract invocation transactions executed for the assessment. A transaction in “EVM runtime exception” was successful in the original invocation but raised an exception during the hard fork assessment. (1) “Invalid JUMP”: destination of the `JUMP` instruction was not a `JUMPEDEST` instruction. (2) “Invalid opcode”: executed instruction was the `INVALID` instruction or not defined in the hard fork. (3) “Reverted”: the `REVERT` instruction was executed. (4) “Output changed”: side effect on replay output changed, disregarding gas usage and account balances. (5) “Out-of-gas”: successful in the original invocation but raised out-of-gas exception in the hard fork assessment. (6) “Increased” & “Decreased”: produced the same output as the original invocation except gas usage and account balances. (7) “Unaffected”: produced the exactly same output as the original invocation.

Muir Glacier are not included because they do not affect the EVM specification for transaction execution. Hard fork *Constantinople / Petersburg* comprises two steps that took effect within the same block and hence were combined for this study. For the assessment of a hard fork on deployed contracts, all historic contract invocation transactions prior to the activation of the hard fork are relevant (cf. Section 2). The activation position of a hard fork on the chain thereby determines the number of transactions that need to be assessed, from the genesis block until the block where the hard fork became active. Column “Assessed transactions” in Table 5 depicts the number of contract invocation transactions that our replayer executed for each of the historical hard forks on the mainnet. Note that the *Istanbul* hard fork took place at block height 9.069 M, whereas the block range of our experiment was 0–9.0 M, but we do not regard the excluded 69 k blocks to be significant for this demonstration of our replayer. In total, our replayer executed 529 million contract invocation transactions as part of this assessment. The experiment took 15.15 h with an overall throughput of 9,694.30 tx/s.

The results, i.e., the effects of each hard fork on the contract invocation transactions prior to its activation on the mainnet, are depicted in Table 5. The columns below “EVM runtime exception” state the percentage of transactions for which the original invocation was successful but raised an exception in the hard fork assessment. `JUMP` instructions to invalid destinations and the `INVALID` instruction have been used as a pragmatic way to throw runtime exceptions. The *Byzantium* hard fork at block 4,370,000 introduced the `REVERT` instruction. The main difference is that `JUMP` and `INVALID` consume all remaining gas but `REVERT` refunds the remaining gas to the sender.

Effects on Execution Path The sum of column “EVM runtime exception” and column “Output changed” is the percentage of transactions for which the EVM specification change resulted in an execution path different from the original invocation. The hard fork with the highest ratio of sum of “EVM runtime exception” and “Output changed” is *Spurious Dragon* with 9.9 %, followed by *Istanbul*, and *Tangerine Whistle* with 5.1 % and 4.3 %. *Spurious Dragon* activated EIPs that increased the gas cost of EVM instructions, limited code size, and cleared empty accounts in the world state trie to protect the network from DoS attacks. The other two hard forks, *Istanbul*, and *Tangerine Whistle*, mainly updated gas costs of EVM instructions. This is an indication that the execution paths of those contracts are highly dependent on the EVM gas system. Hence, updating the gas system may cause such contracts to fail.

Effects on Gas Consumption The hard forks *Tangerine Whistle* and *Spurious Dragon* increased the gas costs of several EVM instructions, resulting in more than 70 % of contract invocations to consume more gas, and 2 % to raise an out-of-gas exception. The *Istanbul* hard fork increased the gas costs of several instructions that access tries and reduced the gas costs of loading call data input, which affected all contract invocations. As a result, 68.5 % of all contract invocations consumed more gas, 7.9 % raised an out-of-gas exception, and 18 % consumed less gas.

6 Related Work

Hartel and Stalduin [26] proposed a tool to generate a replay script for historic transactions based on Truffle. It redeploys the smart contract with historic data for replay on the blockchain. This approach cannot faithfully reproduce historic data because the execution environment may have changed on redeployment. Their re-execution fails to accurately replay 39% of the 1120 sampled smart contracts [26]. In contrast, we identified the complete set of environmental parameters required to faithfully replay transactions. We achieved a replay accuracy of 100% for the 590 million transactions on the Ethereum mainnet up to block 9M. Our approach replays transactions off-the-chain and thereby eliminates the networking and consensus overhead. Our substate database provides direct access to the transaction-relevant substate of any recorded transaction, which allows transaction execution in isolation and at scale. In contrast, [26] can only execute transactions sequentially from the tip of the chain. Their method relies on the availability of the verified contract source code on Etherscan, but only 2.2% of all Ethereum smart contracts deployed until Sept. 2018 have been made available as source code on Etherscan [38].

Transaction replay is often required to find vulnerabilities of smart contracts and verify the soundness of such methods. ContractFuzzer [29] and EVMFuzzer [23] adopted fuzzing techniques to spot weaknesses in smart contracts and EVMs. ContractFuzzer used 6,991 smart contracts for fuzzing and detected seven types of vulnerabilities. EVMFuzzer performed fuzzing for 253,153 contracts to expose vulnerabilities in different types of EVMs. Hartel and Schumi [25] used mutation testing to assess the quality of smart contracts. They injected smart contract specific mutations at a large scale and performed the experiment for more than 2 million transactions.

Replaying the whole blockchain can be conducted to understand the dynamic behavior of the Ethereum ecosystem. Yang et al. [48] and Baird et al. [4] measured transaction execution time for millions of blocks and discovered that time-per-gas ratios of instructions are not uniform, which potentially threatens the decentralization of the Ethereum network. Aldweesh et al. [2] observed a similar result by measuring CPU and gas usage of opcodes independently with their OpBench framework. TokenScope [8] replayed the blockchain to investigate inconsistent tokens in Ethereum. They took a trace-based approach to find inconsistencies by comparing the information about data structure, interfaces, and events. They reported 7,472 inconsistent tokens out of 57,411 tokens from 6 million examined blocks.

7 Conclusion

The Ethereum blockchain and its surrounding environment have been rapidly developed in recent years. This has led to a situation where “the need for software engineers to de-

velop specialized tools and techniques for blockchain-oriented software development” [40] has arisen. However, there is a lack of tools that scale for tasks including third-party auditing, testing, debugging, and quality assurance.

Our work proposes a new infrastructure for the lightweight execution of smart contract transactions. Our framework can exercise smart contracts at scale, multi-threaded, and in isolation. We were able to execute all available smart contracts from the Ethereum mainnet 4.54 times faster in comparison to the standard Ethereum client, Geth. Moreover, we could scale the execution effectively, e.g., on 44 cores our framework runs 50.03 times faster.

Our infrastructure is highly suitable in scenarios that require the fast and repeated execution of smart contracts. We have demonstrated the application of our testing and profiling infrastructure in three use cases: (1) for bytecode metrics, (2) for smart contract fuzzing, and (3) for hard fork compatibility assessment. Our infrastructure scales for the whole blockchain, which has not been possible with prior approaches.

Abstract

On-device learning is an emerging technique to pave the last mile of enabling edge intelligence, which eliminates the limitations of conventional in-cloud computing where dozens of computational capacities and memories are needed. A high-performance on-device learning system requires breaking the constraints of limited resources and alleviating computational overhead. In this paper, we show that employing the 8-bit fixed-point (INT8) quantization in both forward and backward passes over a deep model is a promising way to enable tiny on-device learning in practice. The key to an efficient quantization-aware training method is to exploit the hardware-level enabled acceleration while preserving the training quality in each layer. However, off-the-shelf quantization methods cannot handle the on-device learning paradigm of fixed-point processing. To overcome these challenges, we propose a novel INT8 training method, which optimizes the computation of forward and backward passes via the delicately designed *Loss-aware Compensation* (LAC) and *Parameterized Range Clipping* (PRC), respectively. Specifically, we build a new network component, the compensation layer, to automatically counteract the quantization error of tensor arithmetic. We implement our method in Octo, a lightweight cross-platform system for tiny on-device learning. Evaluation on commercial AI chips shows that Octo holds higher training efficiency over state-of-the-art quantization training methods, while achieving adequate processing speedup and memory reduction over the full-precision training.

1 Introduction

The unprecedented booming of Machine Learning (ML) techniques has achieved great success in the past decade [8, 35]. The magic of ML comes from model training on large-scale datasets, relying on the deployment in the cloud environment to meet the resource-hungry demands [44, 45, 60]. This kind of in-cloud computing paradigm can bring about the essential drawbacks that it is hard to provide personalized models

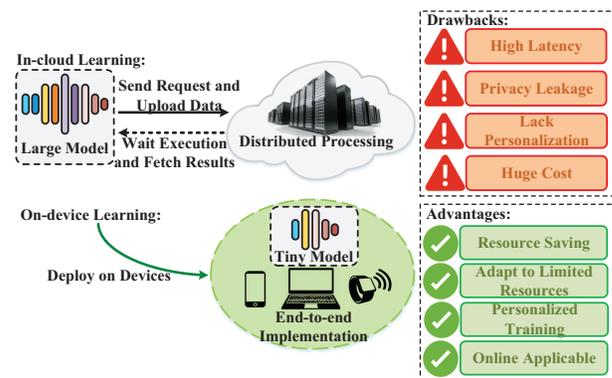

Figure 1: Conventional ML applications rely on the in-cloud learning paradigm, incurring essential drawbacks. A new trend is to use on-device learning to address these issues.

[14], suffering from high latency [46] and privacy leakage [40]. These issues promote the rise of on-device learning [5, 39, 65], which eliminates in-cloud learning’s limitations by handling the end-to-end learning process totally on user devices [4, 57], *e.g.*, mobile and IoT equipment [54]. This edge environment makes on-device learning often subject to limited computational capacity and memory [66]. Therefore, breaking resource constraints is the key step to implement on-device learning systems.

Conventional model compression methods, *e.g.*, Low-rank Decomposition [31, 61–63], Model Pruning [11, 16, 18, 20] and Network Sparsification [1, 19, 37], are insufficient as they are designed for large-scale training tasks and cannot well match the characteristic of tiny on-device learning. Fortunately, previous researches reveal that neural networks are often implemented in a 32-bit floating-point (FP32) format [17] and representing model parameters in such high precision is not always necessary [36]. It is feasible to represent parameters in lower bit precision while not downgrading the entire network quality. Based on our preliminary experiments (§2.4) that handle CNN training in the 8-bit fixed-point (INT8) format [2], we are inspired by the potential improvements and

thus intend to design a full-INT8 quantization-aware training system for on-device learning.

However, existing quantization methods can hardly be employed for on-device training due to the following limitations: (1) cannot apply to the training process [3, 5, 24, 36, 42], (2) cannot support generic networks without specific structure design [34, 47, 58], (3) cannot enable hardware-level INT8 acceleration during the training phase [7, 23, 49, 56], and (4) cannot make the gradient calibration fit on-device resource restrictions in backward pass [32, 67]. Therefore, we need a full-INT8 training method working on devices directly, covering both forward and backward passes.

Designing a desired INT8 on-device training is not easy, and we need to overcome the following challenges: (1) simplifying the computational procedure and truly accelerating processing speed on devices, (2) maintaining model quality when using INT8 quantization-aware training, (3) alleviating system overhead, *e.g.*, reducing memory footprint and I/O bandwidth utilization, and (4) making the system ease-of-use and compatible with multiple platforms. We achieve these objectives via a co-design of neural network constructor and 8-bit training engine.

More precisely, we give deep insights into the rationale of 8-bit training (§4.1) and present a theoretical analysis of layer-wise quantization error (§4.2). We point out the key to preserve model quality in forward pass is to fill the error gap in tensor dot products and thus propose the *Loss-aware Compensation* (LAC) method (§4.3) to approximately recover the quantized output to the full-precision domain. Specifically, we propose a new network component, the compensation layer (§4.3.1), to handle this adjustment with three learnable parameters, and design an L2-regularizer (§4.3.2) to bound the update rate of these parameters for convergence stability. Meanwhile, we optimize the gradient calculation in backward pass by abstracting the calculation of derivative flows (§4.4.1) as a series of primary instructions (*e.g.*, dot product, broadcasting and bit-wise shifting) and introducing symmetric quantization on them. We carefully profile the possible distribution of gradient tensors and propose the *Parameterized Range Clipping* (PRC) method (§4.4.2) to handle INT8 quantization of intermediate derivatives. We address the issue of zero point offset in backward pass by restricting clipping domain in the symmetric scheme, under 95% confidence interval of gradient distribution.

We implement our INT8 training method in Octo, a lightweight cross-platform system for on-device learning tasks. Octo’s training engine and network constructor are built in pure Python without the dependency of other sophisticated third-party libraries, and thus it is easy to port Octo to embedded devices. We evaluate Octo in different operating systems and deploy it on commercial AI platforms, such as HUAWEI Atlas 200DK [26] and NVIDIA Jetson Xavier [27], which can utilize the dedicated INT8 neuron chips. The evaluation results show that Octo achieves higher training

efficiency over state-of-the-art quantization training methods, with tiny system overhead. Specifically, Octo accelerates processing speed by up to $2.03\times$ and saves memory footprint by up to $3.37\times$, over the full-precision training.

Overall, the key contributions of our work are as follows:

- We propose a lightweight INT8 training method, enabling data quantization for both forward and backward stages (§4.1), which is efficient for deploying on-device learning applications.
- We present the theoretical characterization of quantization errors and reveal that filling the error gap caused by inner product is the key to preserve model quality of quantization-aware training (§4.2). This analysis guides us to design the compensation term to adjust quantized convolutional output.
- To achieve stable training efficiency, we propose the *Loss-aware Compensation* (LAC) and *Parameterized Range Clipping* (PRC) methods to handle data quantization in forward pass (§4.3) and backward pass (§4.4), respectively. LAC introduces the novel compensation layers and updates the compensation term based on the feedback of network loss. Meanwhile, PRC maintains bit precision in gradient calculation and avoids offset error of the zero point via symmetric clipping.
- We build a cross-platform system named Octo, which is compatible with different operating systems and can be easily ported to embedded platforms (§5). Octo is specifically designed for on-device training by exploiting the fixed-point computational primitives of embedded processors, with no need of GPUs. Evaluation on HUAWEI Atlas 200DK [26] and NVIDIA Jetson Xavier [27] shows that Octo achieves higher system performance over state-of-the-art quantization training methods, thus verifying the effectiveness of our approach (§6).

To the best of our knowledge, Octo is the first general framework to implement INT8 training on devices, optimizing both forward and backward stages. The project of Octo is open-source¹ and will constantly contribute to the further development of on-device learning techniques in practice.

2 Motivation

We start by discussing the limitations of conventional in-cloud learning (§2.1), and introducing the background of on-device learning applications (§2.2). Then, we will point out quantization-aware training (§2.3) is the key to deploy on-device learning in real-world scenarios, holding significant advantages over conventional model compression methods. We also present a case study to demonstrate the performance improvements (§2.4) by leveraging INT8-based training on

¹<https://github.com/kimihe/Octo>

devices, and analyze the limitations of existing quantization methods (§2.5).

2.1 Limitations of In-cloud Learning

Training ML models is a resource-hungry procedure, relying on a mass of learnable data and computational capacity. Thus, conventional ML applications are often deployed in the cloud environment, requiring expensive cost of machine clusters and distributed processing. However, such an in-cloud learning paradigm is vulnerable to privacy leakage as user information may be exposed to untrusted third parties. More seriously, the high latency for fetching inference results may become the bottleneck to slow down the learning performance. Also, as models are trained in a global scheme (*e.g.*, the Federated Learning [40]), it is not easy to provide customized models for different users to match personalized preferences [4].

2.2 Rise of On-device Learning

With the rapid growth of device processing capacity and memory volume, it comes the rise of on-device learning, which handles the end-to-end ML procedure on devices directly and breaks the limitations of in-cloud learning. A pertinent case in industry is the Apple Face ID [51], which enables personalized face recognition totally on user phones. Here, we briefly introduce the definition and key objectives of on-device learning.

Definition. In general, on-device learning refers to entirely transferring the model training and inference procedure on user devices, with no need of data exchanging to other machines [54]. Besides, on-device learning can apply to edge equipment (*e.g.*, IoT and mobile devices), thus it also corresponds to Edge Intelligence [66] in practice.

Objective #1: Resource Saving. The on-device hardware is often bounded by the resource-constrained environment, with limited computational capacity [30], memory volume [22, 33] and I/O bandwidth [38]. Therefore, saving the system overhead is the key to deploy on-device learning.

Objective #2: Model Quality. The learning algorithm should hold a stable convergence efficiency, with a comparable prediction accuracy and generalization ability as the in-cloud training schemes [39].

Objective #3: Personalized Training. As the training procedure is entirely based on the local data on user devices, it should provide customized models to meet user preference [14], instead of generating a global model for an ensemble of applications.

Objective #4: End-to-end Implementation. Considering the incremental user data, the trained models should keep up-to-date continuously. Thus, the entire learning process requires an end-to-end implementation on the devices [6].

Summary. These four objectives are the key metrics guiding the design of high-efficiency on-device learning systems.

2.3 Bit Precision and Data Quantization

Considering the resource-constrained environment on devices, compressing model size and alleviating computational pressure is the key to applying on-device learning in real-world scenarios. Although there are some common compression methods, *e.g.*, Low-rank Decomposition [31, 61–63], Model Pruning [11, 16, 18, 20] and Network Sparsification [1, 19, 37], they are designed for large-scale training tasks and cannot well match the pattern of tiny on-device learning. Fortunately, data quantization is a promising method to address these limitations.

Definition. The gist of quantization is to represent data via less bit precision, *e.g.*, converting a 32-bit floating-point (FP32) number to the 8-bit fixed-point (INT8) format. Here are two core operations of data quantization.

Operation #1: Number Discretization. The first operation is to map real numbers from a “continuous” domain to certain discrete values, *e.g.*, from floating-point numbers to integers. The number of discrete values is called the quantization level. A common way is to partition the original domain into several intervals and represent the numbers located in an interval by the central point [36]. The objective of number discretization is to reduce the value variety and represent the numbers by a few target points.

Operation #2: Domain Transformation. The second operation is to restrict the values from a wide representation range to a small range, *e.g.*, from 32 bits to 8 bits. The transformation procedure can be abstracted as a step function, where the “width” of the step can be uniformly or non-uniformly assigned [24]. Uniform transformation is hardware-friendly while non-uniform transformation can provide higher bit precision. Therefore, domain transformation aims at storing each real number in the fixed-point format with fewer bits.

Inspirations. Existing ML frameworks often implement the tensor arithmetic in FP32 or FP64 format to maintain high precision of numerical operations. However, previous work reveals that most neural networks are over-parameterized and representing model parameters in such high-precision format is not necessary [36]. It is feasible to maintain parameters in lower bit precision while not downgrading the entire network quality. Besides, numerical operations based on floating-point formats are much more expensive than fixed-point ones, especially for the tiny IoT equipment without floating-point processing units. Therefore, it comes to our motivation to compress model parameters from FP32 to INT8 format and handle the training procedure on devices.

Summary. Overall, we summarize the following properties of data quantization: First, it enables model in bit level, which can effectively reduce memory footprint and accelerate tensor arithmetic. This helps us implement on-device learning systems in resource-constrained cases. Second, quantization is more hardware-friendly for both generic hardware (*e.g.*, CPU/GPU) and specific chips (*e.g.*, FPGA), which can be

	Forward Pass (ms)	Backward Pass (ms)	Per-iteration Time (ms)	Parameter Memory (MB)	Model Accuracy
FP32	95.85	140.03	240.06	18.51	97.6%
INT8	54.57	67.66	126.41	9.42	95.2%
Comparison	1.86×	2.07×	1.89×	1.96×	-2.39%

Table 1: System performance using INT8 and FP32 training.

easily applied to edge intelligence applications.

2.4 Potential Gains

Employing data quantization into model training can save resource costs and accelerate processing speed. Here, we present an illustrative case study to show the potential gains. The experiment is the image classification task on a 3-layer CNN with MNIST dataset [9], running on the HUAWEI Atlas 200DK platform [26] with 10 epochs. We quantize the mini-batch input, weights and gradients of convolutional layers into INT8 format and inspect the system performance in terms of arithmetic efficiency, memory footprint and I/O bandwidth. From the comparison shown in Table 1, the INT8-based quantization-aware training can effectively alleviate system overhead while not downgrading the model quality. This raises an interesting question: can we achieve the same level of FP32 training performance with only INT8 operations for common on-device learning applications (*e.g.*, image classification)? Therefore, we are dedicated to building a lightweight INT8 training system to achieve this target.

2.5 Why not Existing Quantization Methods?

To implement on-device learning systems, existing quantization methods are insufficient due to the following limitations. **#1. Cannot apply to training process.** Most quantization methods are designed for inference only, where quantization is used in the forward pass based on a pre-trained model for accelerating the prediction speed [3, 5, 24, 36, 42]. As these methods have not addressed the issues of calculating gradients on discretized parameters and eliminating error gap after convolutional operations, they cannot be used in training process.

#2. Cannot support generic networks without specific structure design. Some methods aim at quantizing parameters with extremely low bit precision, *e.g.*, the binary [58], ternary [34] and XNOR [47] networks. However, they are specifically designed and require fundamentally modifications of network structures. Thus, they are not suitable for the training of generic networks.

#3. Cannot enable hardware-level INT8 acceleration in training phase. Google has proposed a verifying quantization method, called Fake Quantization [23], which uses INT8-based numerical information for parameter representation, while still packaging values in FP32 format for tensor arithmetic. The subsequent methods [7, 49, 56] also follow this paradigm that tensors are quantized and dequantized before

arithmetic operations. This paradigm cannot fundamentally accelerate processing speed or reduce memory footprint because it does not exploit the hardware-level power of fixed-point processing.

#4. Cannot make the gradient calibration in backward pass fit on-device resource restrictions. Recently, it is a trend to study the quantization-aware training with 8 bits. For example, Zhu *et al.* [67] proposed the unified INT8 training covering both forward and backward passes. However, current researches have not optimized the derivative calculation of model parameters and intermediate tensors during the backward pass, which still follows the fake quantization paradigm. As the backward pass often dominates the per-iteration time, it is of great potential to conduct backward quantization to further improve training efficiency.

Summary. Overall, we aim at designing an INT8 quantization method for training neural networks directly on devices.

3 Overview and Design Challenges

Enabling INT8 quantization on devices requires a co-design of neural network constructor and 8-bit training engine. We present Octo, an INT8 quantization-aware training system that addresses the following key challenges.

Challenge #1: How to fundamentally accelerate processing speed on devices? Existing quantization methods based on fake quantization cannot fully exploit the power of INT8 processing, thus the on-device training performance is still bounded by iterative tensor arithmetic. We need to simplify the computational procedure for more effective acceleration.

Our solution: We introduce the uniform 8-bit quantization into convolutional operations, affine blocks, activation functions and gradient calculation. The data quantization covers both forward and backward passes, thus the entire iteration can be accelerated. Also, the uniform range transformation is hardware-friendly and can be implemented in the layer wise.

Challenge #2: How to maintain model quality when using INT8 quantization-aware training? Introducing data quantization during model training will inevitably impact the numerical precision of parameters and incur accumulative errors cross layers. The final output will be significantly different from the full-precision training. Besides, the gradient calculation will face the same issue if we use quantization in the derivative calculation. These factors will degrade the final model accuracy and even make the training cannot converge.

Our solution: We maintain the model accuracy by adjusting the intermediate results of forward and backward passes together. In the forward pass, we propose the *Loss-aware Compensation* (LAC) method and design a new network component, called the compensation layer, to fill the error gap caused by quantized tensor arithmetic. The parameters inside the compensation layer will be optimized according to the network loss. For a higher updating efficiency, we introduce an L2-regularization term of compensation parameters

to modify the loss function. In the backward pass, we propose the *Parameterized Range Clipping* (PRC) to bound the transformation domain of quantized gradients, using a 95% confidence interval based on our theoretical analysis (§4.2).

Challenge #3: How to alleviate system overhead, especially reducing memory footprint? The training efficiency is often bounded by the limited memory volume and I/O bandwidth. This requires us to conduct memory and storage optimization in the training engine.

Our solution: We preserve all the parameters and intermediate derivatives in INT8 format. This effectively reduces the peak memory footprint and saves the storage cost for accessing parameter cache. Also, introducing LAC and PRC mentioned in challenge #2 may incur extra overhead. We transfer the compensation term from a higher-degree polynomial using FP32 tensors into an affine operation just relying on the output of convolutional layers. This can effectively restrict the computational cost of compensation and clipping.

Challenge #4: How to make the system ease-of-use and compatible with multiple platforms? In real-world cases, devices are often handled by tiny embedded systems that may not be well compatible with commodity learning frameworks (e.g., PyTorch Mobile [41] and TensorFlow Lite [15]). This requires us to build the system based on the standard environment without the dependency of other sophisticated third-party libraries.

Our solution: We first abstract core computation of convolutional and fully-connected layers into the basic operation of tensor-wise dot product. Then, we optimize the dot products by using pure Python and C++. We use the light-weight Pybind tool [43] and C++ header-based Eigen [52] to embed the hardware-level matrix instructions in Python-level training. This kind of hybrid implementation makes our system compatible with most operating systems, including embedded Linux, macOS and Windows.

Summary: The above four challenges and solutions guide the design of our system.

4 Octo Design

We first discuss the rationale of 8-bit training, and highlight the key difference between Octo and the prior fake quantization method (§4.1). Then, we present a theoretical formulation of quantization error and analyze how to preserve training quality (§4.2). We propose the *Loss-aware Compensation* (LAC) and *Parameterized Range Clipping* (PRC) methods to conquer the aforementioned challenges, in forward (§4.3) and backward pass (§4.4), respectively.

4.1 Workflow of 8-bit Training

We describe the gist of 8-bit training by discussing the prior work of fake quantization (§4.1.1), which is helpful for understanding the next steps of Octo design. For a clear explanation,

Variable	Definition
n	The number of bits used for quantization.
W_f	The full-precision FP32 weights.
X_f	The full-precision FP32 input.
W_q	The quantized INT8 weights.
X_q	The quantized INT8 input.
Y_f	The FP32 output of dot product in fake quantization.
Y_q	The INT32 output of dot product in Octo.
s_w	The scaling factor when quantizing W_f .
s_x	The scaling factor when quantizing X_f .
z_w	The offset of zero point when quantizing W_f .
z_x	The offset of zero point when quantizing X_f .
$Q(X)$	The quantization function.
$Q^{-1}(X)$	The dequantization function.
$\text{scale}(M)$	The function for calculating scaling factor of tensor M .
$\text{round}(M)$	The discretization function using stochastic rounding on tensor M .
$\text{clip}(M)$	The clipping function to bound the range of tensor M .
$\text{dot}(X, W)$	The dot product of X and W .
r_x	The error gap incurred by discretizing X_q .
r_w	The error gap incurred by discretizing W_q .
δ	The error gap between FP32 and INT8 dot product.
$\hat{\delta}$	The compensation term to approximate δ .

Table 2: Notations used in INT8 quantization-aware training.

we take a 3-layer CNN (1 CONV + 2 FCs) as the example and list all the notations in Table 2.

4.1.1 Fake Quantization Training

Compared with vanilla full-precision training (Figure 2(a)), fake quantization (Figure 2(b)) first quantizes the input and weight into INT8 format, then it dequantizes these variables back to the FP32 format before conducting tensor dot product. Note that the computational overhead of CONVs and FCs mainly comes from convolutional and affine operations, which can be unfolded as a series of dot products in low-level instructions. Therefore, we regard dot products as the key computation in forward pass. The rationale of fake quantization training can be described as following three steps:

Step #1: Quantization. This step transfers FP32 numbers to INT8 format.

$$X_q = \text{round}\left(\frac{X_f}{s_x} + z_x\right), \quad (1)$$

$$W_q = \text{round}\left(\frac{W_f}{s_w} + z_w\right), \quad (2)$$

$$s_x = \text{scale}(X, n) = \frac{\max(X_f) - \min(X_f)}{2^n - 1}, \quad (3)$$

$$z_x = \max(X_q) - \frac{\max(X_f)}{s_x}, \quad (4)$$

$$s_w = \text{scale}(W, n) = \frac{\max(W_f) - \min(W_f)}{2^n - 1}, \quad (5)$$

$$z_w = \max(W_q) - \frac{\max(W_f)}{s_w}. \quad (6)$$

Step #2: Dequantization. This step recovers the INT8 numbers to FP32 format.

$$X_f = (X_q - z_x) \cdot s_x \quad (7)$$

$$W_f = (W_q - z_w) \cdot s_w \quad (8)$$

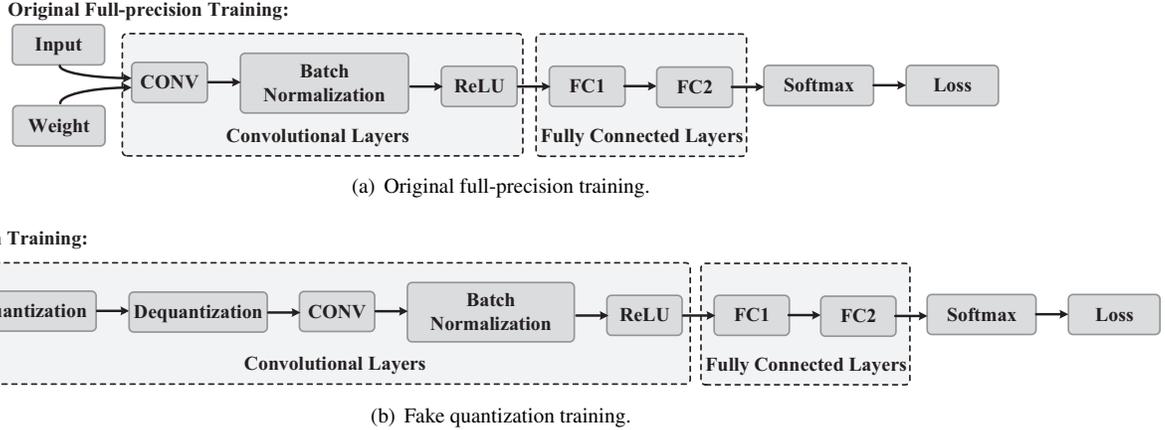

Figure 2: Workflow of previous training methods.

Step #3: Dot Products. This step conducts dot products based on the recovered FP32 tensors and yields FP32 results.

$$Y_f = \text{dot}(X_f, W_f) \quad (9)$$

Performance Analysis. Fake quantization captures the INT8 numerical information while still handling tensor arithmetic in FP32 format. Thus, *it cannot truly alleviate the computational overhead*. Also, the precision degradation after the first two steps mainly comes from the integer rounding, thus the dot products in the third step will not incur much error. However, a practical quantization-aware training method needs to move the dot products between quantization and dequantization, so as to utilize the power of fixed-point hardware. We follow this principle to design Octo’s training.

4.1.2 Octo’s Training

As shown in Figure 3, Octo holds the tensor arithmetic totally in INT8 format and contains the following three steps.

Step #1: Quantization. This step follows the same formulation as Eq. (2) and Eq. (1). We use the stochastic rounding [17] to build the discretization function $\text{round}(M)$, which maps floating-point numbers into integers and can be defined as:

$$\text{round}(M) = \begin{cases} \lfloor x \rfloor, & w.p. \quad 1 - \frac{x - \lfloor x \rfloor}{\varepsilon} \\ \lfloor x \rfloor + \varepsilon, & w.p. \quad \frac{x - \lfloor x \rfloor}{\varepsilon} \end{cases}, \quad (10)$$

where ε represents the smallest positive fixed-point value under given bits. For example, $\varepsilon = 2^{-8}$ in 8-bit quantization. This discretization function holds the unbiased rounding property, thus the expected rounding error is zero, *i.e.*, $\mathbb{E}[\text{round}(M)] = M$. This property alleviates the discretization error caused by integer rounding.

Step #2: Dot Product This step conducts dot products on INT8 tensors and returns the INT32 results to avoid overflow.

$$Y_q = \text{dot}(X_q, W_q) \quad (11)$$

Step #3: Dequantization with compensation This step converts the INT32 tensor to FP32 format and compensates the error of dot products caused by step #2.

Performance Analysis. If $z_x = 0$ and $z_w = 0$, we can simply use the following transformation to restore the INT32 output to FP32 format.

$$Y_f = Y_q \cdot (s_x \cdot s_w). \quad (12)$$

However, realistic INT8 processing requires `int` or `unsigned int` data type, which means the quantized values should be restricted within $[-128, 127]$ or $[0, 255]$, instead of using arbitrary 8-bit domains (*e.g.*, $[100, 355]$ is not feasible). Thus, we need non-zero z_x and z_w to serve as the offset of domain transformation. As z_x and z_w participate the dot product, we cannot recover Y_f by using Eq. (12), because the multiplication of zero point offset will incur a significant error gap. Compared with the vanilla dot product based on FP32 tensors, the dequantized output can be described as follows.

$$Y_f = Y_q \cdot (s_x \cdot s_w) + \delta, \quad (13)$$

where δ is the polynomial related to z_x and z_w . Therefore, step #3 is the key to Octo’s forward pass, and the gist is to *find a proper compensation term to fill the error gap δ while not incurring too much computational overhead*. The details will be discussed in the next section (§4.2).

4.2 Analysis of Error Gap

In this section, we formulate the error gap δ and approximate it as an affine transformation. Due to the page limit, we omit proof details and present the major theorem.

Theorem 1. *The error gap δ between FP32 and INT8 dot product can be approximated as an affine transformation,*

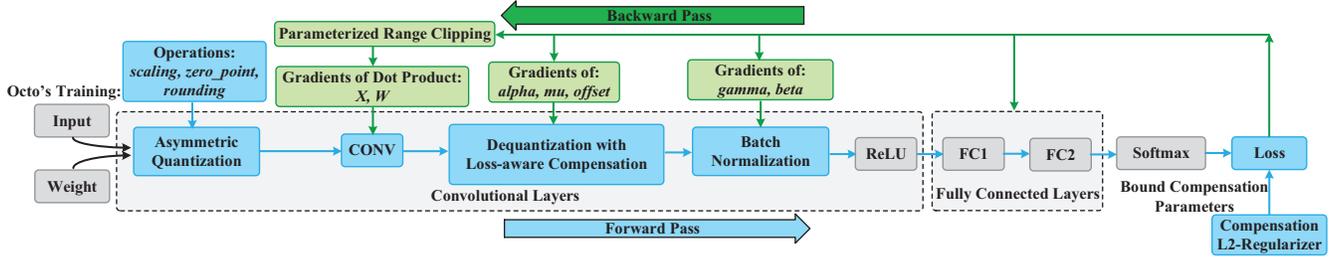

Figure 3: Workflow of Octo's training.

which is defined as:

$$\delta = s_x * \Delta X \cdot W_f + \gamma, \quad (14)$$

$$\Delta X = \frac{X_f}{s_x} - \text{round}\left(\frac{X_f}{s_x} + z_x\right), \quad (15)$$

$$\gamma = X_f(r_w - z_w)s_w - (r_x - z_x)(r_w - z_w)s_x s_w, \quad (16)$$

where $*$ represents the broadcast operation on tensors. Note that $\Delta X \cdot W_f$ dominates the computational overhead of Eq. (14), with the same shape as the dot product. Also, s_x and γ can be regarded as the coefficient factor and bias, respectively. This formulation can be simplified as an affine transformation and we approximate δ as:

$$\hat{\delta} = \alpha * \mu + \beta. \quad (17)$$

We call $\hat{\delta}$ as the compensation term, where the three parameters α , μ and β can be optimized based on the loss function of the network. Specifically, we abstract these parameters as a new network component, *i.e.*, the compensation layer (§4.3), to better adjust the quantized dot product.

4.3 Loss-aware Compensation

We propose the *Loss-aware Compensation (LAC)* method to preserve the numerical precision of tensor arithmetic in forward pass, LAC holds two core modules: (1) compensation layer (§4.3.1) and (2) L2-regularization of compensation parameters (§4.3.2).

4.3.1 Compensation Layer

The compensation layer is a new component injected to the network structure. Our target of introducing the compensation layer is to fill the error gap mentioned in Eq. (13) by approximating $\hat{\delta}$ in an affine transformation. We intend to compensate the quantized output in each layer to avoid the large accumulative errors across layers. Thus, the compensation layer is designed as an independent component that can be added at the end of both convolutional (CONV) and fully-connected (FC) layers. As shown in Fig. 4, we conduct preliminary experiments to inspect the layer completion time on CONVs and FCs. We can observe that the time cost of FCs is far less than that of CONVs. Besides, FCs usually occupy a tiny part

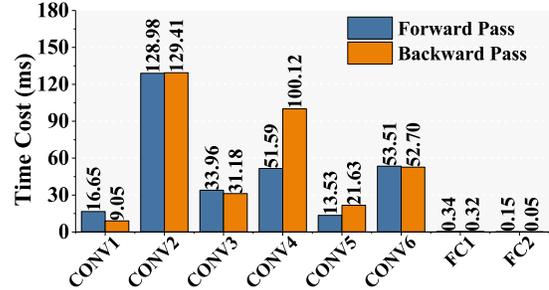

Figure 4: Layer completion time on CONV and FC layers.

of the entire network, quantizing FCs will not bring essential improvements to alleviate computational overhead. Therefore, we focus on using LAC on CONVs (although LAC can also be applied to FCs) and insert a compensation layer at the end of each CONV, following batch normalization to adjust the input distribution before ReLU, as depicted in Figure 3. Indeed, the compensation layer is an optional component, thus we can add a compensation layer after multiple CONVs. Each compensation layer holds three learnable parameters and we summarize their properties as follows.

- #1. α : This is a scalar controlling the scaling factor of compensation term.
- #2. μ : This is a tensor with the same shape as the dot product, which represents the expectation of the distribution of δ .
- #3. β : This is a tensor corresponding to the shape of μ , serving as the bias to adjust the compensation offset.

According to the expression of compensation term in Eq. (17), the calculation of $\alpha * \mu$ is handled by the broadcast operation, instead of the time-consuming tensor dot product. Also, adding β to $\alpha * \mu$ can be optimized as a shift operation, holding much less arithmetic complexity over multiplication. Therefore, calculating the compensation term will not incur much computational overhead.

4.3.2 L2-Regularization of Compensation Parameters

Although adding compensation layers can effectively fill the error gap caused by quantized dot product, the overall training efficiency may be impacted by the initialization of the compensation parameters. Actually, we can treat the approximated compensation term as special “noise” to counteract the

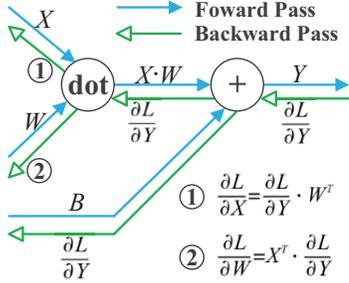

Figure 5: The derivative flows across layers in backward pass.

quantization error. Thus, the network robustness and convergence speed with compensation layers still rely on the update rule of the compensation layers. To improve the stability of compensation layers and accelerate the learning speed of compensation parameters, we design a dedicated L2-regularizer [55, 64] to better capture the significance of compensation layers. By adding the L2-regularization term to loss function, we modify the corresponding gradient calculation rule for updating the compensation parameters more efficiently. The modified loss function L is defined as follows:

$$L = -\underbrace{\frac{1}{N} \sum_{n=1}^n \sum_{k=1}^k t_{nk} \log y_{nk}}_{(1)} + \underbrace{\frac{1}{2} \lambda (\mu^2 + \beta^2)}_{(2)}, \quad (18)$$

where the first term represents the primary cross-entropy error measuring the difference between prediction y and ground truth t , based on mini-batch of size N . Meanwhile, the second term is the L2-regularizer reflecting the compensation performance from μ and β . As α is a scalar, we can omit its impact here. Actually, we can adjust the significance of these two terms by changing the value of λ . For example, we can set λ with a larger value to emphasize the effect of compensation layers. In practice, we empirically set λ as 0.1.

4.4 Backward Quantization

Apart from introducing LAC in forward pass, we also employ data quantization in backward pass as the calculation of gradients can also be abstracted as a series of dot product, following the chain rule of derivative flows (§4.4.1). However, we cannot simply use the INT8 quantization mentioned in forward pass because we cannot add a compensation-like component in backward pass to fill the error gap incurred by zero points. Here, we propose the *Parameterized Range Clipping* (PRC) method to address this issue by restricting the clipping domain in the symmetric scheme (§4.4.2).

4.4.1 Calculation of Derivative Flows

In practice, we usually calculate gradients based on chain rules instead of using numerical differential, for higher computational efficiency. As shown in Figure 5, the derivative

flows will go through the entire network, from the last layer to the first one. Capturing the flows from the $l+1$ -th layer, we can handily calculate the gradients of current l -th layer and push the flows to previous layers. Thus, the essential operations for calculating the parameter gradients ($\frac{\partial L}{\partial X}$ and $\frac{\partial L}{\partial W}$) of CONVs and FCs can also be abstracted as a series of tensor dot products, which are described as follows:

$$\frac{\partial L}{\partial X} = \text{dot}\left(\frac{\partial L}{\partial Y}, W^T\right), \quad (19)$$

$$\frac{\partial L}{\partial W} = \text{dot}\left(X^T, \frac{\partial L}{\partial Y}\right), \quad (20)$$

where W^T and X^T represent the transpose of W and X , respectively. Following these equations, we can also quantize $\frac{\partial L}{\partial Y}$ into INT8 format, and conduct the quantized dot product by using W_q and X_q , which are obtained in forward pass. After that, we can dequantize $\frac{\partial L}{\partial X}$ and $\frac{\partial L}{\partial W}$ based on the corresponding scaling factors by using Eq. (12). Note that this dequantization relies on the prerequisite of using symmetric clipping, which will be discussed in the next section.

4.4.2 Parameterized Range Clipping

As the intermediate derivative flows are also quantized before the dot product for calculating gradients, we thus need to address the issue of zero point offset. However, adding a compensation-like component in backward pass is inefficient in filling the error gap. Instead, we propose the *Parameterized Range Clipping* (PRC) method that makes clipping in the symmetric scheme to avoid the involvement of zero point, such that the FP32 parameter gradients could be recovered after conducting the INT8 dot product. The clipping range will be specifically profiled according to the distribution of the FP32 tensors. More precisely, we will discuss the clipping strategy in the following two cases.

Case #1. The distribution of FP32 tensor locates on both sides of the original point. In this case, we will quantize the FP32 tensor within $[-127, 127]$, which can be covered by the int data type. The clipping function is described as:

$$\text{clip}(M) \in [-a, a], \quad (21)$$

$$a = \min\{|\min(M)|, \max(M)\}. \quad (22)$$

Case #2. The distribution of FP32 tensor locates on one side of the original point. In this case, we will quantize the FP32 tensor within $[0, 255]$ that can be covered by the unsigned int data type. The clipping function is defined as:

$$\text{clip}(M) \in [0, a], \quad (23)$$

$$a = \max\{|\min(M)|, |\max(M)|\}. \quad (24)$$

By profiling the clipping range in these two cases, we can assert the zero point offset as 0 and surpass the issue of error gap. Moreover, we further restrict the clipping range by applying

95% confidence interval on Eq. (21), as the gradient tensors usually follow the long-tailed but bell-shape distribution.

Gradient Recovery: Based on the above clipping, we can recover the FP32 parameter gradients ($\frac{\partial L}{\partial X_f}$ and $\frac{\partial L}{\partial W_f}$) from the intermediate INT8 quantized derivative flows (Y_q , W_q and X_q) as follows:

$$\frac{\partial L}{\partial X_f} = \text{dot}\left(\frac{\partial L}{\partial Y_q}, W_q^\top\right) \cdot (s_y s_w), \quad (25)$$

$$\frac{\partial L}{\partial W_f} = \text{dot}\left(X_q^\top, \frac{\partial L}{\partial Y_q}\right) \cdot (s_x s_y), \quad (26)$$

where s_y , s_x and s_w represent the scaling factors for quantizing Y_f , X_f and W_f , respectively.

5 Implementation

We implement Octo’s training engine and network constructor in pure Python without the dependency of other sophisticated third-party libraries, making it a cross-platform system.

5.1 Network Construction

We abstract different layers for the construction of common CNNs, including CONV layer, FC layer, Batch Normalization, ReLU, Sigmoid, Pooling, Dropout, Softmax, and the proposed compensation layer. Each layer holds uniform APIs to handle the forward and backward passes. We can easily build CNNs by assembling different layers in a proper sequence. We provide a configuration file to set layer size (e.g., neuron number, filter number, filter size and padding) and initialize model parameters. We have embedded AlexNet, VGG11 and other deep CNNs in Octo, supporting the training on MNIST, Fashion MNIST and CIFAR-10/100 datasets. Moreover, we build the auto inspection module to monitor the training performance and record the key metrics, including model accuracy, training completion time, per-iteration cost, computational overhead, memory footprint and compensation performance.

5.2 Gradient Calculation

We implement the gradient calculation based on the chain rule of derivative flows. Each layer can automatically obtain its gradients by invoking the `backward` method. Here, we take the compensation layer as an example and calculate the gradients of α , μ and β by the following Python snippets:

```
def backward(self, dout)
    self.d_alpha = np.sum(dout*self.mu, axis=0)
    self.d_mu = self.alpha * dout
    self.d_beta = dout
    return dout
```

The `backward` method sequentially accepts the derivative of $\frac{\partial L}{\partial Y}$ (denoted as `dout`) from previous layers, calculates the

gradients of three compensation parameters, stores them for model updating, and returns the latest derivative flows to the next layer.

5.3 Hardware Deployment

We mainly extract the computational operations of model training into three types: (1) tensor dot product, (2) tensor broadcast, and (3) tensor addition. We optimize these operations in low-level instructions that can exploit the power of fixed-point processing units. This requires us bridging the C++ level method calling with Python-level training engine. We use the light-weight Pybind tool [43] and C++ header-based Eigen [52] to embed the hardware-level matrix instructions in Python training. This kind of hybrid implementation makes our system compatible with most operating systems, including embedded Linux, macOS and Windows. Specifically, apart from the implementation of common PC and servers, we also deploy Octo on commercial AI devices, such as HUAWEI Atlas 200DK [26] and NVIDIA Jetson Xavier [27], which can utilize the dedicated INT8 neuron chips.

6 Evaluation

We evaluate Octo on real embedded platforms in the production environment. Our key insights are as follows:

#1. Does Octo preserve model quality and how is it compared to FP32 training? Octo achieves stable convergence efficiency in different benchmarks (§6.2) and holds comparable model accuracy as FP32 training (§6.3).

#2. Can Octo improve inference efficiency? Octo accelerates image processing speed, by up to $2.03\times$ faster than FP32-based inference (§6.4).

#3. How could Octo work? Octo can effectively fill the error gap caused by data quantization and maintain tensor distribution as FP32 does. Thus, Octo preserves model quality and makes training more stable (§6.5).

#4. What is the system overhead? Octo reduces the per-iteration time cost while introducing a tiny overhead of data quantization (§6.6.1). Meanwhile, Octo saves real-time memory footprint and decreases the peak memory usage, by up to $3.37\times$ lower than FP32 training (§6.6.2).

6.1 Methodology

Testbed Setup. Considering the on-device learning characteristics, we focus on the experimental results on embedded devices. We deploy Octo on HUAWEI Atlas 200DK [26] based on Ascend 310 AI processors [13] and NVIDIA Jetson Xavier [27] equipped with dedicated INT8 neuron chips. All these devices are operated with the Ubuntu 18.04 LTS system with GNU/Linux 4.15.0-118-generic kernel.

Benchmarks. We use image classification tasks as our benchmark, based on the training of GoogLeNet [50], AlexNet

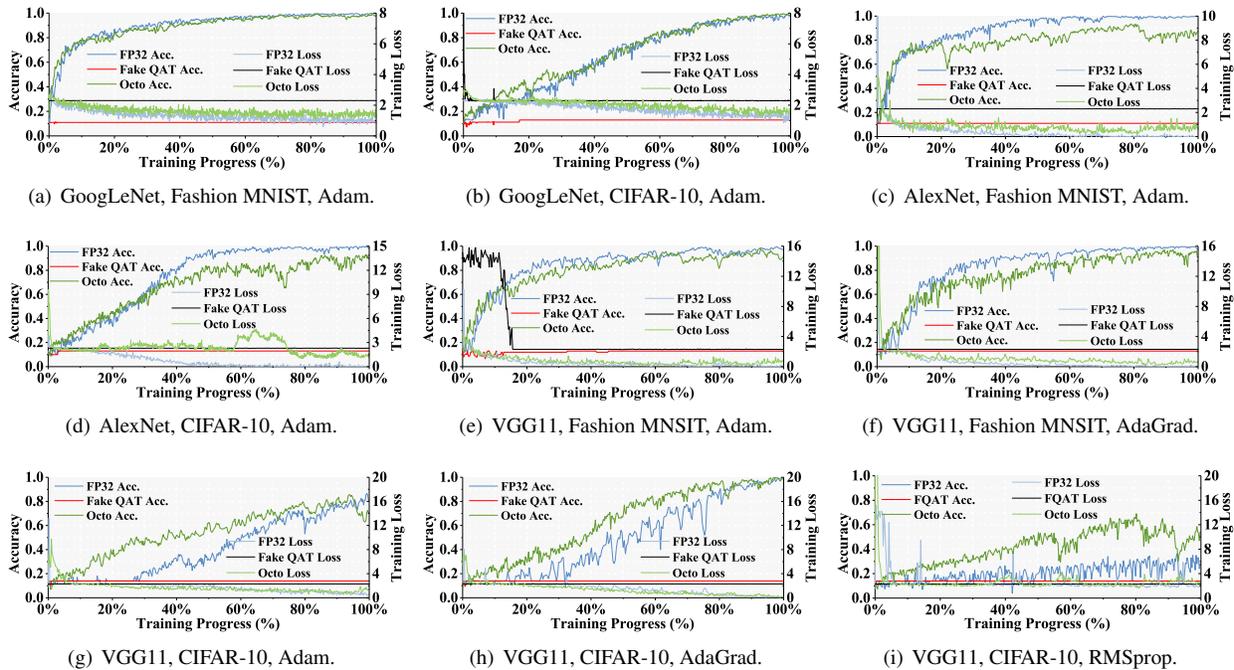

Figure 6: Training convergence efficiency using different benchmarks and optimizers.

	FP32 Acc. (%)	Octo Acc. (%)	Acc. Degradation (%)
GoogLeNet, FM	99.1 – 99.5	97.9 – 98.6	0.9 – 1.2
GoogLeNet, CF	97.8 – 99.2	97.6 – 98.8	0.2 – 0.4
AlexNet, FM	95.6 – 98.4	92.8 – 94.3	2.8 – 4.1
AlexNet, CF	91.8 – 95.2	86.1 – 87.3	5.7 – 7.9
VGG11, FM	97.5 – 98.8	94.4 – 96.5	2.3 – 3.1
VGG11, CF	97.2 – 99.5	96.5 – 98.6	0.7 – 0.9

Table 3: Comparison of FP32 and Octo’s model accuracy (from MIN to MAX) with Fashion MNIST (FM) and CIFAR-10 (CF) datasets, by using AdaGrad optimizer.

[29] and VGG11 [48]. Considering the resource constraints, large-scale datasets (*e.g.*, ImageNet [10]) are not suitable for training. We choose Fashion MNIST (FM) [59], CIFAR-10 (CF) [28] to fit the tiny on-device environment. We set the mini-batch size as 50 with 100 epochs and check Octo under Adam [25], AdaGrad [12] and RMSprop [21] optimizers.

Baselines. We build two pertinent baselines: the vanilla full-precision training (FP32) and fake quantization-aware training without error compensation (Fake QAT), using the performance metrics of training efficiency, model quality, image processing throughput and system overhead.

6.2 Training Efficiency and Quality

Maintaining convergence efficiency is one of the most crucial metrics in INT8 training design, we compare the model accuracy and training loss, by using FP32, Fake QAT and Octo training under different benchmarks in Figure 6. We can observe that Fake QAT fails to converge, where the curves of

loss (in black) and accuracy (in red) almost remain unchanged. This phenomenon indicates that putting tensor arithmetic (*e.g.*, convolutional and affine operations) between quantization and dequantization will incur huge computational errors, thus Fake QAT is not suitable for hardware-level INT8 acceleration in practice. In contrast, Octo (in green) obtains comparable accuracy as the FP32 (in blue) training, holding a just slight degradation in most cases (*e.g.*, Figure 6(a)-6(f)). Specifically, as to the training of the deep VGG11 model, Octo even achieves faster convergence speed over FP32 with close final model accuracy (*e.g.*, Figure 6(g)). Training curves using other optimizers (*e.g.*, Figure 6(h) and 6(i)) also confirm this property because the compensation layers inside Octo can serve as specific ‘noise’ to help optimizers escape saddle points. Also, the PRC method bounds the gradients in a smoother distribution, making models update more stably. Overall, the accuracy comparison and degradation gap are summarized in Table 3, where Octo preserves model quality as FP32 does and is sufficient for INT8 on-device training.

6.3 Ablation Study

We conduct the ablation study to inspect how much improvement is achieved by LAC and PRC separately. The experiments are based on the training of AlexNet model on CIFAR-10 and Fashion MNIST datasets by using Adam optimizer. Note that the LAC and PRC operations are added in CONV2, CONV3 and CONV4. We compare the average model accuracy under different training configurations in Table 4. We can observe that simply adopting INT8 data representation

	Configuration	Acc. (%)	Gap over FP32 (%)
Fashion MNIST	FP32	97.1	0
	INT8	13	-84.1
	INT8 + LAC	90.4	-6.7
	INT8 + PRC	14.8	-82.3
	INT8 + LAC + PRC	93.6	-3.5
CIFAR-10	FP32	93.5	0
	INT8	11	-82.5
	INT8 + LAC	85.2	-8.3
	INT8 + PRC	12.1	-81.4
	INT8 + LAC + PRC	86.7	-6.8

Table 4: Comparison of average model accuracy under different training configurations.

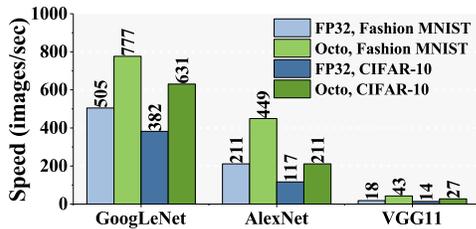

Figure 7: Image processing throughput, *i.e.*, images per second, by using FP32 and Octo trained models.

into training will significantly deteriorate the model accuracy due to large errors of the quantized dot product. Enabling LAC operation can fill this error gap by learning parameters of an affine approximation. Note that directly using PRC on vanilla INT8 training without LAC cannot eliminate the deviation of intermediate results, thus still incurring a great degradation of accuracy. However, PRC can further improve the final accuracy when LAC has been enabled, where the clipped gradients can restrict the training process in a proper convergence boundary.

6.4 Image Processing Throughput

Apart from the training efficiency, we also inspect Octo’s inference performance. We measure the image processing speed, *i.e.*, image count per second, by using the models trained by FP32 and Octo. As model parameters and tensor arithmetic are converted in INT8 format, Octo can effectively reduce I/O bandwidth and computational pressure. Therefore, Octo improves the image processing throughput, by up to $2.03\times$, on average, over FP32 model based inference. This property is significantly meaningful for on-device learning as we can reduce inference latency and improve user experience.

6.5 Octo Deep Dive

Observing the improvement of training and inference performance, we wonder how could Octo achieve this. Here, we give deep insights into how Octo compensates for quantization error and preserves model accuracy. We visualize the intermediate tensor distribution of a CONV layer’s output

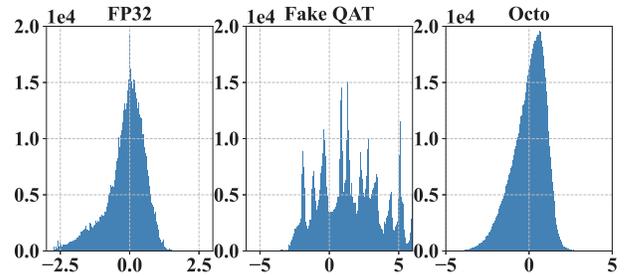

Figure 8: The visualization of tensor distribution of CONV2’s output, under FP32, Fake QAT and Octo’s training. Octo preserves similar distribution as FP32 while Fake QAT cannot.

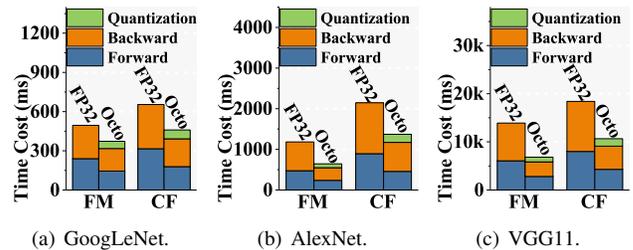

Figure 9: We inspect the details of computational time cost from 300 iterations and measure the overhead of Octo’s data quantization on average, when training Fashion MNIST (FM) and CIFAR-10 (CF) dataset.

by using FP32, Fake QAT and Octo. The data are collected from training an 8-layer deep CNN with CIFAR-10 after 80 iterations. Fake QAT holds a distinct distribution compared with FP32 because conducting dot products in the quantized domain will incur significant error to the final output. In contrast, the compensation layers inside Octo can fill the error gap and achieve similar distribution as FP32 does. Therefore, the model accuracy is maintained. Also, the PRC method in backward pass bounds derivative domains and smooths the tensor distribution, making the training more stable.

6.6 System Overhead

We compare Octo’s system overhead with FP32 training, following two key metrics of embedded platforms: computational time cost (§6.6.1) and memory footprint (§6.6.2).

6.6.1 Computational Time Cost

We measure the average computational time cost of different stages in each iteration, as depicted in Figure 9. Although Octo introduces extra overhead of data quantization, about 17.21% increase on average, it reduces the completion time of both forward and backward passes by using INT8-based processing. Overall, Octo holds shorter per-iteration time, by up to $1.73\times$ faster, on average, over vanilla FP32 training. Therefore, we believe introducing data quantization for on-device training is meaningful.

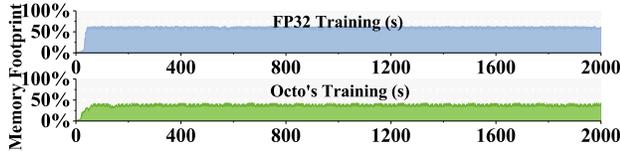

Figure 10: Octo effectively reduces real-time memory footprint over FP32 training.

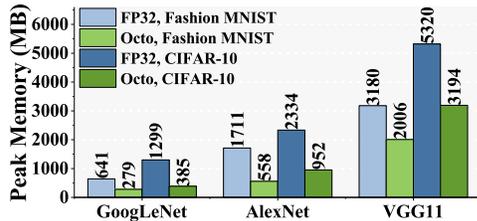

Figure 11: Peak memory usage of FP32 and Octo training.

6.6.2 Memory Footprint

We compare the memory usage under FP32 and Octo’s training, respectively. As shown in Figure 10, we monitor the real-time memory footprint when training GoogLeNet with CIFAR-10 in 2000 seconds. The FP32 training requires about 61.29% memory usage on average, while Octo only requires 40.13%. More precisely, we compare their peak memory usage of different benchmarks in Figure 11. Due to the INT8-based parameters and gradient quantization, Octo can effectively reduce peak memory usage, by up to $3.37\times$ lower than FP32 training. Such a reduction makes it possible to deploy VGG-like models.

7 Discussion

In this section, we will discuss the potential usages, extensions and limitations of Octo.

Deployment on edge devices. We mainly deploy Octo on two kinds of edge devices: (1) Atlas 200DK developer board integrating Ascend 310 AI processors and (2) NVIDIA Jetson Xavier equipped with INT8 neural chips. These devices support hardware-level INT8 operations, thus making Octo truly exploiting the power of quantization-aware training. Note that Octo is a cross-platform system and its INT8 quantization algorithm can apply to most existing ML frameworks. For example, it is possible to extend the TensorRT engine [53] to enable truly INT8 training on NVIDIA Pascal GPUs, rather than current post-quantization or inference-only INT8 usage.

Comparison with existing work. We have to build Octo from scratch due to the following limitations of existing quantization methods. PACT [7] is designed for quantized inference by optimizing the clipping range of activations in forward pass, without the consideration of gradient calculation in backward pass. Fake QAT [23] needs to pre-train a full-precision model and uses INT8 fine-tuning to preserve quantized model quality. Fake QAT only simulates INT8 cal-

culations in forward pass and cannot bring actual acceleration. Directly using Fake QAT to INT8 training will cause large errors of dot product and cannot guarantee model convergence. Unified QAT [67] enables INT8 training by adjusting gradients in backward pass. However, it relies on the calculation of both quantized and full-precision gradients, as well as plenty of exponent arithmetic. This computational overhead requires the support of GPUs and is not feasible to the device’s resource-constrained environment.

Extensions to other types of models and layers. Octo also supports other layers and models (*e.g.*, FC layers for saving more memory and RNNs for time-series prediction) because our basic optimization targets are tensor-level dot product and broadcast operations, which are prevalent in modern neural networks. Although Octo can reduce computational overhead and save memory footprint for most CNN models, we admit that Octo is just a first step to exploit the feasibility of deploying INT8 training on devices. Some complicated scenarios, such as conducting NLP on large-scale datasets or detecting real-time objects with high frame rates may still need supplementary methods, where the construction of compensation layers, clipping strategy of gradients, regularization terms of loss function should be carefully designed.

8 Conclusion

This work demonstrates that introducing INT8 quantization to training is a feasible way to implement on-device learning in practice. To truly enable hardware-level INT8 acceleration, the key of designing an efficient quantization-aware training method is to fill the error gap of dot products. This target is achieved by optimizing data quantization in both forward and backward passes, via the proposed *Loss-aware Compensation* (LAC) and *Parameterized Range Clipping* (PRC) methods, respectively. Specifically, we design a novel compensation layer to adjust the quantized output and smooth the model update procedure. Our method is implemented in Octo, a cross-platform system for tiny on-device learning. Evaluations show that Octo holds higher training efficiency over state-of-the-art quantization training methods and preserves comparable model quality as full-precision training.

Abstract

Fine-tuning is an increasingly common technique that leverages transfer learning to dramatically expedite the training of huge, high-quality models. Critically, fine-tuning holds the potential to make giant state-of-the-art models pre-trained on high-end super-computing-grade systems readily available for users that lack access to such costly resources. Unfortunately, this potential is still difficult to realize because the models often do not fit in the memory of a single commodity GPU, making fine-tuning a challenging problem.

We present FTPipe, a system that explores a new dimension of pipeline model parallelism, making multi-GPU execution of fine-tuning tasks for giant neural networks readily accessible on commodity hardware. A key idea is a novel approach to model partitioning and task allocation, called Mixed-pipe. Mixed-pipe partitions the model into arbitrary computational blocks rather than layers, and relaxes the model topology constraints when assigning blocks to GPUs, allowing non-adjacent blocks to be executed on the same GPU. More flexible partitioning affords a much better balance of the compute and memory-load on the GPUs compared to prior works, yet does not increase the communication overheads. Moreover, and perhaps surprisingly, when applied to asynchronous training, Mixed-pipe has negligible or no effect on the end-to-end accuracy of fine-tuning tasks despite the addition of pipeline stages.

Our extensive experiments on giant state-of-the-art NLP models (BERT-340M, GPT2-1.5B, and T5-3B) show that FTPipe achieves up to $3\times$ speedup and state-of-the-art accuracy when fine-tuning giant transformers with billions of parameters. These models require from 12GB to 59GB of GPU memory, and FTPipe executes them on 8 commodity RTX2080-Ti GPUs, each with 11GB memory and standard PCIe.

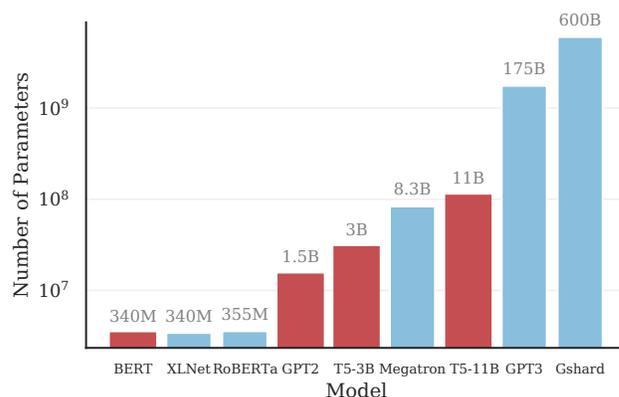

Figure 1: Model size trends. None of these models can be trained on a single NVIDIA RTX-2080-Ti commodity GPU due to memory requirements. Bars in red represent the models evaluated in this paper. FTPipe automatically transforms their sequential implementation into a multi-GPU one.

1 Introduction

Fine-tuning deep neural network (DNN) models is a technique commonly used to achieve state-of-the-art model quality on a wide range of tasks, such as question answering, text generation, translation, and more [46, 55, 56]. In fine-tuning, the model is not trained from scratch. Instead, a short training phase is performed on an already existing model, which has been pre-trained on large application-related datasets to obtain general domain knowledge [16]. By training on user-specific datasets, fine-tuning allows accommodating new inputs [11, 44, 60].

Fine-tuning is becoming increasingly important as models grow to billions of parameters. Since training such *giant* models from scratch is practical only on super-computer-scale

systems [48, 50, 60], a provider-scale pre-training, followed by short fine-tuning on user data, is the key to making the power of giant models broadly accessible [57].

Unfortunately, fine-tuning giant models on *low-cost commodity hardware* is still a significant challenge. Small memory sizes and slow inter-GPU communications are the main characteristics that set apart commodity GPUs from high-end devices, and they dramatically affect the training of giant models.

Small GPU memory is the key problem. For example, about 40 GBs are needed to train T5 model with 3B parameters for Recognizing Textual Entailment (RTE) [56] even with the smallest batch size of 1. This is larger than the memory size of any commodity GPU.

Existing approaches to cope with GPU memory constraints, such as sharding/swapping [45, 54], are ineffective due to slow PCIe communications. This problem is further exacerbated in fine-tuning tasks because the typically-small batch sizes do not allow for overhead mitigation using communication and computation overlapping. Therefore, using a single GPU, or a data-parallel multi-GPU approach for fine-tuning giant models are not viable options.

Model-parallel techniques allow fitting the model into memories of multiple GPUs. However, for commodity GPUs, the poor communication performance rules out the most commonly used Intra-Layer Model Parallelism approach, where each DNN layer is split among multiple GPUs. High volumes of all-to-all communications (AllReduce) with many synchronization points [48, 50] perform poorly over PCIe.

Pipeline-parallel execution exploits the depth dimension of DNN models [17, 37], distributing them across GPUs at a coarse granularity, i.e., DNN layers. A model is partitioned into multiple consecutive stages according to its topology. Each stage runs on a different GPU. During training, the input samples are streamed through the pipeline. This approach allows training giant models on multiple GPUs without the high communication costs of intra-layer parallelism, making it ideally suitable for commodity hardware.

However, existing methods have some drawbacks when applied to fine-tuning giant models.

GPipe [17] demonstrated the benefits of pipeline parallelization, but has pipeline bubbles, leading to low hardware utilization for small mini-batches typical for fine-tuning tasks [55]. The bubbles are caused by GPipe's *synchronous* approach whereby the next mini-batch of samples does not start before the previous one traverses the whole pipeline.

PipeDream [37] improved GPU utilization by introducing *asynchronous* training, where the mini-batches no longer wait for each other to complete. However, PipeDream stores multiple versions of the weights in GPU memory (*weight sharding*) to mitigate the effects of *weight staleness* [61] inherent to

asynchronous training, dramatically reducing the size of the models that can be trained.¹

Last, both GPipe and PipeDream may suffer from *poor load-balance* across GPUs in DNNs with a complex topology, such as giant encoder-decoder DNNs in Natural Language Processing (NLP). We claim that the load-balancing problem stems from the *coarse-grain scheduling decisions* dictated by the model topology constraints, i.e., the structure of the layers and inter-layer connectivity. Our key insight is that *relaxing these constraints when running fine-tuning tasks can mitigate the load imbalance of prior approaches and bring significant performance improvements, without model accuracy tax.*

We introduce **FTPipe**, a novel memory-efficient execution framework for pipelined fine-tuning of giant DNNs on commodity GPUs. Using FTPipe is easy: it *automatically* generates a functional performance-optimized pipeline-parallel multi-GPU version of a given sequential model implemented in PyTorch [39]. It enables the execution of models whose description does not adhere to the conventional sequences of coarse-grain layers.

FTPipe builds on two key observations:

Partitioning without DNN topology constraints. FTPipe optimizes the load balance by relaxing the model topology constraints when distributing it across the GPUs. Specifically, it introduces a novel *mixed-pipe* partitioning scheme which permits assigning any fine-grained combination of model operations to run on GPUs, *even when the assignment does not follow the original sequence of network-architecture layers*. This is in contrast to all prior approaches [17, 37] that use coarse-grain partitioning, with only adjacent layers scheduled to run together on the same GPU. The mixed-pipe scheme exploits the advantages of a new, previously unexplored, point in the trade-off between inter-GPU communications and load-balancing, prioritizing the latter. It enables efficient pipeline-parallel training of neural networks common in NLP, including language models with shared embedding ("tied weights") [20, 42] and giant Transformer-based encoder-decoder networks [53].

Fine-tuning large models is less sensitive to staleness. FTPipe fastest version employs an asynchronous training scheme which is prone to staleness [4, 5]. However, large models with pre-trained weights have properties that make training less sensitive to staleness. These include smooth and slowly-varying optimization trajectories [29], or small (and diminishing) learning rates. Thus, we achieve state-of-the-art results while avoiding costly staleness mitigation techniques.

We evaluate FTPipe on challenging fine-tuning tasks with three modern giant NLP models: T5-3B, T5-11B, GPT2 (1.5B), and BERT (340M). These models cannot be trained on a GPU with 11GB memory. To the best of our knowledge, FTPipe shows the first execution of T5-3B/T5-11B models on an asynchronous pipeline-parallel system, which have been

¹PipeDream still has staleness, with parameter consistency similar to ASGD [10], see Table 1.

particularly challenging due to the diverse computational requirements of different layers.

Our experiments on 8 NVIDIA RTX2080 Ti GPUs demonstrate significant performance benefits of FTPipe over GPipe, which is the only state-of-the-art pipeline execution framework that was able to train all the evaluated models on our hardware. For example, FTPipe is from 8% to $3\times$ faster when fine-tuning T5-3B, with the same accuracy. Mixed-pipe gains $1.08\times$ - $2.47\times$, and asynchronous training an additional $1.19\times$ - $2.98\times$ (results vary between datasets).

Compared to PipeDream, FTPipe trains significantly larger models and avoids partitioning solutions that do not fit in GPU memory. Further, FTPipe outperformed PipeDream by 13% when training BERT, after augmenting PipeDream implementation with checkpointing [7, 12].

Essentially, FTPipe generalizes the pipeline execution of former approaches to *dataflow-aware execution*, avoiding unnecessary communications and allowing more parallelism. Specifically, FTPipe stages can communicate with non-neighbors directly, without passing via adjacent stages. Thus, data is automatically loaded exactly where needed, and the stages can be concurrent in case the network graph allows it. As a result, model parameters and their gradients can be communicated thus making the execution of models with shared weights possible in pipelines.

In summary, our main contributions are as follows:

FTPipe. We present FTPipe, an automatic framework that transforms a sequential DNN implementation into a multi-GPU pipeline-parallel one, enabling fine-tuning of giant state-of-the-art neural networks on commodity GPUs,

Mixed-pipe. We present the fine-grain partitioning scheme which relaxes the model topology constraints when scheduling DNN computations on GPUs, thereby vastly improving load balance across the workers without additional communication overheads,

Evaluation. We evaluate FTPipe on challenging fine-tuning benchmarks, and giant transformers: GPT2 [43], BERT [11], and T5-3B/11B [44], consistently outperforming GPipe and PipeDream while attaining state-of-the-art accuracy.

2 Background

Giant models. We call *giant* those models which do not fit into the memory of a single accelerator during training.

Pipelined training. A pipeline is trained by computing gradients for each *mini-batch*, i.e., a subset of examples assigned together for gradient computations. A mini-batch can be further sliced into smaller *micro-batches* to fit into workers' memory. Micro-batches also help parallelize the mini-batch computation. For example, in GPipe, micro-batches are streamed through the pipeline one-by-one (Figure 2). GPipe attempts to parallelize execution by having a micro-batch proceed to the next pipeline stage while the next micro-batch enters the

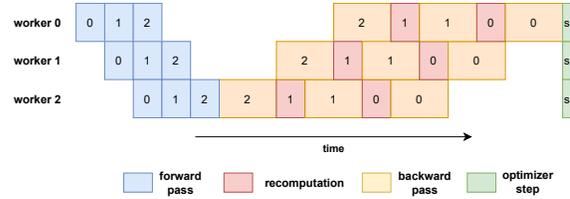

Figure 2: GPipe [17] synchronous training. Each rectangle (number is the micro-batch being processed) represents a pipeline stage running a certain task denoted by its color, except for the last optimizer step.

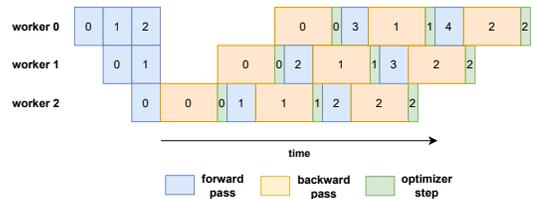

Figure 3: PipeDream [37] asynchronous training.

previous stage (aka intra-batch parallelism). However, GPipe *synchronously* updates the model parameters at the end of the mini-batch execution using the gradients accumulated from all micro-batches, a technique called *gradient accumulation*.

Staleness. An *asynchronous pipeline* as in PipeDream [37] (Figure 3) begins the forward pass of the next mini-batch without waiting for the previous one to finish (aka inter-batch parallelism). In an asynchronous pipeline, the next mini-batch might use old parameters in its forward pass and newly updated parameters on its backward pass, or old parameters in both passes. Pipeline with more stages may have more mini-batches executing concurrently, therefore a higher difference between old and new parameters. This problem, known as *weight staleness* (or simply staleness), was shown to introduce significant disturbances to the training process, deteriorating final model accuracy and, in extreme cases, even preventing convergence altogether [9, 62]. Several methods were proposed to mitigate staleness [4, 61].

3 Motivation

3.1 Importance of fine-tuning giant models

DNN models are constantly growing to achieve higher quality. This trend is particularly pronounced in Neural Language Processing models (Figure 1), where larger models achieve significantly better results [6, 17, 27]. However, such giant models are increasingly hard to train without access to supercomputer-scale resources. For example, training XLNet [60] of 340M parameters using a data set of 158GB required 5.5 days on 512 Google TPUs [23]. Therefore, many pre-trained models have been made publicly available to allow their use by those

who do not have access to such computing capabilities (e.g., NVIDIA Model catalog [1]).

From user point of view it is often desirable to further improve the pre-trained model and tailor it to a user-specific data set. The process, called *fine-tuning*, was shown to be effective across a wide range of tasks [16]. Fine-tuning operates on relatively small data sets and requires much less computing power to complete, compared to training a model from scratch.

Unfortunately, fine-tuning of giant models still require the whole model to be resident in GPU memory, which is a challenge for commodity GPUs. Attempts to fine-tune models by updating a subset of parameters [3, 15, 41] are not generally applicable and their results are usually worse than fine-tuning the entire model [44].

In summary, *fine-tuning of giant models poses a challenge that impedes their broader adoption.*

3.2 I/O benefits of pipeline model parallelism

Pipeline execution has the potential to fully overlap communication and computation in each pipeline stage, thus making the communication overhead negligible even on commodity hardware. There are two primary reasons:

Low communication volume. First, in pipeline-parallel training, as in any model-parallel training, GPUs communicate intermediate activations and activation-gradients, which, according to our experiments, are orders of magnitude smaller than parameter-gradients communicated in data-parallelism, and smaller than the number of state shards between workers. For example, a T5-3B model partitioned into 8 stages communicates a total of 456.4MB for each forward and backward pass across the whole pipeline (micro-batch size of 4, full precision). In comparison, in a data-parallel approach, each update requires collecting and aggregating 12GB of gradients per worker.

Overlapping computation and communication . Pipelines can overlap the communication with the next forward and/or backward passes, and sometimes also with the parameter update operation. This means that stages with large enough computation-to-communication ratio (for GPipe: ≥ 0.5) can completely overlap communication and computation. This is indeed the case for all giant models we consider in this work. For example, the aforementioned T5-3B achieves a per-worker average computation-to-communication ratio of 0.96 and 0.98 for the forward and backward passes respectively, even when communicated over PCIe.

3.3 Challenging load balance

GPipe and PipeDream obey model topology constraints when distributing the model across GPUs. Specifically, only adjacent layers are scheduled to run together on the same GPU.

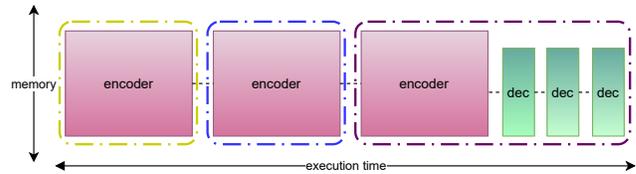

Figure 4: Partitioning unbalanced Encoder-Decoder models. Seq-pipes can assign only adjacent layers per GPU, thus are unable to partition the model for 3 GPUs in a balanced way (dashed lines). In contrast, Mixed-pipe can map one encoder and one decoder per GPU by assigning non-sequential layers to run together on the same GPU.

Such an approach, which we call sequential pipeline, or *seq-pipe*, fails to balance the DNN partitions across workers for some models.

One specific example of practical importance is the encoder-decoder architecture, widely used in NLP for sequence-to-sequence tasks [8, 28, 44, 53]. Consider the T5 Text-To-Text Transformer model, which is currently the state-of-the-art for many NLP tasks. When trained for question answering, the question is fed into the encoder, and the answer is fed into the decoder. In many cases, the answers are much shorter than the questions (e.g., yes/no questions). Thus, such training inputs cause a compute imbalance between encoders and decoders, since the computations in attention layers scale quadratically with the input sequence length. Furthermore, the number of parameters in both layer types is equally large, so grouping many “lightweight“ layers is not possible because it would exceed GPU memory. Thus, partitioning such models into a pipeline under strict model topology constraints (only adjacent layers allocated to the same GPU) is prone to severe compute and memory imbalance as illustrated in Figure 4.

PipeDream combines both pipeline- and data-parallelism, potentially solving the load imbalance by running compute-heavy stages on multiple GPUs using data parallel techniques. However, the amount of additional GPUs required may be impractical: consider the case of unbalanced encoder-decoders as in Figure 4, with N decoders, N encoders, and a computation-load ratio of k between encoder and decoder. A memory limit which allows placing no more than M encoders or decoders in the same device will imply that $\#GPUs = \frac{N}{M} \cdot K$ additional data parallel GPUs are required. In T5-3B for example, $M \leq 12$, $N = 24$, and K varies according to input sequence lengths of encoder and decoder (we measured $K = 5.5$ for two of our datasets where sequences were 512 and 4 respectively).

In FTPipe, we overcome the limitations of existing pipeline partitioning approaches and thus enable fast execution with state-of-the-art accuracy for challenging fine-tuning tasks on commodity GPUs.

4 FTPipe

Overview. FTPipe is a system for training giant models with limited resources. It automatically transforms models which do not fit into the memory of a single accelerator into a multi-GPU pipelined training construction, and runs them on our data-flow execution runtime. A computational graph of the DNN model is decomposed into topologically sorted sub-graphs, grouped into pipeline stages according to their graph distance from the output (called *depth*). The number of stages is determined according to the GPU assignment as discussed in detail below. Computations are then performed according to a work scheduler.

We now describe individual steps.

Tracing execution. Given a model and inputs, FTPipe first identifies the directed acyclic computational data-flow graph of the network. A *computational graph representation* of a neural network is a directed graph $G(V, E)$ where each intermediate computational operation is a node $v \in V$ and each edge $(u, v) = e \in E$ represents a connection according to computation order which is determined by the forward pass (with an indication of whether its also being used for the backward pass). We refer to indivisible blocks of execution as *basic blocks*. There are two granularity choices of basic blocks: full layers (In PyTorch, a layer is a software abstraction defined by ‘torch.nn.Module’ class), or individual operations (default setting). In the latter case, all operations visible in Python are traced, without splitting compiled C++ code or CUDA kernels.

Profiling. Each basic block is profiled to determine its memory consumption and execution time for each of its computational tasks, i.e., forward pass, recomputation (see Section 4.3) and backward pass. Aggregation of these values determines the block’s memory and computing requirements used in the block-to-GPU assignment step. Tensor sizes for activations and gradients are also recorded, and used to compute communication times, given a bandwidth parameter.

We note that tracing and profiling pose an engineering challenge on its own, since the models we discuss cannot run on a single device, hence, for example, cannot be profiled nor executed with dummy inputs to trace their execution graph. We solve this problem by decoupling execution and swapping layers, parameters, gradients, and activations in and out of host memory when needed.

Model partitioning. The objective of pipeline partitioning is to maximize throughput under memory and resource constraints. Maximizing throughput can also be described as minimizing the maximal *stage period* T_{max} among all the pipeline stages. We define T_i for stage i as

$$T_i = C + \max(0, T_{comm_{fwd}} - C) + \max(0, T_{comm_{bwd}} - C) \quad (1)$$

where $C = T_{compute_{fwd}} + T_{compute_{bwd}}$ and $T_{comm_{fwd}}, T_{comm_{bwd}}, T_{compute_{fwd}}, T_{compute_{bwd}}$ are the times of communication and computations for forward and backward

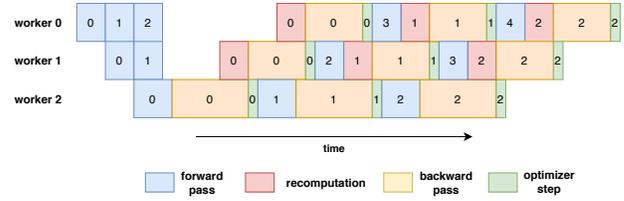

Figure 5: FTPipe asynchronous training. FTPipe uses checkpointing and recomputations to avoid storing multiple activations in memory. The last worker in the pipeline does not recompute, yet has the same period, load-balanced through profiling §4.3.

passes respectively (recomputation time is included in $T_{compute_{bwd}}$).

GPU assignment. The Mixed-pipe approach significantly inflates the search space of potential GPU allocations compared to Seq-pipe, to the point that - for the giant networks considered - an optimal, exhaustive assignment search (e.g., PipeDream’s) is infeasible. Thus, FTPipe’s GPU assignment takes a practical approach, combining efficient general graph partitioning and domain knowledge.

FTPipe employs several partitioning methods and let them compete, eventually selecting the best result according to its final throughput analysis via simulation. Among these schemes are (a) Mixed-pipe partitioning which searches mixed-pipe solutions as described in detail below, (b) PipeDream [37], which performs exhaustive search on the space of all Seq-pipes. (c) Acyclic [35, 36] which performs a greedy search for Seq-pipes, for which we changed the objective to optimize pipeline throughput, and combined with memory constraints. It is useful when an exhaustive search is too long to execute (for a 2000 nodes graph exhaustive search on Seq-pipes takes around 20 minutes). (d) Metis [24], a general graph partitioning scheme that optimizes communications under load balancing constraints. The output can be either a Seq-pipe or a Mixed-pipe. It does not optimize pipeline throughput directly.

Work scheduling. While FTPipe supports both synchronous and asynchronous pipeline work schedules, full fine-tuning acceleration benefits are obtained using an asynchronous work scheduler illustrated at Figure 5. FTPipe is a general pipelined data-flow execution. It supports concurrent stages, shared weights, and data staging. FTPipe’s work scheduling uses checkpointing with careful stage profiles (elaborated on in §4.3). In an asynchronous mode, for a stage of depth d , FTPipe first computes $d + 1$ forward passes for different micro-batches, filling the pipeline, then moves into alternating between backward and forward passes, modifying the model parameters after each mini-batch.

We next discuss Mixed-pipe partitioning and GPU assignment in detail.

4.1 Mixed-pipe model partitioning

Seq-pipe partitioning proposed in prior works assigns only adjacent DNN layers to every GPU in the pipeline. As a result, such partitioning *implicitly* optimizes for reduced communications across GPUs, at the expense of fewer opportunities to balance the load among them. Our intuition for Mixed-pipe is that for giant models and commodity hardware, keeping the computations balanced is sometimes more important than reducing inter-GPU communications. Indeed, for giant models, the overhead of pipeline data transfers is relatively small compared to the computation load per accelerator (See §3). We therefore posit that relaxing the DNN topology constraints and allowing smaller, multiple partitions per GPU may improve load balance, while still affording communication-computation overlap.

However, there are three main challenges in doing so: (a) it is possible that small partitions might increase both communications and GPU invocation overheads; (b) without topology constraints, an exhaustive search for optimal partitioning [37] is not feasible; (c) for asynchronous pipelines, higher-depth partitions may imply additional staleness, which may harm model quality. The Mixed-pipe partitioning scheme addresses these issues, and our evaluation empirically shows that the final model quality is maintained.

For efficient partitioning that mixes blocks of operations among the GPUs, it is imperative that changing the assignment of a block from one GPU to another does not increase communication penalty. To achieve this, notice that when the ratio between computation and communication is sufficiently high (see Equation 1), communication overhead is completely mitigated in FTPIPE by overlapping communication and computation. Thus, to enable dynamic placement of blocks in arbitrary GPUs, it is sufficient to ensure that the blocks have this property, called the *Communication-Computation Overlap* (CCO). The CCO property of a block of operations is easy to verify through profiling, taking into account both the forward edges (activations) and backward edges (gradients). We call a block with the CCO property a CCO block.

The Mixed-pipe partitioning algorithm receives a computational graph of a neural network, which specifies the (traced) basic computational blocks annotated with their memory, communication, and computing requirements. Then, partitioning proceeds in three steps as follows:

4.1.1 Step 1: Coarsening: create L pipeline stages

The graph is coarsened by contracting edges and merging their nodes to reduce its size (typically thousands of nodes) to L non-input stages where each stage fits in GPU memory. Throughout the process, a dynamic topological sort [40] is maintained to ensure that edge contractions do not create cycles.

Coarsening begins by eliminating nodes with either low computational load or high communication load, since both

are bad candidates to become CCO blocks. First, all constants and inputs are removed, later adding and duplicating them if needed to spare redundant communications (typically this process reduces the graph size by half). Second, nodes with a weight of 0 (typically CPU operations) are eliminated by merging them with their smallest neighbor (computation load-wise). Third, nodes for which the communication volume is above the 99th percentile are merged with their neighbors.

We proceed with coarsening with the goal of creating L CCO blocks, to become L pipeline stages. The algorithms involved are very fast, hence we try several coarsening heuristics, of which we describe two that gave the best results for giant networks we evaluated.

Coarsening by type. During tracing, the type and scope of each node are recorded according to its definition in the DNN code. By doing so, large groups of similar nodes can be naturally merged, following user high-level abstractions (e.g. merging all nodes inside ‘SelfAttention’ block of a Transformer [53]). This usually creates many equal-sized blocks of similar nodes, since giant networks typically contain repeated modules. Our experience shows that this process outputs the best partitioning of CCO blocks (and, consequently, pipeline stages) for giant networks.

Coarsening around centers. Adjacent CCO blocks are further joined together (notice that this maintains their CCO property) while obeying the memory constraint, until the block is sufficiently large to become a pipeline stage. One way to do this is to assign L “center blocks” and repeatedly merge their neighbors with them (obeying the memory constraint) in round-robin until no non-center block is left. This procedure may repeat several times with different choices of centers until a good packing of stages is obtained.

Choosing L . L is chosen at a sweet spot of the tradeoff between large L , which enables better load balancing in Step 2, and small L , which is better staleness-wise. To this end, we try several values of L (e.g. $L = 2P, 3P$) where P is the number of GPUs, and take the option yielding the best pipeline throughput (measured at step 3 below), where L does not exceed a pre-defined upperbound which can be found through experimentation.

4.1.2 Step 2: Load balancing

L stages are assigned to P GPUs in a way that optimizes load-balancing while ensuring that tasks allocated to the same GPU fit in its memory.

The assignment to GPUs can be seen as a classical multiprocessor scheduling problem [26]. While the original problem does not target the pipeline execution setup, in practice, and when communications do not add overhead (the CCO property), the optimal multiprocessor schedule is the one with a balanced distribution of tasks among the processors, meeting the goal of the pipeline assignment. Therefore, we apply the broadly used Longest-Processing Time-First heuristics: the L

CCO stages are sorted in a descending order of their computation load, and are assigned to the next least busy GPU with enough memory to run them.

Pipeline stages inside each GPU are created according to the topological order of the stages in the computational graph. A simple algorithm ensures that the depth of the stages is minimized: merge connected components inside each GPU as long as this does not create a cycle with other components. During execution, a stage is invoked by the GPU when its inputs are made available by completion of execution of all previous stages.

4.1.3 Step 3: Refinement

We perform fine-grain tuning of the load balance achieved in Step 2. First, the L stages are un-coarsened into their basic blocks. Then, within each pipeline stage, we greedily find blocks which, if moved to an adjacent stage in the pipeline, can improve the throughput, or lower communication or improve load balance (given also the memory constraints).

The complexity of Mixed-pipe partitioning is dominated by the complexity of coarsening which is $O(N^2d)$, where d is the average node degree. Assuming we try c different coarsening strategies (e.g., initialization of centers, different choices of L , etc.), the overall complexity is $O(cN^2d)$.

4.2 Fine-tuning with staleness

Asynchronous pipelines allow faster execution. However, asynchrony introduces staleness. The key problem with staleness is that it can potentially harm final model quality. Note, however, that this is analogous to large batch training [47] which proved to be a popular and useful technique when applicable. In such cases, empirical evidence of acceleration while maintaining model quality is of practical importance even when shown only for some specific (yet important) cases.

Some staleness mitigation techniques introduce high overheads. For example, weight stashing, applied in PipeDream, causes multiple versions of model weights to be stored for the entire course of the pipeline round-trip. This implies that in a pipeline with K workers, the first worker stores up to K versions of weights, which might effectively nullify the memory benefits of model partitioning across the GPUs.

In the case of pipeline execution of fine-tuning tasks, however, we observe that staleness *does not* have a major deteriorating effect on the training quality. There could be several reasons for this phenomenon: (a) Staleness is higher in the initial phase of the training [18], while in fine-tuning we start with pre-trained weights; (b) Fine-tuning usually uses lower learning rates, hence smaller staleness gaps [4]. (c) Momentum [51] exacerbates staleness, but many fine-tuning tasks do not use momentum. Furthermore, the part of staleness caused by momentum can be mitigated using gradient accumulation and momentum weight prediction [13], both can be employed

Setting	Loss	Forward	Backward
Synchronous	θ_t	θ_t	θ_t
Asynchronous	θ_{t-s}	θ_{t-s}	θ_t
PipeDream	θ_{t-s}	θ_{t-s}	θ_{t-s}
FTPipe	θ_{t-s}	θ_t	θ_t

Table 1: Parameter versions during different phases of back-propagation, under different pipeline execution scenarios. θ_j denotes parameters after j optimization steps. A stale parameter with delay of s is denoted θ_{t-s} . Notice that the pass used for loss calculation ('loss') and the pass used to compute activations for backpropagation ('forward pass') induce two separate calculations.

by FTPipe with no memory overhead and a small computational overhead ($< 5\%$, measured on Bert and GPT2). (d) Large models appear to have smooth and slowly varying loss functions [29], meaning that for large models, the stale loss can be a close-enough approximation to the actual loss. Indeed, as can be observed in the experiments Section 5, FTPipe achieves state-of-the-art results with an asynchronous pipeline of up to 16 stages, while avoiding the memory overheads of staleness mitigation implemented in prior works [37].

4.2.1 Checkpointing and recomputation

Checkpointing [7, 12] is a method to reduce memory by keeping only a small state (essentially, partition-border activations and the seed of the random number generator) rather than the whole computation graph. Checkpointing takes place during the forward pass while computing the loss. In this work, we experimented with checkpointing at pipeline stage borders similar to GPipe (In principle, checkpointing can be used at higher granularity). During the backward pass, recomputation reconstructs the parts of the computation graph required for backpropagation.

Checkpointing is used by FTPipe for saving memory during training, but it also mitigates staleness in two ways: First, during backpropagation, recomputation implies that the gradients are computed on up-to-date parameters (but using a stale loss that was computed in a forward pass on an older set of parameters, Table 1). Second, more computations are shifted toward the end of the pipeline where staleness is lower as a result of the last pipeline stage not recomputing, which makes it possible to increase its computational load by around 33%.

4.3 Profiling

In FTPipe's asynchronous work scheduler (Figure 5) there are two types of stages in the pipeline: (A) the last stage, which does not recompute (B) other stages, which do recompute.

For this reason, the execution of the last stage is faster by approximately 33% [17]. Hence, for precisely estimating the load, FTPipe profiles blocks both with and without recomputation. When a block is assigned to the last stage, it uses its profile without recomputations, and vice versa. However, the partitioning itself needs to know which profile to use when the block goes through the coarsening process, and this profile may eventually end up being the wrong one. Thus, several iterations of the partitioning algorithm may be needed to ensure that the correct profile is selected.

5 Evaluation

In this section, we evaluate the performance of FTPipe.

Summary. First, we show that FTPipe significantly improves the existing methods for fine-tuning of giant models.

Second, we show the benefit of Mixed-pipe for both synchronous and asynchronous pipelines. In both cases, despite communicating more and assigning non-consecutive layers of the trained model to workers, we show that Mixed-pipe accelerates execution compared to a Seq-pipe baseline.

Third, we show the benefits of fine-tuning giant models asynchronously, despite the fact that asynchrony introduces staleness. We do so by comparing FTPipe asynchronous pipeline to GPipe synchronous pipeline when both are employed to train the same model using the same partitioning. Our results show that FTPipe asynchronous pipeline is faster to achieve the same top-accuracy of GPipe, across different architectures, datasets, optimizers, and model sizes. Furthermore, our results empirically prove that the additional staleness generated by the increased number of pipeline stages in Mixed-pipe does not degrade its final accuracy.

Implementation. FTPipe has two main components: (a) an automatic neural network partitioning and assignment which builds a data-flow, and (b) a pipelined data-flow execution runtime that executes the partitioned model on GPUs and automatically handles work scheduling and inter-GPU communications. We use CUDA-Aware OpenMPI for inter-GPU communications. Our implementation accepts as the input a neural network implemented in PyTorch [39] (Python API) and the representative training inputs for this network. A partitioned model is automatically generated with everything necessary for our runtime to run it.²

5.1 Experimental setup

Hardware. We use a server with 8 RTX2080-Ti GPUs each with 11GB memory, connected via PCIe-III, 64-bit Ubuntu 18.04 with CUDA toolkit 10.2 and cuDNN v7.6.5. We note that RTX2080 GPUs are considered 7x more cost-effective than V100 [14].

²The source code of FTPipe is available at: <https://github.com/saareliad/FTPipe>

Models and training methodology. We used three different model architectures: Bert [11], GPT2 [43] and T5 [44]. These models represent the typical kinds of NLP architectures used for fine-tuning: Bert is encoder-only, GPT2 is decoder-only, and T5 is encoder-decoder. We took the PyTorch implementations of the models and pretrained weights from HuggingFace [57].

For each combination of (dataset, model, pipeline, partitioning), we chose the number of micro-batches that achieved the best throughput while keeping the mini-batch size constant. For example, GPipe prefers a higher number of micro-batches for a given mini-batch size to increase its pipeline parallelization level. In contrast, FTPipe prefers a lower number of micro-batches as it uses inter-mini-batch parallelism.

Exact hyper parameters are reported in [Appendix A](#).

Tasks and datasets. We use five different learning tasks and six datasets: Natural Language Inference (NLI) using RTE, Word Sense Disambiguation using WiC, Question answering using SQuAD and MultiRC, Boolean Question Answering using BoolQ and Language Modeling using WikiText2 [34, 46, 55, 56].

Our choices are dictated by the following criteria. We choose the task for a given model if that model is known to achieve state-of-the-art results, implying that smaller models are inferior. For example, RTE, WiC, BoolQ, MultiRC were chosen since T5 improved their accuracy considerably. GPT2 for WikiText2 achieves state-of-the-art results. Our fine-tuning improved the advertised results by 6.32 perplexity points on the test set.

We fine-tuned all models and datasets, achieving accuracy comparable to the top published results.

Baselines. Our choice of the baseline is restricted because of the memory requirements of giant models. In particular, neither Single-GPU, data-parallelism [30] nor PipeDream [37] without checkpointing meet these requirements. Hence, we apply checkpointing to PipeDream. Mesh-TensorFlow model-parallel framework [48] failed to run T5-3B, running out of memory, even with checkpointing, FP16, and micro-batch size of 1. This framework was originally used to run T5 on a TPU cluster, but the commodity hardware restrictions impede its use. In general, however, PipeDream already demonstrated the throughput benefits of pipelined execution over the model-parallel one, which applies to our work too.

GPipe is the only framework that successfully runs all the evaluated models. We used synchronous execution with GPipe to set the target accuracy in our experiments.

5.2 End-to-end evaluation

Table 2 shows that *FTPipe outperforms GPipe for all the cases in terms of time-to-top-accuracy*. As expected, the main

Table 2: Summary of the comparison of FTPIPE with original GPipe Seq-pipe (synchronous pipeline, one stage per GPU) over 8 GPUs. TTA is Time to Top Accuracy. The top accuracy is according to GPipe’s best results. Speedup is a geomean of four runs with random seeds. Mixed-pipe and Seq-pipe are denoted as “mixed” and “sequential” partitioning respectively. WSD is Word Sense Disambiguation, NLI is Natural Language Inference, QA is Question Answering, and LM is Language Modeling.

Model	Size	Task	Dataset	Accuracy	Partitioning	Pipeline	Speedup over GPipe Epoch time	Speedup over GPipe TTA
T5	3B	WSD	WiC	74.92%	mixed	Async	2.48×	³ 11.54×
						Sync	1.19×	1.19×
		NLI	RTE	90.97%	mixed	Async	2.71×	4.1×
						Sync	1.2×	1.2×
		QA	BoolQ	89.05%	mixed	Async	2.13×	2.88×
QA	MultiRC	85.6 F1, 59.3 EM	mixed	Sync	1.08×	1.08×		
GPT2	1.5B	LM	WikiText2	12.02 perplexity	sequential	Async	1.6×	1.6×
Bert	340M	QA	Squad	93.3 F1, 87.2 EM	sequential	Async	2.04×	2.04×

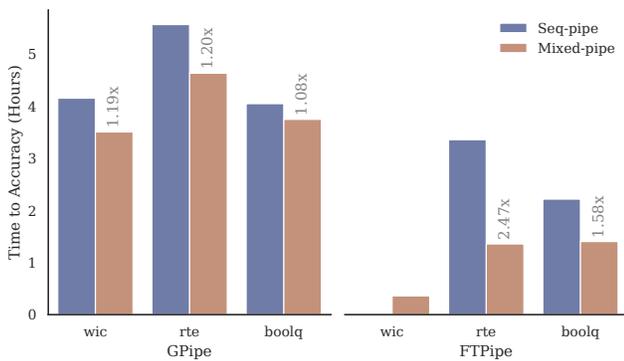

Figure 6: Mixed-pipe speedup over Seq-pipe for reaching top accuracy with T5-3B on three datasets and two pipelines: GPipe (synchronous) and FTPIPE (asynchronous).

speedup is due to faster epoch time, but it is not the only factor.

To explain this phenomenon, Figure 7 shows an example of FTPIPE training accuracy over time for T5-3B on RTE. We observe that both systems achieve 40% or higher accuracy at about the same time, despite the extra epochs needed for FTPIPE. Nevertheless, FTPIPE is much faster in the remaining top 60%. The reason is FTPIPE staleness, which impacts the training process in the beginning, yet diminishes and becomes negligible as the learning steps shorten [18].

In the following sections, we analyze the two factors contributing to acceleration, namely Mixed-pipe and asynchronous execution.

³ FTPIPE required fewer epochs to achieve the top accuracy of GPipe. The speedups vary from 3× to 40× over 4 runs with different seeds.

5.3 Effect of mixed-pipe partitioning

Figure 6 compares the contribution of our partitioning scheme by evaluating different schemes separately for synchronous and asynchronous pipelines for the T5 model on three different tasks and four datasets. Mixed-pipe runs 16 stages (two per GPU). Seq-pipe runs eight stages. We observe that Mixed-pipe is superior to Seq-pipe across all the experiments. We observed that Mixed-pipe balances GPU memory occupancy across GPUs for both synchronous and asynchronous pipelines, keeping more free memory available, thus allowing a bigger micro-batch size. Most importantly, Mixed-pipe improves both synchronous and asynchronous. We note that while the inter-GPU communication volume in Mixed-pipe is higher than in Seq-pipe, 2.6× for MultiRC and BoolQ, 2.5× for RTE and 3.31× for WiC, the benefits of improved load balance outweigh the associated overheads.

The benefits and trade-offs Mixed-pipe introduces differs for synchronous and asynchronous pipelines:

Synchronous pipeline. For the synchronous setting, using Mixed-pipe can only improve performance and does not affect accuracy. Figure 6 shows that Mixed-pipe improves the time-to-accuracy of GPipe up to 1.2×.

Asynchronous pipeline. For FTPIPE asynchronous pipeline, Mixed-pipe may harm accuracy since it adds more pipeline stages, which add staleness. However, in practice, accuracy is not affected. Figure 6 shows that Mixed-pipe both accelerates execution and achieves the same final accuracy result of Seq-pipe. Figure 7 provides the explanation for this phenomena: staleness affects mainly the beginning of the computation, up to the point of reaching 40% of the target accuracy. In this first part of the computation, staleness causes Mixed-pipe to execute more epochs than Seq-pipe, yet they both run at a similar wall-clock speed because Mixed-pipe is

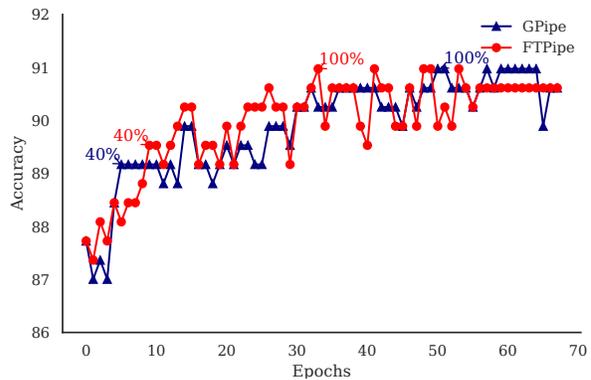

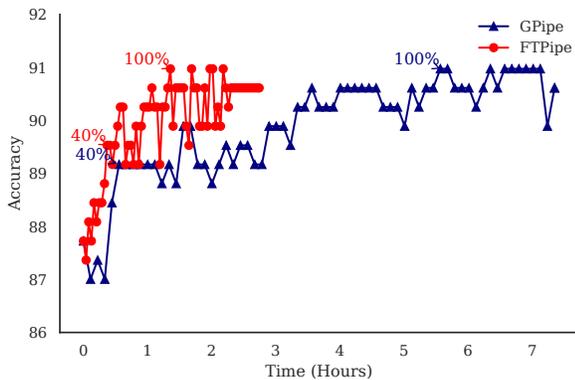

Figure 7: FTPipe acceleration over GPipe for fine-tuning T5-3B with Glue RTE dataset. FTPipe uses Mixed-pipe with 16 stages. GPipe is a synchronous Seq-pipe with 8 stages. We denote the earliest times when at least 40% and 100% of the top accuracy is achieved. Notice that FTPipe is much faster in achieving the last top 60%.

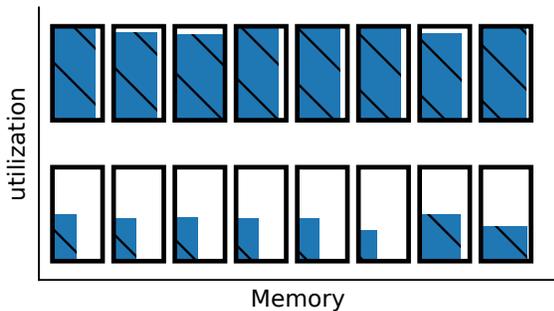

Figure 8: Mixed-pipe load balancing visualization for asynchronous pipelines with T5-3B model on the WiC dataset. Each box is a GPU whose width represents memory consumption and fill represents utilization. Top: Mixed-pipe. Bottom: Seq-pipe.

much faster per epoch. In contrast, during the remaining part of the computations from 40% to 100% of the target accuracy, Mixed-pipe enjoys significant speedup over Seq-pipe with negligible (if at all) effect of staleness as the learning steps gradually shorten [18].

5.3.1 Load balancing analysis

In Figure 8, we present the load balancing analysis of Mixed-pipe, using T5 as a representative example.

As illustrated in Figure 4, the T5 encoder-decoder architecture with unbalanced inputs sequences for encoder and decoder poses a problem for Seq-pipe. In our experiments, Seq-pipe with memory-unaware partitioning methods resulted in out of memory run-time errors, whereas Seq-pipe with memory-aware partitioning methods resulted in computa-

tional load imbalance. In contrast, Mixed-pipe achieves a much better balance both for memory occupancy and computational load.

In summary, *Mixed-pipe improves the performance over Seq-pipe due to two main factors: (1) better computational load balance and (2) better memory balance, thereby enabling larger micro-batch size.*

5.4 Effective fine-tuning with staleness

Table 3 summarises our results for three different model sizes and five different tasks. Each task used the same model partitioning to train GPipe (synchronous) and FTPipe (asynchronous). Note that these results differ from those in Table 2, because here we use the Mixed-pipe partitioning scheme for both FTPipe and GPipe.

In all experiments, FTPipe achieved the same or higher accuracy than GPipe. We note that MultiRC, Squad and WiC achieved slightly better results with FTPipe (85.99 F1 60.44 EM; 93.47 F1 87.38 EM; and 75.54 accuracy receptively).

5.5 FTPipe vs PipeDream

We implemented PipeDream partitioning based on their open-source GitHub code. To focus on conceptual evaluation, the partitioning algorithm is implemented on top of the technically superior tracing, profiling, compilation, and runtime system of FTPipe, which can handle giant models. Furthermore, it is necessary since only FTPipe supports sharing weights.

T5-3B: PipeDream partitioning of T5-3B for 8 GPUs required around 20 minutes and yielded an infeasible solution with hybrid data- and pipeline-parallel stages, some of which do not fit into GPU memory. In particular, lacking the way to specify memory constraints, PipeDream ended up with more than 1.48B parameters in the last stage (a single 32GB V100 GPU can handle only about 1.3B parameters [45]). It also produced

Table 3: FTPipe vs GPipe time-to-accuracy, using the *same* Mixed-pipe partitioning. Top accuracy is set by GPipe best results.

Dataset	Model	Parti- -tioning	Top Accuracy	Speedup	
				Epoch	TTA
wic	T5-3B	mixed	74.92%	2.09×	9.74×
rte	T5-3B	mixed	90.97%	2.25×	3.41×
boolq	T5-3B	mixed	89.05%	2.23×	2.67×
multirc	T5-3B	mixed	85.6 F1 59.3 EM	2.98×	2.98×
Wiki -Text2	GPT2- 1.5B	seq	12.02 perplexity	1.61×	1.61×
Squad	Bert- 340M	seq	93.3 F1 87.2 EM	2.04×	2.04×

an infeasible solution (OOM) when forced to create a simple pipeline (no data-parallel stages). Note that a pipeline with weight stashing and without gradient accumulation would not be able to train T5-3B on 11GB GPUs, even if more GPUs were used, as explained in §4.2.

GPT2-1.5B PipeDream failed to run GPT2-1.5B with 8 GPUs even with checkpointing.

BERT-large: When profiling with micro-batch of size 24, and sequence length 384 (the suggested hyperparameters for SQuAD [11]), PipeDream outputs a purely data-parallel solution (no pipeline) for 2, 4, and 8 GPUs. Such a solution does not fit RTX2080-Ti GPUs even with batch size 1. Only at micro-batch size 1 PipeDream succeeded in creating a working pipeline for 2 GPUs. For fine-tuning SQuAD with 2 GPUs, FTPipe was 12.7% faster than PipeDream in achieving the same accuracy over 5 seeds (std was 1%), attributed to the enhanced profiling of FTPipe.

For 4 GPUs, FTPipe was 4% faster than PipeDream pipeline⁴. For 8 GPUs, both PipeDream (pipeline) and FTPipe achieve comparable accuracy at comparable times, since the advantage of FTPipe profiling diminishes as the number of pipeline workers increases.

5.6 Layers-graph vs Operators-graph

We evaluate the contribution of fine-grain partitioning to the end-to-end performance of T5-3B using WiC dataset.

For Mixed-pipe partitioning the operators-graph results in epoch speedup of 2.2% for the asynchronous pipeline and 1.6% for the synchronous pipeline, compared to the cases of partitioning the layers-graph (standard deviation less than 0.01%). This implies that the primary source of speedup for

⁴We noticed that PipeDream models data-parallel communication as *completely* concurrent to computation, but in practice, 30% of the communications do not overlap [30]. Changing the modeling led PipeDream to output a pipeline solution.

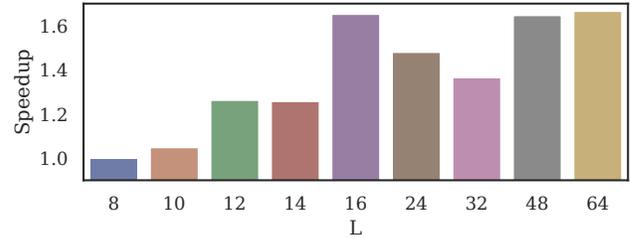

Figure 9: Mixed-pipe performance for different values of L .

this case comes from relaxing the neural network topology when mapping layers (or operators) to GPUs.

However, this is not always the case. We build a small version of T5-11B, with 1 encoder layers and 1 decoder layer (535M parameters), and compare the partitions for $P = 2$ GPUs, once at the granularity of whole layers, and once at the granularity of operators. The latter achieves 45% better min-max-stage-time objective in our simulation.

We also note that the layers-graph is not explicitly expressed in some cases, leaving the operator-granular partitioning as the only option. This is the case, for example, when importing a graph defined in ONNX [2] for further fine-tuning before deployment, or if a programmer does not use the layer software abstraction when defining the network (in PyTorch: ‘torch.nn.Module’).

5.7 Mixed-pipe sensitivity to L

We explore the sensitivity of the Mixed-pipe performance to the choice of L .

In Figure 9 we show the partitioning objective speedup for T5-3B (BoolQ) for $P = 8$ GPUs when using different L for partitioning, with FTPipe’s asynchronous scheduler (Figure 5). We observe that that the sweetspot is at $L = 16$.

5.8 Mixed-pipe vs Seq-pipe for larger models

In this experiment, we partitioned the T5-11B model (BoolQ dataset) to four 32GB V100 GPUs using both Mixed-pipe and Seq-pipe. Mixed-pipe partitioning allowed training the model using 7 workers. Unfortunately, Seq-pipe partitioning resulted in an out-of-memory error. This experiment highlights the importance of better memory balancing among the nodes to allow fine-tuning huge models.

6 Related Work

Parallel, memory efficient methods for training giant neural networks fall into three categories: Sharded Data Parallelism [45], Intra Layer Model Parallelism [48, 50], and synchronous pipeline parallelism with checkpointing [17]. The communication volumes of intra-layer model-parallelism and

shared data-parallelism cannot be overlapped entirely and are too high for commodity interconnects. GPipe [17], similar to sharded data-parallelism, can be made efficient and hide synchronization overheads when using large mini-batches with many micro-batches. However, this is not generally applicable to the batch size used with fine-tuning. Compressing the communication of data-parallelism [32] can significantly reduce its communication volume, making it more suitable for commodity interconnects. For giant networks, however, a combination with another memory reduction technique is required.

In another line of works [18, 19, 21, 59], the backward pass is decoupled and is performed in parallel, but the forward pass is sequential. In Ouroboros [59], shared embedding (aka Tied Weights [20, 42]) of small Transformers were manually placed on the same GPU. In FTPipe, shared weights can also be placed on different GPUs, and it is done with automatic partitioning and with pipelining where communication is overlapped.

PipeDream [37] solves pipeline imbalance problems by incorporating data-parallelism with seq-pipes, allowing a different number of data-parallel GPUs per pipeline stage. This solution requires more GPUs than Mixed-pipe to balance some architectures (see §3.3).

Our experiments with giant models show that the exhaustive search of PipeDream can take a long time for large computational graphs (where FTPipe search took few seconds) and is infeasible for Mixed-pipe. METIS [24] rapidly partitions large computational graphs by multilevel graph partitioning. However, it is focused on optimizing edge-cut under load balance constraints and not on the pipeline throughput. When applied to pipelines, it sometimes unnecessarily creates additional small stages, which Mixed-pipe bounds from above by L .

Concurrently and independently of our work, Tarnawski et al [52] considered searching for non-contiguous pipeline solutions with Integer Programming. They did not model communication and computation overlap and did not limit the number of stages L , thus also ignoring staleness. They did not find the optimal solution and stopped the search after 20 minutes for models smaller than those considered here.

Several asynchronous model parallelization methods have been recently proposed [38, 58]. These works use Seq-pipes and would suffer from imbalance problems solved by Mixed-pipe. FTPipe could be used in heterogeneous systems [38], but the large search space requires additional heuristics. GEMS [22] improve synchronous pipelines in case multiple replicas could fit in the accelerators. Li et al. [31] proposed token-level parallelism which applies to causal language models (only GPT2 in our experiments), and is complementary to FTPipe.

7 Conclusion

Fine-tuning has the potential to bring the power of huge neural networks to users who do not possess high performance compute resources. In this paper we survey the challenges introduced by this paradigm and take a big step towards solving them by enabling fine tuning on affordable commodity hardware. Our future work will show that FTPipe can scale beyond single-machine boundaries, can achieve higher efficiency by incorporating data-parallel components, and can bring value to non-NLP communities. We hope that the ideas underlying Mixed-pipe can apply beyond fine-tuning, to training in general.

Appendix A Hyper-parameters

Table 4 lists the experiments’ hyper-parameters. A checkpoint was saved after every epoch and for WiC every 100 steps. In the T5 and GPT2 experiments, we utilized gradient accumulation to achieve the desired batch size.

T5 experiments used Adafactor optimizer [49] with learning rate of 0.01 and a warm-up of approximately 6% of total fine-tuning steps.

GPT2 experiments used AdamW [33] optimizer with weight decay of 0.01 and a learning rate of 5e-5, decreasing linearly to zero. First and second moment coefficients are 0.9 and 0.999, respectively. We used a mini-batch size of 8 and max sequence length of 1024. We fine-tuned GPT2 for one epoch since further fine-tuning caused over-fitting. Due to large memory consumption caused by the large sequence-length (1024), we used a batch size of 1.

BERT experiments used Adam [25] optimizer with first and second moment coefficients of 0.9 and 0.999 respectively, a learning rate of 3e-5 decreasing linearly to zero. We trained for 2 epochs with mini-batch size of 24 and max sequence length of 384. We loaded weights pre-trained with whole-word-masking.

INFaaS: Automated *Model-less* Inference Serving

Abstract

Despite existing work in machine learning inference serving, *ease-of-use* and *cost efficiency* remain challenges at large scales. Developers must manually search through thousands of *model-variants* – versions of already-trained models that differ in hardware, resource footprints, latencies, costs, and accuracies – to meet the diverse application requirements. Since requirements, query load, and applications themselves evolve over time, these decisions need to be made dynamically for *each* inference query to avoid excessive costs through naive autoscaling. To avoid navigating through the large and complex trade-off space of model-variants, developers often fix a variant across queries, and replicate it when load increases. However, given the diversity across variants and hardware platforms in the cloud, a lack of understanding of the trade-off space can incur significant costs to developers.

This paper introduces INFaaS, an automated *model-less* system for distributed inference serving, where developers simply specify the performance and accuracy requirements for their applications without needing to specify a specific model-variant for each query. INFaaS generates model-variants from already trained models, and efficiently navigates the large trade-off space of model-variants on behalf of developers to meet application-specific objectives: (a) for each query, it selects a model, hardware architecture, and model optimizations, (b) it combines VM-level horizontal autoscaling with model-level autoscaling, where multiple, different model-variants are used to serve queries within each machine. By leveraging diverse variants and sharing hardware resources across models, INFaaS achieves 1.3× higher throughput, violates latency objectives 1.6× less often, and saves up to 21.6× in cost (8.5× on average) compared to state-of-the-art inference serving systems on AWS EC2.

1 Introduction

The number of applications relying on inference from Machine Learning (ML) models is already large [14,47,48,60,67] and expected to keep growing. Facebook, for instance, serves tens-of-trillions of inference queries per day [40,43]. Distributed inference dominates ML production costs: on AWS, it accounts for over 90% of ML infrastructure cost [16].

Typically, an ML lifecycle has two distinct phases – training and inference. Models are trained in the training phase; the training phase is usually characterized by long-running hyperparameter searches, dedicated hardware resource usage,

Application	Accuracy	Latency	Cost
Social Media	High	Medium	Low
Visual Guidance	High	Low	High
Intruder Detection	Low	Low	Low

Table 1: Applications querying a face recognition model with diverse requirements.

and no completion deadlines. In the inference phase, trained models are queried by various end-user applications. Being user-facing, inference serving requires cost-effective systems that render predictions with latency constraints while handling unpredictable and bursty request arrivals.

Inference serving systems face a number of challenges [61, 73] due to the following factors.

(a) Diverse application requirements: Applications issue queries that differ in latency, cost, accuracy, and even privacy [56] requirements [42,45,61]. Table 1 shows the same face recognition model queried by multiple applications with different requirements. Some applications, such as intruder detection, require inference in realtime but can tolerate lower accuracy. Other applications, such as tagging faces on social media, may prefer accuracy over latency.

(b) Heterogeneous execution environments: Leveraging heterogeneous hardware resources (e.g., different generations of CPUs, GPUs, and accelerators like TPU [49] or AWS Inferentia [18]) helps meet the diverse needs of applications and the dynamic changes in the workload; however, it is non-trivial to manage and scale heterogeneous resources [40].

(c) Diverse model-variants: Graph optimizers, such as TVM [22], TensorRT [3], and methods, such as layer fusion or quantization [15], produce versions of the same model, *model-variants*, that may differ in inference latency, memory footprint, and accuracy.

Together, these factors create a large search space. For instance, from 21 already-trained image classification models, we generated 166 model-variants, by (i) applying model graph optimizers, such as TensorRT [3], (ii) optimizing for different batch sizes, and (iii) changing underlying hardware resources (e.g., CPUs, GPUs, and Inferentia). These variants vary across many dimensions: the accuracies range from 56.6% to 82.5% (1.46×), the model loading latencies range from 590ms to 11s (18.7×), and the inference latencies for a single query range from 1.5ms to 5.7s (3,700×). Their computational requirements range from 0.48 to 24 GFLOPS (50×) [61], and the cost of hardware these variants incur [17] ranges from \$0.096/hr for 2 vCPUs to \$3.06/hr for a V100 GPU (32×). As new inference accelerators are introduced and new opti-

*Equal contribution

mization techniques emerge, the number of model-variants will only grow.

This large search space makes it hard for developers to manually map the requirements of each inference query to decisions about selecting the right model and model optimizations, suitable hardware platforms, and auto-scaling configurations. The decision complexity is further exacerbated when the load varies, applications evolve, and the availability of hardware resources (GPUs, ASICs) changes. Unlike long-running batch data analytics or ML training jobs [8, 26, 36, 55, 68] that can be right-sized during or across subsequent executions, the dynamic nature of distributed inference serving makes it infeasible to select model-variants statically.

Our key insight is that the large diversity of model-variants is not a nuisance but an opportunity: it allows us to meet the diverse and varying performance, cost, and accuracy requirements of applications, in the face of varying load and hardware resource availability, if only we can select and deploy the right model-variant effectively for *each* query. However, given the complexity of this search space, existing systems, including Clipper [25], TensorFlow Serving [5], AWS SageMaker [11], and others [1, 6, 35, 38, 75], ignore the opportunity. These systems require developers to select model-variants, batch sizes, instance/hardware types, and statically-defined autoscaling configurations, for meeting application requirements. If these decisions are made without understanding the trade-offs offered by the variants, the impact could be significant (note the wide cost, performance, and accuracy ranges spanned by the variants). We argue that in addition to traditional autoscaling, distributed inference serving systems should navigate this search space of model-variants on behalf of developers, and automatically manage model-variants and heterogeneous resources. Surprisingly, as also noted in prior work [73], no existing inference serving system does that.

To this end, we built INFaaS, an automated *model-less* system for distributed inference serving. INFaaS introduces a *model-less* interface where after registering trained models, developers specify only the high-level performance, cost, or accuracy requirements for each inference query. INFaaS generates model-variants of the registered models, and navigates the large space to select a model-variant and automatically switch between differently optimized variants to best meet the query requirements. INFaaS also automates resource provisioning for model-variants and schedules queries across a heterogeneous cluster.

To realize this, INFaaS generates model-variants and their performance-cost profiles on different hardware platforms. INFaaS tracks the dynamic status of variants (e.g., overloaded or interfered) using a state machine, to efficiently select the right variant for each query to meet the application requirements. Finally, INFaaS combines VM-level (horizontal scaling) and *model-level autoscaling* to dynamically react to the changing application requirements and request patterns. Given the large and complex search space of model-

variants, we formulate an integer linear program (ILP) for our model-level autoscaling that finds the most cost-effective combination of model-variants, to meet the goals for queries in large scale inference serving.

Using query patterns derived from real-world applications and traces, we evaluate INFaaS against existing inference serving systems, including Clipper [25] and SageMaker [11], with 175 variants generated from 22 model architectures, on AWS. Compared to Clipper, INFaaS' ability to select suitable model-variants, leverage heterogeneous hardware (CPU, GPU, Inferentia), and share hardware resources across models and applications enables it to save $1.23\times$ in cost, violate latency objectives $1.6\times$ less often, and improve resource utilization by $2.8\times$. At low load, INFaaS saves cost by $21.6\times$ compared to Clipper, and $21.3\times$ compared to SageMaker.

2 Challenges

2.1 Selecting the right model-variant

A *model-variant* is a version of a model defined by the following aspects: (a) model architecture (e.g., ResNet50, VGG16), (b) programming framework, (e.g., TensorFlow, PyTorch, Caffe2, MXNet), (c) model graph optimizers (e.g., TensorRT, Neuron, TVM, XLA [72]), (d) hyperparameters (e.g., optimizing for batch size of 1, 4, 8, or 16), and (e) hardware platforms (e.g., Haswell or Skylake CPUs, V100 or T4 GPUs, FPGA, and accelerators, such as Inferentia [18], TPU [49], Catapult [32], NPU [7]). Based on the 21 image classification models and the available hardware on AWS EC2 [9], we estimate the total number of possible model-variants would be **4,032**. The performance, cost, and accuracy trade-off space offered by these variants is large [19, 61]. As new inference accelerators are introduced and new optimization techniques emerge, the number of model-variants will only grow.

Existing inference serving systems require developers to identify the model-variant that can meet diverse performance, accuracy, and cost requirements of applications. However, generating and leveraging these variants requires a substantial understanding of the frameworks, model graph optimizers, and characteristics of hardware architectures, thus limiting the variants an application developer can leverage. As shown in Table 1, one can use the same face recognition model for several applications, but selecting the appropriate model-variant depends on the requirements of an application [61].

We argue that inference serving systems should automatically and efficiently select a model-variant for each query on behalf of developers to align with application requirements.

2.2 Reducing cost as load varies

Query patterns and service level objectives (SLOs) of applications, such as real-time translation and video analytics, can vary unpredictably [43, 50, 76]. Provisioning for peak demand leads to high cost, hence distributed inference serving systems need to dynamically respond to changes. Traditional autoscaling focuses on horizontal virtual machine replication

Variant (hardware, framework)	Lat. (ms)	Req/s	Cost (\$/s)
A (4 CPUs, TensorFlow)	200	5	1
B (1 Inferentia core, Neuron)	20	100	3
C (1 V100 GPU, TensorRT)	15	800	16

Table 2: Latency, saturation throughput, and normalized cost (based on AWS pricing) for three ResNet50 variants.

QPS	SLO (ms)	#Var. A	#Var. B	#Var. C	Cost (\$/s)
10	300	2	0	0	2
10	50	0	1	0	3
1000	300	0	2	1	22

Table 3: Cheapest configuration (in #instances) of variants from Table 2 to meet the QPS and SLO; last column shows total cost.

(VM-scaling), adding or removing worker machines [33, 37]. However, relying only on worker replication may incur significant latency, as new machines must be spawned.

Autoscalers used by existing inference serving systems [11, 35, 37] replicate a statically-fixed (developer-specified) model-variant for all the queries of an application. This is insufficient because: (a) the right variant may change with load (e.g., a CPU variant may be more suitable at low QPS to meet the cost SLOs) and (b) the hardware resources needed to replicate the same variant may not always be available (e.g., shortage of GPU instances at some point).

In addition to using VM-scaling and replication-based model-scaling, we introduce *model-level vertical scaling*, where we switch to a differently optimized variant as load changes. The challenge is to identify which variant to scale to given available hardware resources and query requirements. Consider the example shown in Table 2 with three ResNet50 variants. Each variant runs on a different hardware resource and differs in latency, saturation throughput, and cost. In Table 3, we present three input loads and SLO requirements, with the goal of scaling to the most cost-effective combination of variants. In the first case (QPS = 10 and SLO = 300ms), though all variants can meet the QPS and SLO, using two instances of Variant A is the cheapest choice (8× cheaper than using Variant C). In the second case, the load remains unchanged, but due to the stricter SLO, Variant B becomes the cheapest choice (5.3× cheaper than using Variant C). In the third case, the combination of two instances of Variant B and one of Variant C is the cheapest. This configuration is 9× cheaper than using 200 instances of Variant A (the most expensive configuration). Deciding the best configuration becomes more challenging as the number of variants increases and resource availability changes.

2.3 Improving utilization at low load

For predictable performance, one may serve each model-variant on a dedicated machine to exclusively access hardware resources. But, this often results in underutilized resources and cost-inefficiency, especially at low load. Instead, the serving systems should support multi-tenancy by *sharing resources*

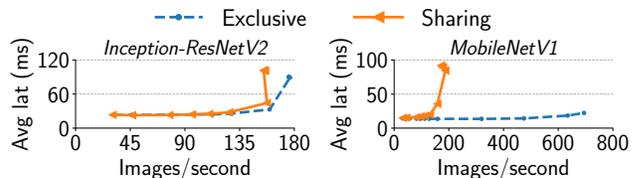

Figure 1: Impact of co-locating Inception-ResNetV2 and MobileNetV1 on a V100 GPU. Both variants are TensorRT, batch-1, FP16. Graphs show average latency and throughput for each model running alone vs sharing, subjected to the same (QPS).

across applications and models, thereby improving utilization and the overall cost. Recent work [36, 71] has shown the benefits of sharing GPUs for deep-learning training jobs. ML inference jobs are typically less demanding for compute and memory resources than the training jobs, making inference jobs ideal for sharing GPUs and other accelerators [46, 74].

However, how to share accelerators across multiple tenants while maintaining predictable performance is not obvious. Figure 1 shows the result of co-locating a large (Inception-ResNetV2) and a small (MobileNetV1) model on a GPU. At low load, sharing a GPU does not affect the performance of either model. At higher load, this co-location heavily impacts the performance of the small model, while the large model remains unaffected. The point when co-location starts affecting the performance varies across models, and depends on both the load and the hardware architecture.

3 INFaaS

Design principles. We design INFaaS based on the following guidelines. First, INFaaS should support a declarative API: Developers should not need to specify the model, model optimizations, suitable hardware platforms, or autoscaling configurations; they should only focus on high-level performance, cost, or accuracy requirements. Second, INFaaS should automatically and efficiently select a model-variant, while considering the dynamic state of the model-variants and the hardware resources, for (a) serving each query, and (b) deciding how to scale in reaction to changing application load. Third, to improve resource utilization, the system should share hardware resources across model-variants and applications, without violating performance-cost constraints. Finally, the system design should be modular and extensible to allow new model-variant selection policies. By following these design principles, we naturally address the challenges raised in Section 2.

Functionality. INFaaS generates new model-variants from the models registered by developers, and stores them in a repository (Section 3.2). These variants are optimized along different dimensions using model graph optimizers such as Neuron and TensorRT. For each inference query, INFaaS automatically selects a model-variant to satisfy its performance, cost, and accuracy objectives (Section 4.1). INFaaS’ autoscaler combines VM-level autoscaling with model-level horizontal and vertical autoscaling to meet application per-

API	Parameters
register_model	modelName, modelBinary, valSet, appID
inference_query	input(s), appID, latency, accuracy
inference_query	input(s), modelName

Table 4: INFaaS’ declarative developer API.

formance and cost requirements while improving utilization of resources (Section 4.2). INFaaS introduces *model-vertical autoscaling* that, through model selection, upgrades or downgrades to a differently optimized model-variant by leveraging the diversity of model-variants (Section 4.2.1). INFaaS efficiently maintains static and dynamic profiles of model-variants and hardware resources to support low latencies for selecting and scaling model-variants (Sections 3.2 and 4). Finally, INFaaS features the model-variant selection policy described in Section 4, but allows developers to extend and customize it.

3.1 Model-less interface for inference

Table 4 lists INFaaS’ model-less API.

Model registration. Developers register one or more models using the `register_model` API. This API accepts a developer-assigned model identifier (`modelName`), the model (`modelBinary`) in serialized format (e.g., a TensorFlow SavedModel or model in ONNX format), and a developer-assigned application identifier (`appID`). Models for different prediction tasks within the same application (e.g., optical character recognition and language translation) can be registered with separate `appIDs`. Lines 1-2 in Figure 2 show how a developer registers two models, a ResNet50 and a MobileNet, for an application with `appID=detectFaceApp`. INFaaS generates multiple variants from these already trained models. For instance, using ResNet50 alone, INFaaS can generate about 50 variants by changing the batch size, the hardware, and the model graph optimizer (Section 3.2). Note that INFaaS is an inference serving system and does not train new models; INFaaS only generates variants from already-trained models. The `register_model` API takes a validation dataset (e.g., `valSet`) as input to calculate the accuracy of the newly generated variants. For each incoming query, INFaaS automatically selects the right model-variant to meet the specified goals.

Query submission. Being declarative, INFaaS’ API allows developers to specify high-level goals without needing to specify the variants for their queries. Using the `inference_query` API, developers can submit inference queries in two ways:

- *Specifying application requirements.* Developers may submit queries for their application and specify high-level application performance, cost, and accuracy requirements (e.g., Line 3 in Figure 2). INFaaS then navigates the search space of model-variants for the given application, and selects model-variants and scaling strategies. For instance, for a query with `appID=detectFaceApp`, INFaaS searches for a suitable variant of ResNet50 and MobileNet to meet the goal of latency (200ms) and accuracy (above 70%).

```

1 register_model("ResNet50", ResNet50.pt, valSet, detectFaceApp)
2 register_model("MobileNet", MobileNet.pt, valSet, detectFaceApp)
# Developer registered 2 models for the detectFaceApp;
# INFaaS generates variants from these two registered models
3 inference_query(input.jpg, detectFaceApp, 200ms, 70%)
# Developer submitted a query with "input.jpg" as the input
# and specified requirements; INFaaS then selects a variant
# automatically to meet 200ms latency and accuracy > 70%

```

Figure 2: Registering models and submitting queries with INFaaS.

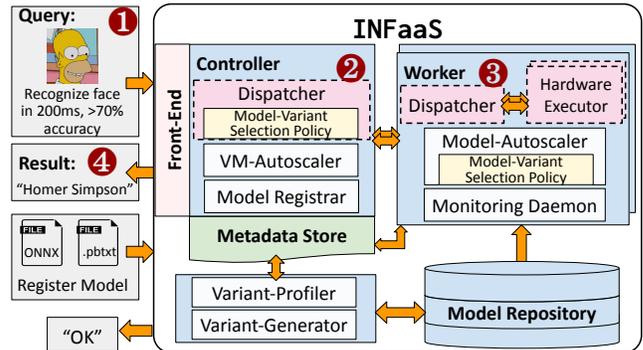

Figure 3: Architecture of INFaaS. Modules in boxes with dashed border are on the critical path of serving queries. All other modules do not impact serving latency. Numbered circles correspond to the typical life-cycle of queries.

- *Specifying a registered model.* Developers may use this interface to specify the model, `modelName`, they registered for the corresponding application (e.g., "ResNet50" for `detectFaceApp`). This interface supports developers who want direct control over the model-variant used. This is the only option offered by existing inference systems. INFaaS then dynamically scales resources for the specified model-variant based on the observed workload.

INFaaS’ serving workflow for an inference query. Applications interact with INFaaS by submitting inference queries through the *Front-End*, logically hosted at the *Controller* (see steps marked in Figure 3). The Controller selects a model-variant and dispatches the inference query to a *Worker* machine. Workers further send inference queries to the appropriate *Hardware Executors* according to the selected model-variant, and reply with inference results to applications.

3.2 Architecture

We now describe INFaaS’ architecture (Figure 3) in detail.

Controller. The logically-centralized controller receives model registration and inference requests. The controller hosts three modules: (a) The Dispatcher that uses the model-variant selection policy for selecting a variant to serve a query, (b) The VM-Autoscaler that is responsible for scaling the number of workers up and down based on the current load and resource utilization, and (c) The Model Registrar that handles model registration.

Workers. Worker machines execute inference queries assigned by the controller. Hardware-specific Executor daemons manage the deployment and execution of model-variants. The

Dispatcher forwards each query to a specific model-variant instance through the corresponding hardware executor. The Model-Autoscaler detects changes in the load and decides a scaling strategy that either replicates running variants or selects a different variant, within the worker. It uses the model-variant selection policy to select a variant to scale to. The Monitoring Daemon tracks the utilization of machines and variants, and manages resources shared by multiple variants to avoid SLO violations.

Variant-Generator and Variant-Profiler. From the registered models, the Variant-Generator generates model-variants optimized for different batch sizes, hardware, and hardware-specific parameters (e.g., number of cores on Inferentia) using model graph optimizers, including TensorRT [3] and Neuron [15]. INFaaS uses the validation set submitted by the developer to calculate the accuracy of the newly generated variants; INFaaS records this information in the Metadata Store. The Variant-Generator does not train or produce new model architectures: variants are generated only from registered models. To help model-variant selection, the Variant-Profiler conducts one-time profiling for each variant where it measures statistics, such as the loading and inference latencies, and peak memory utilization. These parameters, along with the corresponding `appID`, accuracy, and maximum supported batch size are recorded in the Metadata Store. After profiling, a variant is saved in the Model Repository. The total profiling time for all generated variants from a submitted model is a few minutes on a single VM with the variant’s target hardware. This profiling cost will be amortized over long-term serving time in production settings.

Model-Variant Selection Policy. INFaaS invokes the model-variant selection policy in two cases.

(Case I) On arrival of a query: The controller’s Dispatcher uses the policy to select a variant for each incoming query. This model-variant selection lies on the critical path of serving each query. To reduce the latency of decision-making, we designed an efficient variant search algorithm (Section 4.1).

(Case II) On changes in query load: As the query load changes, the worker’s Model-Autoscaler uses the policy to determine whether to replicate existing variants, or vertically scale to a different variant. The Model-Autoscaler monitors the incoming query load and the current throughput of INFaaS to detect the need for scaling. If a change is detected, the Model-Autoscaler invokes the policy in the background to select a suitable scaling strategy (Section 4.2).

To allow for other model-variant selection algorithms, we designed INFaaS to decouple policies from mechanisms [53].

Metadata Store. The Metadata Store enables efficient access to the static and dynamic data about workers and model-variants; this is needed for making model-variant selection and scaling decisions. This data consists of (a) the information about available model architectures and their variants (e.g., accuracy and profiled inference latency), and (b) the resource usage and load statistics of variants and worker machines. The

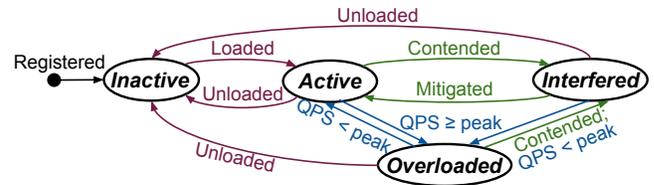

Figure 4: State machine capturing the dynamically changing status of model-variants.

Metadata Store strategically uses data structures to ensure low access latencies ($\sim O(1)$) for efficient decision-making. The Metadata Store runs on the same machine as the controller to reduce access latencies for selecting variants. Implementation and data structure details are described in Section 5.

Model Repository. The Model Repository is a high-capacity persistent storage medium that stores serialized variants that are accessible to workers when needed to serve queries.

4 Selecting and Scaling Model-Variants

INFaaS uses the model-variant selection policy in two cases: (I) On arrival of a query: INFaaS’ controller needs to select a variant for each query to meet an application’s high-level requirements (Section 4.1). This invocation of the selection policy lies on the critical path of inference serving. (II) On changes in query load: As the query load changes, INFaaS’ workers must decide whether to switch to a differently optimized variant (Section 4.2). The worker invokes the selection policy off the critical path. INFaaS provides an internal API, `getVariant`, for invoking model-variant selection policy. In both cases, INFaaS needs to consider both the static and dynamic states of variants and available resources. Only considering statically-profiled metadata is insufficient, since the following aspects can significantly impact the observed performance and cost: a selected variant (a) may not be loaded, hence we need to consider its loading latency, (b) may be already loaded but serving at its peak throughput, (c) may be already loaded but experiencing resource contention from co-located inference jobs, and (d) may not be loaded due to lack of resources required for that specific variant. We next describe how INFaaS tracks the dynamic state of model-variants, and then describe the policy used in the two cases.

State machine for the lifecycle of model-variants. To track the dynamic state of each model-variant instance per-application, INFaaS uses a state machine (shown in Figure 4). All the registered and generated model-variants start in the *Inactive* state: they are not loaded on any worker. Once a variant instance is loaded, it transitions to the *Active* state. These variant instances are serving less than their peak throughput, tracked by the worker’s monitoring daemons. Variant instances enter the *Overloaded* state when they serve at their peak throughput. Finally, variant instances in the *Interfered* state are not overloaded but are still experiencing higher inference latencies than the profiled values. Interference occurs when co-located variants contend over shared resources (e.g., caches, memory bandwidth, or hardware threads).

Algorithm 1 Model-variant selection for case I (arrival of a query)

```
1: function GETVARIANT(appID, accuracy, latency)
2:   if searchActiveVariants(appID, accuracy, latency) then
3:     Get least-loaded worker,  $W_{1l}$ , running activeVariant
4:     return activeVariant,  $W_{1l}$ 
5:   if searchInactiveVariants(appID, accuracy, latency) then
6:     Get lowest-util worker,  $W_{1u}$ , with inactiveVariant's HW
7:     return inactiveVariant,  $W_{1u}$ 
8:   return suggestVariant(appID, accuracy, latency)
```

Maintaining the state machine. Each model-variant instance's state machine is maintained by the worker's monitoring daemons and is organized in the Metadata Store for fast access. This enables INFaaS' Dispatcher to use the model-variant selection policy for serving queries on the order of hundreds of μ s to ms (assessed further in Section 6.4). State machine implementation details are described in Section 5.

4.1 Case I: On arrival of a query

When a query arrives, INFaaS' Dispatcher invokes the `getVariant` method of model-variant selection policy to choose a variant (Algorithm 1). For this case, the input to `getVariant` is the query's requirements, and the output is the variant and worker to serve the query. `getVariant` first checks whether any variants in the *Active* state match the query's requirements (Line 2). Variants in *Active* state do not incur a loading latency. If such a variant is found, INFaaS dispatches the query to the least-loaded worker running the variant instance (Lines 3-4). Otherwise, INFaaS considers variants in the *Inactive* state: `getVariant` first enquires the Metadata Store and retrieves the variant with the lowest combined loading and inference latency that matches the query's requirements (Line 5). If such a variant is found, INFaaS sends the query to the worker with the lowest utilization on the variant's target hardware (Lines 6-7). Otherwise, since no registered or generated variant can meet the developer's requirements, INFaaS suggests a variant that can achieve the closest target accuracy and/or latency (Line 8). We assess the efficiency of this policy over brute-force search in Section 6.4.

Mitigating performance degradation. For better resource utilization, INFaaS co-locates variants on hardware resources; as a result, they may interfere and cause SLO violations. To prevent such violations, INFaaS avoids selecting variants that are in the *Interfered* or *Overloaded* state. For interfered variants, INFaaS triggers a mitigation process in the background to avoid affecting the performance of online serving. If there are idle resources available on the same worker, INFaaS migrates the variant in the *Interfered* state to the available resources (e.g., a different set of cores). This avoids the need to fetch a variant from the model repository. If no resources are available for loading the variant on the worker, the worker asks the controller's Dispatcher to place the variant on the least-loaded worker. For variants in the *Overloaded* state, INFaaS' Model-Autoscaler assesses whether it is more cost-effective to scale to a different variant (see Section 4.2.1).

Extensibility. The state machine and model-variant selection policy are extensible. For instance, `getVariant` can be extended to prioritize particular variants in the *Active* state (e.g., prefer least power-hungry variants).

4.2 Case II: On changes in query load

As query load changes, INFaaS needs to revisit its variant selection decision to check whether a different variant is more cost-efficient. Existing inference serving systems [5, 11, 25, 35, 37] are agnostic to the diversity of model-variants, and only replicate a statically fixed (developer-specified) model-variant for all the queries of an application. However, as discussed in Section 2.2, autoscaling that replicates the same model-variant alone is not enough because: (a) the right model-variant changes with load and (b) the required resources might not be available to replicate a specific variant.

For INFaaS' autoscaling, in addition to using traditional VM-level, horizontal autoscaling, we introduce *model-vertical scaling*: change (upgrade or downgrade) to a differently optimized model-variant, thus leveraging the diversity of model-variants. INFaaS' autoscaling is a joint effort between the workers and the controller. Each worker hosts a Model-Autoscaler that consults with the model-variant selection policy to make model-level autoscaling decisions (Sections 4.2.1, and 4.2.2). The controller hosts a VM-Autoscaler that makes VM-level autoscaling decisions (Section 4.2.3).

4.2.1 Model-Autoscaler at each worker

To react to the changes in query load, INFaaS' Model-Autoscaler needs to decide the type and number of model-variants to use while minimizing the cost of running the variants. To figure out the type and number of model-variants needed, we formulated the following integer linear program (ILP) that decides a scaling action (replicate, upgrade, or downgrade) for each variant. This ILP minimizes the total cost of scaling actions for all the variants to meet the incoming query load.

Formulation. For an application, the outcome (optimization variable) of our ILP is the optimal scaling action, δ_{ij} , for each model-variant v_{ij} , variant j of model architecture i . δ_{ij} is an integer that captures the scaling action as follows: (a) A positive value denotes loading instances of the variant, (b) a negative value denotes unloading instances of this variant, and (c) a value of zero denotes no scaling needed. For a variant v_{ij} that is already loaded, a positive value of δ_{ij} indicates a *replicate* action. A positive value of δ_{ij} for a variant v_{ij} that is not already loaded indicates an *upgrade* or *downgrade* action depending on the hardware cost of v_{ij} .

The objective function that our ILP minimizes is the total cost of all the chosen scaling actions. For a variant v_{ij} , this cost for an action δ_{ij} is the sum of the hardware cost (in \$/second), and the loading latency (in seconds) of the variant:

$$\text{Cost}(\delta_{ij}) = C_{ij}(\delta_{ij} + \lambda T_{ij}^{\text{load}} \max(\delta_{ij}, 0))$$

where C_{ij} is the hardware cost (in \$/second) for running the variant, T_{ij}^{load} is the loading latency of the variant, and λ (in

$\frac{1}{\text{second}}$) is a tunable parameter for the query load unpredictability. Large values of λ place more weight on minimizing loading latency to meet SLOs when the query load is unpredictable or spiky. Small values of λ place more weight on minimizing the hardware cost when the query load is more stable.

Thus, our objective function representing the total cost for all the variants is: $\sum_{i,j} \text{Cost}(\delta_{ij})$. We impose the following constraints on our ILP:

- (1) With the chosen scaling actions, INFaaS supports the incoming query load.
- (2) The newly-loaded instances satisfy applications' SLOs.
- (3) The resources consumed by all variants do not exceed the total system resources.
- (4) The number of running instances is non-negative.

We write these constraints formally as:

$$\begin{aligned} \sum_{i,j} Q_{ij}(N_{ij} + \delta_{ij}) &\geq L + \text{slack} && \text{for all } i, j && (1) \\ T_{ij}^{\text{inf}} &\leq S && \text{if } \delta_{ij} > 0 && (2) \\ \sum_{i,j} R_{ij}^{\text{type}}(N_{ij} + \delta_{ij}) &\leq R_{\text{total}}^{\text{type}} && \text{for all types} && (3) \\ N_{ij} + \delta_{ij} &\geq 0 && \text{for all } i, j && (4) \end{aligned}$$

where (a) Q_{ij} : the saturation QPS of variant v_{ij} , (b) N_{ij} : the number of running instances of variant v_{ij} , (c) L : the incoming query load, (d) slack : configurable headroom to absorb sudden load spikes, (e) T_{ij}^{inf} : the inference latency of variant v_{ij} , (f) T_{ij}^{load} : the loading latency of variant v_{ij} , (g) S : SLO of the considered application, (h) R_{ij}^{type} : the resource requirements of variant v_{ij} , for a resource type (CPU cores, CPU memory, GPU memory, number of Inferentia cores), and (i) $R_{\text{total}}^{\text{type}}$: the total available amount of resources of a type (CPUs, GPUs, Inferentia cores) on the underlying worker machine.

The model-variant selection policy queries the Metadata Store to get the values of these variables.

Practical limitation of the ILP. Unfortunately, this ILP is NP-complete and hence offers limited practical benefits [34, 54, 69]: it has to exhaustively search through all the model-variants, track their dynamically changing state, and accurately estimate the QPS each variant can support to find a scaling configuration that can sustain the changed query workload. Gurobi [41] took 23 seconds to find the optimal number of running variant instances across 50 model architectures, and 50 seconds for 100 model architectures. To meet realtime requirements of latency-sensitive applications, INFaaS must have sub-second response time to query workload changes.

4.2.2 A Greedy Heuristic

The time taken to solve each instance of our ILP makes it impractical to use for INFaaS. Instead, we design a greedy heuristic algorithm that replaces our ILP's large search space by a subset of model-variants. This pruned search space allows INFaaS to meet the outlined constraints at sub-second latency. We evaluate the effectiveness of this algorithm in Section 6.2. Each worker machine runs a Model-Autoscaler that together with the model-variant selection policy approximates

this ILP as follows: (a) Identify whether the constraints are in danger of being violated, (b) Consider two strategies, replicate or upgrade/downgrade, to satisfy the constraints, (c) Compute the objective for each of these scaling actions and pick the one that minimizes the objective cost function, and (d) Coordinate with the controller to invoke VM-level autoscaling if constraints cannot be satisfied with model-level autoscaling.

Scaling up algorithm: To decide if there is a need to scale (Constraint #1), the Model-Autoscaler estimates the current headroom in capacities of running model-variants, given the profiled values of their saturation throughput, and the current load they are serving. We compute the current load served by a variant using the batch size and number of queries served per second. The load served by a worker is estimated by summing the load served by all running variants. The saturation throughput of all running variants is estimated in a similar manner using the profiled values of model-variants. The Model-Autoscaler then computes the current headroom of a worker as the ratio of the combined saturation throughput and the combined load currently served by the running variants on that worker. INFaaS maintains a minimum headroom, `slack-threshold`, on each worker to absorb sudden load spikes. We discuss the value of this tunable parameter in Section 5. When the current headroom is below the required minimum `slack-threshold`, the Model-Autoscaler concludes that we need to scale, and proceeds to answer the second question: *how* to scale (replicate or upgrade) to meet the incoming query load.

To decide how to scale, the Model-Autoscaler uses the model-variant selection policy's `getVariant` method to select the cheapest option between replication and upgrading. For this case, the input to `getVariant` is the incoming query load, and the output is the set of scaling actions. The policy first estimates the cost of model-horizontal scaling (replication) by estimating the number of instances of the running variant that would be added to meet the incoming query load (Constraints #1, #4). Secondly, the policy estimates the cost of model-vertical scaling (upgrade), by querying the Metadata Store to select variants of the same model architecture that can meet the SLO (Constraint #2), and support a higher throughput than the currently running variant. The required number of instances for these variants to meet the incoming query load is then estimated. Finally, the model-variant selection policy computes the cost function of our ILP, by using the hardware cost (\$/s) and the variant loading latency to decide whether to replicate the running variant, or upgrade to a variant that supports higher throughput. The available resources on the worker limit the number of variant instances it can run (Constraint #3). Thus, if the strategy requires more resources than are available on the current worker (e.g., hardware accelerator), the worker coordinates with the controller to load the variant on a capable worker.

Scaling down algorithm: To decide if and how to scale down (remove replicas or downgrade), the Model-Autoscaler

on each worker uses the model-variant selection policy that follows a similar algorithm explained above for scaling up. At regular intervals, this policy checks if the incoming query load can be supported by removing an instance of the running variant, or downgrading to a cheaper variant (optimized for a lower batch size or running on different hardware). The Model-Autoscaler waits for T_v time slots before executing the chosen strategy for a variant v , to avoid scaling down too quickly. T_v is set equal to the loading latency of variant v .

Comparison with ILP. As described in Section 4.2.1, the ILP does not have sub-second response time. Setting a larger headroom to allow the ILP to produce a solution can result in (a) scaling variants too quickly, which leads to underutilization and higher cost, and (b) violating SLOs during unpredictable load spikes. Besides traditional model-horizontal scaling, our model-vertical scaling further reduces cost by upgrading to a variant that supports higher throughput. Thus, INFaaS matches the throughput of the optimal solution, while the deviance from the ILP is bounded by the difference between the optimal cost and the cost of replicating running variants. Our greedy heuristic reacts to load changes (e.g., load spikes) within sub-second response time while reducing the cost over multiple scaling actions.

4.2.3 VM-Autoscaler at controller

In addition to model-level scaling, INFaaS also scales the worker machines for deploying variants. Following the mechanisms used in existing systems [11, 20, 25, 35, 44], the VM-Autoscaler decides when to bring a worker up/down:

1. When the utilization of any hardware resource exceeds a configurable threshold across all workers, the VM-Autoscaler adds a new worker with the corresponding hardware resource. We empirically set the threshold to 80%, considering the time to instantiate VMs (20-30 seconds): a lower threshold triggers scaling too quickly and unnecessarily adds workers; a higher value may not scale in time.
2. When variants on a particular hardware platform (e.g., GPU) are in the *Interfered* state across all workers, the VM-Autoscaler adds a worker with that hardware resource.
3. When more than 80% of workers have *Overloaded* variants, the VM-Autoscaler starts a new worker.

To improve utilization, INFaaS dispatches requests to workers using an online bin packing algorithm [64].

5 Implementation

We implemented INFaaS in about 20K lines of C++ code¹. INFaaS' API and communication logic between controller and workers are implemented using gRPC in C++ [2]. Developers can interact with INFaaS by issuing gRPC requests in languages supported by gRPC, such as Python, Go, and Java. INFaaS uses AWS S3 [10] for its Model Repository. The model-variant selection policy is implemented as an extensible C++ library that is linked into the controller's Dis-

patcher and worker's Model-Autoscaler. `getVariant` is a virtual method, and can be overridden to add new algorithms.

On the controller machine, the Front-End, Dispatcher, and Model Registrar are threads of the same process for efficient query dispatch. The Dispatcher is multi-threaded to support higher query traffic. The VM-Autoscaler is a separate process, that polls system status periodically. We swept the polling interval between 0.5-5 seconds at 0.5 second increments (similar to prior work [51, 63]), and arrived at a 2 seconds polling interval. Longer intervals did not scale up fast enough, especially during load spikes, and shorter intervals were too frequent given VM start-up latencies.

On worker machines, the Dispatcher and monitoring daemon run as separate processes. Every 2 seconds, the monitoring daemon updates compute and memory utilization of the worker, loading, and average inference latencies, along with the current state (as noted in Figure 4) for each variant running on that worker, to the Metadata Store. We deployed custom Docker containers for PyTorch and Inferentia variants, and leveraged Triton Inference Server-19.03 [6] to support TensorRT, Caffe2, and TensorFlow variants on GPU. We used the TensorFlow Serving container for TensorFlow variants on CPU [5]. The Model-Autoscaler's main thread makes scaling decisions periodically. We swept the same range (0.5-5 seconds at 0.5 second increments) as the VM-Autoscaler, and arrived at a 1 second polling interval. The interval is shorter than the VM-Autoscaler's polling interval as model loading latencies are shorter than VM start-up latencies. The main thread also manages a thread pool for asynchronously loading and unloading model-variants. To tune `slack-threshold`, we explored values between 1.01 and 1.1 [31], and set it to 1.05. In our setup, lower thresholds did not scale variants fast enough to meet load changes, while higher thresholds scaled variants too quickly.

We built the Variant-Generator using TensorRT [3] and Neuron [15]; it is extensible to other similar frameworks [22, 59]. For each variant, the Variant-Profiler records the latency for batch sizes from 1 to 64 (power of two increments). For natural language processing models, we record the latencies of varying sentence lengths for each of these batch sizes.

We built the Metadata Store using Redis [62] and the Redox C++ library [4]. The Metadata Store uses hash maps and sorted sets for fast metadata lookups that constitute the majority of its queries. Per-application, each model-variant instance's state is encoded as a {variant, worker} pair that can be efficiently queried by the controller and worker.

6 Evaluation

We first compare INFaaS with all of its optimizations and features to existing systems (Section 6.1). To further demonstrate the effectiveness of INFaaS' design decisions and optimizations, we evaluate its individual aspects: model-variant selection, scaling (Section 6.2), and SLO-aware resource sharing (Section 6.3). Finally, we quantify the overheads of INFaaS'

¹<https://github.com/stanford-mast/INFaaS>

Features	Clipper, TFS, TIS	SageMaker, AI Platform	INFaaS
Model-less abstraction	No	No	Yes
Variant selection	Static	Static	Dynamic
VM-autoscaling	No	Yes	Yes
Model-horizontal scaling	No	Yes	Yes
Model-vertical scaling	No	No	Yes
SLO-aware resource sharing	No	No	Yes

Table 5: Comparison between INFaaS and the baselines.

decision-making (Section 6.4). We begin by describing the experimental setup common across all experiments, the baselines, the model-variants, and the workloads.

Experimental setup. We deployed INFaaS on a heterogeneous cluster of AWS EC2 [9] instances. We hosted the controller on an `m5.2xlarge` instance (8 vCPUs, 32GiB DRAM), and workers on `inf1.2xlarge` (8 vCPUs, 16GiB DRAM, one AWS Inferentia), `p3.2xlarge` (8 vCPUs, 61GiB DRAM, one NVIDIA V100 GPU), and `m5.2xlarge` instances. All instances feature Intel Xeon Platinum 8175M CPUs operating at 2.50GHz, Ubuntu 16.04 with 4.4.0 kernel, and up to 10Gbps networking speed.

Baselines. To the best of our knowledge, no existing system provides a model-less interface like INFaaS; state-of-the-art serving systems require developers to specify the variant and hardware. For a fair comparison, we configured INFaaS to closely resemble the resource management, autoscaling techniques, and APIs of existing systems, including TensorFlow Serving [5] (TFS), Triton Inference Server (TIS) [6], Clipper [25], AWS SageMaker [11] (SM), and Google AI Platform [35]. Specifically, we compared INFaaS to the following baseline configurations for query execution:

- **Clipper⁺:** Derived from TFS, TIS, and Clipper, this baseline pre-loads model-variants, and requires developers to set a pre-defined number of variant instances. Thus, we set the number of variant instances such that Clipper⁺ achieves the highest performance given available resources.
- **SM⁺:** Derived from SageMaker and AI Platform, this baseline scales each model-variant horizontally, but does not support model-vertical scaling that INFaaS introduces.

Table 5 lists the differences between baselines and INFaaS. Configuring the baselines with INFaaS (a) allowed for a fair comparison by removing variabilities in execution environments (e.g., RPC and container technologies), and (b) enabled us to evaluate our design decision individually by giving the baselines access to INFaaS’ features and optimizations, including: support for model graph optimizations, and INFaaS’ detection and mitigation of variant performance degradation.

Clipper vs Clipper⁺. To validate our baseline configurations through INFaaS, we evaluated Clipper⁺ against the open-source Clipper deployment (Clipper) [23] with its adaptive batching and prediction caching features enabled. We deployed two ResNet50 TensorFlow CPU instances for each. For Clipper, we swept its adaptive batching SLO from 500ms to 10 seconds, and found it achieved its maximum

Model Family (Task)	#Vars	Model Family (Task)	#Vars
MobileNet (classification)	13	VGG (classification)	30
AlexNet (classification)	9	Inception (classification)	25
DenseNet (classification)	22	NasNet (classification)	6
ResNet (classification)	61	GNMT (translation)	9

Table 6: Model architectures, tasks, and associated variants.

throughput (7 QPS) when setting the SLO to 1 second. For the same SLO, Clipper⁺ was able to achieve 10 QPS. As prior work has noted [66], Clipper’s adaptive batching is insufficient for maintaining a high QPS, because it relies on an external scheduler to allocate resources for it. Since Clipper⁺ benefits from INFaaS’ resource allocation and management, variant performance degradation detection and mitigation, and variant optimizations, we use Clipper⁺ in the place of Clipper for the remainder of our evaluation.

SageMaker vs SM⁺. We also validated that the latency and throughput of CPU, GPU, and Inferentia variants with SM⁺ closely match SageMaker, while offering the benefits outlined for Clipper⁺. Thus, we use SM⁺ in the place of SageMaker as our baseline.

Model-variants. Guided by the MLPerf Inference benchmark [61], we collected a variety of models. Table 6 shows the 8 model families (22 architectures) and the number of associated variants. Our models are pre-trained using Caffe2, TensorFlow, and PyTorch. Our classification models are pre-trained on ImageNet [30]; translation models are pre-trained on the WMT16 [70] English-German dataset. We generated 175 variants in total, differing in the frameworks (Caffe2, TensorFlow, PyTorch), compilers (TensorRT, Neuron), batch sizes (1 to 64), and hardware platforms (CPU, GPU, Inferentia).

Workloads. We evaluated using both synthetic and real-world application query patterns. For synthetic workloads, we used common patterns [29] indicating flat and fluctuating loads, with a Poisson inter-arrival rate [39, 61]. For real-world inference workloads, we used the timing information from a Twitter trace from 2018 collected over a month [13] since there is no publicly available inference serving production traces. Twitter queries are likely passed through hate speech detection models [28] before being posted. Furthermore, as noted in recent work on inference serving [75], this trace resembles real inference workloads with both diurnal patterns and unexpected spikes (consistent with production serving workloads [65]). For each experiment, we randomly selected one day out of the month from the Twitter trace. We also set the accuracy such that it can always be satisfied by the registered variants; INFaaS’ handling of infeasible accuracy requirements is discussed in Section 4.1.

6.1 INFaaS with production workload

We now show that through model selection, resource allocation, and autoscaling mechanisms, INFaaS improves the throughput, cost, utilization, and reduces SLO violations.

Experimental setup. We mapped the Twitter trace to a range between 10 and 1K QPS for a total of 113,420 batch-1 queries.

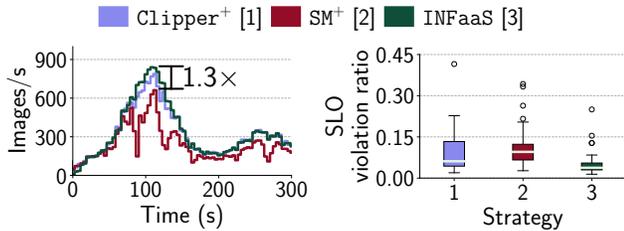

Figure 5: Throughput and SLO violation ratio (# of SLO violations by total # of queries), measured every 4 seconds. Each box shows the median, 25% and 75% quartiles; whiskers extend to the most extreme non-outlier values ($1.5\times$ interquartile range). Circles show the outliers.

We used all 22 model architectures. Based on prior work [52], we used a Zipfian distribution for model popularity. We designated 4 model architectures (DenseNet121, ResNet50, VGG16, and InceptionV3) to be *popular* with 50ms SLOs and share 80% of the load. The rest are *cold* models with SLO set to $1.5\times$ the profiled latency of each model’s fastest CPU variant. Baselines statically selected GPU variants for popular models, and CPU variants for the rest; they used 5 CPU and 7 GPU workers. INFaaS started with 5 CPU, 5 GPU, and 2 Inferentia workers. We computed the worker costs based on AWS EC2 pricing [17].

Results and discussion. Figure 5 shows INFaaS achieved $1.1\times$ and $1.3\times$ higher throughput, and $1.63\times$ and $2.54\times$ fewer SLO violations compared to Clipper⁺ and SM⁺, respectively. INFaaS scaled models both horizontally and vertically: it upgraded to Inferentia or GPU (higher batch) variants when needed. In reaction to the increased load, INFaaS added a 3rd Inferentia worker at 40 seconds. Although SM⁺ scales variants horizontally, it achieved lower throughput and violated more SLOs due to frequently incurring variant loading penalties and being unable to upgrade variants. By leveraging variants that span heterogeneous hardware (CPU, GPU, Inferentia), INFaaS achieved $1.23\times$ lower cost, while keeping SLO violations under 4% on average. INFaaS also load-balanced requests and mitigated overloaded or interfered variants. This resulted in an average worker utilization of 48.9%, with an average GPU DRAM utilization of 58.6%. The latter is $5.6\times$ and $2.8\times$ higher than SM⁺ and Clipper⁺, respectively.

INFaaS achieved higher performance ($1.3\times$ higher throughput) and resource utilization ($5.6\times$ higher GPU utilization), and lower SLO violations ($2\times$ lower) and cost ($1.23\times$ lower) compared to the baselines.

6.2 Selecting and scaling model-variants

Next, we show the efficiency of INFaaS’ model-variant selection policy to select and vertically scale the variants.

Experimental setup. To compare INFaaS with common configurations developers would choose today, we considered two cases for a model: only GPU variants are used (Clipper⁺_{GPU}, SM⁺_{GPU}) and only CPU variants are used (Clipper⁺_{CPU}, SM⁺_{CPU}). We used variants derived from one model architecture, ResNet50, and one worker. Clipper⁺_{CPU}

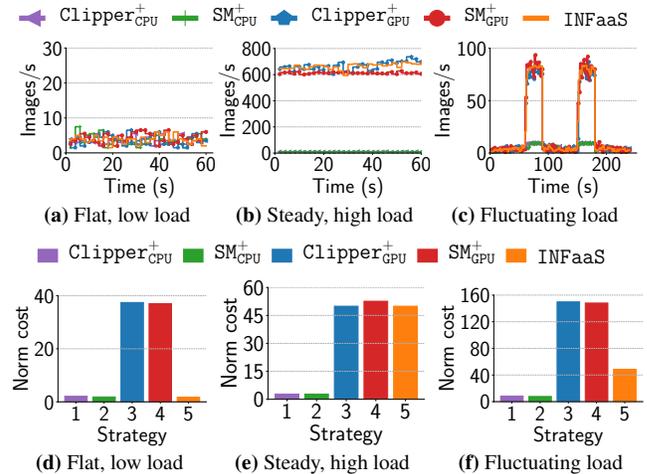

Figure 6: Throughput (top) and cost (bottom), with ResNet50 and batch-1 requests. INFaaS reduced cost and met the load.

pre-loads and persists 2 instances of the TensorFlow CPU variant. Clipper⁺_{GPU} persists one TensorRT variant optimized for batch size of 8, configured to serve the provided peak load by adaptive batching. SM⁺_{CPU} horizontally scales the CPU variant. SM⁺_{GPU} horizontally scales a batch-1 optimized TensorRT variant (the cheapest GPU variant). We measured throughput every 2 seconds, and calculated the total cost. The cost for a running variant instance is estimated based on AWS EC2 pricing [17], proportional to its memory footprint. We normalize cost to 0.031 per GB/s for CPU, 0.190 per GB/s for Inferentia, and 0.498 per GB/s for GPU.

Workloads. We used three query patterns that are commonly observed in real-world setups [29]: (a) a flat, low load (4 QPS), (b) a steady, high load (slowly increase from 650 to 700 QPS), and (c) a fluctuating load (ranging between 4 and 80 QPS). Patterns (a) and (b) represent ideal cases for baselines, as they statically choose a variant; we used the most cost-effective CPU/GPU variant for each baseline.

Results and discussion. Figures 6a and 6d show the throughput and total cost, respectively, for INFaaS and the baselines when serving a flat, low load. While all systems met this low throughput demand, Clipper⁺_{GPU} and SM⁺_{GPU} incurred high costs since they use GPUs. INFaaS automatically selected CPU variants as they met the demand, thus reducing cost by $21.6\times$ and $21.3\times$ compared to Clipper⁺_{GPU} and SM⁺_{GPU}, respectively. For a steady, high load (Figures 6b and 6e), the observed throughput of Clipper⁺_{CPU} and SM⁺_{CPU} (about 10 QPS) was significantly lower than the demand. INFaaS automatically selected the batch-8 GPU variant, and both INFaaS and Clipper⁺_{GPU} met the throughput demand. While SM⁺_{GPU} replicated to 2 batch-1 GPU variants to meet the load, it was 5% more expensive than INFaaS and served 15% fewer QPS. Finally, for a fluctuating load (Figures 6c and 6f), INFaaS, Clipper⁺_{GPU}, and SM⁺_{GPU} met the throughput demand, while both SM⁺_{CPU} and Clipper⁺_{CPU} served only 10 QPS. During low load periods, INFaaS selected a CPU variant. At load spikes

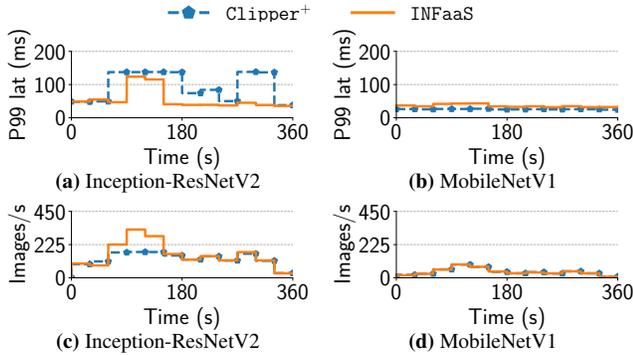

Figure 7: Performance of co-locating GPU model-variants when 80% of queries are served by Inception-ResNetV2.

(60-90 and 150-180 seconds), INFaaS upgraded to an Inferentia batch-1 variant. Hence, on average, INFaaS was $3\times$ cheaper than SM_{GPU}^+ and $Clipper^+_{GPU}$. If INFaaS were limited to CPU and GPU variants, it would still save $1.7\times$ cost over both the baselines. Similarly, even if we allowed baselines to use Inferentia, INFaaS would still save $1.9\times$ cost because baselines cannot dynamically switch between Inferentia and CPU variants. Figures 6a – 6c indicate that a single variant is neither the most cost-effective, nor the most performant for all scenarios. INFaaS achieves ease-of-use while (a) matching the baselines’ performance and cost in ideal cases (steady loads), and (b) outperforming the baselines during load changes. Thus, leveraging variants optimized for different hardware through model-vertical scaling, INFaaS is able to adapt to changes in load and query patterns, and improve cost by up to $21.6\times$ ($10\times$ on average).

6.3 Effectiveness of sharing resources

We now show how INFaaS manages and shares accelerators across models without affecting performance of queries. We found that co-locating models on an Inferentia chip did not cause noticeable interference, since variants can run on separate cores on the chip. Thus, we focus on evaluating GPU sharing. INFaaS detects when model-variants enter the *Overloaded/Interfered* state, and either migrates the model to a different GPU, or scales to a new GPU worker if all existing variants on the GPUs are in the *Overloaded/Interfered* state.

Experimental setup. We used the baseline of $Clipper^+$ with one model persisted on each GPU. Since $Clipper^+$ requires a pre-defined number of workers, we specified 2 GPU workers. For fairness, INFaaS started from one GPU and was allowed to scale up to 2 GPU workers. As noted in Section 2.3, the load at which sharing of GPUs starts affecting the performance negatively is different across models. We selected two model-variants that diverge in inference latency, throughput, and peak memory: Inception-ResNetV2 (large model) and MobileNetV1 (small model). Both variants are TensorRT-optimized for batch-1. We report throughput and P99 latency, measured every 30 seconds.

Workloads. To show the impact of model popularity on re-

source sharing, we evaluated a scenario with a popular model serving 80% QPS, and the other serving 20% QPS. We observed similar results with other popularity distributions or different models. We mapped the Twitter trace to a range between 50 and 500 QPS for a total of 75,000 batch-1 queries.

Results and discussion. Figure 7 shows P99 latency and throughput for both models when Inception-ResNetV2 is popular. When Inception-ResNetV2 and MobileNetV1 exceeded their profiled latencies, INFaaS marked them as interfered around 30 and 50 seconds, respectively. INFaaS started a new GPU worker (~ 30 seconds start-up latency), created an instance of each model on it, and spread the load for both models across the GPUs. The allocated resources for Inception-ResNetV2 with $Clipper^+$ were insufficient and led to a significant latency increase and throughput degradation. Unlike $Clipper^+$, INFaaS could further mitigate the latency increase by adding more GPU workers (limited to two in this experiment). Moreover, INFaaS saved 10% cost compared to $Clipper^+$ by (a) bin-packing requests across models to one GPU at low load, and (b) only adding GPUs when contentions were detected.

6.4 INFaaS’ decision overhead

On the critical path of serving a query, INFaaS makes the following decisions: (a) selecting a model-variant and (b) selecting a worker. Table 7 shows the median latency of making these decisions for INFaaS and the speedup over a brute-force search. Each row corresponds to a query specifying (1) a registered model and (2) application requirements. For each query, we show the decision latency when the selected variant was in (a) *Inactive*, *Overloaded*, or *Interfered* state, and (b) *Active* state. These decisions are made using the model-variant selection policy (Section 4.1).

When the registered model was explicitly specified, INFaaS incurred low overheads (~ 1 ms), as it needed to select only a worker. When the application requirements were provided, and the selected variant was not already loaded (State (a)), INFaaS selected a variant and the least-loaded worker for serving in 3.5ms. Otherwise, when the selected variant was already loaded (State (b)), INFaaS’ decision latency for selecting the variant and a worker was 2.2ms.

To measure scalability, we varied the number of model-variants from 10 to 166 (increments of 50); the latencies of Table 7 remain unchanged as the number of variants increases. This result was expected, since INFaaS’ Metadata Store uses constant access time data structures.

INFaaS keeps low overheads across its query submission modes: up to $44\times$ ($35.5\times$ on average) faster than brute-force.

7 Discussion

Failure Recovery. INFaaS’ VM-Autoscaler detects worker failures using RPC heartbeats, and starts a new worker with the state of the failed worker stored in the Metadata Store. For fault-tolerance, the controller is replicated using existing

Query	Variant Picked (Valid Options)	Median Latency in ms (Speedup vs brute-force)	
		State (a)	State (b)
resnet50-trt	resnet50-trt (1)	1.0 (N/A)	0.9 (N/A)
applD, >72%, 20ms	inceptionv3-trt (5)	3.5 (27×)	2.2 (44×)

Table 7: Median latency and speedup of making variant and worker selection decisions across 3 runs. State (a): variants are in the *Inactive* state, *Overloaded* state, or *Interfered* state. State (b): variants are in the *Active* state.

techniques [21, 37]. If the main controller fails, the incoming queries are re-routed to a standby controller. Since the Metadata Store is on the same machine as the controller, it is a part of the replicated state.

Query fairness. Using heterogeneous variants to serve queries means users may see different performance and accuracy results given the same query requirements, as INFaaS optimizes for cost-efficiency. However, INFaaS will always ensure the query requirements are met. INFaaS’ API is extensible to support further requirements for improved query fairness (e.g., bounding performance/accuracy variation [77]). **Explicitly controlling the runtime.** INFaaS’ model-less abstraction allows it to incorporate the ever-growing number of optimizers and runtimes. It also enables INFaaS’ model-selection algorithms to be extended separately. Explicitly controlling the runtime may allow INFaaS to provide more of a clear-box approach to optimizing inference serving, but may limit its generality and extensibility (e.g., supporting limited hardware platforms).

8 Related Work

Inference serving systems. TensorFlow Serving [5] provided one of the first production environments for models trained using the TensorFlow framework. Clipper [25] generalized it to enable the use of different frameworks and application-level SLOs. Pretzel [52], Nexus [66], and InferLine [24] built upon Clipper for optimizing inference serving pipelines. SageMaker [11], AI Platform [35], and Azure ML [1] offer developers inference services that autoscale VMs based on load. Triton Inference Server [6] optimizes GPU inference serving, supports CPU models, but requires static model instance configuration. DeepRecSys [39] statically optimizes batching and hardware selection for recommender systems, but requires developers to specify a variant, manage and scale model resources as the load varies. Clockwork [38] reduces GPU inference latency variability by ordering queries based on their SLOs and only running one query at a time. Model-Switching [77] switches between models with different accuracies during load spikes, while preserving the fraction of correct predictions returned within an SLO. It assumes pre-loaded models and does not consider heterogeneous hardware resources. Tolerance Tiers [42] allows developers to programmatically trade accuracy off for latency. None of these existing systems offer a simple model-less interface, like INFaaS, to navigate the variant search space on developers’ behalf, or dynamically leverage model-variants

to meet applications’ diverse requirements. However, prior work can be seen as complementary to INFaaS; e.g., INFaaS can adopt DeepRecSys’ recommender system optimizations and Clockwork’s predictable DNN worker.

Model-variant generators. Model graph optimizers [3, 12, 22, 72] perform optimizations, such as quantization and layer fusion, to improve latency and resource usage. However, developers still need to manually create and select variants, and manage the deployed variants. INFaaS uses these optimizers to create variants that can be used for meeting diverse application requirements, and automates model-variant selection for each query to minimize cost as load and resources vary.

Scaling. Autoscale [33] reviewed scaling techniques and argued for a simple approach that maintains the right amount of slack resources while meeting SLOs. Similarly, INFaaS’ autoscalers maintain headrooms and scale-down counters to cautiously scale resources. MARk [75] proposed SLO-aware model scheduling and scaling by using AWS Lambda to absorb unpredictable load bursts. Existing systems [1, 11, 35, 37] only support VM-level and model-horizontal scaling, while INFaaS introduces model-vertical scaling that leverages multiple diverse variants.

Sharing accelerators. NVIDIA MPS [57] enabled efficient sharing of GPUs that facilitated initial exploration into sharing GPUs for deep-learning. Existing systems [6, 27, 46, 74] also explored how to share GPUs spatially, temporally, or both. NVIDIA’s A100 GPUs support MIG [58]: hardware partitions and full isolation. AWS Inferentia supports spatial and temporal sharing via Neuron SDK [15]. INFaaS’ current implementation builds on Triton Inference Server (GPUs) and Neuron SDK (Inferentia), and provides SLO-aware accelerator sharing. INFaaS can also be extended to leverage other mechanisms for sharing additional hardware resources.

9 Conclusion

We presented INFaaS: an automated model-less system for distributed inference serving. INFaaS’ model-less interface allows application developers to specify high-level performance, cost or accuracy requirements for queries, leaving INFaaS to select and deploy the model-variant, hardware, and scaling configuration. INFaaS automatically provisions and manages resources for serving inference queries to meet their high-level goals. We demonstrated that INFaaS’ model-variant selection policy and resource sharing leads to reduced costs, better throughput, and fewer SLO violations compared to state-of-the-art inference serving systems.

Abstract

With the booming of online service systems, anomaly detection on multivariate time series, such as a combination of CPU utilization, average response time, and requests per second, is important for system reliability. Although a collection of learning-based approaches have been designed for this purpose, our empirical study shows that these approaches suffer from long *initialization time* for sufficient training data. In this paper, we introduce the *Compressed Sensing* technique to multivariate time series anomaly detection for rapid initialization. To build a jump-starting anomaly detector, we propose an approach named *JumpStarter*. Based on domain-specific insights, we design a shape-based clustering algorithm as well as an outlier-resistant sampling algorithm for *JumpStarter*. With real-world multivariate time series datasets collected from two Internet companies, our results show that *JumpStarter* achieves an average F1 score of 94.12%, significantly outperforming the state-of-the-art anomaly detection algorithms, with a much shorter initialization time of twenty minutes. We have applied *JumpStarter* in online service systems and gained useful lessons in real-world scenarios.

1 Introduction

In recent years, online service systems based on cloud computing, *e.g.*, online office, e-commerce, are becoming increasingly popular. For example, the number of daily meeting participants of the video conferencing app Zoom jumps to over 300 million before May 2020 [31]. Due to the complexity and the large scale of online service systems, automatic anomaly detection is of ultimate importance to guarantee their reliability [36]. To closely monitor the quality of service, online service providers or cloud computing platforms, such as Microsoft and AWS, continuously collect the monitoring data of each performance metric (*e.g.*, CPU utilization, average response time, and requests per second) at equally spaced

intervals [3, 33]. The monitoring data of a metric form a univariate time series, and thus that of a service system, which has multiple metrics, constitutes a multivariate time series.

Traditional multivariate time series anomaly detection approaches are typically based on detecting univariate time series [15, 32, 36]. However, operators are concerned about the status of the overall service rather than that of a specific metric [28]. Because the univariate time series anomaly detection cannot capture the complex temporal relationships among different univariate time series [28], they tend to cause alert storms [5]. To address this problem, recent works [12, 22–24, 28, 34] use deep learning techniques to build learning models for multivariate time series anomaly detection. For example, the state-of-the-art approach, OmniAnomaly [28], utilizes a stochastic recurrent neural network model to learn the temporal relationships of multivariate time series.

Learning-based approaches are hardly applicable in practice because they usually require a long period of training data. Online service systems are deployed or changed very frequently to deploy new features, fix bugs [35], *etc.* In large service providers, such as Google [3] and Baidu [35], it is reported that thousands of software changes are deployed every day. Due to these software changes, the data distribution of multivariate time series can change dramatically, which is called the expected concept drift [17]. For example, when operators conduct a software change to deploy a service to more instances, the metric “Requests Per Second” in each instance will drop significantly as shown in Figure 1. This is expected to operators, and they do not need to roll back the software change. After the change, this will cause a lot of false alarms or false positives, since it invalidates the learning-based anomaly detection models trained based on the data before the change [17]. It is because the common assumption in deep learning that the data distribution must remain the same across training and test set [10] is violated. Therefore, these learning-based approaches have to be retrained. This retraining process, however, can consume tens to hundreds of days [28, 32] before reaching steady state.

To quantitatively measure how long it takes to “initialize”

an anomaly detection model for multivariate time series, we first define *initialization time*, as the time lag between when the model is launched and when it becomes well trained. We then conduct an empirical study based on the datasets collected from real-world online service systems. Through this study, we summarize two key findings: (1) The average initialization time of existing learning-based approaches ranges from ten days to one hundred days. (2) The state-of-the-art approaches (*i.e.*, OmniAnomaly [28] and MSCRED [34]) do not achieve a satisfactory performance when they are improved with *incremental retraining* [15]. When the period of training data is short, the accuracy of these approaches are low. Therefore, we aim to design a robust anomaly detection approach for multivariate time series with small initialization time.

In this paper, we propose a novel multivariate time series anomaly detection approach, called *JumpStarter*, that is based on *Compressed Sensing* (CS). CS is a signal processing technique where high-energy components in a matrix (multivariate time series) are sparse (*i.e.*, have few high-energy components) [4]. Hence, the difference between the original and the reconstructed multivariate time series, comprised only of low-energy components, should resemble white noise, when the original time series contains no anomaly. The intuition behind using CS for anomaly detection is that anomalies in multivariate time series, such as jitters, sudden drops or surges, usually manifest themselves as strong signals that contain high-energy components, which would differ significantly from white noise [16]. Hence we can tell whether a time series contains anomalies by checking whether the difference between the original and the reconstructed multivariate time series in a sliding window [32] looks very differently from white noise. Since CS only uses a fixed-length window to “train” an anomaly detection model, the initialization time of *JumpStarter* depends on the window size, which is typically twenty minutes. It is much shorter than the initialization time of learning-based approaches. We now provide an intuitive explanation of why CS-based *JumpStarter* requires

much less training data than those learning-based approaches. A learning-based approach has to *explicitly* learn the “behavior” (probability distribution) of a normal multivariate time series in order to detect anomalies. In comparison, in *JumpStarter* the reconstructed multivariate time series of *implicitly* inherits this normal behavior without involving any explicit learning. Due to the complexity of real-world scenarios, however, it is challenging to apply CS to implement a jump-starting multivariate time series anomaly detection in the following situations:

Large number of time series. In large-scale online service systems, tens of time series are monitored for each system forming a multivariate time series [17]. Typically, it is time-consuming for CS to reconstruct a large number of time series, because it needs to solve a convex optimization problem whose time complexity depends on the number of time series. To tackle this challenge, we cluster these time series based on shape. Since the time series in the same group exhibit a similar shape, they can be reconstructed efficiently without losing temporal relationships [14].

Sampling from random anomalous segments in time series. CS typically uses a Gaussian distribution to sample from the original time series to guarantee Restricted Isometry Property (RIP). Nevertheless, it may inevitably generate reconstructed time series sampled from some long-lasting anomalous segments. The anomaly detection model based on these reconstructed time series can cause some false positives and/or false negatives. Therefore, we design an outlier-resistant sampling algorithm to sample from normal time series segments rather than anomalous ones.

We conducted a comprehensive study to evaluate the performance of *JumpStarter* based on three datasets from 28 and 30 large-scale industrial online service systems of two Internet companies, respectively. The first dataset, from company *A*, is a 5-week-long time-series open dataset. The other two datasets are from a top-tier global content platform company *B*, which provides service for more than 800 million users around the world. These datasets contain 7-week-long time series. Our experimental results illustrate that *JumpStarter* outperforms both the state-of-the-art learning-based multivariate time series anomaly detection approaches (*i.e.*, OmniAnomaly [28] and MSCRED [34]) clustering-based LESINN [20]. Also, *JumpStarter* is more suitable than RRCF [11] used in AWS CloudWatch. The average F1 score of *JumpStarter* is 94.12%, while those of the other four approaches are 86.51%, 59.64%, 82.5%, and 36.01% respectively. Also, our results demonstrate that the main components in *JumpStarter* (*i.e.*, shape-based clustering and outlier-resistant sampling) significantly contribute to the overall performance of *JumpStarter*. *JumpStarter* achieves good accuracy with an initialization time as short as twenty minutes, open sourced at <https://github.com/NetManAIops/JumpStarter>. We applied *JumpStarter* to *B* and it indeed achieved a good anomaly detection performance in practice. We also present two cases

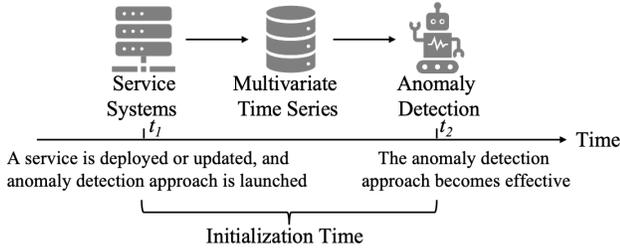

Figure 2: The initialization time of an anomaly detector

and gain lessons for both academia and industry.
