Multivariate time series. In an online service system, operators continuously collect monitoring data of multiple metrics or extract numerical values from logs [37]. A service level metric (*e.g.*, average response time), or a machine level metric (*e.g.*, CPU utilization, memory utilization), is usually collected by equal interval, forming a univariate time series. Any univariate time series alone, however, cannot capture all types of system’s performance issues [28]. Because a system typically has a collection of monitoring metrics, it can be denoted as a multivariate time series [17], which includes diverse types of univariate time series and thus track various aspects of performance issues. With the scale and complexity of the system increasing, it is becoming more difficult to manually inspect system anomalies. Therefore, multivariate time series anomaly detection is of great importance [28, 34]. We denote a multivariate time series at time t as $\mathbf{X}_t = [x_t^1, x_t^2, \dots, x_t^n]^T$, where $x_t^i = [x_{t-w+1}^i, x_{t-w+2}^i, \dots, x_t^i]$ is the univariate time series of the i^{th} monitoring metric, n is the number of metrics, and w is the observation window size. We apply the sliding window, which is a common practice in time series anomaly detection [32, 35], to construct \mathbf{X}_t .

Anomaly detection. Anomaly detection using multivariate time series [28] is important in online service systems. In previous anomaly detection works [12, 22–24, 28, 34], operators have a rough consensus on the following points: 1) A multivariate time series anomaly is a data point or a data segment that significantly deviates from operators’ expectations of normal behavior, and it can be visually observed (*e.g.*, in Figure 1). 2) An anomaly indicates something might have gone wrong, although further investigation may still be needed for verification. 3) Anomaly detection is often used as a failure discovery mechanism. Formally, we define multivariate time series anomaly detection: for time t , given its multivariate time series \mathbf{X}_t , we determine whether an anomaly occurs (*e.g.*, jitter, sudden drop or surge), which is denoted by $y_t = 1$ if yes and $y_t = 0$ otherwise.

Table 1: Comparison of the initialization time (days) on three datasets (S1~S3) used in their works. * denotes univariate time series anomaly detector, which can be used for multivariate time series by combining it with majority vote [28].

Approach	S1	S2	S3	Avg.
MSCRED [34]	7	13	-	10
OmniAnomaly [28]	17	15	17	16.3
LSTM-NDT [12]	69	36	-	52.5
* Opprentice [15]	56	56	56	56
* Donut [32]	102	110	99	103.6

2.2 An Empirical Study on Initialization Time

Anomaly detection initialization time. With a new service being deployed or updated, operators usually launch an anomaly detection approach for it. The initialization time of the anomaly detection approach is the time lag between when it is launched (t_1) and when it becomes effective (t_2), as shown in Figure 2. Many prior approaches, *e.g.*, [12, 22, 23, 28, 34], use a learning-based workflow to detect anomalies. Typically, they are periodically trained based on historical data [15]. The initialization time of these approaches, *e.g.*, tens of days, is relatively long, because they usually need to offer a lot of historical data for training. In Table 1 we list the suggested initialization time of five learning-based anomaly detection approaches on different datasets. For example, OmniAnomaly [28] used two robot system datasets (denoted as S1, S2) and a server dataset (S3, which also used in our experiment as D1). From the last column of Table 1, we can see that the average initialization time of these approaches ranges from 10 days to more than one hundred days, indicating that it is unsuitable to use these approaches for newly deployed or updated systems.

Incremental retraining. Considering the long initialization time of learning-based anomaly detection approaches, one may suggest incremental retaining, *i.e.*, gradually (incrementally) adding a short-period (say one day) of data to train these approaches. In this way, we can improve the performance of these approaches step by step. Adding one day’s data each time is because these learning-based approaches need at least thousands of data points to converge [32]. We then try to apply incremental retraining to the state-of-the-art multivariate time series anomaly detection approaches, *i.e.*, OmniAnomaly [28] and MECRED [34]. The dataset is the same as what is used in OmniAnomaly (see §4.1 for more details). We gradually enlarge the training set from one day’s data to 13 days’ data (*i.e.*, the largest training set of this dataset), and the testing set remains as the data collected after the 13th day.

This sounds ideal, but anomaly detection using incremental retraining cannot ensure satisfactory performance. Figure 3 shows the average F1 score and training time of OmniAnomaly and MECRED as the period of training data increases (day by day), respectively. From Figure 3(a), we can see that the average F1 scores of both OmniAnomaly and MECRED increase along with more training data being used, and

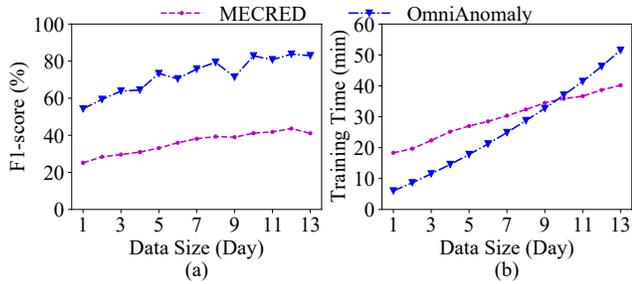

Figure 3: Performance of OmniAnomaly [28] and MECRED [34] by incremental retraining.

they do not converge until 10 days’ data is used for training. One primary reason is that these learning-based approaches have to *explicitly* learn the probability distribution of a multivariate time series from a large amount of training data to capture its normal behavior. Figure 3(b) shows that the training time of both OmniAnomaly and MECRED increases linearly with the size of training data. When the training dataset contains 10 days of data, it takes about 35 minutes to train OmniAnomaly or MECRED. Therefore, these approaches are not suitable for newly deployed or updated systems due to their non-robustness and considerable training cost.

3 JumpStarter Approach

3.1 Key Idea and Challenges

To deal with the aforementioned limitations of learning-based approaches, we propose to use Compressed Sensing (CS) [9] for multivariate time series anomaly detection. CS is a signal processing technique for reconstructing a signal from a series of sampling measurements [8]. The signal reconstructed from these samples preserves the high-energy components of the original signal with high probability under some mild assumptions [8]. As explained earlier, we can detect anomalies in a multivariate time series by checking whether the reconstructed signal differs from the original signal (multivariate time series) by more than white noise. Since CS does not require any training, the initialization time of the CS-based anomaly detection for \mathbf{X}_t is the window size w .

Two Strawman Solutions using CS. Intuitively, we can apply CS to reconstruct \mathbf{X}_t in two ways: treating \mathbf{X}_t as a whole $n \times w$ matrix, or as n separate univariate time series. In the former way, we randomly sample some data from \mathbf{X}_t and then reconstruct it following [26] (more details to be provided in §3.5). Figure 4(a) shows the reconstructed multivariate time series. As shaded in Figure 4(a), there is a significant difference between the original (blue lines) and the reconstructed multivariate time series (dashed brown lines) when an anomaly occurs. This is a desired behavior (of CS). However, the first two reconstructed time series fluctuate frequently all the time, whereas both original time series are stable except

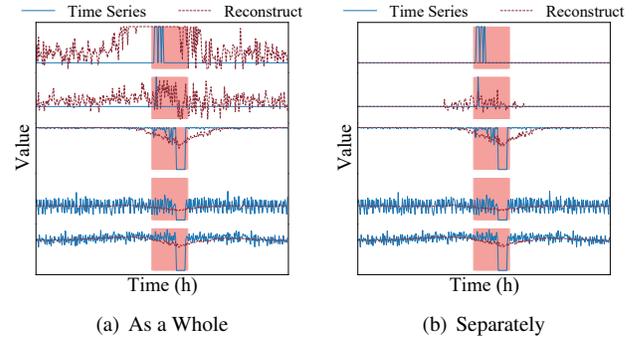

Figure 4: Examples of CS-based anomaly detection when the multivariate time series is reconstructed as a whole $n \times w$ matrix (a) or as n separate univariate time series (b). The red-shaded regions denote the anomalies labeled by operators.

during the anomaly window (shaded). This is an undesired behavior that indicates inaccurate reconstruction. In the latter way, as shown in Figure 4(b), the difference between the original and reconstructed univariate time series manifests as white noise in normal segments and as large fluctuations in anomalous ones, which accurately captures the anomalies for each *univariate time series*. However, it cannot capture the complex relationships among multivariate time series [28]. Moreover, due to the challenge of a large number of univariate time series, the separate reconstruction is more computationally expensive.

Problem of Random Gaussian Sampling. The first step of our CS approach is to sample from a multivariate time series. The sampled matrix needs to guarantee Restricted Isometry Property (RIP) [4] so that it can reconstruct the original multivariate time series properly. It has been shown that random Gaussian sampling satisfies RIP [9]. Random sampling, however, samples some data points also from anomalous segments. In this case, the reconstructed multivariate time series will not be significantly different from the original one when a system becomes anomalous. Thus it inevitably degrades the anomaly detection performance.

3.2 Overview of JumpStarter

The *JumpStarter* approach, which consists of both offline and online processing procedures, is shown in Figure 5. To tackle the challenge of a large number of time series, we adopt a *shape-based clustering* method to group the univariate time series of a multivariate time series into several groups in the offline processing. The sliding window technique is applied to multivariate time series in the online anomaly detection. For each group of univariate time series, we propose a novel *outlier-resistant sampling* algorithm to solve the challenge introduced by sampling from anomalous segments, and apply *compressed sensing* to reconstruct them. After that, we concatenate these reconstructed time series, measure the differ-

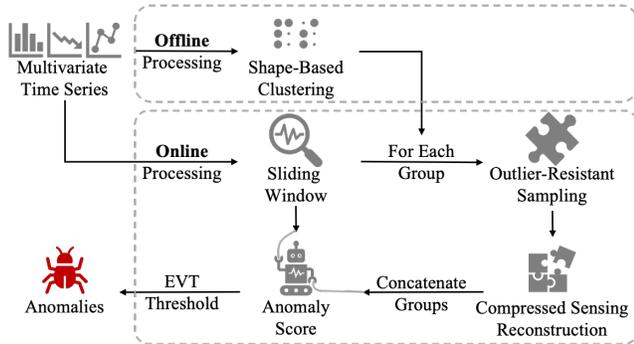

Figure 5: *JumpStarter* approach consists of offline processing and online processing, of which output is whether anomaly or not.

ence between the original and the reconstructed multivariate time series as an anomaly score, and detect anomalies using *EVT threshold* against the anomaly score.

3.3 Shape-Based Clustering

While each strawman solutions has its advantages and drawbacks, we find a way to combine them to get the better of both. Specifically, we split \mathbf{X}_t into several clusters of time series and reconstruct each cluster. The question is, how this splitting should be done. Recall the first strawman solution cannot deal with time series of different shapes. Hence, we choose to split \mathbf{X}_t based on their shape. This solution can achieve both high accuracy and high efficiency.

We adopt shape-based distance [21], a cross correlation-based method, to measure the distance between two univariate time series. It can achieve high computational efficiency when dealing with high-dimensional time series. Different from ROCKA [14], we use hierarchical clustering, which is efficient and need not manually configure the number of clusters, as the base clustering algorithm. Table 2 illustrates an example of clustering results. The nine univariate time series of a multivariate time series are grouped into three clusters. In each cluster, the time series are correlated to the physical meaning of their corresponding monitoring metrics, demonstrating that our method is intuitive.

We cluster univariate time series for every multivariate time series based on one-day worth of data, because most univariate time series are roughly periodical with a 24-hour cycle that coincides with customers’ diurnal usage pattern [17]. Moreover, we observe that the shape of a univariate time series usually remains unchanged after a software change [38]. As a result, it has no need to re-cluster after a software change.

3.4 Outlier-Resistant Sampling

Insight. To solve the problem of random Gaussian sampling, we gain insight from the investigation of a large number

Table 2: An example of clustering the multivariate time series into three clusters. Each univariate time series is named based on its corresponding monitoring metric.

#	Cluster of Univariate Time Series	Explanation
1	rx-pkts-eth0, rx-bytes-eth0	# received packets/bytes
2	tcp-insegs, tcp-outsegs, tx-pkts-eth0	TCP network metrics
3	cpu-ctxt, cpu-user, cpu-system, cpu-nice	CPU utilization metrics

of online service systems and the discussion with operators. Anomalies rarely occur in real-world scenarios [15, 32]. That is, anomalies are usually outliers in an observation (sliding) window [16]. If an anomaly lasts longer than the window size, it can be captured from the beginning since it is significantly different from the normal pattern. Therefore, we can adopt a simple outlier detection algorithm to obtain the *sampling confidence* of each data point. The higher a data point is likely to be an outlier, the lower its sampling confidence is, and the less likely it will be selected. Based on this insight, we design an outlier-resistant sampling algorithm, *i.e.*, one-dimensional random Gaussian, which not only guarantees RIP but also resists outliers.

Algorithm. We describe the design of outlier-resistant sampling in Algorithm 1 and show the main steps in Figure 6. After the shape-based clustering, for each cluster, we can obtain an $w * k$ matrix, which is constituted of k univariate time series. We also configure a sampling ratio, θ , as the input of the algorithm. To begin with, from Line 1 to 4 of Algorithm 1, we initialize a zero $m * w$ matrix \mathbf{T} , where $m = \lceil w * \theta \rceil$. ϕ is initialized as a vector containing m random Gaussian sample timestamps ranging from 0 to w . Motivated by [20], we adopt a light-weight algorithm LESINN to calculate the sampling confidence vector \mathbf{sc} , which determines the sampling confidence of each timestamp. Nevertheless, as demonstrated in §4.2, LESINN itself cannot effectively handle multivariate time series anomaly detection because it cannot capture the complex temporal relationships among these time series. Figure 6(a) shows one example of the original time series (blue line) with a window size of 20 and its sampling confidence (orange dotted line) for each timestamp.

Then, we perform value sampling (Line 5 to 14). We first normalize \mathbf{sc} to make its values sum up to one, and create R equal-width *steps*. Each *step* is mapped to a timestamp t based on the normalized \mathbf{sc} (Line 8). For each *step*, we randomly sample a value from $(0, 1)$, and compare it with the probability of a similar version of Gaussian distribution:

$$P_i(step) = \rho \cdot \exp\left(-\frac{(\phi_i - step)^2}{2\sigma^2}\right) \quad (1)$$

Note that ρ is a parameter representing the max sampling points (height in Figure 6(b)). For more theoretical details, please refer to the work of Barranca, *et al.* [2]. σ is the standard deviation of the distribution. If the random value is smaller than $P(step)$, we add one to $\mathbf{T}[i][t]$. Note that after

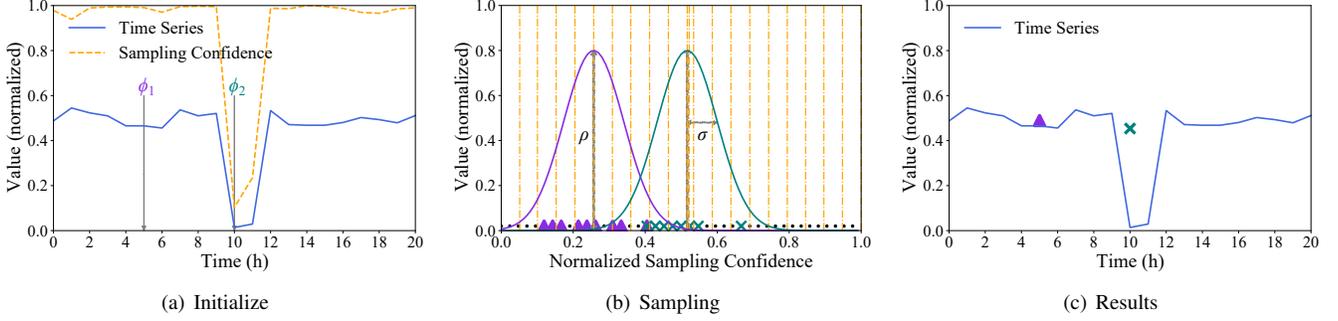

Figure 6: A toy example of outlier-resistant sampling. In (a), to make it simple, we just plot one time series whose values are normalized, and it has an anomalous segment ranging from (timestamp) 9 to 12. We set $m = 2$ in this example. In (b), the small black dot is steps, and the purple and green marks are “selected” steps. (c) shows two sampled data points.

all the iterations, the randomly sampled timestamps in ϕ may not be “shot” by t . Therefore, we add one to $\mathbf{T}[i][\phi_i]$ for each sampled timestamp i . Figure 6(b) shows a concrete example of sampling values. In this figure, there are $R = 42$ steps (the small points in the bottom), and the normalized \mathbf{sc} (the orange box) is shown in its original temporal order, which represents a timestamp.

Finally, we normalize each column of \mathbf{T} (Line 15 to 18). The sampling matrix \mathbf{B} is the dot product of \mathbf{T} and \mathbf{X}_t^c . As shown in Figure 6(c), the purple dot and green cross are the sampled data points in \mathbf{B} . We can see that our algorithm is resistant to anomalous data points because the sampled green cross point represents “normal pattern” even though its corresponding point in the original time series is anomalous. Note that although we apply LESINN to calculate the sampling confidence vector, which is of great importance to the resistant outlier, our algorithm is also robust to other sampling confidence measurements beyond LESINN.

3.5 Compressed Sensing Reconstruction

Here we provide a quick introduction to the signal reconstruction step in compressed sensing, using this anomaly detection problem as the context. The objective of compressed sensing reconstruction is to “solve” [4]:

$$\mathbf{A}\mathbf{X}'_t = \mathbf{B} \quad (2)$$

where \mathbf{X}'_t is the multivariate time series to be reconstructed from \mathbf{B} that is sampled from the original \mathbf{X}_t . We put quotations around the word “solve”, since this equation is not solvable in the usual sense, as it is under-determined. Rather, ideally we would like to compute the sparsest (*i.e.*, containing the smallest number of nonzero components) such \mathbf{X}'_t . However, this computation, known as L^0 minimization, is NP-complete. A classic CS result is that, when \mathbf{X}_t is sparse, minimizing the L^1 of \mathbf{X}'_t (while satisfying Equation 2) results in the same solution as the L^0 minimization with high probability [4].

Algorithm 1: Outlier-Resistant Sampling

Input: $\mathbf{X}_t^c(w * k)$: k univariate time series of \mathbf{X}_t in cluster c ,
 θ : Initial sampling ratio
Output: Sampling matrix $\mathbf{B}(m * k)$

- 1 $m \leftarrow \lceil w * \theta \rceil$
- 2 $\mathbf{T}(m * w) \leftarrow 0$
- 3 $\phi(m * 1) \leftarrow$ randomly sampling m timestamps from $[0, w]$
- 4 $\mathbf{sc}(w * 1) \leftarrow \mathbf{SamplingConfidence}(\mathbf{X}_w)$
- 5 $\mathbf{sc} \leftarrow \frac{\mathbf{sc}}{\sum_{j=0}^{w-1} \mathbf{sc}_j}$
- 6 $step = 0$
- 7 **while** $step \leq 1$ **do**
- 8 $t \leftarrow \arg \min_{0 \leq a < w} step < \sum_{j=0}^a \mathbf{sc}(j)$
- 9 **foreach** $i \in [0, m)$ **do**
- 10 **if** $\mathbf{random}(0, 1) < P_t(step)$ **then**
- 11 $\mathbf{T}[i][t] \leftarrow \mathbf{T}[i][t] + 1$
- 12 $step \leftarrow step + 1/R$
- 13 **foreach** $i \in [0, m)$ **do**
- 14 $\mathbf{T}[i][\phi_i] \leftarrow \mathbf{T}[i][\phi_i] + 1$
- 15 **foreach** $i \in [0, m)$ **do**
- 16 $\mathbf{T}[i] \leftarrow \mathbf{T}[i] / \sum_{j=0}^{w-1} \mathbf{T}[i][j]$
- 17 $\mathbf{B} \leftarrow \mathbf{T} \cdot \mathbf{X}_t^c$
- 18 **return** \mathbf{B}

The sampling matrix \mathbf{A} is calculated as:

$$\mathbf{A} = \phi(\mathbf{D} \otimes \mathbf{D}^T) \quad (3)$$

where \mathbf{D} is the inverse discrete cosine transform [13] of the original time series \mathbf{X}_t^c , and \otimes is the Kronecker product [29].

To solve Equation 2 (by L^1 minimization), we adopt CVXPY [7], an efficient convex optimization tool set, to calculate the L^1 minimum [8]. CVXPY may return no result in some edge cases because the equation is non-homogeneous. Therefore, we gradually increase θ by 0.1 to avoid such a scenario. We set $\theta = 0.2$ based on the evaluation experiments as shown in §4.4. Reconstructing each cluster of univariate time series in a multivariate time series is much more efficient than reconstructing the whole multivariate time series (§4.4).

Anomaly score. We first obtain the reconstructed time series for each cluster of univariate time series to form an original multivariate time series. We then concatenate the reconstructed univariate time series to form a reconstructed multivariate time series \mathbf{X}'_t . Note that the original and reconstructed multivariate time series have the same order of univariate time series. Intuitively, an anomaly score is needed to measure the similarity between the original and the reconstructed multivariate time series. We measure the differences of the n time series between \mathbf{X}_t and \mathbf{X}'_t using euclidean distance [15]: $\mathbf{d}_t^i = |\mathbf{x}_t^i - \mathbf{x}'_t{}^i|$, where $\mathbf{x}'_t{}^i$ is the reconstructed univariate time series of \mathbf{x}_t^i . To avoid an anomaly score being dominated by a single significant spike in a univariate time series, we calculate s_t using the harmonic mean of \mathbf{d}_t^i , i.e., $s_t = n / (\sum_{i=1}^n \mathbf{d}_t^{i-1})$.

Choosing threshold. To properly generate anomaly alerts, we need to accurately choose a threshold to determine whether an anomaly score is high enough to trigger an alert. A static threshold does not work well since the data distribution changes over time. Because an extreme value of the anomaly score generated by *JumpStarter* usually represents an anomaly, we adopt the widely used Extreme Value Theory (EVT) [27] to tailor the anomaly threshold automatically. EVT is a statistical theory aiming to find the law of extreme values, and it does not assume data distribution. It has been demonstrated to accurately choose the threshold for anomaly detection methods [17, 28]. Note that EVT for choosing threshold is not the main contribution of our work.

4 Experiments

In the study, we address the following research questions:

RQ1: How well does *JumpStarter* perform in multivariate time series anomaly detection?

RQ2: Does each component contribute to *JumpStarter*?

RQ3: How do the major parameters of *JumpStarter* influence its performance?

4.1 Experimental Design

4.1.1 Datasets

We conduct experiments on three datasets, including one open dataset¹ – D1 from a large Internet company \mathcal{A} , and two datasets (D2, D3) collected from a top-tier global content platform \mathcal{B} providing services for over 800 million daily active (over 1 billion cumulative) users across all of its content platforms. Specifically, D1 is a five-week-long dataset collected from 28 online service systems, and it is sampled once per minute. These 58 online service systems are located in different servers, which provide services such as searching, ranking, and data processing, etc. D2 and D3 are two datasets

¹<https://github.com/NetManAI/Ops/OmniAnomaly>

Table 3: The detailed information of the datasets (# Training/Test Points = # Online Services * n * # Days * collected data points per day)

Dataset	# Online Services	n	# Training Points (# Days)	# Test Points (# Days)	Anomaly ratio
D1	28	38	19,835,340 (13)	19,835,760 (13)	4.16
D2	30	19	3,283,200 (20)	4,104,000 (25)	5.25
D3	30	19	3,283,200 (20)	4,104,000 (25)	20.26

collected from 30 online service systems over two different seven-week-long periods, respectively. They are both sampled once every five minutes.

This work studies metrics for a single service hosted on one or multiple machines. These metrics are equally important and have no hierarchy among them. The ground truth of anomalies in all the three datasets are manually labeled by operators based on performance issues and failure tickets. The point-wise anomaly rates ($\frac{\# \text{ anomaly data points}}{\# \text{ total data points}}$) are diverse in these datasets. For example, the anomaly rate of D3 (20.26%) is much higher than those of D1 (4.16%) and D2 (5.25%), mainly because D3 contains a severe outage that lasted a long time. Table 3 lists the detailed information of each dataset, including the number of metrics (n), the scale of the training and test sets, and the anomalies ratio. For each service, the monitoring metrics constitute its multivariate time series. The numbers of metrics monitored in D1, D2 and D3 are 38, 19 and 19, respectively. Monitoring tens of metrics is a typical setting for online service systems.

4.1.2 Compared Approaches

We compare *JumpStarter* with two learning-based unsupervised approaches for multivariate time series anomaly detection, namely, MSCRED and OmniAnomaly. We also compare it with two other anomaly detection algorithms: robust random cut forest (RRCF) and least similar nearest neighbors (LESINN). Since it has been demonstrated [28] that univariate time series anomaly detection approaches are not suitable for multivariate time series, we do not compare *JumpStarter* with the baseline methods designed for univariate time series.

RRCF [11]. RRCF is the base anomaly detection algorithm used in AWS CloudWatch, which improves the robustness of original random cut forest probabilistic data structure when detecting anomalies in streaming data. It is open-sourced².

LESINN [20]. LESINN is a time series outlier detection algorithm. For each data point, it calculates the least similar nearest neighbors of it in a time window. If the data point does not have any similar nearest neighbor, it is an outlier.

MSCRED [34]. MSCRED first encodes the temporal correlations among the time series using an attention-based ConvLSTM network, and then reconstructs time series to detect anomalies using a convolutional decoder.

²<https://github.com/aws/random-cut-forest-by-aws>

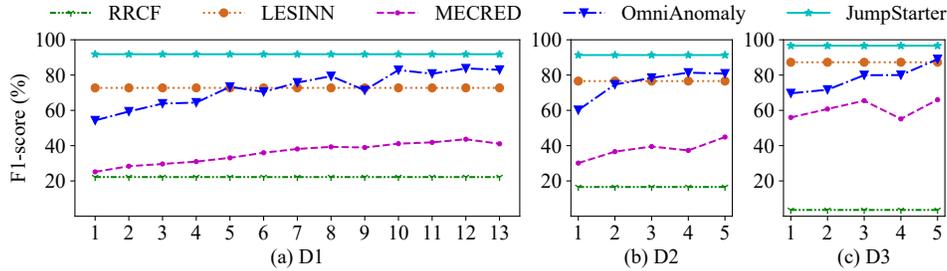

Figure 7: The average F1 score for the three datasets D1, D2, and D3 as a function of the training dataset size in segments.

OmniAnomaly [28]. OmniAnomaly is an unsupervised deep learning based approach. It glues GRU and VAE to model the temporal dependence and stochasticity of time series.

4.1.3 Implementation

JumpStarter is implemented using Python 3.7. For the hyper-parameters, $\rho = 0.1$ and $\sigma = 0.5$ are used in all settings. The detection window size $w = 20$ and the sampling rate $\sigma = 0.2$ are used in §4.4. Our study is conducted on a Dell R420 server with 16 * Intel Xeon E5-2420 CPUs and a 64GB memory.

4.1.4 Evaluation Metrics

The output of a multivariate time series anomaly detection approach for a specific timestamp is either anomalous or not. We use True Positive (TP), True Negative (TN), False Positive (FP), and False Negative (FN) to label an anomaly detection result according to the ground truth. A TP is an anomaly both confirmed by operators and detected by the approach. If an anomaly is labeled by operators but not detected by the approach, we label the item as an FN. An FP is an “anomaly” that is detected by the approach but is actually normal. An item is TN, if neither the operators nor the approach considers it an anomaly. We use three metrics for evaluating the performance of *JumpStarter* and related approaches: Precision = $TP / (TP + FP)$, Recall = $TP / (TP + FN)$, F1 score = $2 * Precision * Recall / (Precision + Recall)$. The accounting of the three metrics is point-adjusted. That is, if any point in an anomalous segment in the ground truth is detected, we consider the entire segment, or all anomalous points therein, as detected correctly. Point-adjusted metrics are widely adopted in anomaly detection [28, 32], since operators care more about anomalies in a contiguous segment than point-wise anomalies.

4.2 RQ1: Performance of *JumpStarter*

We evaluate two aspects of the performance of anomaly detection each using a different partitioning of training and test sets. First, we conduct service anomaly detection in the online mode and evaluate it as an online experiment. In addition, we collect ten software changes from \mathcal{B} for evaluating the performance of these approaches in reacting to a software

change. Second, in the offline experiment, we adopt the same experiment settings as used in previous work.

Online experiment. We evenly split the training set of D1 into 13 segments (1-day-long data per segment and each has a similar number of anomalies), and D2 and D3 each into 5 segments (4-day-long data per segment and each has a similar number of anomalies). D2 and D3 have a longer segment because they have fewer anomalies per day. For each dataset, the test set remains the same for a fair comparison (see Table 3). Figure 7 shows the average F1 score of *JumpStarter* and four baseline methods as the amount (scale) of training data increases from 1 segment to 13 consecutive segments for D1, and to 5 consecutive segments for D2 and D3. As for *JumpStarter*, RRCF and LESINN, they conduct anomaly detection without any training data. Therefore, their performance stays the same when the scale of training data varies.

We can see that *JumpStarter* performs significantly better than the four baseline approaches across all segments on all the three datasets. RRCF is less accurate than the other approaches because it aims to detect the anomalous behavior of a *single data point*, which is not suitable in our scenario where the anomalous behavior of a *time series segment* is studied. The F1 scores of learning-based approaches, namely OmniAnomaly and MSCRED, increase as the scale of training set increases, and approach 90% and 60% respectively toward the end. OmniAnomaly achieves higher accuracy than LESINN when the amount of training data is sufficient. MSCRED does not perform well because it mainly focuses on the inter-correlations rather than the overall performance of multivariate time series. For all approaches except RRCF, they achieve the best performance on D3 because the anomalous patterns in D3 are easier to capture than those in the other two datasets. The outperformance of *JumpStarter* will be explained next, when we will perform experiments concerning software changes.

Anomaly detection after software changes. Recall that software changes occur frequently in online service systems. We evaluate the performance of the five approaches during ten software changes deployed on two service systems. We do so using the average false positive rate (FPR), defined as $FP / (TN + FP)$, as the metric. FPR measures the burden of false alarms, which is an appropriate metric here since anomalies

Table 4: Average Precision (P), Recall (R), and F1 Score (F) of *JumpStarter* and related approaches

Method	D1			D2			D3			Avg.		
	P	R	F	P	R	F	P	R	F	P	R	F

<i>JumpStarter</i>	90.35	94.31	92.29	92.05	94.51	93.26	94.14	99.60	96.79	92.18	96.14	94.12

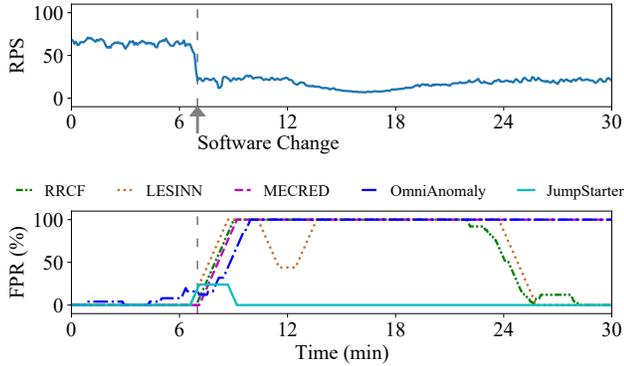

Figure 8: The average False Positive Rate (FPR) during ten software changes. We plot the software changes starting at the seventh minute. The top figure is a constituent univariate time series representing Requests Per Second (RPS).

rarely occur in a short period.

Figure 8 shows the average FPR of the five approaches during the 10 software changes, all of which occur at the seventh minute in the figure. Some constituent univariate times series of the multivariate time series witness level shifts [17]. We observe that all five approaches produce false positives after these software changes. However, *JumpStarter* suffers from high FPR only for about five minutes, after which its FPR becomes quite low. RRCF and LESINN detect anomalies by calculating outliers in a relatively long period, and hence their FPRs do not start to decrease until 17 minutes after software changes. Both OmniAnomaly and MECRED perform well only when the joint distribution of multivariate time series remains unchanged. Consequently, they produce false alarms for a long period after software changes.

Offline experiment. Now we study the potential performance in the offline setting using best F1 score. Since we need a long time to train models of learning-based anomaly detection approaches, we split the dataset into training and test set following the settings in [28]. Then, we calculate the best F1 score of each approach by grid searching their parameters and anomaly thresholds. Table 4 lists the average best F1 scores of *JumpStarter* and baseline approaches on each dataset, as well as their corresponding Precision and Recall. The average best F1 score of *JumpStarter* across the three datasets

Table 5: The average initialization time (IT) and detection time (DT) of *JumpStarter* and baseline approaches

Approach	RRCF	LESINN	MSCRED	Omni-Anomaly	<i>JumpStarter</i>
IT (min)	20	20	>86400	>86400	20
DT (ms)	41.24	118.63	122.82	191.86	127.13

is 94.12%, significantly higher than those of the other four approaches, which are 86.51%, 59.64%, 82.50%, and 36.01%, respectively. This is because D2 contains a large quantity of noises, and none of the other four approaches is robust to such noises. In contrast, *JumpStarter* reconstructs an anomaly-free time series with outlier-resistant sampling, making it robust to such noises in each dataset.

Efficiency. Table 5 lists the average initialization time and detection time of the five approaches. The initialization time of *JumpStarter*, as demonstrated in §4.4, is only twenty minutes, much shorter than those of other approaches. Although RRCF and LESINN achieves the same initialization time as *JumpStarter*, they suffer from low accuracy as shown in Table 4. The detection time of *JumpStarter* for each multivariate time series is 127.13 ms, similar to that of the other approaches. In *JumpStarter*, the shape-based clustering step takes at most 500ms on all three datasets.

4.3 RQ2: Contributions of Components

In this section, we evaluate the relative contributions of two component techniques in *JumpStarter*, namely shape-based clustering and outlier-resistant sampling, to its outperformance. To this end, we reconfigure *JumpStarter* to create three variants. The first two variants concern *JumpStarter* without shape-based clustering. The first variant, called *w/o Clustering: As a Whole*, is to treat all time series as a whole, whereas the second variant, called *w/o Clustering: Separately*, is to sample and reconstruct time series separately. The third variant, called *w/o Sampling*, is *JumpStarter* without outlier-resistant sampling.

Figure 9 shows the comparison results of *JumpStarter* and its three variants on three datasets in terms of average best F1 scores. *JumpStarter* performs better than all its three variants. Specifically, *JumpStarter* improves the average best F1 score of *w/o Clustering: As a Whole*, *w/o Clustering: Separately*, and *w/o Sampling* by 5.81% ~ 14.90%, 2.58% ~ 9.96%, and

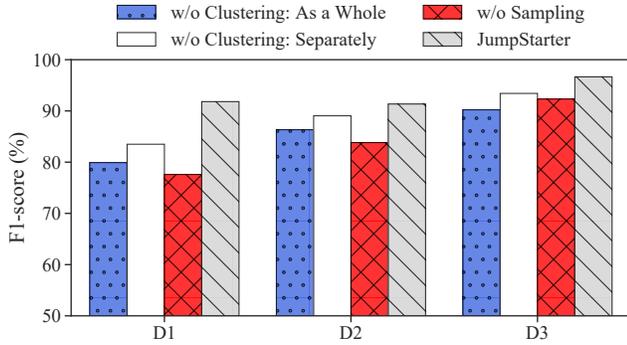

Figure 9: The average F1 score of *JumpStarter* and its three variants on three datasets

4.69% ~ 18.34%, respectively. The results demonstrate that both shape-based clustering and outlier-resistant sampling contribute significantly to a more accurate *JumpStarter*. In addition, *w/o Clustering: Separately* outperforms *w/o Clustering: As a Whole*, because separate reconstruction of time series more accurately captures anomalous patterns than reconstruction as a whole, as shown in Figure 4.

To compare the computational efficiency of different methods, we compare their detection times. For each multivariate time series, the detection time of *w/o Clustering: As a Whole*, *w/o Clustering: Separately*, *w/o Sampling*, and *JumpStarter* is 7891.45 ms, 2056.56 ms, 121.75 ms, 127.13 ms, respectively. This demonstrates that the shape-based clustering technique significantly improves the computational efficiency of *JumpStarter*. In conclusion, the combination of the shape-based clustering and outlier-resistant sampling facilitates an accurate and efficient *JumpStarter*.

4.4 RQ3: Parameter Sensitivity

Recall that our goal is to shorten the initialization time of anomaly detection. The initialization time of *JumpStarter* depends on the detection window size w . We empirically increase the window size from ten minutes to sixty minutes. Figure 10(a) shows how the average best F1 score and point-wise detection time of *JumpStarter* changes as the window size increases. The accuracy of *JumpStarter* increases before the window size reaches 20 minutes, after which it becomes stable, whereas the detection time increases gradually. Therefore, the window size is preset as twenty minutes, which makes *JumpStarter* both accurate and efficient. Note that for those anomalies lasting longer than 20 minutes, *JumpStarter* is still able to detect them because it can easily capture these anomalies when they start.

Another important parameter of *JumpStarter* is σ , the initial sampling rate. Figure 10(b) shows how the average best F1 score and point-wise detection time of *JumpStarter* changes as σ increases. Similarly, when we increase the sampling rate

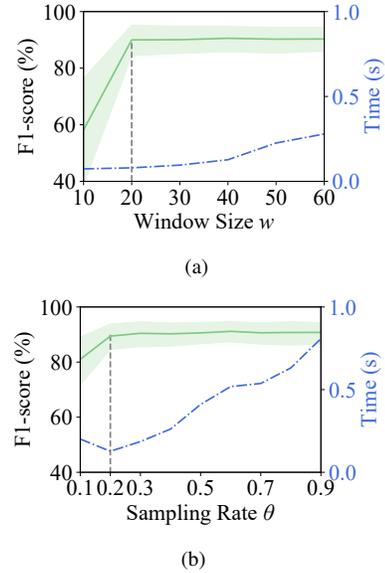

Figure 10: The average F1 score (green line with error bounds) and average point-wise detection time (dotted blue line) of *JumpStarter* under different parameters.

from 0.1 to 0.2, the F1 score of *JumpStarter* increases, and it becomes stable after that. The point-wise detection time of *JumpStarter* decreases with an increase in the sampling rate from 0.1 to 0.2, and it then increases after that. That is because, if the sampling rate is too low (e.g., 0.1), reconstruction is likely to fail, which in turn increases the number of retries. Therefore, we set the sampling rate to 0.2.

5 Deployment and Discussion

5.1 Success Story

Case study. We applied *JumpStarter* into 30 online service systems in a top-tier global content platform \mathcal{B} , which has more than 800 million users around the world. Operators can register a multivariate time series monitor task by ingesting these time series from influxDB and Kafka. From the monitoring dashboard of these services, we can see the multivariate time series of service monitoring. Figure 11 shows some time series of two technical outages.

Case I: Long service response time caused by network issue. As illustrated in Figure 11(a), we observed jitters in time series `tcpext_listdrops` and `tcp_attemptfails`. In the meantime, time series such as `cpu_user` and `load_one` drastically dropped. *JumpStarter* successfully pinpointed this anomaly and generated an alert. After diagnosing the anomaly, operators found that it was a network issue of a database node.

Case II: Service hang-up due to software change. As illustrated in Figure 11(b), time series `tcp_retrans_percentage` witnessed significant jitters and `cpu_idle` plunged to zero. After that, `cpu_sintr`, `cpu_ctxt`, `rx_byptes_eth0` and

tx_pkts_eth0 increased significantly. *JumpStarter* detected and reported this anomaly to operators. Operators conducted software changes and a configuration error occurred in the new version. Thanks to *JumpStarter*, operators found out this error in time and quickly rolled out the software change.

Help with root cause diagnosis. *JumpStarter* can help with root cause diagnosis in two aspects. First, hundreds of multivariate time series need to be monitored. After shape-based clustering in *JumpStarter*, operators can focus on limited time series groups with a similar shape of variations. Second, *JumpStarter* respectively calculates the distance between the original univariate time series and the reconstructed ones. Therefore, it can output a rank list of time series' contributions to the overall anomaly. For example, tcpe_xt_listendrops in Figure 11(a) is detected as the most anomalous time series in this figure. It can explicitly indicate the issue caused by the network component.

5.2 Lessons Learned

Different services may prefer precision and recall differently. With collaboration with different services teams, we found that their preferences on precision and recall are diverse. For example, recall weighs more than precision does in a user interactive core service since operators do not want to miss any potential anomaly that can negatively impact the user experience. In addition, precision is more valuable in a data analysis job because operators would better detect anomalies precisely than to obtain a lot of false alerts. Therefore, the F1 score alone is not a suitable metric for all services. Going forward, we can provide operators with an interface to choose their precision and recall preference level. Specifically, *JumpStarter* can accordingly set the anomaly score using different parameters of the EVT algorithm to guide the sensitivity of detection output. We also observe that severe faults (examples in Figure 11) rarely happen in online services but performance issues do happen a lot. We aim to reduce mean time to restore for severe faults in future work.

Alert system is not just anomaly detection. Our *JumpStarter* for robust and quickly initialized anomaly detection is not the end of the story. Building an intelligent alert system based on anomaly detection results is also a complex task in both engineering and academic aspect. Some anomalies may have no or little signal in the monitored time series. Therefore, *JumpStarter* may miss these anomalies. For this scenario, we aim to collect more types of monitoring data, e.g., logs, traces, to build a more comprehensive anomaly detection model. We believe *JumpStarter* can be easily extended for localizing the anomalous metrics, however, there is a significant gap between anomalous metrics and the root causes of anomalies [16,25]. An intelligent alert system needs to merge similar anomalous cases, pinpoint more sharply to the root causes of anomalies. It also had better learn the priority of differ-

ent anomalous cases [5]. Besides, adeptly integrating domain knowledge into the alert system is also of great importance since the system needs feedback from operators. Therefore, apart from the anomaly detection approach *JumpStarter*, we will improve the alert system behind it.

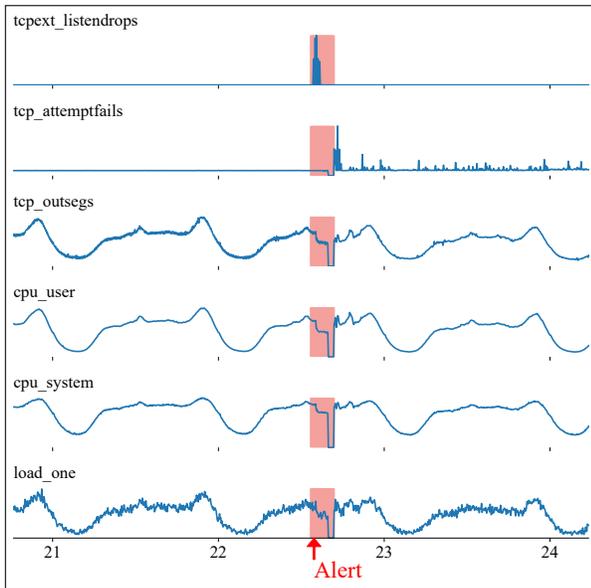

5.3 Threats to Validity

Anomaly labeling. In this work, we use one open dataset from OmniAnomaly and two datasets from real-world services. All the labels in these datasets are provided by operators based on performance issues and incident reports. Manually labeling anomaly points in the timeline may introduce noise (false positives or negatives) because no clear boundaries lie in anomalies and normal patterns. However, domain operators with profound experience suggest the noise in those labels accounts for a very small portion. Besides, operators design evaluation metrics that utilize contiguous anomaly segments instead of point-wise anomalies. Adopting these widely used metrics [17,28,32], we can also eliminate labeling noises.

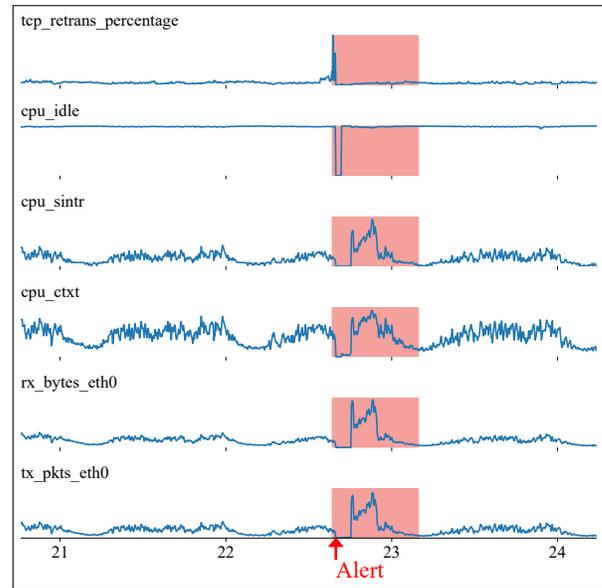

Subject systems. In our experiments, we use an open dataset D1 from a large Internet company. We also collect datasets D2 and D3 from large-scale real-world online service systems. The granularity of the time series of these datasets is one and five minutes, respectively. The efficacy of our algorithm is not influenced by the granularity. With fine-grained granularity, say one second, we believe our algorithm can still work without additional efforts. Since *JumpStarter*'s versatility has been demonstrated using three datasets collected from 58 different services, it should be easy for *JumpStarter* to work with a new dataset. Admittedly, the number of subject services is still limited. We will experiment with *JumpStarter* on a variety of online service systems in the future.

6 Related work

Multivariate time series anomaly detection. Existing approaches include: (1) Traditional statistic method: time series analysis [6], RRCF [11] and clustering-based LESINN [20] do not need training data thus the initialization time is short. However, they all suffer from parameter tuning [15] and being not robust in real practice [17]. (2) Supervised learning based method: Opprentice [15] is an ensemble supervised approach. It needs operators to label anomalies for a long period to train a model. (3) Unsupervised learning based method: LSTM-NDT [12], LSTM-VAE [22], MSCRED [34] and OmniAnomaly [28] build anomaly detection models by learning the anomaly patterns using a large span of historical data. These methods suffer long initialization time for training the model and are less accurate when facing software change [17]. Different from them, we take advantage of compressed sensing, which is a quick initiated signal processing based approach without any training data.

(a) Network Issue

(b) Software Change

Figure 11: Two anomaly cases with selected time series (service performance metrics, *e.g.*, average response time, error rate, are hidden for the confidential reason). Time (X-axis) is shown in days. The alert is generated by *JumpStarter*.

Signal processing based anomaly detection. Since time series of online service systems fluctuate and not always periodic [35]. Other signal processing methods are not suitable in this scenario. For example, Fourier transform can only capture period, the global information of time series [38]. For local information, wavelet analysis can capture local patterns but it is very time consuming [1]. Kalman filtering [18] and PCA [19] are not suitable for variation time series of online service systems [15]. Different from them, our work adopts compressed sensing as the base technique and our experimental results have demonstrated the effectiveness of *JumpStarter* in multivariate time series anomaly detection scenario.

Compressed sensing. As body of theory regarding signal recovery, CS has been widely used in image reconstruction [2], genome-wide association study [30], and many other applications [9]. *JumpStarter* is parallel to them, as it detects anomaly adopting the idea of CS reconstruction.

7 Conclusion

In recent years, online service systems are increasingly deployed on cloud computing platforms. To adapt to frequent changes in online service systems, multivariate time series anomaly detection approaches should be robust and quickly initialized. In this paper, we propose a jump-starting multivariate time series anomaly detection approach with a relatively short initialization time of only twenty minutes. Based on the compressed sensing technique, *JumpStarter* adopts a shape-based clustering strategy to deal with the large number of

univariate time series in a multivariate time series, and outlier-resistant sampling to avoid sampling anomalous values. Experiments conducted on 58 real-world online service systems of two Internet companies demonstrate the effectiveness of *JumpStarter*, achieving an average F1 score of 94.12% and outperforming four state-of-the-art approaches. Besides, our results also endorse the contributions of the main components. In particular, we have applied *JumpStarter* in a real-world online service system and gained some useful lessons.

Palleon: A Runtime System for Efficient Video Processing toward Dynamic Class Skew

Boyuan Feng, Yuke Wang, Gushu Li, Yuan Xie, and Yufei Ding
University of California, Santa Barbara
{boyuan,yuke_wang,gushuli,yuanxie,yufeiding}@ucsb.edu

Abstract

On par with the human classification accuracy, convolutional neural networks (CNNs) have fueled the deployment of many video processing systems on cloud-backed mobile platforms (e.g., cell phones and robotics). Nevertheless, these video processing systems often face a tension between intensive energy consumption from CNNs and limited resources on mobile platforms. To address this tension, we propose to accelerate video processing with a widely-available, but not yet well-explored runtime input-level information, namely *class skew*. Through such runtime-profiled information, it strives to automatically optimize CNNs toward the time-varying video stream. Specifically, we build Palleon, a runtime system that dynamically adapts and selects a CNN model with the least energy consumption based on the automatically detected class skews, while still achieving the desired accuracy. Extensive evaluations on state-of-the-art CNNs and real-world videos demonstrate that Palleon enables efficient video processing with up to $6.7\times$ energy saving and $7.9\times$ latency reduction.

1 Introduction

Convolutional neural networks (CNNs) based video processing plays an important role in many emerging applications [3, 4, 7, 9, 10, 16, 31, 35] deployed on cloud-backed mobile platforms. Among them, cognitive assistants and robotic visions are two representative categories. Smart glasses [7, 16, 31], for example, continuously recognize the surrounding environment with CNNs and help the blind person with ordinary tasks (e.g., reading a handwritten note, navigating the grocery store, and even running the Boston Marathon). Robotic visions could automatically search specific animals and document the secret lives of them in the wild [9], as well as detect landmines in various environments [35].

While these applications enjoy both the mobility of the wide deployment in real world and the high accuracy of CNNs, they also face the tension between the limited resource budget on mobile platforms and the high energy consumption and latency of CNNs. A popular CNN, VggNet [67], can easily consume 3.6W and introduce 1.4-second latency, which

makes a large smartphone battery (e.g., 2.7-Ah battery in iPhone X [36]) out of power within 2 hours on continuous image classification. To improve the execution efficiency, many techniques have been proposed such as pruning [28, 46, 48] and quantization [56, 76, 80] to reduce the size of CNN models. However, these existing works fail to exploit the special characteristics of video streams; furthermore, the compromised model accuracy also limits the overall pruning or quantization ratio.

Complementing existing model compression techniques, a strong *temporal locality* in video streams is investigated here to enable efficient video processing on mobile platforms. Considering a video stream collected from a continuous camera feed, it is common that only a small number of classes keep appearing in a large number of consecutive frames. For example, in a film scenario, only a small number of people would come to the master shots frequently, generally lasting for a few minutes, and another group of people will not appear until the scenario has changed. A study on Youtube videos of day-to-day life [65] also shows that more than 90% frames are comprised of less than 10 classes.

We first turn such an abstract concept, *temporal locality*, into something concrete and measurable, *class skew*. Specifically, class skew is formally defined as an unbalanced class distribution that flexibly and effectively extracts the scenario information of both *class cardinality* and *visual separability*. Class cardinality here captures the number of classes in a class skew. By exploiting this class cardinality, we can tailor a general CNN, which is usually trained to recognize thousands of classes, into a specialized model, which only needs to recognize a small number of classes in the current class skew. Meanwhile, we notice that class skews show diverse visual separability under the same class cardinality. For example, a class skew with two classes (e.g., houses and dogs) is easier to recognize compared to that with two more subtle classes (e.g., Husky and Alaskan). By exploiting visual separability, we can use a more compact model for computation and energy saving without loss of accuracy compared with a full model.

We then identify several key challenges that hinder the

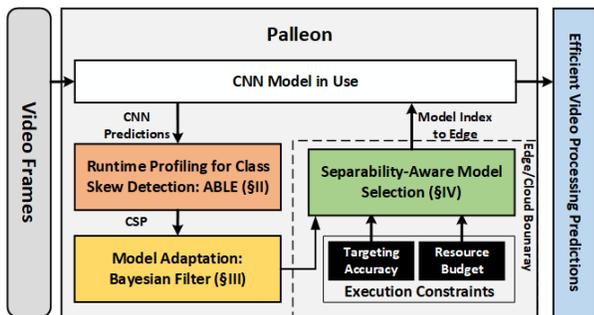

Figure 1: Overview of the Palleon Runtime System.

successful utilization of class skews. First, new class skews may appear and disappear suddenly as time goes, namely *class skew switches*, making it hard to precisely capture the class skew and respond fast to class skew switches. Second, a class skew may last for minutes or even hours between two class skew switches, but this lasting time varies across different videos and even scenarios, thus cannot be decided offline. Third, with the detected class skew, it is still hard to adapt deep models at runtime, since existing model adaptation techniques of retraining fully connected layers are computation-intensive and not affordable on mobile platforms. Forth, a single model adapted toward various class skews may show a significant difference in accuracy due to the diverse visual separability. This difference in accuracy either allows more lightweight CNNs for more energy saving or requires more computation-intensive CNNs to achieve a satisfactory accuracy. Finally, model selection adaptive to class skews may introduce high overhead, making it infeasible to execute on mobile platforms.

To address these challenges, we build a runtime system, Palleon, which could not only detect class skews during runtime, but also dynamically adapt and select a CNN model with the least energy consumption accordingly. In contrast, some existing works [32, 42, 43], which share a similar high-level motivation with us, only target some specific application scenarios that are already known offline—If you want to, you could think of these as "static" class skews without dynamic switches. A recent work, FAST [65], has made some progress along this research direction. FAST assumes that the exact set of class skews (and their duration time) in a video stream are foreknown, and FAST trains a set of compact models for each known class skew offline. During runtime, FAST only needs to detect these foreknown class skews with a simple window-based detector and directly apply those pre-trained models accordingly. To this end, Palleon adopts a pure runtime approach and targets a more realistic setting that the class skews in the video stream are not foreknown.

As illustrated in Figure 1, the Palleon runtime system continuously takes video frames and efficiently generates video processing predictions with three novel components. First, we propose an agile class skew detector, **ABLE** (Section 2), to abstract class skews from video streams. ABLE comes with the *static class-skew profiling* and the *dynamic class-skew*

switch detection. The former automatically detects the class skew and generates a precise *Class Skew Profile* (CSP) when a class skew is detected. The latter continuously catches class skew switches during runtime without the offline information about the class skew lasting time.

Second, we propose **Bayesian Filter** (Section 3) to adapt CNNs toward the detected class skew during runtime. While Bayesian Filter does not directly lead to energy efficiency, it improves the accuracy of compact models with low resource consumption and allows the compact models to replace the complex model. Bayesian Filter is a lightweight module comprised of a *Rescaling* mode that adapts CNNs towards detected CSP without online finetuning and a *Direct Pass* mode that allows the adapted CNNs to still recognize classes out of the current CSP. This lightweight module resolves the complex trade-off between accuracy improvement and adaptation overhead in exploiting class skews.

Third, we design a cloud-backed model selection scheme, namely **Separability-Aware Model Selection** (Section 4), to further squeeze system energy consumption. This scheme exploits visual separability with an *efficient online model selection* that identifies the CNN with the least resource consumption while achieving satisfactory accuracy on the detected class skew. Meanwhile, this scheme contains an *edge-cloud duplicated model bank* to mitigate the model selection overhead on mobile platforms and deliberately schedule the runtime workload between the edge and the cloud.

In summary, we build Palleon, a runtime system that automatically detects input-level information with ABLE and dynamically adapts the given CNNs online with Bayesian Filter. Palleon also controls a set of tuning knobs for balancing the accuracy and the resource efficiency with separability-aware model selection. We build Palleon upon TensorFlow [1] and evaluate it on a cloud-backed mobile platform (with NVIDIA Jetson Nano [40] as the edge device and Dell Workstation T7910 [17] as the cloud server). We evaluate Palleon on various CNN models and different datasets. In particular, for CNN models, we use a variety of the state-of-the-art CNNs from two major domains – object classification (MobileNet [37], VGGNet [67], ResNet [30], and DenseNet [33]) and face recognition (VGGFace [57]). For datasets, we take both synthesized videos and several real-world movies. Extensive experiments confirm the effectiveness of Palleon and show that it could achieve up to $6.7\times$ energy saving and $7.9\times$ latency reduction while achieving an equivalent or better accuracy.

2 ABLE for Class Skew Detection

We build a class-skew detector, namely *ABLE*, to detect class skews during runtime and enable class-skew based optimizations. Our goal is two-fold: 1) giving a precise class-skew profile (CSP) in static regions between adjacent class-skew switches, and 2) detecting when the class-skew switches occur. To this end, we break down our class-skew detection into two sub-tasks: **Static Class-Skew Profiling** and **Dynamic**

Class-Skew Switch Detection.

2.1 Static Class-Skew Profiling

A static CSP generates the distribution of classes in a *static region* where no class skew switch happens. Palleon approximates the CSP in each static region with an empirical distribution [64], which enjoys theoretical properties of converging fast to the ground truth CSP. As illustrated in Figure 2a, given a time window with $r_t = 10$ frames, we collect the predicted labels for each frame and count the frequency of each class. For example, E appears for 4 times out of 10 frames in total, leading to 0.4 for class E in the estimated CSP.

Formally, at time t , in a given frame window with r_t frames (ranging from the $t - r_t + 1^{th}$ to the t^{th} frame), the probability of class j in the CSP is computed as

$$p(j|r_t, x_{1:t}) = \frac{1}{r_t} \sum_{i=t-r_t+1}^t \mathbb{1}_{x_i=j} \quad (1)$$

where x_i is the *predicted label* for the i^{th} frame, $\mathbb{1}_{x_i=j}$ is an indicator function [62] on whether x_i equals j , and $x_{1:t}$ denotes all t predicted labels in the history. The CSP for the given frame window (with r_t frames ending with the t^{th} frame) is computed as a probability vector of all classes:

$$CSP_{t,r_t} = \{p(1|r_t, x_{1:t}), p(2|r_t, x_{1:t}), \dots, p(d|r_t, x_{1:t})\} \quad (2)$$

where d is the total number of classes.

Early Optimization by Adaptive Waiting Scheme. Palleon splits each static region as two phases (Figure 2a): a *waiting phase* to collect a precise CSP based on the full model and an *optimization phase* to apply class-skew based optimizations. In the optimization phase, we use a compact model adapted toward CSPs, which saves energy and reduces latency while achieving an equivalent accuracy to the full model. By allocating smaller number of frames in the waiting phase, Palleon can start the optimization phase early and squeeze more optimization opportunities for more frames, leading to better system performance. However, an imprecise CSP may be generated when allocating too few frames to the waiting phase. Hence, we select the frame number carefully to improve system performance and retain precise CSPs.

We develop an *adaptive waiting scheme* to determine whether Palleon has collected a precise CSP and the waiting phase can be terminated. Suppose the waiting phase has already lasted r_t frames and the current class-skew profile is CSP_{t,r_t} , this scheme computes a minimal frame number F_{min} based on CSP_{t,r_t} . If $F_{min} < r_t$, it terminates the waiting phase. Otherwise, it continues and repeatedly applies such check. In principle, F_{min} guarantees a negligible profiling error ϵ between the true probability p_j and the profiled probability \hat{p}_j

$$\max_{1 \leq j \leq d} |\hat{p}_j - p_j| / p_j \leq \epsilon \quad (3)$$

We next discuss how F_{min} is computed and why it guarantees a negligible profiling error. In addition, we will also

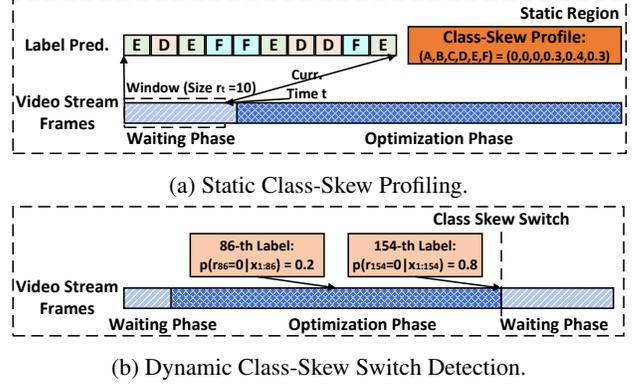

Figure 2: Illustration of ABLE for Class Skew Detection.

propose some practical designs for efficiently computing F_{min} . We start with a theorem, which gives the minimum number of frames to profile a particular class in the class skew.

Theorem 1. (Asymptotic Error Bound). With $n = Z_c / (\epsilon \sqrt{\hat{p}_j})$ samples (frames), the probability of achieving a negligible error $P(|\hat{p}_j - p_j| / p_j < \epsilon) > 1 - c$ for class j holds asymptotically, where Z_c is a Gaussian Distribution Z-score with confidence level $1 - c$ and ϵ is a tolerable error bound.

Proof. Due to the property of multinomial distribution, estimator \hat{p}_j computed with Equation 1 is a maximum likelihood estimator (MLE). Based on the asymptotic normality of MLE, we have $\sqrt{n}(\hat{p}_j - p_j) \rightarrow N(0, FI^{-1})$, where FI is the Fisher Information matrix $FI_{wh} = E_X[-\frac{\partial^2 \ln f_p(x_t)}{\partial p_w \partial p_h}]$. Clearly $FI_{wh} = n/p_w$ if $w = h$; 0, otherwise. Based on the marginalization property of multivariate normality, we can see that $(\hat{p}_j - p_j) \rightarrow N(0, \frac{p_j}{n})$. Following this asymptotic distribution, we can derive the required sample number $n = Z_c / (\epsilon \sqrt{\hat{p}_j})$.

Considering that CSP is stable only if estimators for most classes j are stable, we set the minimum number of frames as

$$F_{min} = \max_{\hat{p}_j > \xi} Z_c / (\epsilon \sqrt{\hat{p}_j(r_t, x_{1:t})}) \quad (4)$$

Here we only consider classes showing *significant existence* ($\hat{p}_j > \xi$, where $\xi = 1/(2 * d)$ is a probability threshold). The intuition is that *CNNs may make wrong predictions randomly spanning in various classes with significantly low probabilities, leading to an unnecessarily long waiting time*. This strategy can mitigate the effect of prediction errors and focus on the effect of correct predictions.

For an arbitrary class number d , computing F_{min} has a low time complexity of $O(d)$, where the main computation resides in iterating through all classes j (Equation 4) and estimating the probability $\hat{p}_j(r_t, x_{1:t})$. This estimation can be conducted efficiently in constant time, based on a *computation reuse* technique detailed in the following section.

2.2 Dynamic Class-Skew Switch Detection

Dynamic class-skew switch detection identifies class skew switches and provides static regions for the static class skew profiling, as shown in Figure 2b. Specifically, dynamic class-

skew switch detection identifies the timestamp t when the previous class skew ends and a new class skew appears. There are two standard techniques to detect class skew switches: Window-based approach [5, 65] and Bayesian-based approach [2, 19, 39, 49, 63, 78]. The former splits video streams into a sequence of windows with a fixed window size k and periodically detects the class skew switch at the boundary. The latter detects class skew switch at each timestamp t by tracking all historical windows, where the $k^{th} \in \{1, 2, \dots, t\}$ historical window contains the $t - k + 1^{th}$ frame to the t^{th} frame. However, the former only detects the class skew switch when a time window has finished, leading to a detection delay up to the fixed window size. While the latter reacts fast to class skew switches by tracking all historical windows, it introduces high overhead with a quadratic time complexity $O((d+t) * t)$, in the number of frames t and the number of classes d . The latter shows more than 1500-millisecond latency per frame after processing a 3-minute video clip. By contrast, Palleon checks class skew switches at each label prediction x_t (Figure 2b) while introducing low computation complexity of $O(d * k)$, where k is the number of sampled windows ($k \ll t$).

At a high level, we sample a subset of window sizes $r_t \in \{w_1, w_2, \dots, w_k\}$ and flag a class skew switch when the probability $p(r_t = 0 | x_{1:t})$ is higher than the probability of the other r_t . We estimate the probability $p(r_t | x_{1:t})$ of each window size r_t when a new predicted label x_t comes:

$$p(r_t | x_{1:t}) = p(r_t, x_{1:t}) / \sum_{r_t=0}^t p(r_t, x_{1:t}), \quad (5)$$

where $p(r_t, x_{1:t})$ is the joint possibility of the lasting time r_t and the predicted labels $x_{1:t}$:

$$p(r_t, x_{1:t}) = \sum_{i=1}^k p(r_t | r_{t-1} = w_i) \cdot p(x_t | r_{t-1} = w_i, x_{1:t-1}) \cdot p(r_{t-1} = w_i, x_{1:t-1}) \quad (6)$$

Here, $p(r_t | r_{t-1} = w_i)$ is a survival function [44] of the probability that a class skew of length r_{t-1} is still alive at r_t , and $p(x_t | r_{t-1} = w_i, x_{1:t-1})$ is the probability that the predicted label x_t comes from the same distribution as last r_{t-1} labels, computed by Equation 1.

Overhead Reduction by Window Sampling. Window sampling selects k windows (*i.e.*, w_1, w_2, \dots, w_k) that minimize the mean absolute error between tracking the selected k windows and all t windows:

$$\min_{w_1, w_2, \dots, w_k} \sum_{r_t=1}^t |p(r_t, x_{1:t}) - p_f(r_t)|, \quad (7)$$

where $f(r_t)$ maps time window r_t to one of the sampled time window $\{w_1, w_2, \dots, w_k\}$. A small number of k windows can approximate all t windows since a window size with low possibility $p(r_{t-1}, x_{1:t-1})$ tends to still have low possibility $p(r_t = r_{t-1} + 1, x_{1:t})$ when new data comes:

$$p(r_t, x_{1:t}) = p(r_t | r_{t-1}) p(x_t | r_{t-1}, x_{1:t-1}) p(r_{t-1}, x_{1:t-1}) \leq p(r_{t-1}, x_{1:t-1}) \quad (8)$$

A straightforward approach is to only track the k most possible windows. However, this approach may not work well when a large number ($> k$) of windows have equally high probability $p(r_t, x_{1:t})$. To this end, we group all t windows into k clusters and select a representative window out of each cluster. To cluster windows, we first sort the possibility $p(r_t, x_{1:t})$ for all time windows r_t and split into clusters at the top $k - 1$ gaps in the sorted sequence. Then, we select the windows with the median probability to represent this cluster and give this window a weight based on the number of windows in the cluster. Intuitively, we exclude the top $k - 1$ gaps by splitting clusters at these gaps to minimize the mean absolute error.

Fast Update by Computation Reuse. Another optimization opportunity is the computation reuse in estimating the conditional distribution $p(x_t | r_{t-1}, x_{1:t-1})$. Since the estimation for each window r_{t-1} at most traverses all data points and all classes, the time complexity of the estimation is linear to the number of data points and classes $O(d + t)$. Since adjacent windows differ only by one input, we can reuse the class frequency in adjacent windows, reducing the time complexity for each window to be $O(d)$. Specifically, the class frequency counts in adjacent windows $r_{t-1} = i$ and $r_{t-1} = i + 1$ differ only by one in a single class, determined by the label x_{t-i} . Thus, with the class frequency count $[C_1, C_2, \dots, C_d]$ in window $r_{t-1} = i$, we can update the frequency count in window size $r_{t-1} = i + 1$ by $C'_j = C_j + 1$, if $j = x_{t-i}$; $= C_j$, o.w.

3 Bayesian Filter for Model Adaptation

In this section, we develop a highly flexible module, namely *Bayesian Filter*, to enable class-skew based optimizations. This module consumes a Class Skew Profile (CSP) detected by ABLE and has two functionalities: 1) adapting CNNs toward the detected class skew with low computation overhead and low latency during runtime; 2) allowing the adapted CNNs to recognize classes out of the current CSP for enabling the detection of class skew switches. To this end, we design a **Rescaling** mode (Section 3.1) for scenario reference (*i.e.*, model adaptation) and a **Direct Pass** mode (Section 3.2) for retaining confident predictions.

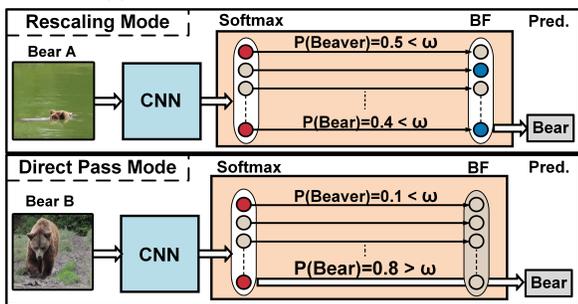

Figure 3a exhibits two videos with extreme class skews, which are intentionally made simple for understanding. In most video frames, the objects are easy to recognize, during which Palleon extracts a precise CSP based on classes recently detected with high confidence. This CSP helps for frames in which objects are hard to recognize (*e.g.*, the animals jump into the water and turn around).

3.1 Rescaling

Rescaling mode is a lightweight module for model adaptation with low computation overhead and low latency. This design avoids the heavy computation overhead and latency in existing work [27, 32, 43, 65], which retrains fully connected layers in CNNs during online and may introduce a long latency (up to 14 seconds) [65]. When considering the energy efficiency,

(a) Two videos with extreme class skews

(b) Intuition behind Bayesian Filter.

Figure 3: Overview of Bayesian Filter.

this retraining procedure either introduces heavy computation overhead when conducted on the edge, or heavy network communication overhead when retraining is conducted on the cloud and updated weights are transferred to the edge. By contrast, Rescaling mode adapts CNNs by appending an extra layer after the fully connected layer. We stress that Rescaling mode requires neither weight update nor model retraining.

Rescaling mode adapts CNNs toward the detected class skew by initializing the extra layer with the CSP generated by ABLE. Since CSP contains the probability of all d classes, the extra layer is designed to have the same number of d nodes, whose weights are initialized by each probability in CSP. In this way, the magnitude of node weights indicates the frequency of the corresponding class in the CSP. When a frame comes, the CNN will generate a probability for each class in the softmax layer and these probabilities will be adjusted according to the magnitude of corresponding node weights. Specifically, the extra layer rescales the probability of softmax-layer predictions (red nodes) toward the current CSP (blue nodes) when the highest softmax-layer probability does not pass a pre-defined threshold ω (*i.e.*, not confident enough). Following the spirit of Bayesian statistics [64], Rescaling mode updates the probability for each class by considering both the prior and the posterior information. We tried several different designs, and it turns out that a simple rescaling scheme based on Bayes theorem would already work effectively, as shown in Formula 9.

$$P(i|X) = \frac{P(i) \cdot P(X|i)}{P(X)}, \quad i \in \{1, 2, \dots, d\} \quad (9)$$

where d is the total number of classes.

Formula 9 computes the posterior probability of class i for a given image X . The prior probability $P(i)$ is the profiled probability of class i in the current CSP. And the likelihood $P(X|i)$ describes the possibility that an image X comes from class i , according to the softmax-layer probability of class i . $P(X)$ stands for the marginal likelihood for observing the image X , which is same for all classes and does not change the rescaling results. Thus, we can avoid computing $P(X)$ and, instead, use a handy rescaling mechanism as $P(i|X) \propto P(i) \cdot P(X|i)$. To the best of our knowledge, we are the first to design Bayesian rescaling on CNNs for runtime model adaptation toward class skews.

3.2 Direct Pass

Direct Pass mode selects the original prediction without rescaling when the predicted probability is higher than a pre-selected threshold ω (Direct Pass mode in Figure 3b). This design allows detecting class skew switches by identifying classes out of the current CSP. This design is inspired by observations [25, 54] that *neural networks usually achieve higher accuracy when they predict a high probability*.

Formally, Bayesian Filter with both Rescaling mode and Direct Pass mode can be written as

$$P(i|X) \propto \begin{cases} P(i) \cdot P(X|i) & \text{if } P(X|i) < \omega \\ P(X|i) & \text{if } P(X|i) \geq \omega \end{cases} \quad (10)$$

where $P(i)$ is the prior probability of observing class i provided by class skew, $P(X|i)$ is the predicted probability from CNNs. We utilize a hyper-parameter ω as the confidence threshold deciding whether Bayesian Filter should enter the direct pass mode. When a model makes a prediction with high probability ($> \omega$), we believe its prediction is correct and Bayesian Filter will not interfere with the decision. Note that two models with different accuracy—for example, a model A with 70% accuracy and a model B with 95% accuracy—could predict with similar high probability when they are making the correct predictions. Their accuracy difference comes from those frames where the poorer model makes a mistake while the stronger model is still correct, not from those frames where both models are correct. Thus, we select the same threshold ω across different CNNs. In particular, we experiment with diverse ω on an extensive collection of the state-of-the-art CNNs and find that a threshold ω between 75% and 95% exhibits similar performance. By default, we use 90% as the threshold ω in following sections.

4 Separability-Aware Model Selection

We propose Separability-Aware Model Selection to enable class-skew based optimizations by exploiting the visual separability. The key observation is that, the same model under different class skew profiles (CSP), even with the same number of classes, may have significantly different accuracy. Figure 4 illustrates two CSPs with different visual separability (*i.e.*,

Figure 4: Class Skews with Different Visual Separability.

one is easy to classify and the other one is hard). To exploit visual separability, Palleon maintains a set of models with different accuracy and energy consumption, and automatically switches to compact models for saving energy when the detected CSP is easy to classify. We are inspired by the fact that people will relax and spend less energy when objects have significantly different appearance, in contrast to distinguishing similar objects (*e.g.*, cat breeds). To this end, we propose an **Efficient Online Model Selection** (Section 4.1) to automatically select models with low resource consumption, and an **Edge-Cloud Duplicated Model Bank** (Section 4.2) to reduce model selection overhead and network overhead.

4.1 Efficient Online Model Selection

We conduct online model selection on the cloud when we detect class skew switches. There are two baseline strategies. One approach records an average accuracy for each model on all classes, and another approach records the accuracy of one model over all possible CSPs (*i.e.*, multiple accuracy for one model). Both approaches are unsatisfactory. On the former approach [27], the selected model may fail to satisfy the accuracy requirement during runtime since the same model may produce significantly different accuracy on different CSPs. On the latter approach [65], a prohibitive offline profiling overhead and online memory overhead may be introduced due to the huge number of CSPs.

By contrast, we propose a hybrid approach that selects models on the cloud for only class skews detected during runtime. During offline preparation, we profile a single accuracy for each model over all classes and store the model in the order of this accuracy. During online model selection, we use binary search to profile the CNN accuracy on the detected CSP. This binary search leads to logarithm time complexity, compared to the linear time complexity of enumerating all models. Behind the binary search, our key observation is that, while the model accuracy on each CSP may change dramatically, the relative accuracy order of models on all classes stays the same over various class skews. In particular, if one model performs better than another model on all classes, the former one generally performs still better than the latter model on various CSPs. Similar observations have also been made in computer vision area [30, 37] that larger models (*e.g.*, ResNet-50) usually give higher accuracy than smaller ones (*e.g.*, ResNet-18) on the same task. Figure 5 illustrates the online model selection. Suppose we have 5 models with decreasing energy consump-

	A	B	C	D	E
CSP I	97	91	87	84	81
CSP II	90	88	82	79	77

Figure 5: Example of Online Model Selection (Unit:%). Dashed boxes refer to un-profiled models due to binary search.

tion and recognition accuracy, and target 90% accuracy. For each CSP, we conduct binary search to find the most compact model with satisfactory accuracy (> 90%). In this case, we will select B for CSP I but A for CSP II.

Cache Service to Avoid Redundant Model Selection.

Palleon records the model selection results along with the CSP and skips model selection for a CSP that have appeared previously. In particular, Palleon maintains a cache service between the CSP and the selected model. When a new CSP comes, Palleon will first retrieve the CSP in the cache. On a cache hit, Palleon immediately returns the selected model. On a cache miss, Palleon conducts online profiling and records the selected model for reuse. In our evaluation, a high cache hit rate is achieved quickly after less than 5 model selections, since the same CSP appears frequently in real videos.

4.2 Edge-Cloud Duplicated Model Bank

Palleon’s goal of saving energy and improving accuracy is affected by the quality of its model bank. We design a duplicated model bank to store only Pareto-Optimal models and duplicate these models on both the edge and the cloud for reducing network overhead. For each candidate model, Palleon stores the computation graph, the pre-trained weights, and the metadata including energy consumption and latency.

Model Bank Generation with Offline Profiling. For each energy budget, we conduct offline profiling to identify candidate models with the highest accuracy. This offline profiling selects only models on the Pareto-optimal curve to reduce online search space and runtime overhead. Specifically, we first generate a large number of candidate models by applying compression techniques on CNNs. Then, we conduct offline profiling to select models on the Pareto-optimal curve [55], defined as the models that we cannot further reduce energy consumption without worsening the accuracy.

This candidate model generation is *conducted once on all classes*, instead of repeating on different CSPs, since good models on all classes tend to consistently produce good performance over various CSPs. The insight is that *unsalient positions remain similar for all CSPs*. For example, when we repeat a compression technique, Perforation [20], for several CSPs on Dense-40 [33], the positions in later blocks will be deleted first while the positions in the leading block remain unchanged until all later blocks have been pruned. More generally, even though the best model (*i.e.*, the one with the highest accuracy under a given reduction in energy consumption) might change between different CSPs, the set of *top-k best* models tends to remain stable over all CSPs. Thus, we can avoid repeating the selection on all CSPs and, under any

Table 1: Profiling on selected compact models. Latency and energy are measured on Jetson Nano.

Compressed From	Layer Remove Ratio (%)	Filter Remove Ratio (%)	Latency (ms)	Energy (J)
ResNet-50	20	10	65.6	0.63
DenseNet-40	30	10	48.4	0.46
MobileNet-128	30	30	34.5	0.35
MobileNet-128	30	40	20.6	0.18
VggNet-19	60	60	10.1	0.07

specific energy-saving requirement, use the best model for all classes to approximate the best model for a specific CSP.

Our full model is a DenseNet-40 with 40 layers. Starting from 4 base models (i.e., MobileNet-128, VGGNet-19, ResNet-50, DenseNet-40), we generate 25 compact models from each of these base models. In particular, we first remove {10%, 20%, 30%, 40%, 60%} of layers from the base model. For the remaining layers, we remove {10%, 20%, 30%, 40%, 60%} of filters. While more sophisticated compression techniques can be applied, we adopt this simple compression technique to validate the effectiveness of model selection. From these pruned models, we select N_{CW} (=5, by default) compact models and put them into our model bank for online use in our evaluation. We have experimented with several numbers and found that 5 compact models can provide a relatively diverse range of accuracy and resource consumption. We show the profiling data on raw latency and raw energy consumption in Table 1, measured on Jetson Nano [40]. For each frame, these models have inference latency from 10.1 ms to 65.6 ms and energy consumption from 0.07J to 0.63J. Here, all pruned models are retrained over all classes during offline model bank generation.

Edge/Cloud Duplication to Reduce Network Overhead.

We maintain a duplicated model bank on both the edge and the cloud to avoid weight transportation from the cloud to the edge. The duplicated model banks on the edge and the cloud contain the same deep models and pre-trained weights, while giving each model an index. During online model selection, the cloud will select a model from the duplicated model bank and only send the selected index to the edge. The edge uses the received index to identify the selected model. This design avoids the network overhead of frequently transporting model weights when class skew switches frequently.

4.3 System Overhead Analysis

Model Bank Memory Overhead. The model bank introduces negligible memory overhead compared to the simple setting with only large CNNs. In the simple setting, the memory consumption is

$$Mem_{Simple} = Mem_{LW} + Mem_{LF} \quad (11)$$

where Mem_{LW} and Mem_{LF} are the memory for storing weights and features of the large CNN, respectively. In our

setting with model bank, the memory consumption is

$$Mem_{Bank} = Mem_{LW} + \max(Mem_{LF}, Mem_{CF}) + N_{CW} \cdot Mem_{CW} \quad (12)$$

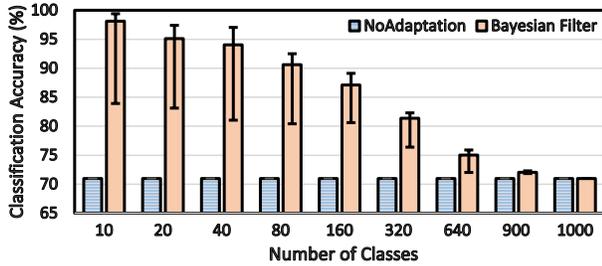

where N_{CW} is the number of compact models, Mem_{CW} and Mem_{CF} are the memory for storing weights and features of compact CNNs. We use $\max(\cdot, \cdot)$ on CNN features since each input frame is processed by only one CNN. Comparing Equation 11 and 12, the model bank only introduces overhead of $N_{CW} \cdot Mem_{CW}$, which is less than 5MB and is negligible compared to the GB-level memory in modern edge devices (GB) (e.g., 1GB in Raspberry Pi 3B+ [59] and 4GB in Jetson Nano [40]). In particular, we use a small N_{CW} (=5, by default), since Bayesian Filter can adapt compact models toward the detected CSPs during runtime with low overhead (Section 3). The Mem_{CW} is usually less than 1MB on compact models generated with compression techniques, especially when the base model also consumes negligible memory (e.g., 0.5MB in SqueezeNet [34] and 2MB in MobileNet [37]).

Runtime Overhead. Palleon’s runtime overhead comes from three sources. The first is the model selection overhead. While this overhead is relatively large, model selection is conducted on the cloud which is powerful and can evaluate several models concurrently. Also, we have sorted the models and proposed a binary search for accelerating the model selection. This procedure introduces negligible runtime overhead (<1%). The second is the data transfer overhead. Existing work usually transfers frames (around 100 KB per frame) to the cloud, which introduces heavy network overhead. Instead, we summarize the surrounding environment into the CSP (a short string within 1KB) and only need to transport the CSP from the edge to the cloud through a wireless network. This network overhead is low since we only transport CSP instead of data or CNN weights. Besides these two overhead from model selection, the third comes from class skew detection on the edge, which is negligible due to optimizations for low-overhead detection in Section 2.2.

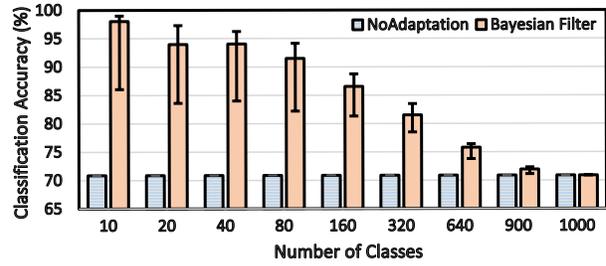

5 Evaluation

To show the effectiveness of Palleon, we perform extensive experiments on both synthesized videos and real videos. We first evaluate Palleon on **synthesized videos** (Section 5.1) to study the performance in diverse settings, including varying class numbers, class types, and lasting time of each class skew. We then conduct **real video experiments** (Section 5.2) to further validate the performance of Palleon for detecting and exploiting class skews during runtime.

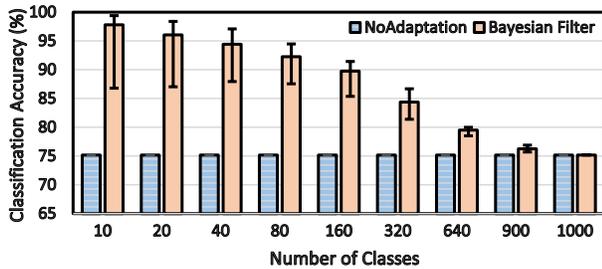

Experiment Platform. We have implemented Palleon in Tensorflow [1] for our CNNs. For the edge device, we use NVIDIA Jetson Nano [40] which is a popular mobile GPU platform with wide deployment in robotics [53], AI glasses [52], and doorbell cameras [51]. Jetson Nano runs Ubuntu 18.04 with built-in support for Tensorflow. For the cloud server, we use a Dell Workstation T7910 with an NVIDIA

All energy measurements mentioned are directly measured unless otherwise specified, using an Extech EX330 Compact Digital Multimeter [50].

5.1 Synthesized Video Experiments

In this section, we extensively evaluate Palleon on synthesized videos in diverse settings. We generate synthesized videos based on ImageNet dataset [18] with diverse class skews. The ImageNet dataset consists of 1,200,000 images categorized into 1,000 classes. We generate class skews with varying numbers of classes and diverse lasting time. These synthesized class skews create challenging scenarios and showcase the robustness of Palleon in challenging settings. We train CNNs on ImageNet with all classes and conduct offline profiling to generate a single accuracy over all classes and collect their latency/energy consumption on mobile devices (e.g., Jetson Nano). This offline profiling is conducted only once. During online, we use Bayesian Filter for online model adaptation and do not use online finetuning (*i.e.*, retraining CNNs on the detected CSPs). On dynamic class skews, we also have online profiling about the model accuracy on the detected CSP, which is conducted on the cloud and introduces negligible overhead.

5.1.1 Bayesian Filter on Fixed Class Skews

Figure 6 shows the accuracy improvement from Bayesian Filter in an ideal case that the true class skew is known and fixed. Under this setting, there is no detection delay and Bayesian Filter can adapt CNNs toward the true class skew. To show the generality of Bayesian Filter, we use four state-of-the-art CNNs as base models (*i.e.*, MobileNet [37], VGGNet [67],

ResNet [30], and DenseNet [33]). When synthesizing fixed class skews, for each $N \in \{10, 20, \dots, 1000\}$ classes, we generate 100 CSPs. Each CSP contains 1000N images by randomly selecting N classes and 1000 images from each class following a uniform distribution. For each number of classes, we run the adapted model and present the average, minimum, and maximum accuracy. We note that we use Bayesian Filter to adapt the model and do not use online finetuning.

Bayesian Filter provides on average 25% accuracy improvement when there are 10 classes. This accuracy improvement shows the effectiveness of Bayesian Filter in adapting models. As the number of classes increases, this accuracy improvement diminishes gradually until all 1,000 classes appear in the class skew (*i.e.*, no scenario information to exploit). The reason is that, as the number of classes increases, opportunities to rule out classes decreases. For example, Bayesian Filter rules out 990 classes when the CSP contains 10 (out of 1000) classes, but only rules out 100 classes when the CSP contains 900 (out of 1000) classes. Surprisingly, an accuracy improvement around 2% still exists when there are 900 classes in the class skew, considering that underlying models can only recognize 1,000 classes. This result shows that Bayesian Filter can consistently improve accuracy on challenging class skews with a large number of classes.

A large accuracy difference exists for each model and each number of classes, demonstrating the existence of visual separability. In particular, an accuracy difference of 15% can be observed for MobileNet when there are 10 classes. This accuracy difference becomes less significant as the number of classes increases, since a smaller number of classes indicates larger variation in the constituent classes. Comparing across models (*e.g.*, ResNet v.s. MobileNet), we see that a model tends to perform better than another model on a specific class

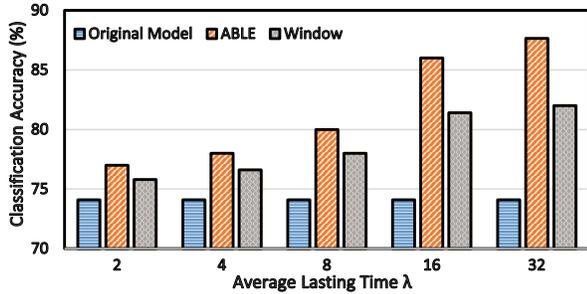

Figure 7: Accuracy with Various Detection Methods.

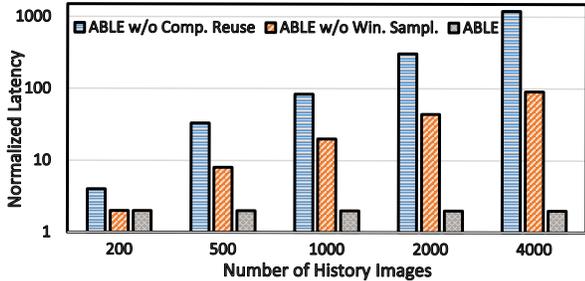

Figure 8: ABLE Latency relative to Window Detector.

skew, if the former model has higher accuracy on all classes than the latter model. This observation indicates that the relative order of model accuracy is invariant over various class skews and supports our binary profiling.

5.1.2 ABLE on Dynamic Class Skews

In this section, we show the accuracy improvement when the true class skew is unknown and may switch abruptly, namely *dynamic class skew*. Under this setting, the class skew detector decides the CSP quality and the detection delay, which has a significant impact on the classification accuracy of the adapted models. When synthesizing dynamic class skews, we randomly generate 30 CSPs. For each CSP, we first randomly select a small number (ranging from 10 to 20) of classes. Among all testing images from a given set of classes, a CSP uniformly samples $lastingTime = 60 * T$ images. T is a random variable following the Poisson(λ) distribution and $\lambda \in \{2, 4, 8, 16, 32\}$ controls the average number of images. We choose the Poisson distribution, as it outputs positive integers. We use DenseNet as the original model and elide the results on other CNNs due to the similar behavior.

Average Accuracy. Figure 7 shows the classification accuracy on dynamic class skews when combining Bayesian Filter with two class skew detectors (*i.e.*, Window and ABLE). In the Window detector, we sample a sequence of window sizes for each synthesized video and present the best accuracy for a strong baseline. Comparing across λ , we can see a clear trend that the classification accuracy increases as λ increases. In particular, “ABLE” can increase accuracy by 13.65% when the average lasting time λ reaches 32. This trend indicates that a class skew lasting longer provides more optimization opportunities to exploit. Comparing across detectors, we can see that ABLE achieves higher accuracy improvement around

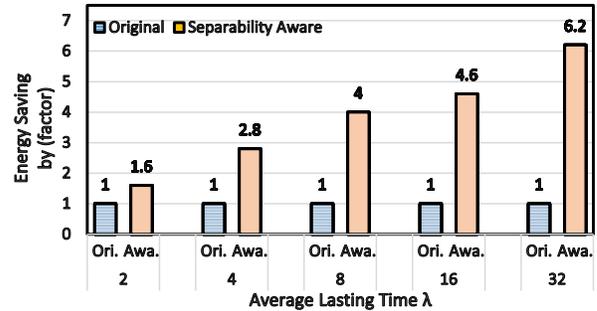

Figure 9: Energy Saving with Model Selection.

5% than the window-based detection. The reason is that the lasting time for a specific class skew varies even for a fixed average lasting time λ , such that a fixed window size can hardly hit the balance between CSP quality and detection delay.

ABLE Detection Latency. Figure 8 shows the ABLE detection latency reduction. This detection latency measures the computation overhead of incurring ABLE on an incoming CNN prediction. *Number of history images* is the total number of images in a synthesized video representing the video length, ranging from 200 to 4000 images. “ABLE” represents ABLE with both computation reuse and window sampling where $k = 30$ windows are sampled. “ABLE w/o Win. Sampl.” disables window sampling and “ABLE w/o Comp. Reuse” further disables computation reuse. “ABLE w/o Comp. Reuse” shows a quadratic increase in the latency over time, which becomes costly when the number of inputs increases gradually. By adding computation reuse, “ABLE w/o Win. Sampl.” decreases this quadratic time complexity to linear time complexity, leading to a much lower computation overhead. When adding window sampling, we can see that “ABLE” further reduces the linear time complexity to a constant complexity, which is similar to the Window detector.

5.1.3 Separability-Aware Model Selection

In this section, we show the energy-saving, runtime speedup, and the memory overhead from Separability-Aware Model Selection. To study the impact of lasting time, we adopt the same setting as dynamic class skew (Section 5.1.2). In each dynamic class skew, we randomly generate 30 class skews and report the average energy saving and runtime speedup.

Energy Saving. Figure 9 shows energy saving when targeting the same accuracy as the baseline model. Palleon can save energy consumption up to $6.2 \times$ while maintaining the accuracy. This benefit comes from automatically replacing the original large model with small models by separability-aware model selection. In addition, we can observe that the energy saving increases as lasting time increases, since a longer lasting time indicates less class skew switches and less system overhead for detecting and exploiting new class skews.

Runtime Speedup. Figure 10 shows the overall runtime speedup when targeting the same accuracy as the baseline model. Palleon can achieve up to $5.48 \times$ speedup, consider-

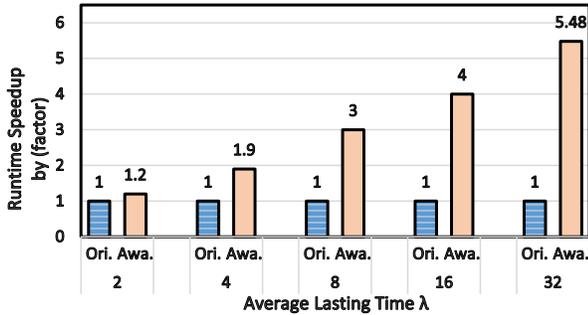

Figure 10: Runtime Speedup with Model Selection.

ing both the model execution speed and the system latency, including the model adaptation latency, the model selection latency on the cloud, and the network latency. Note that the model selection on cloud only introduces latency and has no impact on the energy consumption on the edge device. Similar to the observation in energy saving, we can observe an increase in runtime speedup as the lasting time increases, due to the reduced system overhead.

Memory and data transfer overhead. We observe negligible memory overhead in our current system with 5 compact models. In particular, these compact models usually consume less than 1MB memory and Jetson Nano has 4GB memory. On the data transfer overhead, we only transfer a short CSP (within 1KB) to the cloud when ABLE detects class skew switches. This is significantly smaller than alternative system designs that transfer frames (around 100 KB per frame) or CNN weights with the cloud.

5.2 Real Video Experiments

We evaluate Palleon on real videos to show the end-to-end accuracy improvement, runtime speedup, and energy saving, including the overhead from model adaptation and class skew detection. We compare Palleon with a state-of-the-art energy-efficient video processing system, FAST [65]. FAST approach studies the benefit of class skews in an ideal case, assuming that all class skews that may appear at runtime are known offline. In particular, FAST adapts a large number of compact CNNs towards each class skew during offline preparation and identifies these foreknown class skews with a window detector. As such, we denote it as FAST (offline). For a fair comparison of our online framework, we further extend FAST (offline) to an online version, namely FAST (online). The only difference between these two versions is that FAST (online) does not have the pre-trained CNN models for different class skews. Instead, it adopts a standard retraining method [68], which retrains the last few CNN layers toward the online detected class skews, for online model adaptation. To strike a good balance between accuracy and performance, we manually tune the number of layers for retraining and find that two is a good number and use it in our experiments. Different from FAST, we do not foreknow the class skews offline. We conduct online class skew detection with ABLE, online model adaptation with Bayesian Filter, and online model selection.

Table 2: Real videos for evaluating Palleon. “#Switch” indicates the number of class skew switches and “#Class” shows the average number of classes in each class skew.

Video Name	Len. (min)	#Switch	#Class
Friends	24	45	2.8
Good Will Hunting	14	4	3.5
The Departed	9	8	2.4
Ocean’s Eleven / Twelve	6	25	2.0

Real Video Datasets. We evaluate Palleon and FAST on four real videos [65] depicted in Table 2. These videos come from several movies for face recognition and have diverse length ranging from 6 minutes to 24 minutes. “#Switch” indicates the number of class skew switches in each video and “#Class” represents the average number of classes (faces) in each class skew between adjacent class skew switches. For example, “Friends” is a 24-minute video with 45 class skew switches and each class skew contains 2.8 classes on average. While the total number of classes in these real videos is large (> 20), each class skew contains only a small portion of classes (2 to 3.5). This is a common case in films and Youtube videos, as we have discussed in introduction. The lasting time for each class skew varies on videos from 10 seconds to 4 minutes (about 1.3 minutes on average), computed by “Len.(min) / #Switch”. This diversity makes it a challenging setting to detect and exploit class skews during runtime.

During the detection of faces, we follow the standard two-phase pipeline in object detection [23, 24, 60] and face recognition [6]. We first use a Viola Jones detector [70] to locate faces in video frames, which is agnostic to class skews. Then we crop faces and feed into CNNs for face recognition [57]. Note that this procedure can be easily applied to other object detection tasks by retraining the face recognition CNNs.

Base Model for Real Video Datasets. For a fair comparison with FAST, we choose the state-of-the-art deep model, VGGFace [57], as our full model for face recognition. We generate 5 compact models with diverse resource consumption and accuracy, following the model bank generation in Section 4.2. We use the same compact models for FAST. We train these models from scratch following the hyper-parameter setting in FAST, and achieve comparable accuracy as reported. This offline training is conducted once on LFW dataset. During online, we use Bayesian Filter for model adaptation and do not use online finetuning.

Accuracy Improvement. Figure 11 shows the overall classification accuracy on real videos of the most compact VGGFace model, FAST (offline), and our online approach. We skip the accuracy of FAST (online) since it consistently provides lower accuracy than the Fast (offline) by around 1%, since we retrain only the last two layers in Fast (online) to hit a good balance between accuracy and performance. Palleon provides 6.2% accuracy improvement on average, compared

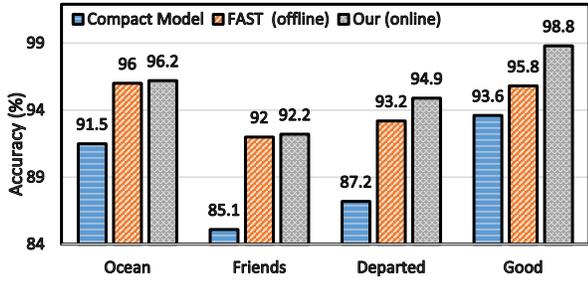

Figure 11: Accuracy Improvement on Various Videos.

to utilizing the compact model without adaptation. This accuracy improvement comes from Bayesian Filter that dynamically adapts models to class skews detected in real videos, containing only 2 to 4 people on average ('#Class' in Table 2). This reduced number of faces greatly eases the task compared to recognizing thousands of faces in un-adapted models.

Comparing to FAST (offline) relying on offline adapted models, Palleon provides 1.3% accuracy improvement due to the faster class skew switch detection in ABLE. When a class skew switches, Window detector in FAST (offline) leads to a detection delay up to 10 seconds, during which the accuracy suffers from a dramatic drop. Moreover, ABLE can effectively detect 98% class skew switches while Window detector can only detect 86% class skew switches, since Window detector fails to detect class skews that exist for only a few seconds.

Runtime Speedup. Figure 12 shows the end-to-end runtime speedup on real videos when targeting the same accuracy as the full model. Palleon achieves on average $5.43\times$ speedup (up to $7.9\times$ speedup on Good) compared to the full model. This speedup comes from automated model selection by replacing the full model with a compact model. When both assuming that the class skews are not foreknown and adapting models at runtime, Palleon achieves $26.9\times$ speedup over the FAST (online) approach. Indeed, FAST (online) shows a $5\times$ slow down due to heavy overhead from online model adaptation. This comparison demonstrates the efficiency of Palleon in online class skew detection and online model adaptation. For FAST (offline) with strong assumption that true class skews are foreknown and models are adapted during offline preparation, Palleon can still achieve a higher speedup, due to the early optimization strategy in ABLE. Comparing across videos, the speedup becomes more significant when class skews have longer lasting time (Good Will Hunting), showing the same pattern as evaluations on synthesized videos (Section 5.1.3). We note that Palleon takes 14.2 ms latency on average to process one frame, which is significantly faster than the real-time requirement of 30 ms per frame.

We also observe negligible overhead from model switches ($<1\%$) due to several reasons. First, the number of model switches is much smaller than the number of class skew switches, since class skew switches can usually be handled by the Bayesian Filter without model switches. In particular, only 20% class skew switches lead to model switches. Second, the

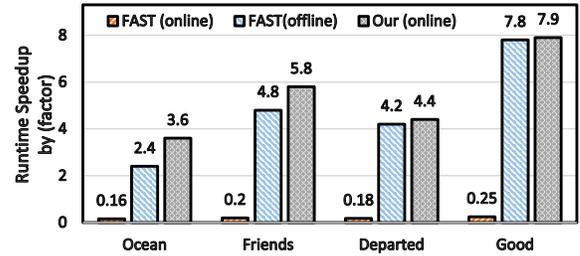

Figure 12: Runtime Speedup on Various Videos.

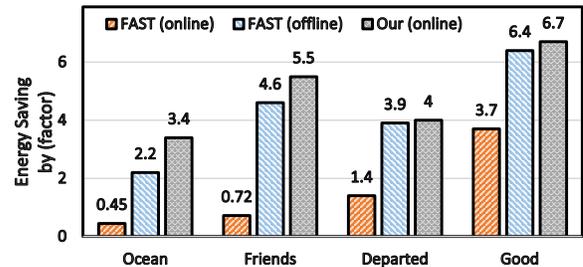

Figure 13: Energy Saving on Various Videos.

model selection is conducted on the cloud and we cache all models in the memory to avoid the repeatedly loading models, which introduces negligible memory overhead.

Energy Saving. Figure 13 shows the end-to-end energy saving on real videos when targeting the same accuracy as the full model. Palleon achieves on average $4.9\times$ energy saving (up to $6.7\times$ on Good) compared to the full model. Palleon achieves a higher energy saving compared to "FAST (offline)" (*i.e.*, without counting the energy consumption in retraining) due to the early optimization strategy in ABLE. FAST (online) conducts model adaptation on the cloud and transfers the adapted model weights (in megabytes) to the edge through the network, leading to extra energy consumption from network communication. This network overhead becomes intensive when class skew switches frequently (Ocean and Friends), leading to more energy consumption in FAST (online) compared to the full model. This overhead reduces when class skews have longer lasting time (Departed and Good), leading to energy saving. By contrast, Palleon shows a consistent benefit on all four videos due to Palleon's low overhead.

Workload Distribution over Models. We observe that most frames are processed by the most compact model. For example, on "Friends" dataset, the most compact model processes 85% frames. While workload distribution varies for different CSPs, we observe similar trends across datasets. The reason is that CSPs usually only contain a few classes (Table 2) and the most compact model with Bayesian Filter can provide high accuracy.

6 Discussion

Comparison with alternative design that trains a model for each CSP. One alternative design to exploit class skews is to train many small models to recognize only a small set of

classes for individual class skews. This alternative design has two intrinsic drawbacks. First, we usually do not foreknow the class skew in an online video such that we can hardly train compact models for each class skew offline. Second, even if we assume that all class skews are foreknown (as the case in FAST), we may need to train a large number of models due to the large number of class skews. By contrast, Palleon does not assume that class skews are foreknown and trains the model on all classes offline. During online video analytics, we use ABLE to conduct online class skew detection, Bayesian Filter for efficient online model adaptation, and separability-aware model selection to automatically select CNNs for balancing the accuracy and resource efficiency.

Generality to other CNNs. Palleon can accelerate a large number of workloads on mobile devices with the temporal locality that a small number of classes keep appearing in a large number of consecutive frames. We have shown the performance benefits of Palleon on object classification and face recognition. Palleon can be generalized to 2D object detection [15] and 3D point cloud analytics [29] which share a similar pipeline as face recognition. We also note that Palleon can benefit from more compact models and pruning techniques designed for mobile systems. In particular, these compact models can be incorporated during model bank generation to provide Pareto-optimal boundary with reduced resource consumption and equivalent accuracy.

7 Related Work

Model Compression. Model compression has been widely explored for accelerating video processing. The popular compression techniques include resolution reduction [21, 37, 45, 58], matrix factorization [38, 61, 77], matrix pruning [14, 28], and distillation [8, 11, 13, 47]. Model compression is orthogonal to our work in exploiting class skews and usually leads to accuracy drop. By contrast, Palleon exploits class skews in video streams and maintains accuracy while reducing energy consumption and processing latency. Meanwhile, Palleon can integrate these compression techniques into our Separability-Aware Model Selection for generating compact models.

Video Processing with Low-Level Temporal Information. Using low-level temporal information can improve accuracy or reduce energy consumption. From the perspective of system design, existing work exploits low-level temporal information by caching processing results of the most recent frames for future computation reuse [26, 74] or adjusting sampling rate [41, 79]. From the perspective of algorithm design, existing work often augments the traditional 2D-CNN with optical flow [66, 71, 72] for explicitly capturing object motions across frames. A new CNN design, 3D-CNNs [12, 22, 69], has also been proposed to implicitly learn object motions by stacking several 2D-CNNs and processing adjacent video frames in a combined way. These works are orthogonal to our work because we focus on exploiting high-level temporal information across minutes, not on low-level temporal infor-

mation in a few seconds. Palleon could be integrated with one of these approaches for further performance improvement.

Video Processing with High-Level Temporal Information. Several video processing systems [27, 32, 43, 65, 73, 75] have been proposed to exploit high-level temporal information across minutes, in terms of scenario information. Several early work [27, 32, 43, 75] simplifies processing tasks by targeting a specific scenario and only recognizing a specific object, *e.g.*, buses at a crosswalk. Recent work [65] conducts offline-profiling over a few scenarios and only reduces energy consumption when these offline-profiled scenarios appear, which would be in-effective for more realistic settings that class skews may switch during runtime. By contrast, Palleon abstracts these specific scenarios to a more general class skew of unbalanced distributions and enables online class skew detection and online model adaptation.

8 Conclusion

Efficient video processing on mobile platforms is an important workload. We present Palleon, a runtime system for efficient video processing, by detecting and exploiting class skews in video streams. We propose ABLE to detect class skews in video streams. Based on these detected class skews, Palleon uses Bayesian Filter for online model adaptation and Separability-Aware Model Selection to select the most energy-efficient model during runtime. Evaluations on both synthesized videos and real videos demonstrate that Palleon achieves up to $6.7\times$ energy saving and up to $7.9\times$ latency reduction. We conclude that Palleon is a highly practical and effective approach for efficiently processing video streams.

Abstract

Serverless computing, or Function-as-a-Service (FaaS), enables a new way of building and scaling applications by allowing users to deploy fine-grained functions while providing fully-managed resource provisioning and auto-scaling. Custom FaaS container support is gaining traction as it enables better control over OSes, versioning, and tooling for modernizing FaaS applications. However, providing rapid container provisioning introduces non-trivial challenges for FaaS providers, since container provisioning is costly, and real-world FaaS workloads exhibit highly dynamic patterns.

In this paper, we design FAASNET, a highly-scalable middleware system for accelerating FaaS container provisioning. FAASNET is driven by the workload and infrastructure requirements of the FaaS platform at one of the world's largest cloud providers, Alibaba Cloud Function Compute. FAASNET enables scalable container provisioning via a lightweight, adaptive function tree (FT) structure. FAASNET uses an I/O efficient, on-demand fetching mechanism to further reduce provisioning costs at scale. We implement and integrate FAASNET in Alibaba Cloud Function Compute. Evaluation results show that FAASNET: (1) finishes provisioning 2,500 function containers on 1,000 virtual machines in 8.3 seconds, (2) scales 13.4× and 16.3× faster than Alibaba Cloud's current FaaS platform and a state-of-the-art P2P container registry (Kraken), respectively, and (3) sustains a bursty workload using 75.2% less time than an optimized baseline.

1 Introduction

In recent years, a new cloud computing model called serverless computing or Function-as-a-Service (FaaS) [40] has emerged. Serverless computing enables a new way of building and scaling applications and services by allowing developers to break traditionally monolithic server-based applications into finer-grained cloud functions. Developers write function logic while the service provider performs the notoriously tedious tasks of provisioning, scaling, and managing the backend servers [36] that the functions run on.

Serverless computing solutions are growing in popularity and finding their way into both commercial clouds (e.g., AWS Lambda [5], Azure Functions [7], Google Cloud Functions [12] and Alibaba Cloud Function Compute¹ [2], etc.) and open source projects (e.g., OpenWhisk [54], Knative [15]). While serverless platforms such as AWS Lambda

and Google Cloud Functions support functions packaged as .zip archives [8], this deployment method poses constraints for FaaS applications with a lack of flexibility. One constraint is a maximum package size limit (of up to 250 MB uncompressed for AWS Lambda functions).

A recent trend is the support of packaging and deploying cloud functions using custom container images [3, 13, 19, 20]. This approach is desirable as it greatly enhances usability, portability, and tooling support: (1) Allowing cloud functions to be deployed as custom container runtimes enables many interesting application scenarios [4], which heavily rely on large dependencies such as machine learning [23, 47], data analytics [31, 32, 58], and video processing [26, 35]; this would not have been possible with limited function package sizes. (2) Container tooling (e.g., Docker [9]) simplifies the software development and testing procedures; therefore, developers who are familiar with container tools can easily build and deploy FaaS applications using the same approach. (3) This approach will enable new DevOps features such as incremental update (similar to rolling update in Kubernetes [18]) for FaaS application development.

A potential benefit that makes the FaaS model appealing is the fundamental resource elasticity—ideally, a FaaS platform must allow a user application to scale up to tens of thousands of cloud functions on demand, in seconds, with no advance notice. However, providing rapid container provisioning for custom-container-based FaaS infrastructure introduces non-trivial challenges.

First, FaaS workloads exhibit highly dynamic, bursty patterns [50]. To verify this, we analyzed a FaaS workload from a production serverless computing platform managed by one of the world's largest cloud providers, *Alibaba Cloud*. We observe that a single application's function request throughput (in terms of concurrent invocation requests per second or RPS) can spike up to more than a thousand RPS with a peak-to-trough ratio of more than 500× (§2.2.1). A FaaS platform typically launches many virtualized environments—in our case at Function Compute, virtual machines (VMs) that host and isolate containerized functions—on demand to serve request surges [5, 24, 56]. The bursty workload will create a network bandwidth bottleneck when hundreds of VMs that host the cloud functions are pulling the same container images from the backing store (a container registry or an object store). As a result, the high cost of the container startup process²

¹We call Function Compute throughout the paper.

²A container startup process typically includes downloading the container

makes it extremely difficult for FaaS providers to deliver the promise of high elasticity.

Second, custom container images are large in sizes. For example, more than 10% of the containers in Docker Hub are larger than 1.3 GB [60]. Pulling large container images from the backing store would incur significant cold startup latency, which can be up to several minutes (§2.2.2) if the backing store is under high contention.

Existing solutions cannot be directly applied to our FaaS platform. Solutions such as Kraken [16], DADI [42], and Dragonfly [10] use peer-to-peer (P2P) approaches to accelerate container provisioning at scale; however, they require one or multiple dedicated, powerful servers serving as root nodes for data seeding, metadata management, and coordination. Directly applying these P2P-based approaches to our existing FaaS infrastructure is not an ideal solution due to the following reasons. (1) It would require extra, dedicated, centralized components, thus increasing the total cost of ownership (TCO) for the provider while introducing a performance bottleneck. (2) Our FaaS infrastructure uses a dynamic pool of resource-constrained VMs to host containerized cloud functions for strong isolation; a host VM may join and leave the pool at any time. This dynamicity requires a highly adaptive solution, which existing solutions fail to support.

To address these challenges, we present FAASNET, a lightweight and adaptive middleware system for accelerating serverless container provisioning. FAASNET enables high scalability by decentralizing the container provisioning process across host VMs that are organized in function-based tree structures. A *function tree* (FT) is a logical, tree-based network overlay. A FT consists of multiple host VMs and allows provisioning of container runtimes or code packages to be decentralized across all VMs in a scalable manner. FAASNET enables high adaptivity via a tree balancing algorithm that dynamically adapts the FT topology in order to accommodate VM joining and leaving.

Note that the design of FAASNET is driven by the specific workload and infrastructure requirements of Alibaba Cloud Function Compute. For example, Function Compute uses containers inside VMs to provide strong tenant-level isolation. A typical FaaS VM pool has thousands of small VM instances. The scale of the FaaS VM pool and the unique characteristics of FaaS workloads determine that: (1) a centralized container storage would not scale; and (2) existing container distribution techniques may not work well in our environment as they have different assumptions on both workload types and underlying cluster resource configurations.

We make the following contributions in this paper.

- We present the design of a FaaS-optimized, custom container provisioning middleware system called FAASNET. At FAASNET’s core is an adaptive function tree abstraction that avoids central bottlenecks.

image manifest and layer data, extracting layers, and starting the container runtime; in our paper we call the startup process *container provisioning*.

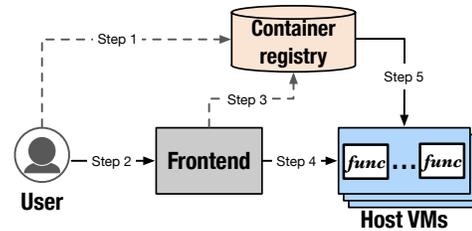

Figure 1: Overview of Alibaba Cloud’s FaaS container workflows.

- We implement and integrate FAASNET in Alibaba Cloud Function Compute. FAASNET is, to the best of our knowledge, the first FaaS container provisioning system from a cloud provider with published technical details.
- We deploy FAASNET in Alibaba Cloud Function Compute and evaluate FAASNET extensively using both production workloads and microbenchmarks. Experimental results show that FAASNET: finishes provisioning 2,500 function containers within 8.3 seconds (only $1.6\times$ longer than that of provisioning a single container), scales $13.4\times$ and $16.3\times$ faster than Alibaba Cloud’s current FaaS platform and a state-of-the-art P2P registry (Kraken), respectively, and sustains a bursty workload using 75.2% less time than an optimized baseline.
- We release FAASNET’s FT and an anonymized dataset containing production FaaS cold start traces at <https://github.com/mason-leap-lab/FaaSNet>.

2 Background and Motivation

In this section, we first provide an overview of the FaaS container workflows in Alibaba Cloud Function Compute. We then present a motivational study on the FaaS workloads to highlight the bursty patterns and their demands of a scalable and elastic FaaS container runtime provisioning system.

2.1 FaaS Container Workflows in Alibaba Cloud Function Compute

Function Compute allows users to build and deploy FaaS applications using custom container images and container tools. Figure 1 shows a typical workflow of function deployment and invocation. To deploy (or update) a containerized function, a user sends a `create/update` request in order to push the container image to a centralized container registry (Step 1 in Figure 1). To invoke a deployed function, the user sends `invoke` requests to the frontend gateway (Step 2), which checks the user’s request and the status of the container image in the registry (Step 3). The frontend then forwards the requests to the backend FaaS VM cluster for servicing the requests (Step 4). Finally, host VMs create function containers and pull their container data from the registry (Step 5). After all the previous steps are successfully completed, host VMs become ready and start serving the invocation requests.

2.2 Workload Analysis

Step 5 in Figure 1, container runtime provisioning, must be fast and scalable in order to enable high elasticity for

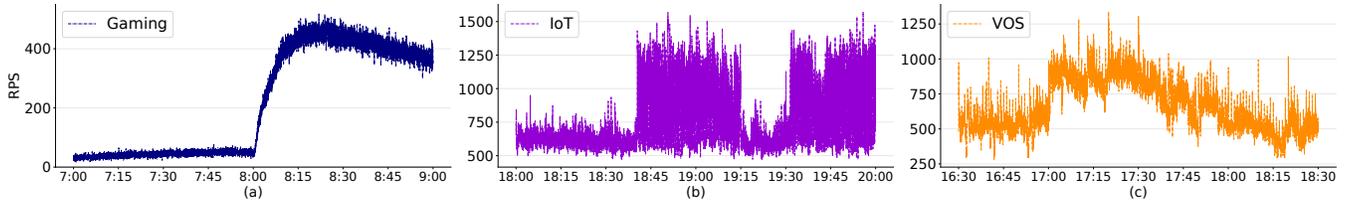

Figure 2: 2-hour throughput timelines of example FaaS applications.

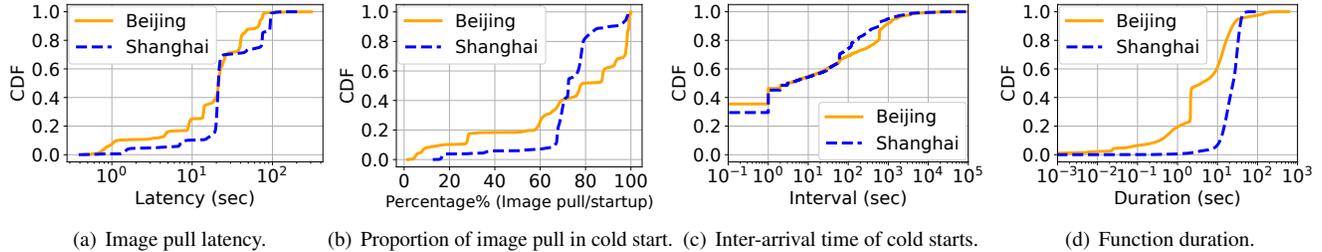

Figure 3: Performance characteristics of container image pulls (a, b) and function invocations (c, d) in CDF.

FaaS workloads. To obtain a better understanding of the workload requirements, we analyze the workload traces that were collected from Function Compute.

2.2.1 Workload Burstiness

FaaS providers charge users using a fine-grained, pay-per-use pricing model—they bill on a per invocation basis (e.g., \$0.02 per 1 million invocations for AWS Lambda) and charge the CPU and memory bundle resource usage at the millisecond level. This property is attractive to a broad class of applications that exhibit highly fluctuating and sometimes unpredictable loads; compared to traditional VM-based deployment approach that charges even when the VM resources are idle, FaaS is more cost-effective as tenants do not pay when the load is zero. Therefore, we analyzed the workload traces and verified that bursty behaviors are indeed common. Figure 2 reports the behaviors of three representative FaaS applications: gaming, IoT, and VOS (video processing).

Figure 2(a) shows that a request spike shoots from 22 to 485 RPS with a peak-to-trough ratio of $22\times$. As well as being bursty, IoT and VOS show different patterns. As shown in Figure 2(b), IoT exhibit a sustained throughput of around 682 RPS, but the throughput suddenly increased to more than 1460 RPS; the peak throughput lasts for about 40 minutes and the second peak starts 15 minutes after the first peak ends. Whereas for VOS (Figure 2(c)), for the first 30 minutes, it observes an average throughput of 580 RPS with a maximum (minimum) throughput of 982 (380) RPS; the average throughput increases to 920 RPS at 30 minutes, and gradually reduces back to an average of 560 RPS.

Implication 1: *Such dynamic behaviors require scalable and resilient provisioning of large numbers of function containers to rapidly smooth out the latency spikes that a FaaS application may experience during a request burst.*

2.2.2 Cold Start Costs of Containerized Functions

Next, we focus on cold start costs of containerized functions. A cold start, in our context, refers to the first-ever invocation of a custom-container-based function; a cold start latency is typically long, ranging from a few seconds to a few minutes as it requires the FaaS provider to fetch the image data and start the container runtime before executing the function. As noted in prior work [25, 48, 50, 56], the high cold start penalty is a notorious roadblock to FaaS providers as it hurts elasticity. The cold start issue is exacerbated when custom container feature with sizeable dependencies is supported.

We analyzed the container downloading costs in two FaaS regions, *Beijing* and *Shanghai*, managed by Function Compute. We retrieved a 15-day log, which recorded the statistics of the function container registry and reported the performance characteristics of 712,295 cold start operations for containerized functions. As shown in Figure 3(a), for *Beijing*, about 57% of the image pulls see a latency longer than 45 seconds, while for *Shanghai* more than 86% of the image pulls take at least 80 seconds.

We next examined the proportion of time spent on image pull with respect to the total function cold start latency. Figure 3(b) shows that more than 50% and 60% of function invocation requests spend at least 80% and 72% of the overall function startup time on pulling container images, for *Beijing* and *Shanghai* respectively. This indicates that the cost of image pull dominates most functions' cold start costs.

To put the cold start costs into perspective, we further inspected cold starts' inter-arrival time and function duration. Figure 3(c) plots the interval distribution of consecutive cold start requests. In both of the two regions, about 49% of function cold starts have an inter-arrival time less than 1 second, implying a high frequency of cold start requests. As shown in Figure 3(d), about 80% of the function executions in *Beijing* region are longer than 1 second; in *Shanghai* region, about

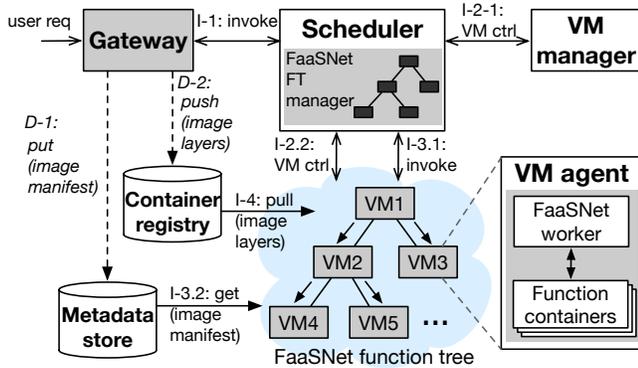

Figure 4: FAASNET architecture. Our work is in the gray boxes. Function invocation requests (solid arrow: invoke, VM ctrl, get(image manifest), and pull(image layers)) are online operations. FAASNET minimizes the operation of I-4: pull(image layers) and efficiently decentralizes container provisioning (i.e., image load and container start) across VMs. Function deployment requests (dashed arrow, italic font: *D-1: put(image manifest)* and *D-2: push(image layers)*) are offline operations.

80% of the function duration is less than 32.5 seconds, with a 90th percentile of 36.6 seconds and a 99th percentile of 45.6 seconds. This distribution indicates that cold start costs are of the same magnitude as the function duration, stressing a need for optimizing container startups.

Implication 2: *Optimizing the performance of container provisioning will provide a huge benefit on reducing the cold start costs of container-based cloud functions.*

3 FAASNET Design

3.1 Design Overview

This section provides a high-level overview of FAASNET’s architecture. Figure 4 illustrates the architecture of the FaaS platform running FAASNET. FAASNET decentralizes and parallelizes container provisioning³ across VMs. FAASNET introduces an abstraction called *function trees (FTs)* to enable efficient container provisioning at scale. FAASNET integrates a *FT manager* component and a *worker* component into our existing FaaS scheduler and VM agent for coordinated FT management. Next, we describe the main components in our FaaS platform.

A *gateway* is responsible for (1) tenant identity access management (IAM) authentication, (2) forwarding the function invocation requests to the FaaS scheduler, and (3) converting regular container images to the I/O efficient data format.

A *scheduler* is responsible for serving function invocation requests. We integrate a FAASNET *FT manager* into the scheduler to manage *function trees* (§3.2), or *FTs* for short, through *FT’s insert* and *delete* APIs. A *FT* is a binary tree overlay that connects multiple host VMs to form a fast and

³While this paper mainly focuses on container runtime provisioning, FAASNET supports provisioning of both containers and code packages.

scalable container provisioning network. Each VM runs a FaaS VM agent, which is responsible for VM-local function management. We integrate a FAASNET *worker* into the VM agent for container provisioning tasks.

On the function invocation path, the scheduler first communicates with a *VM manager* to scale out the the active VM pool from a free VM pool, if there are not enough VMs or all VMs that hold an instance of the requested function are busy. The scheduler then queries its local FT metadata and sends RPC requests to FAASNET workers of the FT to start the container provisioning process (§3.3). The container runtime provisioning process is effectively decentralized and parallelized across all VMs in a FT that do not yet have a container runtime locally provisioned. The scheduler sits off the critical path while FAASNET workers fetch function container layers on demand and creates the container runtime (§3.5) from the assigned peer VMs in parallel.

As described in §2.1, on the function deployment path, the gateway converts a function’s regular container image into an *I/O efficient* format (§3.5) by pulling the regular image from a tenant-facing container registry, compresses the image layers block-by-block, creates a metadata file (an image manifest) that contains the format-related information, and writes the converted layers and its associated manifest to an Alibaba Cloud-internal container registry and a metadata store, respectively.

3.2 Function Trees

We make the following design choices when designing FTs. (1) A function has a separate FT; that is, FAASNET manages FTs at function granularity. (2) FTs have decoupled data plane and control plane; that is, each VM worker in a FT has equivalent, simple role of container provisioning (data plane), and the global tree management (control plane) to the scheduler (§3.3). (3) FAASNET adopts a balanced binary tree structure that can dynamically adapt to workloads.

These design choices are well aligned with Alibaba Cloud’s existing FaaS infrastructure and are attuned to achieve three goals: (1) minimizes the I/O load of container image and layer data downloading on backing container registry, (2) eliminates the tree management bottleneck and data seeding bottleneck of a central root node, and (3) adapts when VMs join and leave dynamically.

Managing Trees at Function Granularity. FAASNET manages a separate, unique tree for each function that has been invoked at least once and has not been reclaimed. Figure 5 illustrates the topology of a three-level FT that spans five host VMs. Function container images are streamed from the root VM of the tree downwards until reaching the leaf nodes.

Balanced Binary Trees. At FAASNET’s core is a balanced binary tree. In a binary tree, except for the root node and leaf nodes, each tree node (in our case a host VM)⁴ has one incoming edge and two outgoing edges. This design can

⁴We use “node”/“VM” interchangeably when describing tree operations.

effectively limit the number of concurrent downloading operations per VM to avoid a network contention. A balanced binary tree with N nodes has a height of $\lfloor \log(N) \rfloor$. This is desirable as a balanced binary tree guarantees that the image and layer data of a function container would traverse at most $\lfloor \log(N) \rfloor$ hops from the top to the bottom. This is critical as the height of a FT would affect the efficiency of data propagation. Furthermore, the structure of a balanced binary tree can dynamically change in order to accommodate the dynamicity of the workloads. To this end, FAASNET organizes each FT as a balanced binary tree. The *FT manager* (Figure 4) calls two APIs, *insert* and *delete*, to dynamically grow or shrink a FT.

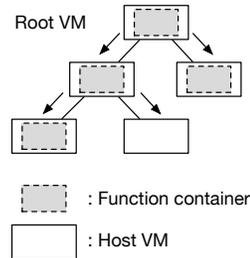

Figure 5: An example FAASNET FT.

insert: The very first node of a FT is inserted as a root node. The FT manager tracks the number of child nodes that each tree node has via BFS (breadth-first search) and stores all nodes that has 0 or 1 child in a queue. To insert a new node, the FT manager picks the first node from the queue as the parent of the new node.

delete: The scheduler may reclaim a VM that has been idling for a period of time (15-minute in Alibaba Cloud configuration). Thus, FaaS VMs have a limited lifespan. To accommodate VM leaving caused by reclamation, the FT manager calls *delete* to delete a reclaimed VM. The *delete* operation rebalances the structure of FT if needed. Different from a binary search tree such as an AVL-tree or a red-black tree, nodes in a FT do not have a comparable key (and its associated value). Therefore, our tree-balancing algorithm only needs to hold one invariant—a balancing operation is triggered only if the height difference between any node’s left and right subtree is larger than 1. The FT implements four methods to handle all imbalance situations—*left_rotate*, *right_rotate*, *left_right_rotate*, and *right_left_rotate*. Due to the space limit, we omit the details of the tree balancing algorithms. Figure 6 and Figure 7 show the process of *right_rotate* and *right_left_rotate* operations, respectively.

3.3 Function Tree Integration

In this section, we describe how we integrate the FT scheme into Alibaba Cloud’s FaaS platform. The integration spans two components of our existing FaaS platform, the scheduler and the VM agent. Specifically, we integrate FAASNET’s FT manager into Alibaba Cloud’s FaaS scheduler and FAASNET’s VM worker into Alibaba Cloud’s FaaS VM agent, respectively (Figure 4). The scheduler manages VMs of a FT via the FT manager. The scheduler starts a FAASNET worker on each VM agent. A FAASNET worker is responsible for (1) serving scheduler’s commands to perform tasks of image

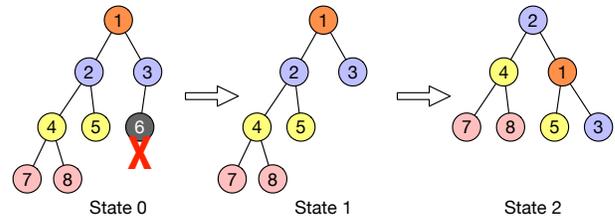

Figure 6: An example *right_rotate* operation. The FT manager detects that Node 6 was reclaimed and calls *delete* to remove it. Removal of Node 6 causes an imbalance, which triggers a *right_rotate* rebalancing operation. The FT manager then performs right rotation by marking Node 2 as the new root and marking Node 5 as Node 1’s left subtree.

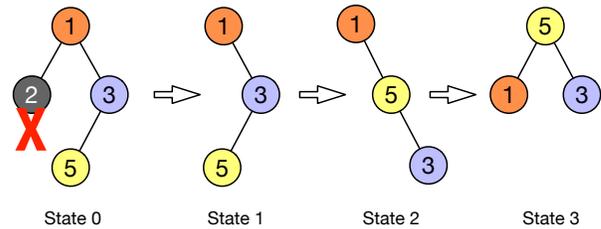

Figure 7: An example *right_left_rotate* operation. FT manager detects that Node 2 gets reclaimed and calls *delete* to remove it. Removal of Node 2 triggers a rebalancing operation. FT manager first right-rotates the right subtree of Node 1 by marking Node 5 as the parent of Node 3. FT manager then performs a *left_rotate* by marking Node 5 as the root.

downloading and container provisioning, and (2) managing the VM’s function containers.

FT Metadata Management. The scheduler maintains an in-memory mapping table that records the $\langle functionID, FT \rangle$ key-value pairs, which map a function ID to its associated FT data structure. A FT data structure manages a set of in-memory objects representing functions and VMs to keep track of information such as a VM’s *address:port*. The scheduler is sharded and is highly available. Each scheduler shard periodically synchronizes its in-memory metadata state with a distributed metadata server that runs *etcd* [11].

Function Placement on VMs. For efficiency, FAASNET allows one VM to hold multiple functions that belong to the same user. Function Compute uses a binpacking heuristic that assigns as many functions as possible in one VM host as long as the VM has enough memory to host the functions. As such, a VM may be involved in the topologies of multiple overlapping FTs. Figure 8 shows an example of a possible FT placement. In order to avoid network bottlenecks, FAASNET limit the number of functions that can be placed on a VM—in our deployment we set this limit to 20. We discuss a proposal of the FT-aware placement in §5.

Container Provisioning Protocol. We design a protocol to coordinate the RPC communications between the scheduler and FAASNET VM workers and facilitate container provisioning (Figure 9). On an invocation request, if the scheduler detects that there are not enough active VMs to serve the request

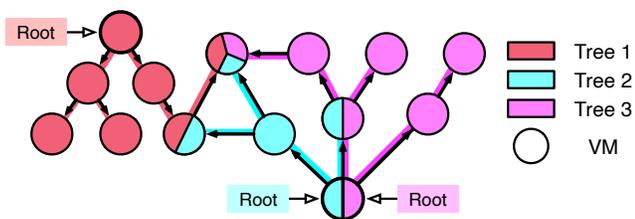

Figure 8: Example function placement on VMs. The color codings of trees and tree edges are red for tree 1 (left), blue for tree 2 (center), and purple for tree 3 (right). Arrows denote provisioning flows.

or all of current VMs are busy serving requests, the scheduler reserves one or multiple new VMs from the free VM pool and then enter the container provisioning process. Without loss of generality, we assume only one VM (VM_1) is reserved in this case. In Step 1, the scheduler creates a new metadata object for VM_1 and inserts it to the FT associated with the requested *functionID*. The scheduler then queries the FT in order to get the *address:port* of the upstream peer VM (VM_2). In Step 2, the scheduler sends the function metadata and *address:port* of VM_2 to VM_1 . Once receiving the information, VM_1 performs two tasks: (1) downloads the *.tar* manifest file of the function container image from the metadata store (§3.1), and (2) loads and inspects the manifest, fetches the URLs of the image layers, and persists the URL information on VM_1 's local storage. In Step 3, VM_1 replies back to the scheduler that it is ready to start creating the container runtime for the requested function. The scheduler receives the reply from VM_1 and then sends a *create container* RPC request to VM_1 in Step 4. In Step 5 and 6, VM_1 fetches the layers from upstream VM_2 based on the manifest configuration processed in Step 2. In Step 7, VM_1 sends the scheduler an RPC that the container has been created successfully.

FT Fault Tolerance. The scheduler pings VMs periodically and can quickly detect VM failures. If a VM is down, the scheduler notifies the FT manager to perform tree balancing operations in order to fix the FT topology.

3.4 FT Design Discussion

FAASNET offloads the metadata-heavy management tasks to the existing FaaS scheduler, so that each individual node in a FT serves the same role of fetching data from its parent peer (and seeding data for its child nodes if any). FT's root node does not have a parent peer but instead fetches data from the registry. FAASNET's FT design can completely eliminate the I/O traffic to the registry, as long as a FT has at least one active VM that stores the requested container. Earlier, our workload analysis reveals that a typical FaaS application would always have a throughput above 0 RPS (§2.2). This implies that, in practice, it is more likely for a request burst to scale out a FT from 1 to N rather than from 0 to N .

An alternative design is to manage the topology at finer-grained layer (i.e., blobs) granularity. In this approach, each individual layer forms a logical layer tree; layers that belong

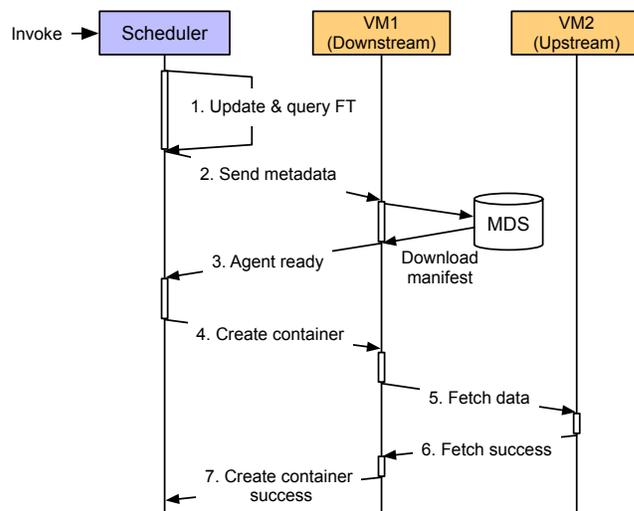

Figure 9: Container provisioning protocol. MDS: metadata store.

to a function container image may end up residing on different VMs. Note that FAASNET's FT is a special case of a layer tree model. Figure 10 shows an example. In this example, one VM stores layer files that belong to different function container images. Thus, a network bottleneck may occur when many downstream VM peers are concurrently fetching layers from this VM. This is because many overlapping layer trees form a fully-connected, all-to-all network topology. An all-to-all topology might scale well if VMs are connected with high-bandwidth network. However, the all-to-all topology can easily create network bottlenecks if each VM is resource-constrained, which is our case in Alibaba Cloud. We use small VMs with 2-core CPU, 4 GB memory, and 1 Gbps network in our FaaS infrastructure.

Existing container distribution techniques [16, 42] rely on powerful root node to serve a series of tasks including data seeding, metadata management, and P2P topology management. Porting these frameworks to our FaaS platform would require extra, dedicated, possibly sharded, root nodes, which would add unnecessary cost to the provider. FAASNET's FT design, on the other hand, keeps each VM worker's logic simple while offloading all logistics functions to our existing scheduler. This design naturally eliminates both the network I/O bottleneck and the root node bottleneck. In §4.3 and §4.4 we evaluate and compare FAASNET's FT design against a Kraken-like approach [16, 21], which adopts a layer-based topology with powerful root nodes.

3.5 Optimizations

We present the low-level optimizations that FAASNET uses to improve the efficiency of function container provisioning.

I/O Efficient Data Format. Regular `docker pull` and `docker start` are inefficient and time-consuming as the whole container image and the data of all the layers must be downloaded from a remote container registry [37] before

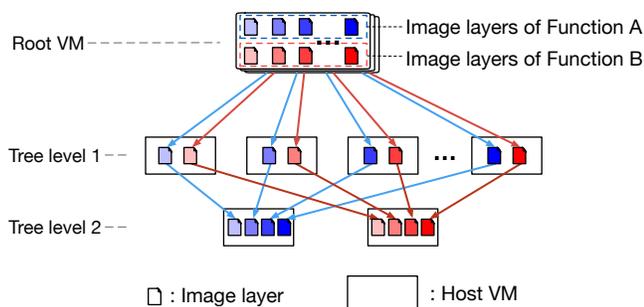

Figure 10: An example tree that manages the topology at layer granularity and relies on root node for data seeding and tree management.

the container can be started. To solve the issue, we design a new block-based image fetching mechanism within Alibaba Cloud. This mechanism uses an I/O efficient compression data file format. Original data is split into fixed-sized blocks and compressed separately. An offset table is used to record the offset of each compressed block in the compressed file.

FAASNET uses the same data format for managing and provisioning code packages. A code package is compressed into a binary file, which will be extracted by VM agent and eventually mounted inside of a function container. FAASNET distributes code packages the same way as it does for container images. §4.5 evaluates the performance benefit of I/O efficient data format on code package provisioning.

On-Demand I/O. For applications that do not need to read all the layers at once on startup, our block-based image fetching mechanism provides them with an option to fetch layer data at fine-grained block level, in a lazy manner (i.e., on-demand), from a remote storage (in our case, a container registry or a peer VM). First, the application, in our case, a FAASNET VM worker, downloads the image manifest file from a metadata store and does an image load locally to load the `.tar` image manifest. Second, it calculates the indices of the first and last (compressed) block and then consults with the offset table to find the offset information. Finally, it reads the compressed blocks and decompresses them until the amount of data that has been read matches the requested length. Since a read to the underlying (remote) block storage device must be aligned to the block boundary, the application may read and decompress more data than requested, causing read amplification. However, in practice, decompression algorithm achieves much higher data throughput than that of a block storage or network. Thus, trading extra CPU overhead for reduced I/O cost is beneficial in our usage scenario. We evaluate the effectiveness of on-demand I/O in §4.6.

RPC and Data Streaming. We build a user-level, zero-copy RPC library. This approach leverages non-blocking TCP `sendmsg` and `recvmsg` for transferring an `struct iovec` incontinuous buffer. The RPC library adds an RPC header directly to the buffer to achieve efficient, zero-copy serialization in the user space. The RPC library tags requests in order to achieve request pipelining and out-of-order receiving, similar

to HTTP/2’s multiplexing [14]. When a FAASNET worker receives a data block in its entirety, the worker immediately transfers the block to the downstream peer.

4 Evaluation

In this section, we evaluate FAASNET using production traces from Alibaba Cloud’s FaaS platform. We also validate FAASNET’s scalability and efficiency via microbenchmarks.

4.1 Experimental Methodology

We deploy FAASNET in Alibaba Cloud’s Function Compute platform using a medium-scale, 500-VM pool and a large-scale, 1,000-VM pool. We follow the same deployment configurations used by our production FaaS platform: all VMs use an instance type with 2 CPUs, 4 GB memory, 1 Gbps network; we maintain a free VM pool where FAASNET can reserve VM instances to launch cloud functions. This way, the container provisioning latency does not include the time to cold start a VM instance. FAASNET uses a block size of 512 KB for on-demand fetching and streaming. Unless otherwise specified: we use a function that runs a Python 3.8 PyStan application for about 2 seconds; the size of the function container image is 758 MB; the function is configured with 3008 MB memory; each VM runs one containerized function.

System Comparison. In our evaluation, we compare FAASNET against the following three configurations:

1. **Kraken:** Uber’s P2P-based registry system [16, 21]. We deploy a *Kraken* `devcluster` [17] with one origin node on our resource-constrained VM infrastructure.
2. **baseline:** Alibaba Cloud Function Compute’s current production setup. *baseline* downloads container images using vanilla `docker pull` from a centralized container registry.
3. **on-demand:** An optimized system based on *baseline* but fetches container layer data on demand (§3.5) from the container registry.
4. **DADI+P2P:** Alibaba’s DADI [1, 42] with P2P enabled. This approach uses one resource-constrained VM as the root node to manage the P2P topology.

Goals. We aim to answer the following questions:

1. Can FAASNET rapidly provision function containers under bursty FaaS workloads with minimum impact on workload performance (§4.2)?
2. Does FAASNET scale with increasing invocation concurrency levels (§4.3)?
3. How does function placement impact FAASNET’s efficiency (§4.4)?
4. How does FAASNET’s I/O efficient data format perform (§4.5)?
5. How effective is FAASNET’s on-demand fetching (§4.6)?

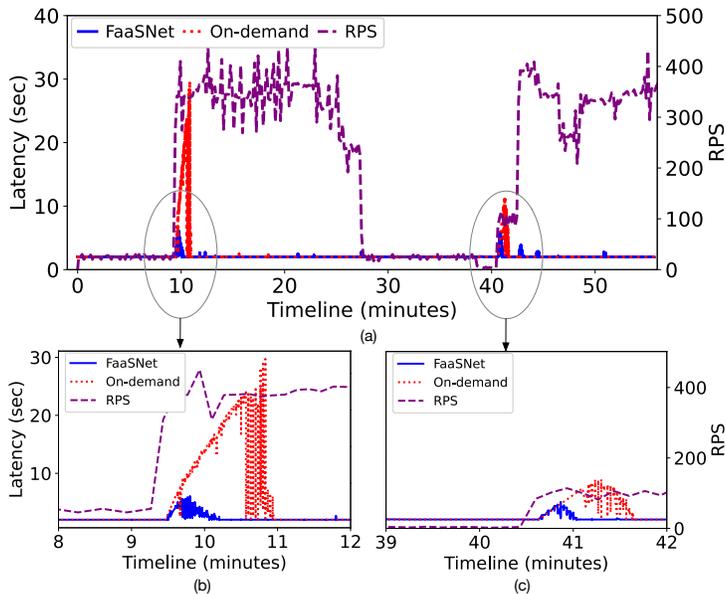

Figure 11: IoT trace timeline.

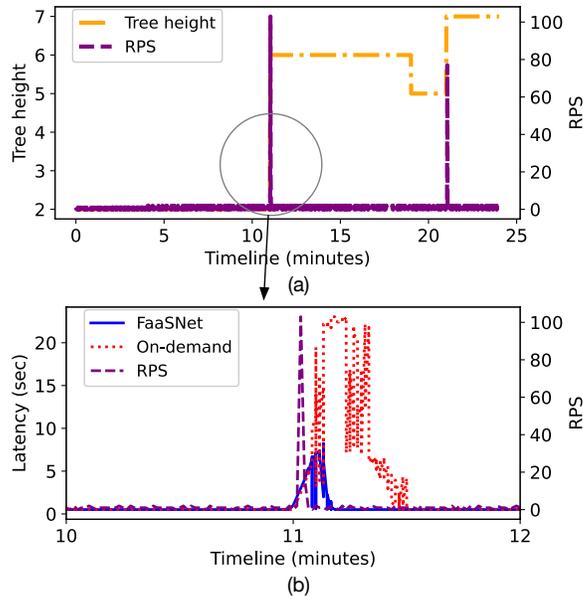

Figure 12: Synthetic trace timeline.

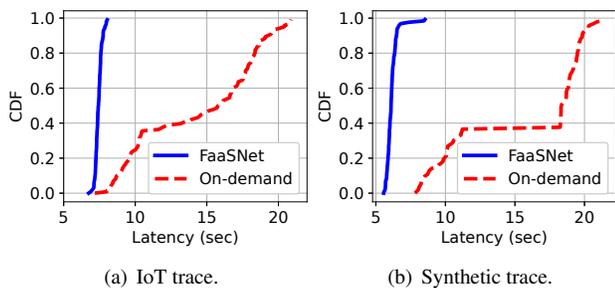

Figure 13: Distribution of container provisioning latency.

4.2 FaaS Application Workloads

In this section, we evaluate FAASNET using (scaled-down) application traces collected from our production workload (detailed in §2.2).

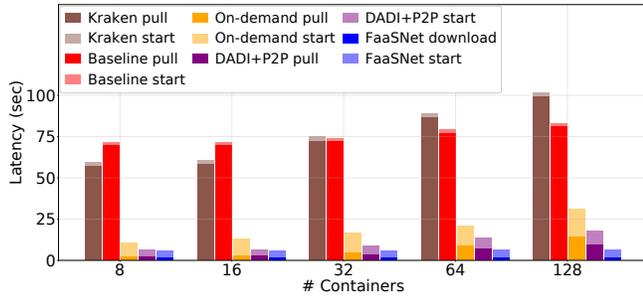

Trace Processing and Setup. We evaluate FAASNET using two FaaS applications: an IoT app and a gaming app. Since the original gaming workload exhibits a gradual ramp-up in throughput (Figure 2(a)), we instead create a synthetic bursty workload based on the gaming workload to simulate a sharp burst pattern for stress testing purpose. Our testing cluster has up to 1,000 VMs, so we scale down the peak throughput of both workload traces proportional (about 1/3 of the original throughput) to our cluster size and shorten the duration from 2 hours to less than 1 hour.

IoT Trace. The IoT trace exhibits two invocation request bursts. The first burst happens at 9 minute and the throughput increases from 10 RPS to 300-400 RPS; the peak throughput lasts for about 18 minutes and returns back to 10 RPS at 28 minute. The second burst happens at 40 minute and the throughput increases to 100 RPS, and then in about 2 minutes, jumps to around 400 RPS. Figure 11(a) plots the 55-minute timeline of the workload’s throughput and latency changes.

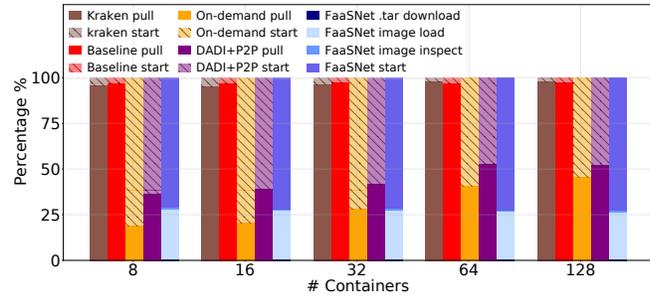

At 10 minute, the instantaneous throughput increase causes a backlog of function invocation requests at the FaaS scheduler side. Thus, the scheduler scales out the active VM pool by reserving a large number of free VMs from the free VM pool and starts the function container provisioning process. In *baseline* case, all newly reserved VMs start pulling container images from the registry, which creates a performance bottleneck at the registry side. As a result, the application-perceived response time—the end-to-end runtime that includes the container startup latency and the function execution time of around 2 seconds—increases from 2 seconds to about 28 seconds. Worse, the registry bottleneck inevitably prolongs the time that *baseline* requires to bring the response time back to normal. As shown in Figure 11(b), *baseline* finishes the whole container provisioning process and brings the response time back to normal in almost 113 seconds.

In contrast, FAASNET avoids the registry bottleneck—instead of downloading the container image from the registry, each newly reserved VM fetches image data block-by-block from its upstream peer in the FT, forming a data streaming pipeline. As long as a VM fetches enough data blocks, it starts the container. FAASNET reduces the maximum response time from 28 seconds to 6 seconds. Out of the 6 seconds, around 4 seconds are spent on fetching image layers from the upstream peer VM. (We present the container provisioning latency later in Figure 13.) More importantly, FAASNET requires only 28 seconds to bring the service back to normal, an improvement of 4× compared to the *on-demand* case.

Synthetic Trace. In the synthetic trace test, we simulate two function invocation request bursts and evaluate FT’s adaptivity. Figure 12(a) shows the timeline of a FAASNET FT’s height changes. At 11 minute, the throughput suddenly grows from 1 RPS to 100 RPS. FAASNET detects the burst and

(a) Average function container provisioning latency.

(b) Fraction of time spent at different stages.

Figure 14: Container provisioning scalability test.

rapidly scales the FT from a height of 2 (one root VM and one peer VM) to 7 (82 VMs in total). The FT starts parallel container provisioning instantly at 11 minute and sustains the latency spikes in about 10 seconds (Figure 12(b)). After the first burst, the throughput drops back to 1 RPS. Some VMs become cold and get reclaimed by the VM manager in about 15 minutes since the first burst. The number of VMs gradually reduces to 30 before the second burst arrives. Correspondingly, the height of the FT reduces from 6 to 5 (Figure 12(a)). When the second burst comes at 21 minute, the FT manager decides to grow the FT by adding another 62 VMs. With a total of 102 VMs, the height of the FT reaches up to 7 for serving the concurrent requests of the second burst.

Container Provisioning Cost We next analyze the container provisioning latency seen in the two workloads. As shown in Figure 13, since the registry in *on-demand* incurs a performance bottleneck, *on-demand* sees highly variant container provisioning latency, ranging from around 7 seconds to as high as 21 seconds. About 80% of the containers take at least 10 seconds to start. The container startup latency is highly predictable in FAASNET, with significantly less variation. For the synthetic workload, around 96% of the functions require only 5.8 seconds to start. For the IoT workload, almost all the functions start execution within a short time range between 6.8-7.9 seconds. This demonstrates that FAASNET can achieve predictable container startup latency.

4.3 Scalability and Efficiency

Next, we evaluate FAASNET’s scalability and efficiency via microbenchmarking.

Scaling Function Container Provisioning. In this test, we measure the time FAASNET takes to scale from 0 to N concurrent invocation requests, where N ranges from 8 to 128. Each invocation request creates a single container in a VM. Figure 14 reports the detailed results. As shown in Figure 14(a), *Kraken* performs slightly better than *baseline* under 8 and 16 concurrent requests but scales poorly under 32-128 concurrent requests. This is because *Kraken* distributes containers at layer granularity using a complex, all-to-all, P2P topology, which creates bottlenecks in the VMs. *Kraken* takes 100.4 seconds to launch 128 containers.

baseline achieves slightly better scalability than *Kraken*. The average container provisioning latency reaches up to 83.3 seconds when *baseline* concurrently starts 128 functions. Two factors contribute to the delay: (1) the registry becomes the bottleneck, and (2) *baseline*’s `docker pull` must pull the whole container image and layers (758 MB worth of data) from the registry and extract them locally.

Adding *on-demand* container provisioning to *baseline* improves the latency significantly. This is because *on-demand* eliminates most of the network I/Os for image layers that will not be instantly needed container startup. Despite pulling much less amounts of data from the registry, *on-demand* still suffers from the registry bottleneck; provisioning 128 function containers requires $2.9\times$ longer time than provisioning 8 containers in *on-demand* system.

DADI+P2P enables VMs to directly fetch image layers from peers, further avoiding downloading a large amount of layer blocks from the registry. However, *DADI+P2P* still has two bottlenecks: one at the registry side—image pulls are throttled at the registry, and layer-wise extract operation may also be delayed in a cascading manner by local VMs; the other bottleneck at the P2P root VM side—in addition to seeding data, the root VM in *DADI+P2P* is responsible for a series of extra tasks such as layer-tree topology establishment and coordination, thus forming a performance bottleneck. This can be evidenced from Figure 14(b) that the fractions of *DADI+P2P*’s image pull and container start maintain at the same level when scaling from 64 to 128 function starts.

Figure 14(a) shows that FAASNET scales perfectly well under high concurrency and achieves a speedup of $13.4\times$ than *baseline* and $16.3\times$ than *Kraken*. FAASNET is $5\times$ and $2.8\times$ faster than *on-demand* and *DADI+P2P*, respectively. As shown in Figure 14(b), FAASNET’s average container provisioning latency is dominated by two operations: image load and container start. FAASNET eliminates the bottleneck on both the two operations—on image load, FAASNET enables decentralized image loading (functionality-wise equivalent to image pull) at each VM by allowing each FAASNET worker to fetch the image manifest from the metadata store (with negligible overhead) and then starting the image loading process locally in parallel; on container start, each FAASNET VM

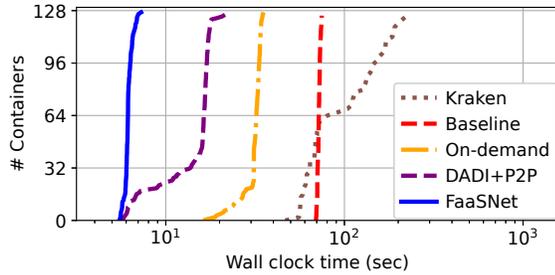

Figure 15: Container provisioning scalability test: wall clock time (X-axis) for starting N functions (Y-axis).

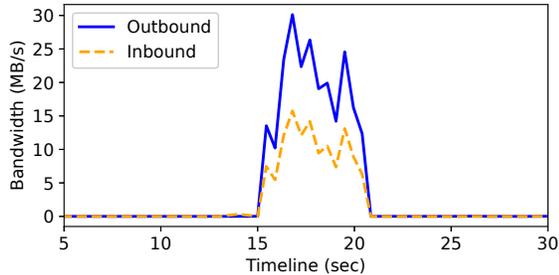

Figure 16: A timeline of the VM network bandwidth usage.

worker directly fetches layer blocks from peer VM and starts the function container once enough blocks are fetched. With all these optimizations, FAASNET maintains almost identical latency when scaling from 8 to 128 function startups.

Function Container Provisioning Pipeline. We next examine how long the whole container provisioning process spans. Figure 15 plots the timeline process that each system goes through to start N function containers. We only report the 128-function concurrency case. We observe that FAASNET starts the first function at 5.5 second and the 128th function at 7 second respectively. The whole container provisioning process spans a total of 1.5 seconds. Whereas *on-demand* and *DADI+P2P* span a total duration of 16.4 and 19 seconds, respectively. Specifically, it takes *DADI+P2P* a total of 22.3 seconds to start all the 128 containers, which is $14.7\times$ slower than that of FAASNET. This demonstrates that FAASNET’s FT-based container provisioning pipeline incurs minimum overhead and can efficiently bring up a large amount of function containers almost at the same time.

Figure 16 shows the bandwidth usage timeline for a VM that we randomly select from the 128-function concurrency test. Recall that a FAASNET worker along a FT path (i.e., not the root VM nor the leaf VM) performs two tasks: (1) fetches layer data from the upstream VM peer, and (2) seeds layer data to the two children VM peers in its downstream paths. We observe that the bandwidth usage of the inbound connection (fetching layers from upstream) is roughly half of that of the two outbound connections (sending layers to downstreams) during container provisioning. The aggregate peak network bandwidth is 45 MB/s, which is 35.2% of the maximum network bandwidth of the VM. We also observe that, the outbound network transfer is almost perfectly aligned

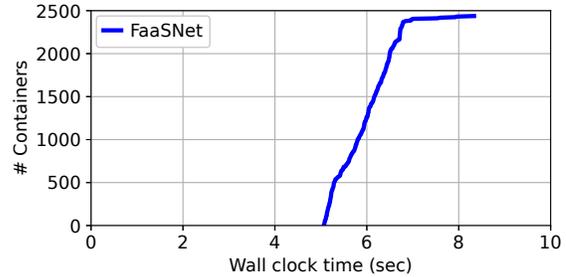

Figure 17: Large-scale function container provisioning: the wall clock time (X-axis) for starting N functions (Y-axis).

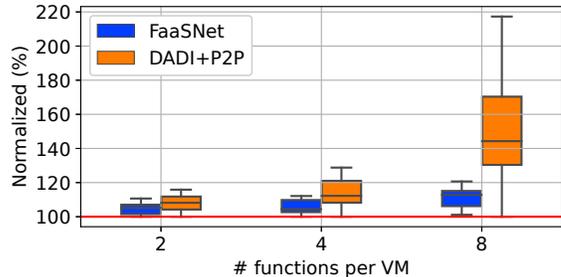

Figure 18: Container provisioning latency as a function of various function placement situations. For FAASNET and *DADI+P2P*, the latency is normalized to that of provisioning a single container in one VM in their own case.

with the inbound network transfer, again demonstrating the efficacy of FAASNET’s block-level data streaming scheme.

Large-Scale Function Startup. In this test, we create 1,000 VMs and concurrently invoke 2,500 functions on them. Each function uses a container of 428 MB and is configured to run with 1024 MB memory. Each VM runs two or three functions in this test. Figure 17 shows that all function containers finish provisioning and start running between 5.1 second and 8.3 second, again demonstrating FAASNET’s superb scalability. None of *on-demand* and *DADI+P2P* finishes the test due to timeout errors.

4.4 Impact of Function Placement

We conduct a sensitivity analysis to quantify the impact of function placement on container provisioning. In this test, we concurrently invoke 8 functions on N VMs, where N varies from 4 to 1. Each function has a different container (75.4 MB) and is configured to use 128 MB function memory (since a VM has 4 GB memory, it is allowed to host as much as 20 functions with 128 MB memory). We compare the container provisioning latency between FAASNET and *DADI+P2P*. As shown in Figure 18, *DADI+P2P* sees much higher latency variation when 4 functions and 8 functions are placed on the same VM, because *DADI+P2P*’s root VM is overloaded by the establishment processes of many small layer trees.

4.5 I/O Efficient Data Format

We next evaluate how the I/O efficient format helps with code package provisioning. We choose three functions: a simple, Python-written HelloWorld function that sleeps for 1 second

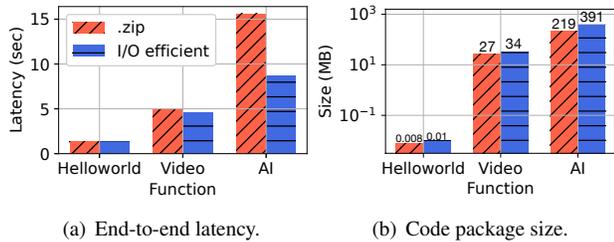

Figure 19: End-to-end invocation latency and code package size comparison between I/O efficient format and .zip.

(Helloworld), an FFmpeg video encoding function (Video), and a TensorFlow Serving function (AI), and compare FAASNET’s I/O efficient format with the baseline .zip format.

Figure 19(a) plots the end-to-end function invocation performance including the latency of code package downloading and function duration. Our I/O efficient format performs the same as .zip for Helloworld, since Helloworld’s code package has only 11 KB in size (Figure 19(b)). The I/O efficient format achieves better performance compared to .zip for Video and AI since the I/O efficient format fetches data on demand rather than extracting all data as .zip does. Figure 19(b) shows the code package sizes. Functions have a larger code package size when using I/O efficient format, because I/O efficient format’s compression incurs extra storage overhead.

4.6 On-Demand I/O: Sensitivity Analysis

Finally, we evaluate on-demand I/O and compare the impact of block sizes on read amplification. With on-demand fetching, a FAASNET worker only needs to fetch enough layer data blocks in order to start the function container. We choose three different function container images: (a) a 195 MB hello-world image with a Python 3.9 runtime pulled from Docker Hub; (b) a 428 MB PyStan image based on an AWS Lambda Python 3.8 base image; and (c) a 728 MB PyStan image based on an Alibaba Cloud Python 3.8 base image.

As shown in Figure 20, on-demand fetching can reduce the amount of data transferred via network. The reduction is especially profound for image b and c, because base images are dependency-heavy and are commonly used in the image building process. For example, with a block size of 512 KB (the block size configuration that we use in our evaluation), on-demand fetching sees a 83.9% reduction in network I/Os, compared to that of regular `docker pull`.

We also observe different levels of read amplification under different block sizes. This is because the starting and ending offset position is likely to be misaligned with the boundary of the (compressed) blocks in the underlying block device, the larger the block size is, the more useless data the FAASNET worker may read from the starting and ending blocks. The actual amount of data read (for starting a container) after decompression is even smaller, indicating that most of the dependencies included in the original container image is not used at the container startup phase. Exploring optimization

Figure 20: Amounts of data fetched (on-demand) as a function of block sizes. Left-most bar in each bar cluster represents the size of the original container image; right-most bar in each bar cluster represents the actual amount of data read from the data blocks fetched via network.

to reduce the read amplification is part of our future work.

5 Discussion

In this section, we discuss the limitations and possible future directions of FAASNET.

FT-aware Placement. When the number of functions grows, the contention of network bandwidth ensues. Though §4.4 proves it less a concern in FAASNET than prior work, for the sake of safety in production, we program the system to avoid co-locating multiple functions if the cluster resources permit. Anticipating a future demand increase of custom containers, we plan to address the problem by extending the container placement logic. The general goal is to balance the inbound and outbound communication of each VM when multiple functions are being provisioned. Intuitively, by adjusting container placement, we can control the number of FTs that a VM is involved in and the role (e.g., leaf vs. interior node) a VM serves, and thus the bandwidth consumption. A further optimization is to co-locate functions that share common layers, so they could reduce the amount of data transfer.

Multi-Tenancy. As mentioned, Alibaba Cloud achieves strong, tenant-level function isolation using containers and VMs. As such, our FaaS platform cannot share VMs among tenants. This means that FAASNET’s FTs are naturally isolated between different tenants. Porting FAASNET to other secure and lightweight virtualization techniques [24, 45, 52, 57] is our ongoing work.

FAASNET for Data Sharing. Technically, our work can enable the sharing of container images among VMs through P2P communication, There is potentiality for it to generalize to a broader scope: data sharing for general container orchestration systems such as Kubernetes [27]. Such a need is arising in FaaS platforms with the emergence of data-intensive applications, such as matrix computation [31, 51], data analytics [39, 49], video processing [26, 35], and machine learning [30, 38], etc. Most of them rely on a centralized storage for data exchange, which is a similar bottleneck as the container registry in our work. Hence we believe the design of FAASNET can also accelerate data sharing, only with two additional challenges: (1) how to design a primitive interface

for users; (2) how to adapt the tree management algorithms for more frequent topology building and change. We leave the exploration as a future work.

Adversarial Workloads. Extremely short-lived functions with a duration at sub-second level and sparse invocations may be adversarial to FAASNET and custom-container-based FaaS platforms. Function environment caching and pre-provisioning [22, 48, 50] can be used to handle such workloads but with extra infrastructure-level costs.

Portability. FAASNET is transparent to both upper-level FaaS applications and underlying FaaS infrastructure. It reuses Function Compute’s existing VM reclaiming policy and could be applied to other FaaS platforms without introducing extra system-level costs. Porting FAASNET to Alibaba Cloud’s bare-metal infrastructure is our ongoing work.

6 Related Work

Function Environment Caching and Pre-provisioning. FaaS applications face a notoriously persisting problem of high latency—the so-called “cold start” penalty—when function invocation requests must wait for the functions to start. Considerable prior work has examined ways to mitigate the cold start latency in FaaS platforms. FaaS providers such as AWS Lambda and Google Cloud Functions pause and cache invoked functions for a fixed period of time to reduce the number of cold starts [22, 55, 56]. This would, however, increase the TCO for providers. To reduce such cost, researchers propose prediction methods that pre-warm functions just in time so that incoming recurring requests would likely hit on warm containers [50]. SAND shares container runtimes for some or all of the functions of a workflow for improved data locality and reduced function startup cost [25]. SOCK caches Python containers with pre-imported packages and clones cached containers for minimizing function startup latency [48]. PCPM pre-provisions networking resources and dynamically binds them to function containers to reduce the function startup cost [46]. While function requests can be quickly served using pre-provisioned, or cached, virtualized environments, these solutions cannot fundamentally solve the issue of high costs incurred during function environment provisioning.

Sandbox, OS, and Language-level Support. A line of work proposes low-level optimizations to mitigate FaaS cold start penalty. Catalyzer [34] and SEUSS [29] reduce the function initialization overhead by booting function instances from sandbox images created from checkpoints or snapshots. Systems such as Faasm [53] and [28] leverage lightweight language-based isolation to achieve speedy function startups. Unlike FAASNET, these solutions either require modified OSes [29, 34] or have limited compatibility and usability in terms of programming languages [28, 53].

Container Storage. Researchers have looked at optimizing container image storage and retrieval. Slacker speeds up the container startup time by utilizing lazy cloning and

lazy propagation [37]. Images are stored and fetched from a shared network file system (NFS) and referenced from a container registry. Wharf [61] and CFS [44] store container image layers in distributed file systems. Bolt provides registry-level caching for performance improvement [43]. These work are orthogonal in that FAASNET can use them as backend container stores. Kraken [16] and DADI [42] use P2P to accelerate container layer distribution. These systems assume a static P2P topology and require dedicated components for image storage, layer seeding, or metadata management, which leave them vulnerable to high dynamicity (demanding high adaptability of the network topology) and unpredictable bursts (requiring highly scalable container distribution).

AWS Lambda Containers. AWS announced the launch of container image support for AWS Lambda [19] on December 01, 2020. Limited information was revealed via a re:Invent 2020 talk [6] about this feature: AWS uses multi-layer caching to aggressively cache image blocks: (1) microVM-local cache, (2) shared, bare-metal server cache, and (3) shared, availability zone cache. The solution, while working for powerful, bare-metal server-based clusters that can co-locate many microVMs [24], is not suitable for our FaaS platform, which is based on thousands of small VMs managed by Alibaba Cloud’s public cloud platform.

P2P Content Distribution. VMThunder uses a tree-structured P2P overlay for accelerating VM image distribution [59]. A BitTorrent-like P2P protocol is proposed for achieving similar goals [33]. Bullet uses an overlay mesh for high-bandwidth, cross-Internet file distribution [41]. FAASNET builds on these works but differs with a new design that is attuned to the FaaS workloads.

7 Conclusion

Scalable and fast container provisioning can enable fundamental elasticity for FaaS providers that support custom-container-based cloud functions. FAASNET is the first system that provides an end-to-end, integrated solution for FaaS-optimized container runtime provisioning. FAASNET uses lightweight, decentralized, and adaptive function trees to avoid major platform bottlenecks. FAASNET provides a concrete solution that is attuned to the requirements of a large cloud provider’s FaaS platform (Alibaba Cloud Function Compute). We show via experimental evaluation that FAASNET can start thousands of large function containers in seconds. Our hope is that this work will make container-based FaaS platforms truly elastic and open doors to a broader class of dependency-heavy FaaS applications including machine learning and big data analytics.

To facilitate future research and engineering efforts, we release the source code of FAASNET’s FT prototype as well as an anonymized dataset containing production FaaS cold start traces collected from Alibaba Cloud Function Compute at: <https://github.com/mason-leap-lab/FaaSNet>.

Experiences in Managing the Performance and Reliability of a Large-Scale Genomics Cloud Platform

Michael Hao Tong, Robert L. Grossman, Haryadi S. Gunawi
University of Chicago

Abstract

We share our technical experiences in improving the performance of long-running jobs on the Genomic Data Commons (GDC), a large-scale cancer genomics cloud platform. We show how common bioinformatics workloads can cause VMs to age after several days, causing a large number of Extended Page Table (EPT) violations that significantly impact performance. We present host- and VM-level EPT monitoring and evaluate several possible mitigation scenarios. We highlight the long investigative process required for this research, with experiments requiring many days to complete.

1 Introduction

Since the invention of DNA sequencing in 1977, tremendous volumes of genomic sequencing data have been produced, and the number of biological databases has been doubling about every 15 months [1]. A driving force behind this is the exponential drop in the cost for sequencing a human genome, which is shown by the solid purple line in Figure 1 [2]. As can be seen from Figure 1, the cost of sequencing a genome has been decreasing faster than Moore’s Law (shown by the dashed green line).

With this tremendous growth in biological data, it has become more challenging to manage and analyze the data. As a result, in the recent years, a wide range of bioinformatics methods, techniques, algorithms and tools have been developed to analyze the experimental data and understand the underlying biological mechanisms and their significance [3].

Genomic sequencing data is particularly important in cancer, since cancer is in large part driven by genomic mutations. The GDC was launched in 2016 with the goal of providing a repository for cancer genomics data and for harmonizing data that is submitted to it with a common set of bioinformatics pipelines. The GDC is large-scale cloud based system that stores, analyzes, and shares genomic, clinical and imaging data from patients with cancer. The GDC is a hybrid cloud system and uses both a private on-premise cloud and the public AWS cloud. The GDC is one of the

largest bioinformatics platforms that support the cancer research community (see Section 2 for more details).

An important backbone of the GDC is GPAS, the GDC Pipeline Automation System that is used for processing data submitted to the GDC and running a wide range of bioinformatics pipelines over the data. It is important to note that at the scale the GPAS operates, using public compute and storage clouds would be 1.5x or more expensive than using private on-premise clouds. On the other hand, using public clouds is important for GPAS for burst computing, for making use of a wider variety of machine configurations, for running portions of larger, more complex pipelines, and for flexibility in general.

On the compute side, GPAS runs a large on-premise VM cloud powered by OpenStack/KVM, and the on-premise GPAS clusters uses a combination of Ceph and Cleversafe for storage. While there are many interesting experiences to share, this paper focuses on technical matters that might benefit the systems community. In particular, we present our experiences in managing the bioinformatics pipelines and KVM performance in GPAS.

KVM performance (EPT violations under extreme memory fragmentation). We reveal a significant VM performance problem that surfaced in GPAS. We noticed that a significant number of jobs in GPAS exhibited much slower performance compared to other similar jobs, with a *degradation of up to 10x*.

GPAS workloads are I/O intensive, require large memory instances, and, most importantly, are *long running*. For example, many jobs take weeks to complete. These characteristics made the problem difficult to troubleshoot. Online monitoring tools that we typically use only report high-level aggregate metrics and did not pinpoint the root cause. Trying to replicate the problem in an “offline” setting also did not reveal the root cause because of the different environments (fresh vs. aged VMs). Recording more online metrics did not give us quick outcomes because the problem did not appear in the early days of the jobs.

Because of all of these observations, we speculated that the problem could be related to memory fragmentation of aging VMs where many sequential guest pages are not mapped sequentially on the physical pages, causing extreme translation lookaside buffer (TLB) misses. More specifically, this brought us to the root cause, the overhead of hardware-

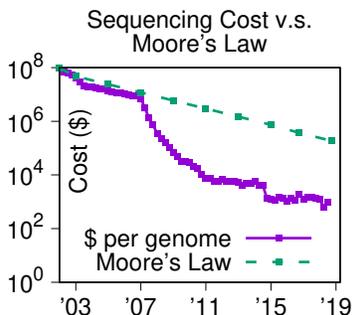

Figure 1: Sequencing cost.

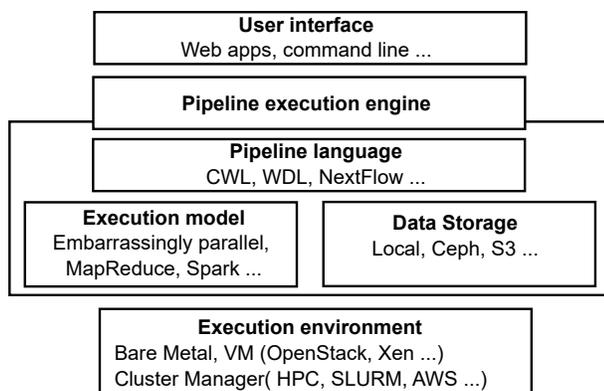

Figure 2: **Full stack bioinformatics pipeline platform.**

assisted Intel Extended Page Table (EPT) [4] technology used by the virtual machine memory management in the VM hypervisor [5]. Interestingly, we confirmed that the problem only surfaces in the OpenStack/KVM stack. We were not able to reproduce the problem in cloud VMs used by Amazon Web Services (AWS) and Google Cloud Platform (GCP). We speculate that public clouds might use their own proprietary virtualization technology (that is not available to us to analyze).

Besides presenting our findings, this paper also shows challenges in monitoring EPT performance issues. We also present several mitigation scenarios that we tried out, such as rebooting the VMs, defragmenting the memory, running on bare metal, and using public clouds, along with their advantages and disadvantages.

2 Background and Motivation

Figure 2 illustrates the full stack of layers of a typical bioinformatics cloud platform from the user/administrative interface to the execution platform. In order to improve portability and replicability, bioinformatics pipelines are often written in a workflow language [6], such as the Common Workflow Language (CWL) [7] or the Workflow Description Language (WDL) [8]. Bioinformatics pipelines are also typically containerized. There are several systems available for executing workflows expressed in workflow languages, including CWLtool [9] for CWL and Cromwell for WDL [8]. As this paper discusses the core systems aspect of GPAS, we have put additional information about the pipelines in the supplemental material [10]. To improve isolation to support security requirements, GPAS runs each containerized pipeline in a virtual machine. GPAS manages virtual machines using OpenStack/KVM. GPAS currently uses CWLtool. CWLtool does not support parallelizing tasks of a pipeline across different machines, however tasks can run in parallel across cores of a machine. Currently, GPAS uses a policy of allocating one VM per physical node, since many GDC pipelines benefit from this allocation. GPAS uses SLURM as the cluster manager for the VM pool and sched-

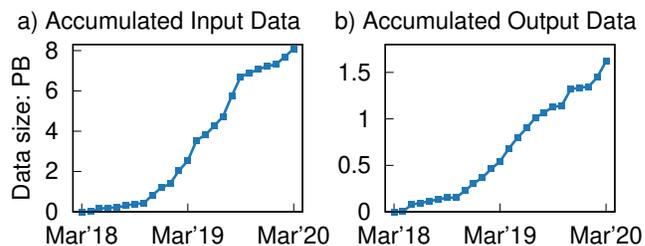

Figure 3: **Accumulated input consumption and output production over the months, §2.**

Clouds	Approx. Hourly	Approx. Annual
On premise	\$0.31	\$691,000
AWS (Spot)	\$0.75	\$1,693,000
AWS (3-yr Reserved)	\$1.06	\$2,386,000
AWS (On-Demand)	\$2.50	\$5,645,000

Table 1: **The approximate costs of on-premise vs. public cloud, §2.** For AWS, we assume that EC2 *i3.xlarge* instances are used, which are roughly similar to the on-premise instances.

ules jobs to run on SLURM. In bioinformatics, the terms “pipeline” and “workflow” are often used interchangeably.

On average, over 3,000 researchers use GDC every day, with over 100,000 unique researchers using the GDC each year. Over 1 PB of data is accessed or downloaded from the GDC in a typical month. GDC currently manages over 15 PB of data across almost 100 storage servers, including the released data, the data being processed for release, temporary files, and backup copies. There are over 200 compute nodes containing 7500 cores, 50 TB of RAM, and 900 TB of local disk/SSD storage. Figures 3a and 3b show the accumulated amount of data that GPAS has processed and produced by month for a two year period. Interested readers can refer to the GDC Documentation [11] for more details.

The GPAS on-premise cloud annually processes about 322,000 workflows requiring 35 million core hours. At this scale, the costs using a public cloud would be significantly higher, as shown in Table 1. For this comparison, on-premise costs assume a 4-year amortization of equipment costs and a 15-year amortization of data center costs. The comparison assumes that on-premise nodes are used at 100% utilization.

3 Workloads in GPAS

3.1 The bioinformatics pipelines and tools

GPAS uses a wide range of pipelines that include various bioinformatics analytical tools and serve different analysis purposes. At this time, there are 10 open-sourced pipelines in the GDC GitHub repository [12].

Table 2 lists the open-source pipelines and the main tools used in these pipeline. GPAS uses a large variety of tools that include in-house software or scripts, such as HTSeq Tool and GDC VEP Tool, and widely used third-party bioinformatics tools, such as BWA and GATK. In addition to those listed in

Pipeline	Main tools used
DNA-Seq Alignment	BWA [13], Biobambam2 [14], Picard Tools [15], GATK [16]
RNA-Seq Alignment	STAR [17]
miRNA Alignment and Profiling	BWA [13]
RNA-Seq HTSeq Quantification	HTSeq Tool [18]
WXS Variant Calling	MuSE [19], SomaticSniper [20], VarScan2 [21], MuTect2 [22]
WXS Variant Filtering	Picard Tools [15]
WGS Variant Calling	CGP WGS [23]
VEP Variant Annotaton	GDC VEP Tool [24]
Mutation Annotation File (MAF) Generation	MAF Tools [25]
SNP6 Segmentation	snp6cbs [26]

Table 2: **Open-source GDC Pipelines and the main tools used in the pipelines.**

Tool	Language	I/O Intensity	Computing Intensity
samtools	C	High	Low
BWA	C	High	High
FastQC	Java	Medium	Low
MuSE	C++	Low	High
MuTect2	Java	Low	High
SomaticSniper	C	High	High
VarScan2	Java	High	High

Table 3: **Characteristics of the tools used in GPAS.** *The observations are based on the way we used the tools in GPAS, the results may differ if they are used in different ways*

the table, FastQC [27] and samtools [28] are also commonly used across all the GDC pipelines.

Due to the large number of tools that exist in bioinformatics, it is difficult to characterize the computing resource demand and performance of each tool before putting them into use. We list the the characteristics of some tools in Table 3 that are used in the DNA-Seq alignment and whole exome sequencing (WXS) variant calling workflows, two of the longer running workflows in GPAS. Note that the way GPAS uses the tools in Table 3 is that, for samtools, FastQC, MuSE, MuTect2, SomaticSniper, VarScan2, GPAS spawns multiple processes each of which runs the same tool on separate input files, even though the tool may support multi-threading by itself [10]; for BWA, GPAS uses BWA’s own multi-threading functionality.

Table 3 shows that even though MuSE, MuTect2, SomaticSniper and VarScan2 are all somatic variant calling tools, due to different algorithms and program designs, they expose different patterns in I/O intensity. The GPAS pipelines are quite varied, and some GPAS pipelines, such as the MAF generation pipeline, require significantly less time to complete.

3.2 Pipeline Job Performance

For simplicity of discussion, we mainly measure job-level performance. A pipeline job is an execution of the pipeline that handles a specific set of input data. Readers who are interested in knowing the logical abstraction and composition of the pipeline can read our extended report [10].

The majority of the jobs in GPAS process a large amount of input data and take a long time to complete. Thus, a simple metric for understanding job performance and its degradation is the processing rate:

$$processing\ rate = \frac{job\ execution\ time}{input\ data\ size} \quad (1)$$

The unit of *processing rate* is *seconds/GB* or *hours/GB*, thus a larger *processing rate* value means means the performance is worse (as more time is needed for processing one GB of input data).

Due to the complexity of bioinformatics pipelines in GPAS, the job performance shows quite interesting patterns. The job performance shown in this section are collected from jobs that ran on bare metal nodes, so that we avoid the interference from VMs (which will be discussed later).

Through linear regression and significance-test analysis, it is found that, among all the parameters known at the time a job starts (such as number of input files, number of CPUs allocated, etc.), input data size exhibits the strongest correlation with *processing rate*.

To better illustrate the correlation between input size and *processing rate*, jobs are sorted by their *processing rate*, and divided into 20 buckets according to the percentile of *processing rate*. Average input size of each bucket is shown in Figure 4 and 5. There can be either positive or negative correlation between input size and *processing rate*, depending upon the specific pipeline. There are three relationships that emerge from this analysis:

Larger input size means slower/larger processing rate (positive correlation): As shown in Figure 4, *processing rate* is positively correlated with input size for some pipelines. This is the case for sequence alignment pipelines. Note that, as can be seen in the graph to the right, *processing rate* of this pipeline is generally very large, more than 1500 seconds/GB. Sequence alignment involves multiple string searches and exhibits positive correlation between input data size and *processing rate*.

Larger input size means faster/smaller processing rate (negative correlation): Contrary to the previous result, Figures 5 shows that *processing rate* is negatively correlated with input size for some pipelines. For example, this is the case for some utility pipelines that involve accessing and extracting files from cloud buckets for processing. Note that *processing rate* in this pipeline is much faster than for the jobs in the previous one. With a high-bandwidth network and I/O, *processing rate* is higher. However, since the execution time for such pipeline jobs is short, the overhead of

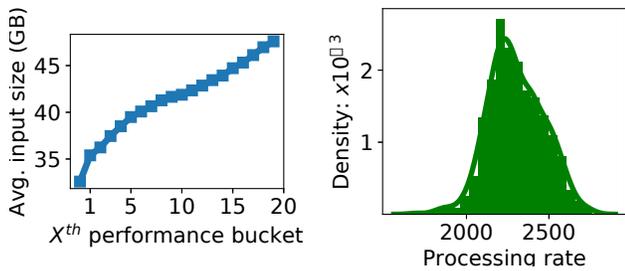

Figure 4: **A DNA-Seq alignment pipeline shows larger input size has slower/larger processing rate.** Each performance bucket contains 5% jobs, and buckets that have larger number demonstrate worse performance, §3.2

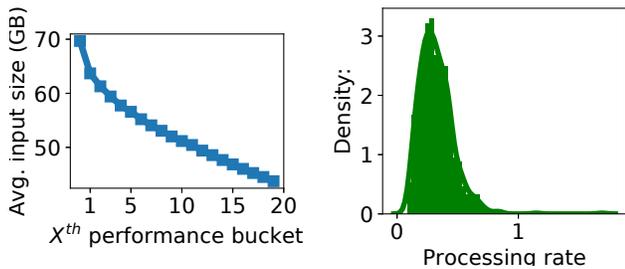

Figure 5: **An internal light-weighted pipeline shows larger input size has faster/smaller processing rate.** Each performance bucket contains 5% jobs, and buckets that have larger number demonstrate worse performance, §3.2

spawning containers and other components is significant in comparison. As a result, smaller input size leads to worse processing rate.

External factors interference: In addition, there are some cases that may not comply with the previous behaviors. Figure 6 shows a distribution with two peaks for the job processing rate of a pipeline. By inspecting job logs, it is found that jobs at the right peak (slower jobs) spent significantly longer times downloading data. That suggests that there might have been network congestion in the cluster during that time. Hence, in some cases, we need to take the external environment into account to understand the processing rate of jobs.

To conclude, through statistical analysis of the jobs, although there are some degrees of variation, we find that processing rate for pipelines is highly correlated with a job's input size. The exact correlation depends on the workloads associated with the pipeline. Sometimes, the processing rate might also be subject to external factors during some parts in the job. It is important to understand the nature of the job so that good interpretation can be formed.

In the next section, we will discuss performance issues that arise and create long tail distributions when jobs are executed on VMs.

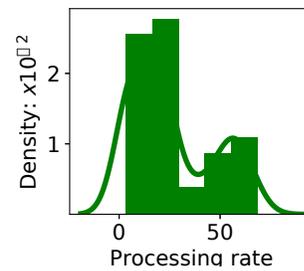

Figure 6: **Abnormal Processing rate Distribution.** Each performance bucket contains 5% jobs, and buckets that have larger number demonstrate worse performance, §3.2

4 Performance Issues: Aging VMs and EPT Violations

The GDC uses over 20 complex pipelines for processing data. Some of the pipeline components are I/O bound and some are memory bound. Complicating matters, some of the pipelines are long-running and can take several weeks to complete. After several months, it became apparent that some of the pipelines failed to complete, especially the longer running ones, which required retrying the pipelines, and which decreased the overall throughput of the system. After some experimentation, it appeared that long running pipelines performed better on bare metal nodes versus using virtual machines, and some of the nodes running virtual machines were replaced with bare metal nodes for this reason.

Figure 7a shows the success rate for jobs in each month. GPAS serves more than 20,000 jobs per month and has achieved over 90% monthly success rate for the jobs. The figure shows the success rate of jobs running on VMs (red) and bare metal (green). As noted, for long running jobs (those that require weeks), performance, as measured by GB processed per hour, tends to decline, and failures tend to become more common. Some jobs have to be stopped in the middle due to their very poor performance.

Starting in June 2019, GPAS began to run some jobs on bare metal nodes, while continuing to run most jobs on virtual machines. Although using bare metal nodes improves job completion rates, it significantly complicates the management of GPAS, since the GDC in general is designed around the setup, management, and monitoring of virtual nodes. For this reason, identifying the root cause of the higher failure rate for long-running jobs and mitigation strategies for improving the completion rate was important.

4.1 Job Performance Variance

Our next step was to quantify the slowdown. Originally, the GPAS compute pool used only VMs managed by OpenStack.

We divide pipeline jobs into comparable groups [10], and Figure 7b shows the cumulative distribution function (CDF) of processing rate of jobs on VMs and bare metal nodes that

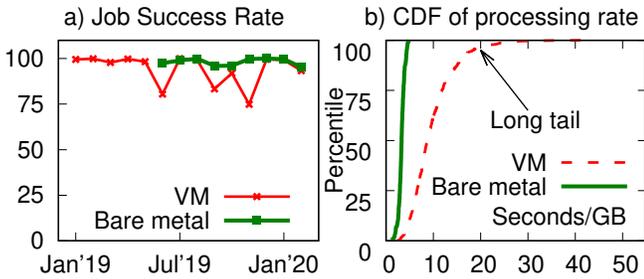

Figure 7: **Performance of jobs running on VMs and bare metal nodes, §4.** *a)* shows the success rate over the months for jobs running on VMs and bare metal nodes (which were added to the computing pool at a later time); *b)* shows processing rate CDF comparison between VMs and bare metal nodes.

we profiled in our deployment for one of the groups. For this figure, there are 796 and 247 jobs on VMs and bare metal, respectively, and all the jobs run the same type of pipeline (called “variant-filtration.pindel”), hence all the jobs should observe similar performance. In Figure 7a, the nearly vertical solid line represents *stable processing rate* of jobs on bare metal nodes. However, the dashed line of Figure 7b shows that *processing rate* on VMs is generally worse than *processing rate* on bare metal nodes. While this is expected, the issue lies in the *tail* performance especially at high percentiles. According to the zoomed graph in Figure 7b, starting from the 80th percentile, *processing rate* on VMs is 3 times worse than bare metal nodes, and in higher percentiles, the performance gets worse by an even larger magnitude.

We also would like to note again that the jobs in Figure 7b are jobs that come from one type of job pipeline (“variant-filtration.pindel”) that generally only spends not more than 40 seconds/GB. However, there are other more CPU/memory-intensive pipelines that spend 1000 – 3000 seconds for each GB. The problem raised in this paper becomes worse for these even more intensive pipelines.

Besides, the performance variation is a wide-spread issue across all of the pipelines mentioned in Section 3. And in fact, we divided all the pipeline jobs (around 200K) into 474 comparable groups at the time of writing this paper. Among the largest 20 groups (constituting 36.5% of all the jobs), all of them exhibit a long tail in performance, and 95th percentile performance is larger than 1000 seconds/GB for 12 groups.

To show that the behavior in Figure 7b is not because of degraded machines or hardware, we take six VMs that run on six different machines and show the statistics of the job performance on these VMs in Figure 8 in a boxplot. In every VM (*e.g.*, VM1 on machine1), users can run the same job pipeline repeatedly. Maximum and minimum *processing rate* are represented by the top and bottom bars, and 75th and 25th percentiles are represented by the top and bottom edges of the rectangle box, and median value is represented by the line inside the rectangle box. As shown in the fig-

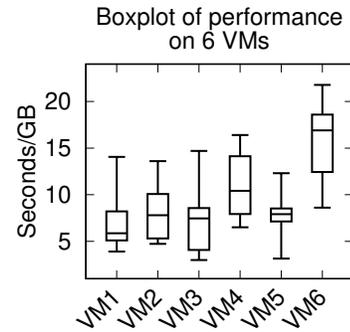

Figure 8: **Performance variance across VMs, §4.1.**

ure, the *processing rate* in a single VM varies (even though the same pipeline) and the performance across the VMs also varies (even though the VMs have the same configuration).

4.2 Application-Level Measurement

We manually noticed that jobs started running slower on VMs that have been running for *several days*. Thus, in order to understand the root cause to the issue, we conducted a set of experiments that included micro-benchmarks and real workloads. All experiments were conducted on a pair of VMs with the same virtual hardware setup and the same software setup, except that one of the VMs was cold-restarted before the experiment. We refer this cold-restarted VM as a *Fresh VM*. The other VMs (*Aged VM*) had been running for a few days and were selected for close monitoring after slow jobs were observed. Each VM was the only tenant on its host and configured to have 40 vCPUs, 226GB RAM and 2.5 TB storage. The hosts were equipped with two 2.20GHz 12-core 24-thread Intel Processors Xeon E5-2650 v4, 504GB RAM and 7.3 TB SSD RAID-5 storage. Linux-4.4 kernel, libvirt 1.3.1 and OpenStack Nova 13.1.4 were installed for virtual machine support.

First, we ran a simple application to reproduce our observation about a *Fresh VM* vs an *Aged VM*. To simplify the experiment, we broke down a widely used pipeline in GPAS (Somatic Variant Calling) and only selected one of the tools, VarScan2 [21]. Job pipelines in GPAS are spawned as multiple processes, hence VarScan2 can run as multiple processes. The details and the reason for parallelism is explained in [10].

Since the input data for all the tests in this experiment are the same, here we do not use *processing rate*, but instead *execution time* as the performance metric. A higher execution time implies worse performance (the same as in *processing rate*).

We define an “*n*-process VarScan2 task” as a task that uses *n* VarScan2 processes to process the input data. We define a “*test*” as an experiment that concurrently runs 5 tasks of the 8-process VarScan2 on a single VM. The input data is replicated 5 times and each task performs the same computation on the same content but distinct replicas of the data. After a test completes, we measure and record the *average execution*

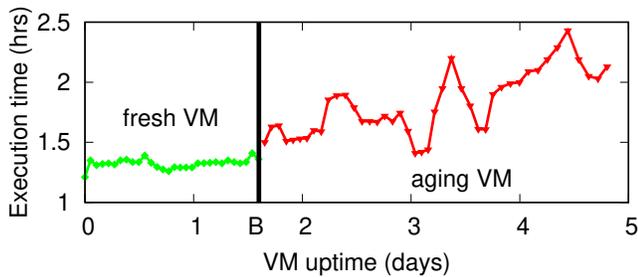

Figure 9: **VarScan2 experiment, §4.2.** Each point in the figure represents a test of five 8-process VarScan2 tasks.

time of the 5 tasks in the test and then repeat the test until 5 days have elapsed.

Figure 9 shows the average execution time of the tasks across several days. Every y point represents a test; the y value of a point shows the average execution time of the 5 concurrent tasks in the test. We can observe that between day 0 and 1.6 (marked by line B), the execution time of the test is relatively fast with low variance. However, after approximately 1.6 days, the performance starts to degrade. We observe that VarScan2 tasks perform normally on a *Fresh VM*, but perform much worse on an *Aged VM*.

4.3 Kernel-Level Measurement

To understand the slow performance in an *Aged VM*, we conducted further experiments including micro-benchmarks and in-kernel measurements in the *Aged VM*.

We use `sysbench` [29], a configurable multi-threaded benchmark tool that provides a variety of tests for benchmarking CPUs, multi threading, memory operation, and file I/O performance. We performed many varieties of experiments (not shown here for space) and found that most benchmarking results do not reveal much difference between an *Aged VM* and a *Fresh VM* (not shown), except for file I/O performance. Not only does the I/O throughput show different results; but, more interestingly, the monitored CPU utilization on *Aged VM* and *Fresh VM* are quite different when compared to that of the host OS.

A common way to monitor CPU utilization is calculating the difference of accumulated values in the pseudo file system (`/proc/stat`). Simply speaking, the values represent how many time slices have been used for each type (user, system, etc) and for each CPU. There are many tools that profile CPU utilization including `top` and `scolllector`. We use the latter as it collects and saves raw data, and we can use other tools to calculate and visualize it in desired ways.

Figure 10 shows the comparison of CPU utilization collected from the host OS versus inside an *Aged VM*. In the VM, we ran a `sysbench` file I/O test (on an SSD). It is worth noting that there are two lines in the figure (`UtilRaw` and `UtilDrv`) representing two ways we calculate CPU utilization. `UtilRaw` is the raw CPU utilization number (in %)

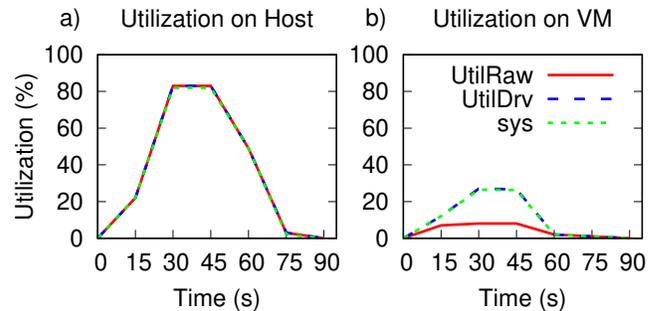

Figure 10: **CPU utilization of sysbench, §4.3.** CPU utilization during `sysbench` file I/O test is presented in this figure. The graph to the left shows CPU utilization collected from the host OS, while the one to the right is collected from an Aged VM. The VM is the only tenant on its host.

that `scolllector` outputs in every second. In addition to the raw CPU utilization, `scolllector` also outputs more detailed information, including `cpuUserSlices`, `cpuSysSlices`, and `cpuIdleSlices`. We define `UtilDrv` (for derived) by summing the user and system time slices and dividing by all slices ($(\text{cpuUserSlices} + \text{cpuSysSlices}) / \text{allSlices}$). Again the difference is that `UtilDrv` simply sums the `cpuUserSlices` and `cpuSysSlices` without considering the `idleSlices`. The figure also shows another line `sys`, which represents `cpuSysSlices` divided by all the slices (in %).

We make the following important observations: (a) System (`sys`) CPU utilization is high on the host and equal to the overall CPU utilization. A similar observation can be found in the *Aged VM*. We consider this abnormal because the workload is I/O bound. (b) At the peak utilization, the CPU utilization observed on the host is 82%, while it is only 27% on the *Aged VM*. Note again that there is only one VM on the host and no other heavy workloads running on the host. This implies that *the hypervisor works intensively, a hidden CPU overhead*. (c) On the VM, there is a gap between the two ways we measure CPU utilization (the gap between `UtilDrv` and `UtilRaw`). Normally, these two lines should overlap as in the host-level measurement (left graph). What happens here is that `scolllector` assumes the VM always gets all the CPU slices from the host OS. However, with our method, `UtilDrv`, it shows there is a “loss of time” due to the hidden overhead in the hypervisor. CPU time that is supposed to be used for tasks in the VM was used for other system tasks in the host. (d) On a separate measurement on a *Fresh VM* (not shown for space), we found no such high system CPU usage nor a gap between the two lines.

4.4 Memory Fragmentation

A major problem of aging resources is fragmentation. We started suspecting there was a memory fragmentation problem where sequential guest pages were not mapped sequentially on the physical pages. To get more evidence, we ran concurrent processes and analyzed read operations. Roughly

Tasks	1 × 1	1 × 8	4 × 8	5 × 8
Steps #1-4	< 1	< 2	< 12	< 20
Step #5	5	92	290	512
Total	6	94	306	552

Table 4: **Read latency break-down, §4.4.** Average total time (in seconds) that each process spends in the five steps during read operations are listed in the table. $x \times n$ at the top row means a test with x number of n -process VarScan2 tasks.

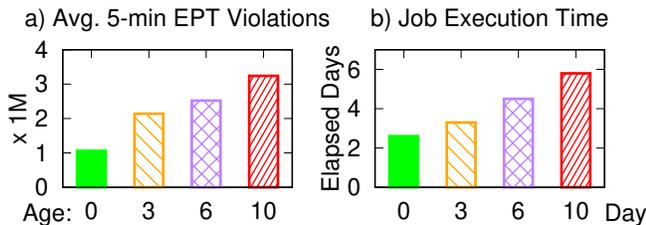

Figure 11: **Correlations between EPT violations and job execution time, §4.5.** Each bar represents the statistics for jobs when the VM is 0, 3, 6, and 10 days old. EPT violations are recorded by enabling tracing on the physical host.

speaking, a file read operation goes through five steps: 1) check the page cache to see whether the data is already in memory; 2) conduct a synchronized read request at the file system level; 3) send out an asynchronized read request at the block level; 4) wait for completion; and, 5) copy the data from the kernel to the user space. Step (5) represents the most memory-intensive step among all the steps.

We conducted an experiment that records the time spent in each of the steps. We set up four tests. The first test runs a single 1-process VarScan2 task, and the other four tests run 1, 4, and 5 (concurrent) 8-process tasks, respectively.

Table 4 shows the average time every process spends on each I/O step. Note that most of the time is spent in Step #5 (memory copying). With just 1 process (1x1), a process only takes 5 seconds in total for memory copying. With 40 processes (5x8), every process now takes 512 seconds in step #5, which is roughly a $100x$ slowdown. We note that there is other contention in the SSD (as can be seen in steps #1-4); but, even with 40 processes, the I/O waiting time is not as severe as the slowdown from memory-copying. We also note that we have a 48-core machine, hence CPU contention should be almost negligible with 40 processes.

4.5 The Root Cause: EPT Violation

In this section, we quantify the root cause. After considerable investigation, we found that the root cause resides in the *extended page table (EPT)*, which is a technology invented to increase virtual memory performance for VMs. The use of EPT by the hypervisor is designed to be transparent to VM users. To our knowledge, EPT is used by only certain hypervisor implementations, such as Linux KVM. In a nutshell, EPT serves as a page table that stores the mapping between

the VM memory address and the host physical memory address. Modern CPUs use the translation look-aside buffer (TLB) to store a small subset of the EPT entries. Whenever there is a TLB miss, an *EPT violation* occurs, which causes the hypervisor to interrupt the VM to handle the violation.

Figure 11 shows an experiment with 5 jobs using 30 cores running repeatedly on a fresh state VM for ten days. Figure 11a shows the average number of EPT violations (in millions) observed in every 5 minutes. The figure clearly shows that the longer the VM has been running, the higher the number of EPT violations. Figure 11b confirms the correlation between the number of EPT violations and job execution time.

In conclusion, VM aging leads to more frequent EPT violations causing the hypervisor to interrupt the VM more frequently. In the next two sections, we describe how we monitor and mitigate the problem.

5 Performance Management

To manage this performance problem, we discuss the two parts of our solution: monitoring and mitigation.

5.1 Monitoring

We suggest two methods to detect VM aging: monitoring EPT violation (in the host) or CPU utilization gap (in the VM), along with with the challenges.

Host-Level EPT Violation Monitoring One direct way to measure the problem is to count the number of EPT violations observed in the hypervisor, however the result is relative—how do we know whether the number represents a higher than normal number of EPT violations. We found another more concrete metric to measure this problem: *address distance of subsequent EPT violations* (which basically attempts to measure the level of memory fragmentation). For example, if two subsequent violations at time T and $T+t$ are about translation misses of guest pages #100 and #2000, respectively, then the distance recorded is $1900 \times 4\text{KB}$. Essentially, we argue that when the addresses of subsequent EPT violations are farther apart, the memory tends to be more fragmented and more EPT violations will occur, causing more time to be spent managing EPT violations.

We return to the experiment in Section 4.5 and this time plot the distribution of address distances of subsequent EPT violations. Figure 12 shows different distributions categorized based on the age of the VM age. Notice that older VMs have distinctly larger address distances. For example, in a 10-day old VM, we can see a distance of at least 50GB in roughly 40% of the time ($x=50\text{GB}$, $y=0.6$).

This method requires access to the host. It can provide performance alerts in advance. For example, the distance distribution in a 3-day old VM can be clearly distinguished from a fresh VM. Here, the resulting job execution time has

Application / VM	vCPU Efficiency (%)	Execution Time
Heavy / Fresh VM	99	16.0 hrs
Heavy / Aged VM	83	39.0 hrs
Light / Fresh VM	99	5.4 hrs
Light / Aged VM	99	5.6 hrs

Table 5: **vCPU Efficiency, §5.1.** vCPU Efficiency and execution time for applications on the Fresh VM and Aged VM are listed in the table. There only shows a difference in vCPU Efficiency for the “heavy” application.

been increased by 27% (which was hard to observed in the middle of the job). Thus, this kind of monitoring allows us to predict job performance degradation even before the job ends. In terms of performance overhead, sampling violations in an online manner may bring an impact to system performance. However, our experiment where the trace is enabled for five minutes every ten minutes does not show a negative impact on performance.

VM-Level /proc/stat Monitoring

While the above method requires host-level access, we now present another method that can be done at the VM level. As explained before, the Linux kernel implements the `proc` pseudo-filesystem which provides an interface to kernel data structures. The `/proc/stat` file provides time-slice statistics across user, system, and idle processes from the time the system boots up. In our deployment, the Linux time slice is configured to 10ms.

Inspired by the “gap” shown in Figure 10 earlier, it is possible for users to monitor the gap at the VM level. *The gap is caused by a phenomenon where a time slice in the VM is actually (and significantly) less than 10ms because the hypervisor is handling EPT violations.* Thus, we can introduce a simple metric, *vCPU Efficiency*, which is the sum of all the time-slice values in `/proc/stat` (user, sys, and idle values) divided by the real time slices that have elapsed (since the last time we read `/proc/stat`). The metric should be near 100%, but when EPT violation is high, it is expected that the efficiency will be much lower than 100%.

Table 5 shows *vCPU Efficiency* and the job execution time for the same experiments we ran before. Here, we select one “heavy” and one “light” application, where the heavy application uses all 6 available cores per job and the light application uses 1 core per job. We can see that for heavy workloads, there is a large difference in *vCPU Efficiency* and

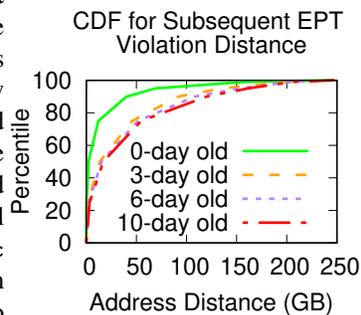

Figure 12: **EPT violation distance CDF, §5.1.**

Mitigation	Pros	Cons
Using Huge Pages	Performance is close to bare metal nodes.	Huge page VMs are more complicated to configure, and less flexible. Benefits of huge pages could be offset with even larger memory size and memory usage.
Restarting VM	Performance is best after restarting.	The system must support job check-pointing. Longer down time.
Defragmenting Memory	Performance is improved, short down time.	Cannot provide the best performance. Improvement is only temporary.
Running on bare metal	Performance is best and sustainable.	Does not provide the flexibility, management advantages, nor security isolation of VMs
Using public clouds	Based on one-week experiments, the performance is best and sustainable. Easy to manage.	higher costs for some workloads.

Table 6: **Pros and cons of five mitigation methods, §5.2.**

execution time. For example, when *vCPU Efficiency* drops from 99% to 83%, the resulting job execution time increases from 16 to 39 hours.

The disadvantage of this method is that we cannot detect VM aging unless we run a heavy application that can be impacted by the aging. Table 5 shows that for a light application, there is no visible difference in the *vCPU Efficiency* and execution time, even though the VM is already degraded at the time of running. We also want to emphasize that VM aging *cannot* be crudely defined by the number of days a VM has been up running. In our deployment, VMs age fast (after 3-6 days) because we ran complex bioinformatics pipelines.

5.2 Mitigations

This section describes several ways that we tried to address the problem. The choice of which mitigation to use depends upon the system requirements, and system administrators will need to decide which mitigation technique works best for them. Table 6 summarizes the pros and cons of the mitigation techniques we discuss below.

Using Huge Pages Just like a standard page table, the EPT size increases as the memory grows larger. Also the smaller the page size, the higher the probability of misses. Increasing the page size to 1MB for example (*i.e.* using “huge” pages) shrinks the size of the EPT table and reduces the probability

Restart Strategy	Jobs per day
Proactive restart	1.92
Slowdown-triggered restart	1.69
No restart	1.23

Table 7: **Rebooting VM mitigation, §5.2.**

of misses. However, in GPAS this is not an easy option to adopt. Huge page VMs are less flexible. Configuring and debugging huge page VMs in a production environment takes time. Hence, it is not easy to reconfigure and troubleshoot all the machines with a huge page configuration. In addition, a huge page size that is “huge” enough for now is not a permanent solution given the growing sizes of memory and the increasing application memory usage expected in the future [30]. Another option is to keep the 4KB page unit, but allocate smaller VMs to reduce memory fragmentation. However, in GPAS, resource requirements differ across jobs, and many jobs require large memory VMs.

Restarting VMs to avoid performance degradation Another method is to restart the VMs occasionally to “reset” the memory fragmentation. According to Figure 11, it is possible to detect EPT violations early before performance degrades significantly. With such a detection, we can decide when is a proper time to restart. We conducted a simple experiment with the same jobs as in Figure 11. Table 7 shows that restarting increase the number of jobs finished per day. Here, “proactive restart” implies restarting the VM after every job finishes (*i.e.*, do not reuse the VM across jobs) and “slowdown-triggered restart” implies restarting when the monitored *vCPU Efficiency* drops below 90%. The throughput numbers in Table 7 might also suggest that restarting in the middle of a long job might improve its execution time. However, this requires checkpointing the job progress, which a feature that is not supported in GPAS.

Defragmenting Memory The burst of EPT violations in aging VMs is essentially caused by the loss of data locality of the VM memory on the host physical memory. We can use the built-in memory defragmentation tool in Linux to reorganize the memory layout. A simple experiment with VarScan2 workloads shows that defragmentation indeed helps decrease EPT violations. As shown in Table 8, the test runs 21% faster after defragmentation when the VM has been heavily used for 7 days. The number of EPT violations during the test is decreased by 58%. However, comparing to performance of the fresh state, this method is still 44% slower and EPT violations are nearly 100 times more. In other words, memory defragmentation can be a temporary method to improve performance by a small margin, but restarting VMs leads to a better outcome.

Running on Bare Metal In GPAS, the most viable alternative is to run jobs directly on bare metal nodes without

VM age	Exec. Time (s)	EPT violations
0 day	587	630,636
7 days	1,073	140,677,142
7 days, defragmented	847	58,607,955

Table 8: **Memory defragmentation, §5.2.**

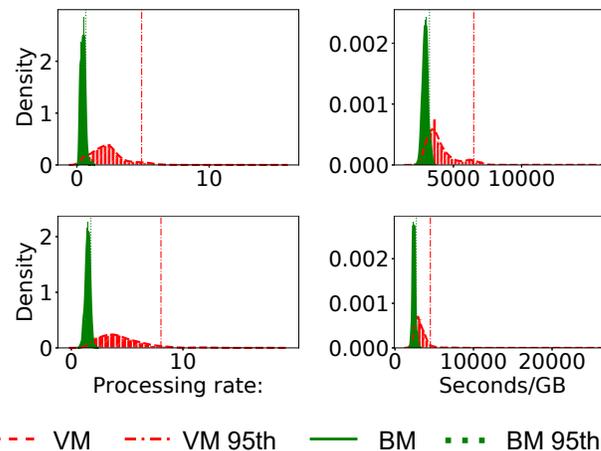

Figure 13: **Gaussian density estimation on processing rate, §5.2.** Gaussian density estimation has been applied to processing rate of jobs for four pipelines. Histograms are also shown for each pipelines. Vertical lines show where the 95th percentile processing rate resides for bare metal nodes and VMs.

VMs. The caveat is that not all research projects (jobs) can run in this mode; some research projects require the security isolation provided by running the jobs in a secure VM. For this reason, GPAS now uses a combination of bare-metal and VM deployments. The statistics presented below are from job pipelines that have more than one hundred jobs on bare metal nodes.

In Figure 13, a Gaussian kernel density estimation is calculated for jobs of four particular pipelines on bare metal (BM) nodes and VMs. Bare-metal jobs exhibit much less variance than VM jobs (the bell shapes of bare-metal jobs are more localized across the x-axis). In addition, bare-metal jobs have higher *processing rate* than VM jobs. The 95th percentile *processing rate* is marked in the graphs. Note that the *processing rate* tail of the bare metal jobs is relatively short.

Table 9 shows the performance improvements of using bare metal vs VMs for the fifteen GPAS pipelines that had at least 100 or more bare metal jobs. The *processing rate* improvement (in %) at is shown in the table for different percentiles. For example, the 95th percentile *processing rate* is improved by between 22% and 95%. The average performance improvement is between 18% and 87% (not shown).

In summary, given these benefits, the GDC platform uses a combination of bare metal and VM nodes, which provides good performance, but more complexity when scheduling jobs and more overhead when managing nodes.

Using Public Clouds We next turn to the question of whether there are problems with long running bioinformatics

Percentile	Improvement	Percentile	Improvement
25 th	14 – 78	95 th	22 – 95
median	18 – 79	97 th	20 – 97
75 th	19 – 81	max	28 – 100

Table 9: **Running on bare metal, §5.2.** *Processing rate improvements on different percentiles by running jobs on bare metal nodes are listed in the table.*

pipelines on the virtualization stacks used in public clouds. Different virtualization stacks are likely to use different approaches, which may, or may not, have the same issues with EPT violations. Some vendors [31, 32] recommend in their documentation that VMs with large memories use configurations with huge page memory, but with no more specific guidance given. On the other hand, hypervisors such as Xen, use an approach to implement virtual machine memory management that directly maps guest virtual address to host physical address (called direct paging). For this reason, they do not incur any additional overhead when resolving the mapping from guest to host, as KVM does.

We did experiments using Amazon Web Services (AWS) and Google Cloud Platform (GCP) to understand whether there are any problems with long running bioinformatics pipelines in their virtualization stacks. To simplify the experiments, we ran VarScan2 using open access data so that the full security and compliance infrastructure normally required by GPAS would not have to be used.

Amazon Web Services has developed their own Nitro system based on KVM. We rented a dedicated host (z1d) and allocated a large memory VM (12xlarge). The one-week experiment does *not* show performance degradation. For the dataset we used, the minimum execution time is 3.6 hours and the maximum is 3.9 hours, as shown in Table 10. Nitro may offload many tradition virtualization functions to dedicated hardware, which we suspect avoids the address translation overhead.

Google Cloud Platform also developed their hypervisor based on KVM [33]. We rented a 96-core sole-tenant host to avoid sharing with other users and allocated a 90-core 576GB VM on the host. We repeated the same experiment while scaling the maximum number of jobs to 14. The experiment results also does *not* show any degradation either. The minimum and maximum execution times are 5.7 and 6.0 hours, respectively. Although they use KVM, the same problem might not appear due to one of the following potential reasons: they use huge pages; they use software-based memory management instead of EPT; or the CPUs they use have larger TLBs.

In summary, public cloud platforms do not have the problems with performance degradation for long running pipelines that we observed with our on-premise Open-Stack/KVM platform. On the other hand, as mentioned, the

	Tests	Min (hrs)	Max (hrs)
One on-prem VM	36	10	15.3
Amazon Web Services	69	3.6	3.9
Google Cloud Platform	98	5.7	6.0

Table 10: **DNA alignment workload execution time on public cloud, §5.2.**

large scale GPAS on-premise system has lower costs than public clouds for many of the GDC workloads.

For all of the reasons stated in this section, the GDC platform uses a combination of VM and bare-metal, with occasional VM restarts. The GDC also uses public clouds for some workloads, to provide flexibility, and for burst computing. In summary the GDC today uses a hybrid on-premise/public cloud to take advantage of the flexibility of public clouds and the lower costs provided by large scale on-premise clouds for some workloads.

6 Future Challenges

After addressing the EPT violation problem, our future goal is to improve resource utilization of our cluster. The GPAS job management system runs jobs that are encapsulated as CWL workflows [7] and Dockerized. Data that is submitted to the GDC are organized into projects or portions of a project called batches. First, GPAS must schedule different competing projects/batches. For simplicity, we will just describe the process for scheduling projects, since scheduling batches is similar but more complicated. Projects typically contain multiple data types and the appropriate CWL pipelines must be run over each data type. In the first step, GPAS schedules the running of the required CWL pipelines over the different data types in each project. In the second step, CWLtool processes the DAG in the CWL pipeline and schedules each step in the DAG. In the third step, SLURM manages the running of jobs submitted by CWLtool on the VM pool of the available compute nodes.

Currently, each bioinformatics pipeline is encapsulated in a single CWL workflow that is containerized, and the container is scheduled and assigned to a virtual machine for execution. The pipelines were developed by the research community over a period of time and some employ threads efficiently, while others are less efficient. Since portions of pipelines may be either CPU-bound or I/O bound, inefficiencies can arise. For example, Figure 14 shows five Somatic-Variant-Calling (I/O intensive) jobs consuming different input files. The left figure shows that I/O utilization is full but the total bandwidth is lower than the maximum bandwidth of the hard drive (due to seek contention). The right figure shows that for most of the time, CPU is spent in waiting for I/O. The end part (5PM) of the figure also highlights the problem in the last paragraph where there is low I/O activity but the CPUs are not fully utilized.

	CURRENT:						PROPOSED:					
P1:	A1	A2	A3	B1	B2	B3	A1	A2	A3			
P2:			A3		B3		B1	B2	A3	B3		
P3:										B3		
Time:	1	2	3	4	5	6	1	2	3	4		

Inefficiencies can also arise due to the fact that currently GPAS assigns a VM per CWL container, and different portions of the CWL workflow benefit from different number of processors. As a specific example, assume we have a machine with three processors (P1–P3), and two jobs A and B, each of which has three serialized tasks (1, 2, 3) and task# 3 runs as threads. Assume that the maximum resource that A and B need are two processors, but that these are just needed for a portion of the pipeline. In this case, we have a classical scheduling allocation problem, if we devote two processors for A and B, then there are periods in which the CPUs are under utilized as shown in the Figure (the white spaces).

It would be more efficient to allocate the processors as shown on the right, where we allow both jobs A and B to be assigned on the same machine even though the total processors needed exceeds the number of processors ($4 > 3$). A simple simulation of some jobs in our cluster shows such an approach like this can increase CPU utilization up to 20% and reduce job execution time up to 15%.

While there is a vast literature on job/task scheduling (see Section 7), the challenge here is that the CWL workflows must either be rewritten and an appropriate scheduling algorithm used or the CWL execution engine itself must have a greater ability to parallelize portions of the DAG being executed. Both of these approaches are currently being developed.

7 Related work

We now discuss related work briefly for space (please see our supplemental material for more [10]).

The introduction of EPT is aimed to increase the performance of VM memory management. In its early stage of development, many found it to be effective in reducing the translation overhead compared to software-based solutions [34]. Multiple recent studies [4, 35–37] show that *short-term* benchmarks running on more advanced modern CPUs, the overhead from TLB misses and EPT violations is small and the VM performance is comparable to bare-metal performance. We found this is not true for our large bioinformatics jobs. Huge pages can reduce TLB misses to a large extent [38, 39], but it is not always a viable solution. More recent research in the community [30, 40–44] has devoted themselves to devise a better virtual memory management or mitigate the overhead of TLB misses. Another lesson that can be taken here is the need for tools to quickly reproduce memory (allocation) aging just like the popular utility of filesystem aging tools [45–53].

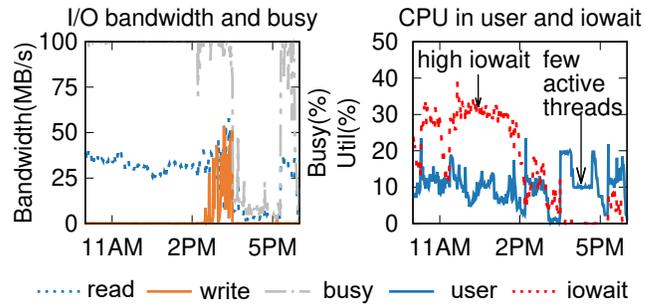

Figure 14: CPU under utilization.

On task scheduling, the literature is also rich on techniques that suggest finer-grained scheduling [54–56], better fairness [57–61], VM/Container backup/migration [62–64], hybrid scheduling [65–67]. The majority of the literature is concerned with optimizing new jobs that are written for a system, while the challenge with GPAS is parallelizing batches of older pipelines, most of which were designed for a single multi-core machine running a single job rather than for processing large datasets of multiple heterogeneous jobs running on a distributed platform.

8 Conclusion

To the best of our knowledge, we are the first to conduct a prolonged performance evaluation of virtualization stack for jobs that are both long running and memory intensive, such as bioinformatics jobs, and hence causing extreme virtual memory fragmentation. Diagnosing this problem has been a long and onerous process, primarily because the problem cannot be quickly reproduced; every experiment must be repeated for days to provide the evidence required. We hope the contributions of this paper can help other deployments similar to ours and lead to new research activities (*e.g.*, memory aging tools).

Abstract

The scale of computer clusters has grown significantly in recent years. Today, a cluster may have 100 thousand machines and execute billions of tasks, especially short tasks, each day. As a result, the scheduler, which manages resource utilization in a cluster, also needs to be upgraded to work at a much larger scale. However, upgrading the scheduler — a central system component — in a large production cluster is a daunting task as we need to ensure the cluster’s stability and robustness, e.g., user transparency should be guaranteed, and other cluster components and the existing scheduling policies need to remain unchanged. We investigated existing scheduler designs and found that most cannot handle the scale of our production clusters or may endanger their robustness. We analyzed one most suitable design that follows a shared-state architecture, and its limitations led us to a fine-grained staleness-aware state sharing design, called partitioned synchronization (ParSync). ParSync features the simplicity required for maintaining the robustness of a production cluster, while achieving high scheduling efficiency and quality in scaling. ParSync has been deployed and is running stably in our production clusters.

1 Introduction

In Alibaba, we operate large clusters each containing tens of thousands of machines. Every day, billions of tasks are submitted to, scheduled and executed in a cluster. A *cluster scheduler*, or *scheduler* for short, manages both machines and tasks in a cluster. Based on the resource requirements (e.g., CPU, memory, network bandwidth) of tasks, a scheduler matches tasks to appropriate resources using various scheduling algorithms and makes complex trade-offs among multiple scheduling objectives such as scheduling efficiency, scheduling quality, resource utilization, fairness and priority of tasks.

The ability to balance these objectives largely depends on both technical and business factors, and thus varies from company to company and cluster to cluster.

Due to the rapid growth in our businesses in recent years, we have faced serious challenges in scaling our scheduler, which is a centralized architecture similar to YARN [44], as there have been substantially more tasks and machines in our clusters. Today, the size of some of our clusters is close to 100k machines and the average task submission rate is about 40k tasks/sec (and considerably higher in some months). This scale simply exceeds a single scheduler’s capacity and an upgrade to a distributed scheduler architecture is inevitable.

In this paper, we present *a design for a distributed scheduler architecture that can handle the scale of our cluster size and task submission rate, while at the same time achieving low-latency and high-quality scheduling*. The design presented also satisfies two hard constraints (§2): *backward compatibility* and *seamless user transparency*. The scheduler’s robustness and stability derived from these constraints are of vital importance for our production environment.

Cluster schedulers have been extensively studied [9, 13, 14, 17, 25, 30, 32, 36, 37, 39, 44, 45] and we discuss the suitability of existing schedulers for our cluster environment and workloads in §3. Among them, a *shared-state scheduler architecture*, described in *Omega* [39], is able to handle our cluster size and satisfy the two hard constraints because it requires minimal intrusive architectural changes. In *Omega*, a master maintains the **cluster state**, which indicates the availability of resources in each machine in the cluster. There are multiple schedulers, each of which maintains a local copy of the cluster state by synchronizing with the master copy *periodically*¹. Each scheduler schedules tasks *optimistically* based on the (possibly stale) local state and sends resource requests to the

¹Omega [39] assumes that there is no synchronization overhead and thus each scheduler synchronizes the entire local state with the master whenever it communicates with the master to commit a task. But the synchronization overhead is not negligible in our cluster as it has a large state (due to the large size of the cluster), which does not allow us to synchronize the state at every task commit because of the high task submission rate (much higher than those in [39]). Thus, we synchronize the state periodically.

*Co-first-authors ordered alphabetically.

†This work was done when the authors were visiting Alibaba.

master. As multiple schedulers may request the same piece of resource, this results in **scheduling conflicts**. The master grants the resource to the first scheduler that requested it, and the other schedulers will need to reschedule their task. The scheduling conflicts and rescheduling overheads lead to high latency when the task submission rate is high, which we validate in §4 using both analytical models and simulations. Our results show that the *contention on high-quality resources* and the *staleness of local states* are the two main contributors to high scheduling latency as they both substantially increase scheduling conflicts.

Then in §5, we propose **partitioned synchronization (ParSync)** to mitigate the negative impacts of these two factors. ParSync partitions the cluster state into N parts (N is the number of schedulers), such that each scheduler synchronizes $1/N$ of distinct partitions instead of the entire state each time. As a result, at any time each scheduler has a fresh view of $1/N$ of the partitions and can first schedule its tasks to these partitions. This significantly reduces the contention (with other schedulers) on high-quality resources. Based on when a partition is synchronized, a scheduler knows how stale its partitions are; thus, algorithm designers can now better balance scheduling latency and scheduling quality by adjusting the preference to fresher partitions. We also devise an adaptive strategy to dynamically choose between lowering scheduling latency and improving scheduling quality. We validate the effectiveness of ParSync and various scheduling algorithms developed based on ParSync in §6. ParSync has been deployed in Fuxi 2.0, which is the latest version of the distributed cluster scheduler in Alibaba, and is running stably in our production clusters, where each production cluster contains thousands to 100K machines.

2 Background and Challenges

Workload statistics. Millions of jobs are submitted to a cluster each day in Alibaba. Figure 1a (solid curve) plots the number of jobs processed in a cluster each day in a randomly picked month, which ranges from 3.34 to 4.36 million jobs. A job consists of many tasks and Figure 1a (dotted curve) shows that the number of tasks each day ranges from 3.1 to 4.4 billion. The majority of tasks are short tasks. As shown in Figure 1b, 87% of tasks are completed in less than 10 seconds.

Motivation for scheduler upgrade. Our previous cluster scheduler follows a typical master-worker architecture [44]. A single *master* manages all the resources in a cluster and handles all the scheduling work. Each worker machine has an *agent* process, which sends the latest status of the worker via heart-beat messages to the master. The master receives jobs submitted by users and then places each job in its corresponding *quota group* [26]². The cluster operator configures a

²Jobs belong to projects and projects are assigned resource quotas according to their budgets. A *quota group* can be considered as a virtual cluster

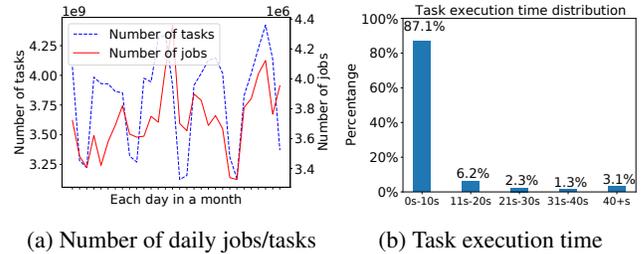

Figure 1: Job/task statistics

quota group to specify the minimum and maximum amounts of resources the group can acquire. In particular, when the cluster is overloaded, resources have to be divided among all the groups by weighted fairness (based on their quotas).

In recent years, the scale of our cluster has significantly increased and a single cluster can have 100k machines. *Statically partitioning a large cluster is not an option* because there are some extremely large jobs from critical projects and a large cluster is required to ensure that these large jobs and a large number of daily production jobs can be both processed without extended delay. There are also important technical reasons (e.g., resource fragmentation [45], limited visibility [39]) and business factors (e.g., projects need to access the data of other projects in the same business unit that stores its data in a single cluster for operational and management reasons), *which require scheduling over an entire large cluster rather than breaking it down into smaller ones*.

However, the previous monolithic single-master architecture could not handle the scale of the current clusters in Alibaba. First, the 10x larger number of machines requires a larger time gap between two consecutive heart-beat messages from a worker to the master so that the master, which is on the critical path of all decisions, would not be overloaded. But a larger gap is more likely to leave idle machines unused for a longer period of time during the gap. Second, the significantly larger number of tasks simply exceeds the capability of a single scheduler. Specifically, our previous scheduler could only handle task submission rates in the range of a few thousand tasks per second, but the average task submission rate is 40K/sec (and the peak is 61K/sec) for the 30 days in Figure 1a.

Objectives and constraints. In addition to the scalability challenges posed by both the workload and the cluster size, the new scheduler should also achieve a good trade-off among various scheduling objectives. We focus on the following objectives: (1) *scheduling efficiency or delay*, i.e., how long a task waits for its required resources to be allocated; (2) *scheduling quality*, i.e., whether the resource preference of a task (e.g., machines where its data are stored, machines with larger memory or faster CPUs) is satisfied; (3) *fairness* [19] and

that is allocated with a certain amount of resources according to a project's available resource quotas.

priority; and (4) *resource utilization*. These objectives often contradict each other. For example, high scheduling quality may prolong the scheduling delay; maintaining strict fairness can leave resources unused and thus hurt utilization.

Over the years, the complicated logic for balancing these objectives has been programmed into various scheduling strategies. In addition, other cluster components such as application masters and worker agents are maintained by other teams in Alibaba, and it takes years' collaborative efforts to make them robust and behave as expected. Thus, *the new scheduler design should make as few changes to the existing codebase as possible, so as to ensure the entire system's robustness and backward compatibility (e.g., other cluster components need not be changed and the existing scheduling strategies can be applied in the same way)*. Finally, *the system upgrade should be transparent to both the internal users and cloud clients of Alibaba*.

Methodology. We first investigate existing works that may serve as a potential solution and pick the most suitable one for further analysis. We then develop a simplified model to gain insights mathematically. As it is hard to acquire an accurate mathematical solution and the simplified model also leaves out critical factors that cannot be dismissed in a real production environment, we use a simulation to find out the determining factors, which are used to derive our solution to the scalability problem. Finally, we evaluate our solution in a high-fidelity simulation cluster with workloads sampled from the production clusters as shown in Figure 1b.

3 Can We Adopt an Existing Scheduler?

As many schedulers have been proposed, we first examine if our problem can be addressed by an existing scheduler.

3.1 Shared-State Architecture

Omega [39] proposed the *shared-state scheduler architecture* as described in §1. This architecture addresses the limitations in *monolithic*, *two-level*, and *static partitioning* approaches, respectively. First, each scheduler in the shared-state architecture can run a different scheduling strategy programmed in separate code bases for different types of jobs, as to avoid the software engineering difficulties of maintaining all strategies in one code base and using multi-threading for solving head-of-line blocking in *monolithic* architecture. Second, each scheduler has a global view of the cluster, thus solving the problem of limited visibility in *two-level* schedulers such as Mesos [25]. This allows global policies (e.g., fairness and priority) to be implemented. Third, each scheduler can assign tasks to any machine in the cluster instead of a fixed subset of partitions, which reduces resource fragmentation in *statically partitioned* clusters and achieves higher utilization [45].

The shared-state architecture is a neat design that also satisfies our two hard constraints given in §1. First, interactions between application masters, worker agents and schedulers would require little change. An application master still talks to only one scheduler and performs application-level scheduling on a pool of committed resources. An agent reports the status of each task to its corresponding scheduler in the same way. Thus, backward compatibility is ensured. Second, users rely on the behaviors of global policies such as fairness and priority to organize their workflows to ensure job completion before deadline and effective resource utilization. They may have accumulated many scripts for arranging job submissions over the years. With global policies unchanged, these scripts can be reused.

With the hard constraints resolved, we move on to analyze whether this architecture also meets our other design goals given in §1, i.e., scalability, low latency and high scheduling quality. We present our analysis in §4, but before that, we also consider other alternatives below.

3.2 Schedulers Focusing on Scalability

Shared-state approaches. Apollo [9], Mercury [30] and Yaq-d [37] also use a shared state. They do not resolve conflicts by a centralized coordinator as in Omega, but let schedulers push tasks to distributed queues in workers. Based on task duration estimation, Apollo shares a *wait-time matrix (WTM)* as the state to keep the queue length in each worker. The WTM allows a scheduler to infer future resource availability instead of being limited to present resource availability. Yaq-d discusses queue sizing and reordering strategies based on wait time. In Mercury, tasks with guaranteed resources are handled by a centralized scheduler in order to enforce fairness and priority, while other tasks are handled by distributed schedulers.

These schedulers are not as general as Omega's design (e.g., their designs cannot be easily adopted in cluster) for the following reasons. First, task duration estimation can be inaccurate due to little prior information, changing input data size, data skewness [11, 33] and temporal interference [8, 16]. Task duration estimation is particularly difficult for modern clusters (e.g., clouds, our data centers) as they process diversified tasks from both internal and external users running on a broad range of systems. Second, predicted resource availability improves scheduling quality primarily due to disk locality, e.g., in Apollo's cluster [9]. A scheduler would assign a task to a busy machine as long as the benefit from disk locality is greater than the extra time the task waits to be executed. However, disk locality becomes less important [7] when faster switches, NICs [1, 6] and compressed file format [2–5, 42] are in use. Third, distinguishing tasks as in Mercury complicates the intra-job scheduling design of the applications, which compromises backward compatibility.

Other approaches. There are also distributed schedulers that do not share a cluster state. Sparrow [36] uses batch sampling and late binding to improve scheduling efficiency and task completion time. Tarcil [17] extends Sparrow by dynamically adjusting sampling sizes. Hawk [14] dispatches long batch jobs to a centralized scheduler, which adopts the least-waiting-time strategy, and short jobs to a set of distributed schedulers. Hawk also reserves a small portion of the cluster for short jobs and uses task stealing to avoid short tasks being blocked by long tasks. Eagle [13] takes one step further to proactively avoid assigning a short task to a machine with long tasks running or waiting. It also enables a worker machine to repetitively fetch remaining tasks from a job to mimic the least-remaining-time-first strategy.

The designs of these schedulers are also not general and adopting them has the following key concerns. First, they also rely on accurate task duration estimation as in shared-state approaches. Second, Sparrow does not have a global view of a cluster to implement global policies, and its strategy is customized for fine-grained tasks of Spark jobs [35] and the duration of such tasks is in the range of milliseconds. Hawk and Eagle focus on using a single scheduling algorithm to reduce the JCT of homogeneous workloads. In contrast, Omega’s design offers a global cluster view and allows multiple schedulers to run different scheduling algorithms.

3.3 Other Related Work

Schedulers such as YARN [44], Mesos [25], Borg [41,45] and Kubernetes [32] consider various issues in production clusters such as generality, extensibility, robustness and resource utilization, in contrast to schedulers discussed in §3.2 which focus on high scalability and low scheduling latency. Apart from scheduler architectures, many scheduling algorithms have been proposed. [23, 29, 31] focus on intra-job task scheduling to optimize job completion time. Job scheduling algorithms that aim to achieve objectives such as fairness [10, 19, 27, 47], high resource utilization [12, 15, 16, 20, 20, 21, 27, 28, 34, 40, 46], job completion time [22, 43], and workload autoscaling [38] may also be adopted in our schedulers according to the application needs of our clusters. These works do not focus on scheduler architecture design and are orthogonal to our work.

4 An Analysis on Scheduling Conflicts

In §3 we singled out Omega’s shared-state architecture [39] as a potential solution to our problem. As mentioned in §1, *multiple schedulers may contend for the same piece of resource*, which leads to **conflicts** and hence scheduling delay. Thus, we want to study the following questions: (1) *What are the factors that determine the conflict rate? how important is each of these factors?* (2) *How bad can the scheduling delay be?* (3) *How can we avoid or alleviate the scheduling delay? What price do we need to pay?*

4.1 Conflict Modeling

We first quantify conflicts by constructing an analytical model for scheduling using the shared-state architecture presented in §1. The scheduling of a task may be delayed when there are not enough available resources to be allocated for the submitted tasks, or when there are enough available resources but the scheduler cannot keep up with the task submission rate. As we focus on the scheduler design, we only investigate the second case, i.e., the scheduler is the potential bottleneck of allocating available resources to tasks in time.

One extreme case that puts schedulers on the test is when the task submission rate and the resource needs of the tasks just match with the total amount of resources in a cluster. Suppose that there are S slots of resources in the cluster and each task takes one slot for its execution. At each unit of time (UT), J tasks are submitted for scheduling and each of the tasks runs for a fixed duration of T UT. If we have a single ideal scheduler that assigns tasks without delay and incurs no conflict, then all the J tasks will be committed immediately as long as there are available slots. We say that a task is **committed** when its requested resources are allocated. In reality, however, we do not have such an ideal scheduler. Instead, we have multiple schedulers that can lead to conflicts. By queuing theory, the scheduling delay will grow to infinity. However, as we will discuss below, this extreme case helps us see how much overhead due to conflicts is added by introducing multiple schedulers and how much price we should pay to fix this problem. We are particularly interested in this extreme case as it gives the scheduler the most pressure.

Now suppose that a scheduler can only schedule and commit $K < J$ tasks within each UT *given that there is no conflict*. To keep up with the task submission rate, i.e., J tasks/UT, we need to use at least $N = J/K$ schedulers to share the scheduling load. We assume that tasks are uniformly distributed to the schedulers and each scheduler independently makes its own scheduling decision based on the latest synchronized local cluster state, where available slots are randomly chosen for assignment. We will discuss the implications of these assumptions in §4.2.

We name the above setting as the **Baseline**. As conflicts cannot be avoided in reality, a scheduler cannot commit all its K tasks within the current UT when conflicts occur, which leads to scheduling delay. We investigate how many conflicts can be incurred. Consider that the cluster has S_{idle} idle slots. We denote the number of schedulers picking slot i as a random variable X_i . Since each scheduler picks a slot with probability $\frac{K}{S_{idle}}$, X_i follows a binomial distribution. We denote the number of conflicts at slot i as a random variable $Y_i = \max(X_i - 1, 0)$.

Then, we can deduce the expectation of Y_i as:

$$\begin{aligned}
\mathbb{E}(Y_i) &= 0 \cdot \Pr\{X_i \leq 1\} + \sum_{j=1}^{N-1} j \cdot \Pr\{X_i = j + 1\} \\
&= \sum_{j=1}^{N-1} (j+1) \cdot \Pr\{X_i = j+1\} - \sum_{j=1}^{N-1} \Pr\{X_i = j+1\} \\
&= \mathbb{E}(X_i) - \Pr\{X_i = 1\} - (1 - \Pr\{X_i = 1\} - \Pr\{X_i = 0\}) \\
&= \frac{NK}{S_{idle}} - 1 + \left(1 - \frac{K}{S_{idle}}\right)^N \quad (1)
\end{aligned}$$

Since we have S_{idle} idle slots in total, the expectation of the total number of conflicts is given by:

$$\mathbb{E}\left(\sum_{i=1}^S Y_i\right) = S_{idle} * \mathbb{E}(Y_i) = NK - S_{idle} + S_{idle} * \left(1 - \frac{K}{S_{idle}}\right)^N \quad (2)$$

To reduce conflicts, naturally we may consider to add more slots (so as to reduce the contention for resources) or more schedulers (so as to increase the capacity to handle conflicts). We analyze each of them as follows.

Adding extra slots. Merely adding extra slots to a cluster can never reduce the expectation of the number of conflicts to 0 according to Eq.(2). We may reduce conflicts by adding more extra slots, but Eq.(2) shows that the effect of increasing the number of extra slots (i.e., S_{idle}) is superlinearly diminishing.

Adding extra schedulers. In the Baseline setting, each scheduler is operating at its full capacity and does not have room to resolve conflicts. By adding more schedulers, each scheduler may handle less than K tasks in each UT and now have time to reschedule tasks due to conflicts. However, this may lead to more conflicts, as the following analysis shows. Suppose now we have $A * N$ (where $A > 1$) instead of N schedulers, and thus each scheduler has $\frac{K}{A}$ tasks to schedule. Substituting N with $A * N$ and K with $\frac{K}{A}$ in Eq.(2), we obtain:

$$f(A) = \mathbb{E}\left(\sum_{i=1}^S Y_i\right) = AN \frac{K}{A} - S_{idle} + S_{idle} * \left(1 - \frac{K}{AS_{idle}}\right)^{AN} \quad (3)$$

$$= C_1 + C_2 * \left(1 - \frac{1}{x}\right)^{x * C_3}, \quad (4)$$

where $C_1 = NK - S_{idle}$, $C_2 = S_{idle}$, $C_3 = \frac{NK}{S_{idle}}$, and $x = \frac{AS_{idle}}{K}$.

In Eq.(4), since C_1 , C_2 and C_3 are independent of A and $C_2, C_3 > 0$, $f(A)$ increases if $\left(1 - \frac{1}{x}\right)^x$ increases. Since $\left(1 - \frac{1}{x}\right)^x$ increases monotonically as A increases when $x \geq 1$, $f(A)$ also increases as A increases, i.e., the expected number of conflicts increases when more schedulers are added. Thus, we need to find out *whether the overhead of having more conflicts can be covered up by the benefit of having more time for rescheduling tasks such that these tasks will be committed within the same UT in which they are submitted.*

Adding extra slots and schedulers. Due to the diminishing returns by adding extra slots only or schedulers only, it is reasonable to believe that adding both of them can lead to

a more cost-effective solution. However, as S_{extra} and A are intertwined in Eq.(4) and Eq.(4) only indicates the number of conflicts in a single round of scheduling, it is hard to derive an accurate mathematical solution for S_{extra} and A to achieve 0 scheduling delay in a series of rounds of scheduling. Nevertheless, we can make use of the equations we have derived for quantifying conflicts to construct a simulator for the scheduling process. By simulating different combinations of N, J, K, S , with the constraints $J * T = S$ and $N * K = J$, we can examine the minimal requirements for S_{extra} and A .

4.2 The Implications of Our Assumptions

Before we present the simulation, we remark that although the assumptions made in §4.1 lead to an easier analysis, some of them diverge from the reality in the following aspects:

[A1] It is assumed that schedulers pick slots for tasks in a uniformly random fashion. In reality, some machines may be preferred (e.g., because of more advanced hardware or data locality) and result in more conflicts than the expectation.

[A2] It is (implicitly) assumed that all the schedulers schedule tasks synchronously round after round, and the local cluster states can be synchronized with the master state as frequently as we want. However, in reality each scheduler acts asynchronously with each other. We also cannot piggyback the synchronization of the cluster state on the return trip of every commit request as in Omega [39], as explained in Footnote 1 in §1. Instead, a time gap G is set between two synchronizations of a local state with the master. In-between the gap, when a scheduler commits a task to some slot, the slot's status in the master state and the scheduler's local state is updated. Such updates make the local states of other schedulers *stale*, and scheduling decisions based on a stale view of the state lead to more conflicts than indicated by our equations in §4.1.

[A3] We assume conflicts are uniformly incurred on schedulers. But in reality commit requests from schedulers are handled by the master in an FIFO manner and thus schedulers whose requests are sent earlier will get fewer conflicts.

4.3 Simulation Analysis

We construct a simulator following most of the setting in §4.1. We also integrate the factors listed in §4.2 into the simulator as follows.

To address [A1], we assign a score to each slot based on a normal distribution and schedulers pick desired slots by weighted sampling according to their scores (instead of in a uniformly random fashion as in §4.1). We vary the variance of slot scores to control how much slots should be contended.

To address [A2], we set a **synchronization gap** G . At each time period G , schedulers synchronize their local state with

the master state. Each scheduler makes its scheduling decisions independently based on its own local state, which may become stale until its next synchronization. Since G controls the staleness of the local states, we vary G to examine its impact on scheduling delay.

To address [A3], commit requests are sent to the master asynchronously by schedulers in our simulation and the requests are processed in FIFO. We also distribute the master state by partitioning so that commit requests to a slot are only sent to the partition that contains the slot. We vary the number of partitions to examine the effects of having a long queue at a single master versus shorter queues at distributed partitions.

Simulation setting. We assume that the cluster has 200K slots, and each task takes 1 slot and uses it for 5s, which is to simulate a typical scenario in our cluster, i.e., task submission rate is around 40K tasks/s and the duration of most tasks is between 1s to 10s (§2). Suppose that a scheduler takes 0.25ms to schedule a single task (close to our real scheduling latency) and thus we need at least 10 schedulers to just match with the 40K/s task submission rate (assuming no conflicts). Tasks are submitted in batches, where each batch has 100 tasks, and 10 batches are submitted to each scheduler in each second. Each scheduler makes scheduling decisions for a whole batch and schedules the next batch only after the tasks in the current batch have all been committed.

We vary task submission rate R , synchronization gap G , slot scores, and the number of partitions P of the master state, to examine how S_{extra} changes with $A = 2, 4, 8$. We want to find which factors are the main contributors to conflicts. For each simulation, we use the following *default setting*: $R = 40K/s$, $G = 0.5s$, a normal distribution of slot scores with mean = 10 and variance $V = 2$, and $P = 1$ (i.e., no partitioning).

In the simulation, we try to find the minimum number of combinations of A and S_{extra} to achieve a small scheduling delay. With a larger A , the number of tasks B in one batch is adjusted to $B_{new} = \frac{B}{A}$. With a larger S_{extra} , the number of conflicts decreases. In the simulation, tasks are submitted at a fixed rate for 90 seconds (similar patterns are observed after 90s), and we say that the scheduling delay is small when the simulation finishes in less than $110\% \times 90s = 99s$.

Simulation results. Figures 2a, 2b and 2c show that a significant number of extra slots needs to be added as we increase R , G or V . This is because a larger R means more work for each scheduler, a larger G means making scheduling decisions based on a staler state and for longer time, and a larger V means more contentions for higher-quality slots, all of which lead to more conflicts. To maintain the same scheduling delay, more extra slots can help reduce the contentions for slots and hence conflicts. However, Figure 2d shows that the impact of P is minimal. This is because even when the master state is not partitioned, some schedulers may have more conflicts at one point of time but the number of conflicts evens out among all schedulers over time.

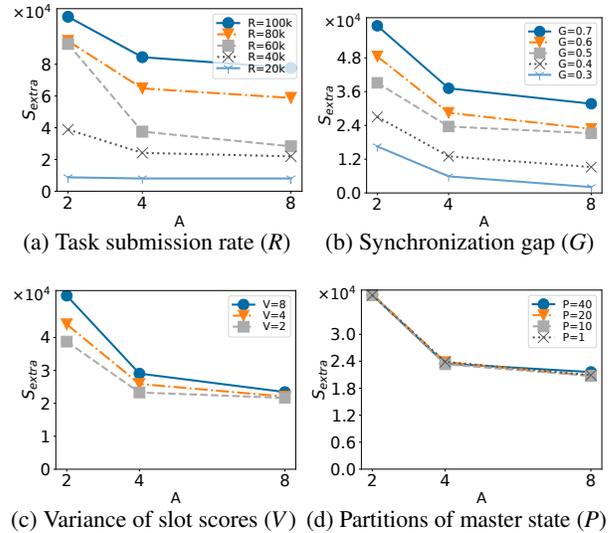

Figure 2: Simulation results

In each simulation, we also increase the number of schedulers to 2, 4 and 8 times more to see how a larger A helps reduce scheduling delay. Figures 2a-2d consistently show that increasing A has diminishing benefits. This conforms with our findings in §4.1 as sharing the same total amount of work by more schedulers leads to more conflicts. Moreover, it is costly to operate many schedulers in a real cluster, as we use active standbys to replace failed ones to meet our SLAs.

Adding a large number of extra slots and schedulers is a big price to pay for a large-scale production cluster, considering both the extra machine costs and daily operation costs. Thus, we want to look for a new solution. According to the simulation results, task submission rate, slot scores and synchronization gap are the main factors that contribute to conflicts. However, we cannot change task submission rate as it is fixed by the workloads. Slot scores are related to the resources desired by tasks, which may be compromised (e.g., a task may also accept a fast machine instead of the fastest machine) to alleviate the contentions and hence reduce conflicts. Synchronization gap affects performance as it controls the staleness of the local states, which in turn determine the probability of conflicts. Our solution will focus on the last two factors, i.e., **slot quality** and **staleness of the local states**.

5 Partitioned Synchronization

As our solution aims to reduce conflicts, we first describe an alternative that offers no-conflict guarantee, namely *pessimistic scheduling*. One implementation of pessimistic scheduling is to let each scheduler have *exclusive partitions* of a cluster, but this can lead to resource under-utilization as some partitions may hold idle resources that can be used by other schedulers [39, 45]. Another implementation is by applying

locks on resource slots, but this can block the actions of other schedulers and increase scheduling delay due to reduced concurrent processing [24, 39]. We want to avoid the limitations of pessimistic scheduling and reduce conflicts in optimistic scheduling (as in Omega), while enjoying their benefits, i.e., *high concurrent processing while having few conflicts*.

5.1 The Design

Observation. We found that scheduling delay increases disproportionately within the period G . When the cluster state is just synchronized, it is fresher and scheduling has fewer conflicts. But when the state becomes more outdated towards the end of G , scheduling decisions result in more conflicts. Conflicts lead to rescheduling, which may in turn cause new conflicts, and hence rescheduling recursively. Consider our default simulation setting in §4.3 and $S_{extra} = 15,000$, and divide G into two equal intervals: 0s-0.25s and 0.25s-0.5s. The average conflict rate in the first interval is 48% and that in the second interval is increased to 64%. As a result, the average delay of the first interval is only 23% of the total average delay, while the second interval contributes to 76% of the total. In other words, most of the delay is caused by the staler view of the cluster state in the later interval of G .

Main idea. Our main idea is *to reduce the staleness of the local states and to find a good balance between resource quality (i.e., slot score) and scheduling efficiency*, as these two are the main contributors to conflicts according to our findings in §4.3. We present our solution, **partitioned synchronization (ParSync)**, as follows.

ParSync logically partitions the master state into P parts. Assume that we have N schedulers, where $N \leq P$. Each scheduler still keeps a local cluster state, but *different schedulers synchronize different partitions of the state each time*, in contrast to *synchronizing the entire state* (let us denote it as **StateSync**) as in the approach discussed in §4. Specifically, assume (for simplicity) P is a multiple of N , the i -th scheduler starts its synchronization from the $(\frac{P}{N} * (i - 1) + 1)$ -th partition to the $(\frac{P}{N} * i)$ -th partition of the state in each round of synchronization, and the subsequent rounds of synchronization continue in a round-robin manner. Thus, in each round, all schedulers synchronize different partitions of the cluster state. This is also why we require $P \geq N$, as otherwise some schedulers would synchronize the same partition(s).

How does ParSync work? First, each scheduler has a *fresh* view of $\frac{P}{N}$ partitions of the cluster resources, so that the scheduler can commit its tasks to available slots in these partitions with a high success rate (since its view on these partitions is fresher than that of any other schedulers). This design is particularly favorable for scheduling short tasks in a highly contended cluster like ours. For short tasks, it is more critical to acquire resources sooner for their execution, instead of spending long time to find the most suitable slots because bet-

ter slots may not compensate for the scheduling delay (which itself can be comparable with or even longer than the execution time of a short task). Note that the majority of the tasks in our workloads are short tasks, as shown in Figure 1b.

Second, ParSync also effectively reduces the average *staleness* of the entries in a local cluster state, which we explain as follows. As the granularity of synchronization is changed from the entire cluster state to $\frac{P}{N}$ partitions, which effectively changes the synchronization gap to $\frac{G}{N}$. In contrast to synchronizing the entire state at every G time units, with ParSync each scheduler synchronizes $\frac{P}{N}$ partitions of its local state at every $\frac{G}{N}$ time units. Now let us define the **staleness** of a partition as the period of time since its latest synchronization, and let **AS** be the **average staleness** of all the partitions of a local state. Whether ParSync is used or not, the average of “AS”s over all time points is always $\frac{G}{2}$. However, ParSync reduces the variance of “AS”s, which we explain as follows.

Suppose that there is only one partition, then the minimum and maximum AS are 0 and G (at time 0 and G , respectively). If there are two partitions, then the minimum and maximum AS are $(0 + \frac{G}{2})/2 = \frac{G}{4}$ and $(\frac{G}{2} + G)/2 = \frac{3G}{4}$. Thus, when we increase the number of partitions from 1 to 2, we also bound the AS in the range of $[\frac{G}{4}, \frac{3G}{4}]$ instead of $[0, G]$. Intuitively speaking, using more partitions here is like sacrificing the period when the AS is small (i.e., $[0, \frac{G}{4}]$) to avoid the period when the AS is large (i.e., $[\frac{3G}{4}, G]$). But *this sacrifice can lead to significant reduction in the scheduling delay, because conflicts increase much faster in the later interval of G as we discussed in the Observation earlier*.

As having more partitions bounds the AS in a smaller range, consequently the variance of AS is also reduced. When the number of partitions becomes sufficiently large, we push the minimum and maximum AS close to $\frac{G}{2}$. Thus, *the eventual effect of ParSync on scheduling delay can be approximately viewed as reducing G to $\frac{G}{2}$, which also means that we reduce the average staleness of a local state*.

The above analysis is important because our Observation earlier also indicates that a reduction in the staleness of the local state can significantly reduce the number of conflicts and hence also the scheduling delay.

ParSync allows us to better balance resource quality and scheduling efficiency. For example, as conflicts are less likely to happen in periods when the cluster is not in intensive use, a scheduler may take higher risk of rescheduling and try to commit tasks to high-quality slots in other staler partitions (instead of its freshest $\frac{P}{N}$ partitions). In this case, ParSync may adopt optimistic scheduling to prioritize resource quality (i.e., slot score). In contrast, a scheduling strategy aiming for successful commits may take a pessimistic approach (but with all schedulers concurrently working). In addition, each scheduler still has a global view of the cluster and hence global scheduling policies can also be implemented.

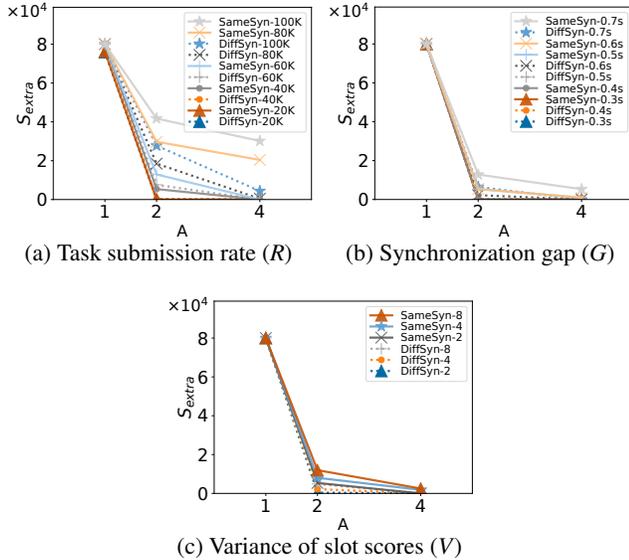

Figure 3: The effects of different synchronization strategies

5.2 Simulation Analysis on ParSync

We further analyze the effectiveness of ParSync by simulation. In all the simulations, we use the same setting and the default values of the parameters as in §4.3.

Synchronization strategies. We first compare two synchronization strategies: (1) **DiffSyn**: each scheduler synchronizes different partitions of the cluster state, i.e., the strategy used in ParSync; (2) **SameSyn**: all schedulers synchronize the same partitions, i.e., all schedulers synchronize the $(\frac{P}{N} * (i - 1) + 1)$ -th to $(\frac{P}{N} * i)$ -th partitions in the i -th round, for $1 \leq i \leq N$. In this simulation, a scheduler may pick slots from any partition in the cluster (i.e., using optimistic scheduling).

We vary task submission rate R , synchronization gap G , the variance of slot scores V , and the number of schedulers (i.e., AN) from N to $4N$, where $N = 10$. As shown in Figures 3(a)-(c), SameSyn requires more extra slots than DiffSyn in order to achieve the same latency, which can be explained as follows.

We found that schedulers tend to pick slots from fresher partitions. This is because when a scheduler tries to commit a task to a slot, it also updates the status of the slot in its local partition to “taken” (either by this task or already taken). Over time, more and more slots in the staler partitions are marked “taken”, which are refreshed until the partitions are synchronized. This becomes a problem for SameSyn because all schedulers are competing for available slots from the same fresher partitions, thus leading to more conflicts. In contrast, under DiffSyn, the fresher partitions of each scheduler are different, meaning that each scheduler always has higher commit rate in its own fresher partitions. Each scheduler under DiffSyn still has high conflict rate when committing tasks to its

staler partitions, but this situation also happens to SameSyn.

Scheduling strategies. We examine three scheduling strategies: **Quality-first**, **Latency-first**, and **Adaptive**. In Quality-first, a scheduler schedules a task by first choosing the partition with the highest average slot score and then picking available slots by weighted sampling based on slot scores. In Latency-first, each scheduler schedules a task by first picking slots from its freshest partitions, but if suitable slots are not found, then it looks for slots in other partitions (from the least stale partition first).

Adaptive uses Quality-first when it does not incur much scheduling delay, while it adopts Latency-first when scheduling efficiency is more critical. It calculates an exponential moving average (EMA) of scheduling delay, such that Quality-first is used when the EMA is smaller than a threshold τ , and Latency-first is used otherwise. Note that τ is usually the SLA for the scheduling delay specified by the cluster operator or users. Here we intend to show that the adaptive strategy can bound the scheduling delay by τ when the cluster is busy, and attain high slot quality as Quality-first when the cluster is not busy, instead of arguing what is the best trade-off we can make. We run simulation by setting $\tau = 1.5s$ as a demonstration.

We simulate three scenarios that may happen in our production cluster on a typical day as follows. We create two groups of schedulers, A and B, and divide the timeline into three phases: (1) A and B are both operating at 2/3 of their full capacity; (2) A is operating at full capacity while B remains the same; (3) A and B are both operating at full capacity. Each phase is run for 30s.

Figure 4 plots the median and the 10th-90th interval of the slot scores and scheduling delay of Group A (dark color) and Group B (pale color), respectively. We also plot the cluster utilization rate as a thick dashed curve in Figures 4b, 4d and 4f for reference.

During Phase 1, the three strategies have similar slot quality and scheduling delay. This is because the task submission rate is only 2/3 of the full load and the cluster is only 60%-70% utilized, and thus all schedulers (from both groups) have high-quality slots to pick without incurring many conflicts.

During Phase 2, the three strategies start to behave differently as Group A is now undergoing a stress test. When Quality-first is used, Figure 4a shows that the slot quality is not degraded compared with Phase 1; but Figure 4b reveals the real problem as the scheduling delay of Group A schedulers surges, while that of Group B remains stable. Thus, Quality-first is not effective when the scheduling load is high. When Latency-first is used, Figures 4c&4d show that both the slot quality and scheduling delay of both groups only become slightly worse. This is because even though Group A is fully loaded, the overall cluster utilization rate is only about 80% and thus the schedulers can still have enough quality slots to pick from their freshest partitions. When Adaptive is used, Figure 4f shows that the scheduling delay of Group A

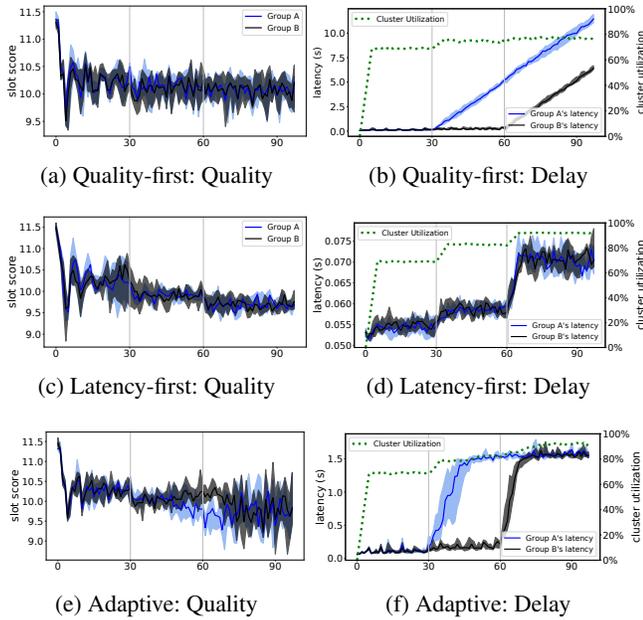

Figure 4: The performance of different scheduling strategies (dotted green line denotes the cluster utilization)

increases to 1.5s and then remains bounded there, as τ is set at 1.5s (note that this is much lower than the delay of Group A in Figure 4b, which rises to 4.7s). This means that Group A schedulers now switch to use Latency-first, while Group B still use Quality-first. As a result, Group A now has lower slot quality than Group B as shown in Figure 4e. Although Group B uses Quality-first while Group A uses Latency-first, the scheduling delay of Group B is actually much lower than that of Group A in Phase 2 of Figure 4f because Group B is only operating at 2/3 of its full capacity.

During Phase 3, even though Quality-first maintains the same slot quality, the scheduling delay of both groups keeps increasing. The slot quality of both Latency-first and Adaptive worsens compared with Phase 2 due to the heavier load and now the schedulers are competing more for quality slots. Figure 4d shows that the delay of Latency-first for both groups also increases, though still much lower than Quality-first and Adaptive. Adaptive bounds the delay of both groups at 1.5s.

In summary, Quality-first works well when the scheduling load or the cluster load is not heavy, as it leads to high-quality slot allocation. When the load is heavy, the delay of Quality-first may become too high and Latency-first is preferred as it achieves both high efficiency and slot quality. Adaptive is also a good choice as Adaptive keeps the latency bounded (which is particularly desirable as the bound can be tied to the SLA), while Adaptive can also take advantage of Quality-first to get high-quality slots when the load is not heavy.

To deploy ParSync in our cluster, we discuss some details to important issues such as what changes are needed in the upgrade, how the scheduling objectives are achieved, and how

the cluster is partitioned in Supplemental Material B in [18].

6 Performance Evaluation

We conducted our experiments in a high-fidelity testing environment called *Wind Tunnel*. Note that although ParSync is deployed in large production clusters in our company, conducting real experiments to evaluate ParSync’s scalability on these large clusters is prohibited by company policy as not to cause unexpected interruption to normal business operations. The company relies heavily on *Wind Tunnel* to test the robustness and performance of every cluster scheduler component and scheduling algorithm, and any change must be tested extensively in *Wind Tunnel* before applied to the production clusters.

The results obtained from *Wind Tunnel* are close to the true performance of the schedulers in our production clusters as *Wind Tunnel* uses the same codebase of the entire production cluster system and it incorporates critical factors from our production environment. First, in *Wind Tunnel*, each scheduler or resource manager is deployed on an independent machine and executes code used in production. A set of machines is then used to simulate resource slots in a production cluster. The interaction between schedulers, resource managers, and workers are the same as in production. *Wind Tunnel* makes the staleness of local states to be more reflective of real situations by deploying resource managers and schedulers on a real network topology. Second, the schedulers execute the same scheduling logic as in our production cluster, which enables the evaluation to reproduce the true scheduling capacity of each scheduler. Third, each job has a list of *preferred slots* computed at runtime for its tasks (instead of using a static score for each slot as in the simulations in §5.2) to better reflect the contentions on slots in reality.

The main difference between the high-fidelity simulation by *Wind Tunnel* and a production cluster is that the execution of a task is effectively “sleeping”, and each worker machine in *Wind Tunnel* is simulating many worker machines in a production cluster. All the rest are based on the same code base. Therefore, the results obtained from *Wind Tunnel* are similar to the results obtained from the production clusters.

Settings. In the experiments, we used the following default settings unless otherwise specified. We deployed 20 machines in *Wind Tunnel* for schedulers and 2 machines for resources managers. We used another 30 machines in *Wind Tunnel* to simulate 200k slots and each resource manager oversees 100k slots. The workload we used was sampled from the production trace whose statistics is shown in Figure 1. The baseline peak task submission rate from the sampled workload is around 40k/s, and we varied the rate to 50%, 80% and 95% of 40k/s to simulate different levels of pressure. The cluster state was partitioned into 20 parts in ParSync. The synchronization gap in our production cluster is around 0.5s.

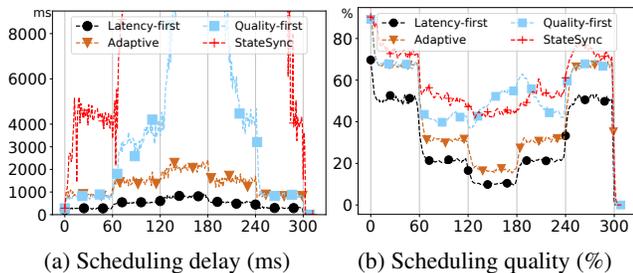

Figure 5: Performance of ParSync and StateSync

Performance metrics. We use *scheduling delay* and *scheduling quality* as the major measures. Scheduling quality is the percentage of tasks that are allocated to their preferred slots. We also report the *scheduling throughput* and the *number of conflicts* to analyze the performance.

6.1 Performance Comparison

There are many works related to cluster scheduling (§3). The scheduling algorithms mentioned in 3.3 are orthogonal to our work as many of them can also be applied for scheduling in ParSync. As discussed in §3.2, most existing schedulers are not as general as Omega’s shared-state design (§3.1), as they have specific requirements (e.g., accurate task duration estimation, strong disk locality) or cannot provide important features such as backward compatibility, support of multiple scheduling algorithms and global view. While these schedulers are effective in their own settings, we do not compare ParSync with them since the design objectives are different (and it is also difficult to create an environment in Wind Tunnel for a fair comparison, if possible, with these systems).

Instead, we compared ParSync with StateSync, which simulates Omega. We also tested StateSync with only 1 scheduler, which simulates our previous centralized scheduler (similar to YARN), but the delay is nearly two orders of magnitude worse than StateSync and thus we do not report the details.

For ParSync, we tested Latency-first, Quality-first and Adaptive ($\tau=2s$) introduced in §5.2. StateSync adopts the shared-state architecture in §4, which synchronizes the entire state each time. Both ParSync and StateSync used 20 schedulers. Tasks were submitted during a 300-second period, which was divided into five 60-second phases with different submission rates: 50%, 80%, 95%, 80%, 50% of 40k/s. The 50%, 80% and 95% rates simulate medium, medium-heavy and heavy loads of a cluster.

Figure 5a shows that the average scheduling delay of ParSync using Latency-first is significantly smaller than the other approaches throughout the five phases. The delay of ParSync using Adaptive is bounded by τ . The delay of Quality-first increases much faster than Latency-first and Adaptive dur-

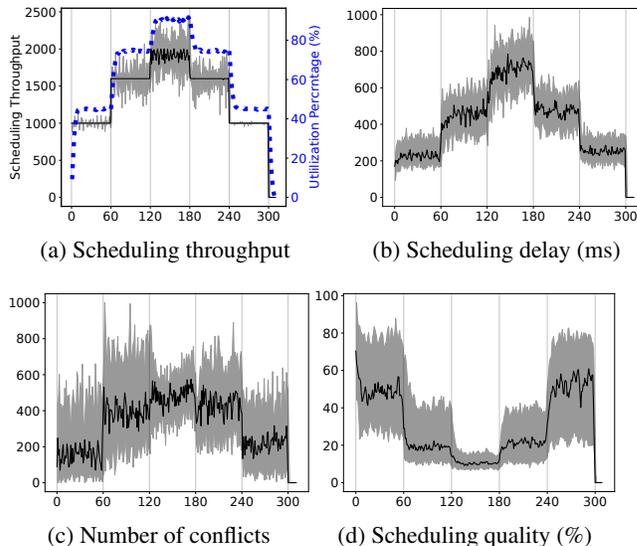

Figure 6: Results of ParSync using Latency-first

ing the peak periods (e.g., Phase 3), but is still much smaller than that of StateSync. Starting from Phase 2, StateSync’s delay increases rapidly as its schedulers are not able to handle the high task submission rate and uncommitted tasks starts to accumulate. The high delay starts to drop only in Phase 5 when the accumulated tasks from the previous phases are gradually committed. Although Figure 5b shows that the *scheduling quality of StateSync is actually quite good, its high scheduling delay makes it infeasible for production use.*

The results verify our findings in §4 that *sharing the whole cluster state without partitioned synchronization cannot scale to handle high task submission rates in our cluster, as the number of conflicts and the scheduling delay increase rapidly.*

6.2 Scheduling Delay and Scheduling Quality

Next we analyze in details the performance of ParSync, as reported in Figure 6 and Figure 7. In each figure, the dark curve plots the median and the shadows plot the 10- and 90-percentile values among the 20 schedulers.

Scheduling throughput. Figures 6a and 7a show that both Latency-first and Quality-first can handle the task submission rate. In Phase 3, schedulers using Quality-first have throughput lower than 1.9K/s in Figure 7a (note that on average, each of the 20 schedulers receives 1K, 1.6K, 1.9K, 1.6K, and 1K tasks per second in each of the five phases). This is because of the surge in the scheduling delay in Phase 3 (Figure 7b), and hence some tasks are accumulated and only successfully committed during Phase 4. This also explains why the throughput of most schedulers goes above 1.6K/s at the beginning of Phase 4. Figures 6a and 7a also show that the

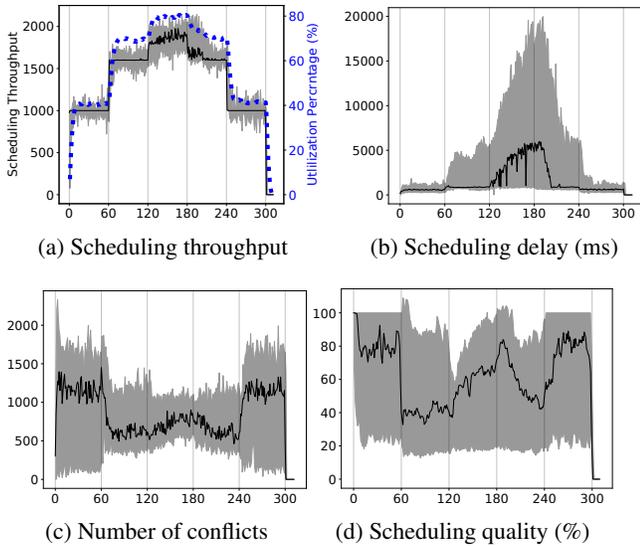

Figure 7: Results of ParSync using Quality-first

cluster utilization (plotted in thick dash curves) is reflected by the scheduling throughput in each phase.

Scheduling delay. Figure 6b shows that the scheduling delay of Latency-first increases with the task submission rate, which is mainly due to increasing scheduling conflicts as shown in Figure 6c. The median and mean delay roughly follow the task submission rate in each phase. We also observed that the total number of uncommitted tasks accumulated by each scheduler in each second is small and does not keep growing even during Phase 3 (see detailed results in Supplemental Material A.1 in [18]). This demonstrates that Latency-first is able to sustain and provide reasonable latency under heavy scheduling loads even if the peak period continues. In contrast, Figure 7b shows that using Quality-first, the scheduling delay increases rapidly in Phase 2 and Phase 3. The delay starts to drop in Phase 4 but is still high because it needs to clear the accumulated uncommitted tasks, which surges from 1,700 in Phase 2 to 5,800 in Phase 3 (1,700 and 5,800 are median values, details are reported in Supplemental Material A.1 in [18]). This is because Quality-first has a higher scheduling overhead as it checks all partitions to find preferred slots, its delay increases quickly when there are a large number of tasks to schedule. We also remark that Quality-first’s high delay is not primarily due to conflicts, as the number of conflicts of Quality-first is not much larger than that of Latency-first in Phase 3 as shown in Figures 6b and 7c.

Number of Conflicts. Figure 6c shows that Latency-first has an insignificant number of conflicts in Phase 1 as there are plenty of idle slots inside the freshest partition of each scheduler. There are more conflicts during Phase 2 to Phase 4 as

a scheduler may schedule some tasks to other less fresh partitions due to insufficient idle slots in its freshest partition. Interestingly, we observe an inverse pattern in Figure 7c, as Quality-first has a higher number of conflicts in Phase 1 and Phase 5 than in other phases. We examined the details and found that, in Phase 1 and Phase 5, Quality-first schedulers schedule tasks to preferred slots in all the partitions evenly since they all have plenty of idle slots. But from Phase 2, each scheduler starts to have an *increasingly* more idle slots in its own fresher partitions than in staler partitions (as discussed in §5.1). Thus, each scheduler tends to schedule more tasks to its fresher partitions, which incurs fewer conflicts.

Scheduling quality. Figures 6d and 7d show that Quality-first achieves considerably better quality than Latency-first. Note that there are always some tasks that may not get their preferred slots, as tasks are competing for preferred slots that may not be enough for all the tasks wanting them. Thus, the percentage of tasks getting their preferred slots drops accordingly when more tasks are submitted in Phases 2-4. However, Quality-first is actually able to allocate most slots to tasks that prefer them, although this is at the cost of higher delay when the scheduling load is heavy.

Compared with the more ideal simulation results in Figure 4, we observe more variations in the results shown in Figures 6 and 7 due to the introduction of real factors in our production cluster. But overall, the results are still consistent with our findings in §5.2, except that the trade-off between latency and quality becomes more obvious in Figures 6 and 7. The results in Figure 5 also validate that StateSync cannot handle our high task submission rates as ParSync does.

6.3 The Performance of the Adaptive Strategy

In this set of experiments, we evaluated how the latency threshold τ affects the performance of ParSync using the Adaptive strategy, by setting $\tau = 1000, 2000$ and 3000 . The range $1000 \leq \tau \leq 3000$ is representative of our workloads and it is not common to set the delay bound higher than 3,000 ms. We ran the same five phases as in the experiments in §6.2.

Figure 8 reports the median values (more details are reported in Supplemental Material A.2 in [18]) of the scheduling delay and quality of all schedulers. For all values of τ , Adaptive’s performance in Phases 1 and 5 is similar to that of Quality-first (see Figure 7), because Adaptive uses Quality-first when the scheduling load is not heavy. From Phase 2 to Phase 4, while Quality-first’s delay increases quickly as reported in Figure 7b, Figure 8a shows that Adaptive can effectively bound the delay at τ . Whenever the EMA is greater than τ during Phases 2-4, Adaptive switches to use Latency-first and thus it does not accumulate uncommitted tasks as in Quality-first. Consequently, its delay also drops quickly from Phase 3 to Phase 4, in contrast to Figure 7b. However,

Table 1: The effects of slot quality: in each cell, *left middle right* values = *Latency-first Adaptive*($\tau=1000$) *Quality-first* results (**STET**: average sum of task execution time; **JSD**: average job scheduling delay; **JCT**: average job completion time)

Metric(sec)/ α	0.9			0.8			0.7			0.6			0.5			0.4		
STET	922	914	904	888	873	854	858	822	772	836	788	712	797	726	622	762	600	542
JSD	0.4	0.8	3.7	0.4	0.8	3.3	0.4	0.8	2.9	0.4	0.8	2.0	0.4	0.8	1.9	0.4	0.7	1.5
JCT	10.3	10.6	12.7	10.3	10.5	12.1	10.2	10.3	11.2	10.2	10.0	9.9	10.1	9.5	9.1	10.1	8.6	8.4

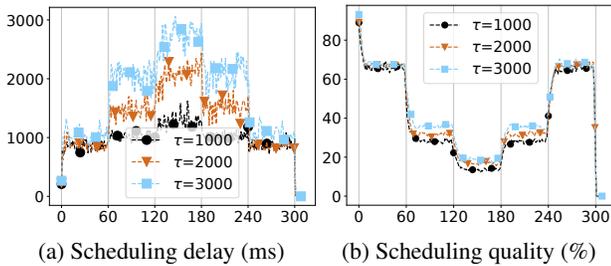

Figure 8: Results of the Adaptive Strategy

Figure 8b shows that Adaptive’s scheduling quality also drops in Phases 2-4, although its quality is still higher than that of Latency-first in Figure 6d because Adaptive uses Quality-first to get more quality slots until the EMA reaches τ . This is also why the quality of $\tau = 3000$ is generally better than those of $\tau = 2000$ and $\tau = 1000$.

Overall, *the results demonstrate the effectiveness of Adaptive in balancing scheduling delay and quality under different values of τ* . We report more details in Supplemental Material A.2, which show that we can choose different values of τ to bound scheduling delay without significantly affecting scheduling quality, throughput and the number of conflicts.

6.4 The Effects of Slot Quality

Running a task in its preferred slot reduces the task execution time (TET). The shorter the TET, the more room it creates for tolerating scheduling delay. Thus, if scheduling tasks to their preferred slots can shorten their TET significantly, Quality-first could be preferred to Latency-first. To test the effects of slot quality, we use a factor α to adjust the benefit of running a task in its preferred slot as follows: if the TET of running a task in a non-preferred slot is t , then its TET in a preferred slot is αt , where $0 < \alpha < 1$.

Table 1 reports the average sum of TET (**STET**, i.e., the sum of the TET of all tasks in a job, averaged over all jobs), average job scheduling delay (**JSD**, i.e., the duration between the time when a job is submitted and when all its tasks are committed), and average job completion time (**JCT**, i.e., the duration between the time when a job is submitted and when all its tasks are completed).

When we increase the benefit of preferred slots (i.e., smaller α), Quality-first is favored in terms of STET since it schedules more tasks to their preferred slots than both Latency-first and Adaptive as reported in §6.2 and §6.3. The JSD of Quality-first also decreases as α becomes smaller, because shorter TET releases occupied slots to other tasks earlier and hence leads to fewer conflicts. However, due to the higher scheduling overhead of Quality-first, its JSD is still much larger than that of Latency-first. In terms of JCT, since it benefits from both shorter TET and JSD, Quality-first starts to achieve a smaller JCT than Latency-first when the benefit of preferred slots exceeds its scheduling overhead, i.e., when $\alpha \leq 0.6$. In comparison, *the JCT of Adaptive always closely follows the best one of Quality-first and Latency-first, which proves the effectiveness of the adaptive strategy*.

6.5 Other Experimental Results

We also examined the effects of the number of partitions (which also changes the synchronization gap) and the scalability of ParSync. Due to the page limit, we report the details in Supplemental Material A.3 and A.4 in [18], and summarize the results here: (1) increasing the partition number has almost no impact on the scheduling performance; and (2) ParSync achieves stable performance as the scale of the cluster and task submission rate increases by 1 to 4 times of the capacity of our current cluster.

7 Conclusions

We presented ParSync, which increases the scheduling capacity of our production cluster from a few thousand tasks per second on thousands of machines to 40K tasks/sec on 100K machines. ParSync effectively reduces conflicts in contending resources to achieve low scheduling delay and high scheduling quality. The simplicity of ParSync allows us to maintain user transparency and backward compatibility that are essential to our production clusters.

Abstract

Incidents and outages dramatically degrade the availability of large-scale cloud computing systems such as AWS, Azure, and GCP. In current incident response practice, each team has only a partial view of the entire system, which makes the detection of incidents like fighting in the “fog of war”. As a result, prolonged mitigation time and more financial loss are incurred. In this work, we propose an automatic incident detection system, namely Warden, as a part of the Incident Management (IcM) platform. Warden collects alerts from different services and detects the occurrence of incidents from a global perspective. For each detected potential incident, Warden notifies relevant on-call engineers so that they could properly prioritize their tasks and initiate cross-team collaboration. We implemented and deployed Warden in the IcM platform of Azure. Our evaluation results based on data collected in an 18-month period from 26 major services show that Warden is effective and outperforms the baseline methods. For the majority of successfully detected incidents (~68%), Warden is faster than human, and this is particularly the case for the incidents that take long time to detect manually.

1 Introduction

Reliability is a key quality attribute of large-scale cloud systems such as AWS, Azure, and Google Cloud Platform (GCP). Although tremendous effort has been devoted to improving reliability, cloud systems still suffer from incidents and outages [8, 10, 11]. Monitoring is widely used by cloud systems to check their runtime status. A monitoring system collects, processes, and aggregates quantitative data about a cloud system. When a system problem occurs, an alert is sent to an on-call engineer, who is expected to triage the problem and work toward its mitigation. A severe enough alert (or a group of aggregated alerts) is escalated as an *incident*.

*Work done during Xin Zhao’s internship at Microsoft.

†Qingwei Lin is the corresponding author of this work.

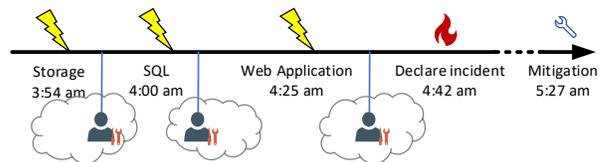

Figure 1: The timeline of handling a cross-service incident, where it took nearly 50 minutes to understand the situation and declare the incident.

Timely incident management is the key to reduce the system downtime. However, according to our experience, a reactive and ad-hoc incident detection is often employed in practice, which hinders effective incident management. We motivate our work using a real-world example. Fig. 1 shows the timeline of an incident caused by a flawed configuration change in the Storage service. The failed storage accounts affected several SQL databases, and the failure was further propagated to Web Application instances that were depending on the impaired databases. The failure triggered cascading alerts for Storage, SQL, and Web Application at 3:54 am, 4:00 am, and 4:25 am, respectively. After many rounds of discussions (which took nearly 50 minutes), the engineers finally realized that this was a cross-service issue, and an incident was declared. An experienced Incident Commander (IC) [4, 6] was then engaged to coordinate the mitigation process. Eventually, at 5:27 am, the incident was mitigated and all services were back to normal.

In this work, we focus on automatic incident detection for cloud systems, so that incidents could be declared and mitigated as early as possible. Incident declaration turns the mitigation process from chaotic to managed, especially for issues that require cross-team collaboration: the mitigation tasks are prioritized, teams are aligned, and customer impact is reduced. Our study is based on the Incident Management (IcM) platform of Microsoft Azure, one of the world-leading cloud computing platform. Though different companies [1–3]

implement slightly different incident response processes, we argue that they are essentially similar.

Incident detection is challenging. For a cloud system with extraordinary complex dependency among thousands of components, the on-call engineers, like in the fog of war, usually only have a partial view of the big picture. In the above-mentioned example, the engineers handling the storage alert could only see the affected storage accounts, but it was time-consuming to understand who was impacted. For engineers in the SQL and Web Application teams, it also took them a considerable amount of time to understand that they were affected by the underlying services. According to our interview with on-call engineers from the several service teams, such a diagnostic process could take as long as an hour. Also, there were a large number of concurrent alerts, making the situation even more challenging. Better communication processes/protocols can help, but will not solve the problem completely.

In this work, we propose Warden for effective and timely incident detection in IcM. Warden detects alerts that can potentially turn into incidents by employing a data-driven approach. A simple rule-based approach with human knowledge is insufficient in practice as it can be easily overwhelmed by a massive number of complex and ever-changing rules in a large-scale production cloud system. An example rule is “once a Storage alert was immediately followed by a SQL alert and they happened in the same datacenter, it is likely that they were related and constituted an incident”.

We develop a machine learning model to detect the incidents, and point out incident-indicating alerts for the on-call engineers. We have evaluated Warden using data collected in an 18-month period from 26 major services on Azure. According to our experimental results, Warden is effective and outperforms the baseline methods. Warden is also faster than human for the majority of successfully detected cases (~ 68%).

Our major contributions are summarized as follows:

- We study the problem of incident detection in the incident management (IcM) platform of Microsoft Azure. We have identified the obstacles that result in prolonged incident declaration time.
- We propose Warden, a framework to automatically detect incidents based on alerts in IcM. Warden quickly detects incidents and assists in task prioritization and cross-team collaboration.
- We evaluate Warden with real-world data collected from 26 major services on Azure. The evaluation results confirm the effectiveness of the proposed approach. We have successfully deployed Warden in IcM.

2 Background and Problem Formulation

In this section, we briefly describe the basic concepts about alerts and incidents and then formulate the incident detection problem. To help explain the concepts and the problem, we perform an empirical study of 5 services (named Big5) of Azure, namely Compute, Storage, Networking, SQL DB, and Web Application. These 5 services are common to almost all cloud computing platforms.

Alert ID: 200603407	Title: Ongoing VM critical failures	Severity: High
Service: Compute	Team: OS	Owner: Lily
Start Time: 2020-03-13 07:30:00	Mitigation Time: 2020-03-13 08:23:00	
Region: A	Data Center/Cluster (Optional): xxx/xxx	
Diagnosis logs	Monitor ID: DataCenterFailure	
Declare Time: 2020-03-13 07:52:00		Commander: Bob
Related Alerts		
Postmortem: summary, 5 why, timeline, root cause, repair items, etc.		

Figure 2: Main fields of an alert. Additional fields (grey colored) are appended when an alert is escalated into an incident. The escalated alert becomes the primary alert of the incident, while related alerts are manually linked.

2.1 Alerts and Incidents

Alerts represent system events that require attention, such as API timeouts, operation warnings, unexpected VM reboots, or network jitters. An alert consists mainly of fields shown in Fig. 2. Each alert has an impact starting time. Its mitigation time is filled when the problem is fixed. Alerts have different severity levels - low, medium, and high. Alerts are reported by monitors, which are continuously running programs that keep tracking the health status of a certain aspect of a service component. Each alert carries its monitor ID. Most alerts has its region information and some with more fine-grained location information such as datacenter or cluster.

Figure 3 shows the number of alerts per day for Big5 services in a one-year time frame. There are tens of thousands of concurrent alerts produced by a large number of components in the cloud system. Even for high severity alerts, the number could be hundreds or even several thousands. Figure 4 shows the number of active monitors per month. The number is gradually increasing as the platform scaling up and being improved.

In general, incidents are declared under severe situations. Often, problems taking a long time to solve or requiring cross-team collaboration are also declared as incidents. One incident usually triggers correlated alerts [21, 53]. An incident is thus

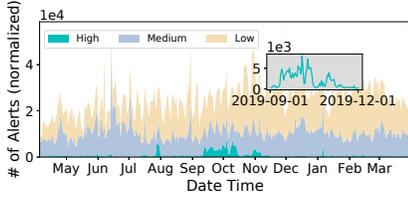

Figure 3: Number of alerts of different severity levels for the Big5 services.

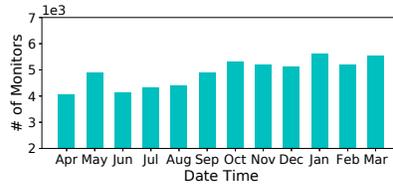

Figure 4: Number of monitors of the Big5 services actively reporting alerts per month.

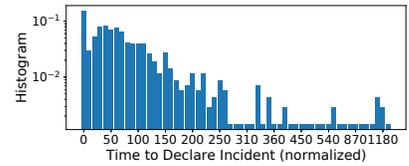

Figure 5: The histogram of time to declare incidents for the Big5 services.

escalated from one alert or a group of correlated alerts. Additional fields are added when alerts are escalated into incidents as shown in Fig. 2. The *primary* alert of an incident is usually the one closest to the root cause or with the earliest alerting time. The incident commander and the on-call engineers manually link related alerts with the primary alert based on expert knowledge. In the one-year-length period, there were several hundreds of incidents caused by the Big5 services, among which $\sim 67\%$ are incidents impacting more than one services. These incidents are typically the hard ones for detection and mitigation due to the partial view issue.

Fast incident detection is critical for ensuring timely incident management. The time to declare incidents takes around one-third of the whole mitigation time in our study. Figure 5 shows the histogram of time to declare incidents for the Big5 services. We normalized the time to declare incidents in Fig. 5 to protect company sensitive data. The reader could use the public incident reports [8, 10, 11] as a reference for the incident mitigation time. About one-third of the incidents are declared within minutes. Most of these incidents are single service issues that could be straightforwardly detected based on rules. Nearly half (47.6%) of the incidents take more than 30 NTUs (normalized time units) to declare, and a long tail of incidents require even hours. We manually analyzed these cases and found that most of these cases fall into the category where a small issue slowly turns into a big one. Our proposed approach is thus helpful by detecting incidents from a global perspective.

2.2 Problem Formulation

We now formally define the problem of incident detection. We denote the current wall clock as t . The input is the set of alerts coming from different services within the time window \mathcal{W}_t^l whose duration is $(t - w, t]$, where w is the length of the window. One monitor can be triggered many times over its lifetime. The series of alerts reported by any monitor m is called an *alert signal*, denoted as s^m .

From the input time window, we want to estimate the probability of $P_t = P(I_t | \mathcal{A}_t)$, where $I_t \in \{0, 1\}$ is the indicator of incident. \mathcal{A}_t is the observed set of alert signals in the time window that ends at t . We then infer that an incident has occurred

by examining whether P_t surpasses a threshold.

In addition, we need to extract a subset of alert signals which are indicating the incident from the time window, denoted as $\hat{\mathcal{A}}_t \subset \mathcal{A}_t$. System failures often lead to correlated alert signals. The physical meaning is that each alert signal $s^m \in \hat{\mathcal{A}}_t$ therein is one symptom caused by the underlying incident. We name $\hat{\mathcal{A}}_t$ as *incident-indicating* alert signals. According to our definition, we shall have $P_t = P(I_t | \mathcal{A}_t) = P(I_t | \hat{\mathcal{A}}_t)$.

In summary, we divide the incident detection problem into two steps. The first step is incident detection based on the observed alert signals from different services in a recent time window. The second step is to understand which alert signals are likely caused by the detected incident, i.e., identify the incident-indicating alert signals. When we detect the incident, we only notify the relevant on-call engineers. We describe the details of our solution in the next section.

3 The Proposed Approach

The workflow of Warden is shown in Fig. 6, which consists of the following major steps:

Alert signal selection Monitoring a very large-scale system is challenging due to the sheer number of components being watched. The raw alert data is not only large in volume but also contains noise. Therefore, we select only a subset of monitors which exhibit relatively strong association with incidents. Details about alert signal selection could be found in Sec. 3.1.

Incident Detection We adopt a data-driven paradigm for incident detection. We carefully extract a set of features from alerts in a recent time window based on domain knowledge in Sec. 3.2.1. Then, the feature vector is fed to a Balanced Random Forest (BRF) [37] model constructed offline. With this model, we could detect the occurrence of incidents. Section 3.2.2 explains how we train and apply the model.

Incident-indicating alerts identification We developed a novel approach to identify the incident-indicating alerts. We start by dividing the alert signals into groups. Then, we assign

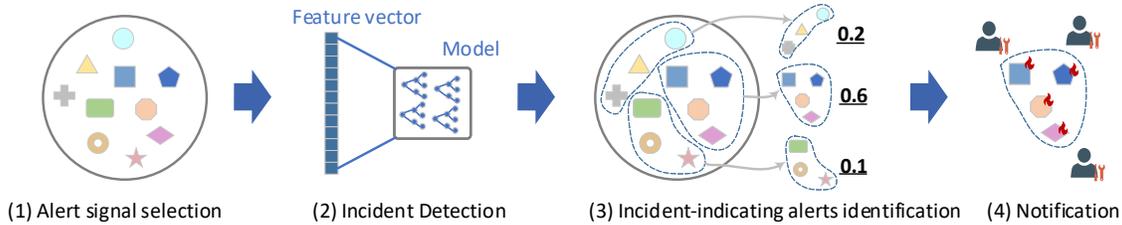

Figure 6: (1) Recent alert signals in a time window are selected and cached. (2) A feature vector is extracted and fed to a model for incident detection. (3) We extract a group of alert signals which most significantly indicate the detection result. (4) Relevant on-call engineers are notified for further investigation.

a score to each group based on an algorithm of our design called Group Shapely Value (GSV). The group of alert signals with the highest importance score is identified as the incident-indicating alerts. We explain the grouping and group-based model interpretation in Sec. 3.3. This approach is inspired by model interpretation [43], which is about understanding the relationship between inputs and outputs of a machine learning model. However, our goal is to extract a group of alerts indicating the detection result as shown in Fig.6 (3). The difference between incident-indicating alert identification and model interpretation is discussed in Sec. 5.

Notification We integrated our system into the IcM of Azure. A notification is pushed to all involved alerts when a potential incident is detected. When the corresponding on-call engineers are aware of the detected emerging issue, they could better understand the big picture and form a collaboration group to declare and resolve the incident. We introduce the practical usage scenario in Sec. 3.4.

3.1 Alert Signal Selection

Feeding alerts from all monitors could overwhelm the detection model. Figure 3 and Figure 4 show the number of active monitors and produced alerts for the Big5 services, respectively. There are even more monitors and alters considering other services. In contrast, the number of incidents is relatively small.

The purpose of alert signal selection is to identify a subset of monitors which emit alerts exhibiting a relatively high correlation with incidents. For this purpose, we calculate a score for each monitor. The higher the score, the more likely the alert signal from this monitor will indicate that the cloud is experiencing an incident. If we observe that the alerts from a certain monitor co-occur with incidents frequently, we should assign a high score to that monitor. With this intuition, we adopt the Weighted Mutual Information (WMI) [26]. WMI is a measure of the mutual dependence between two variables, i.e., quantifying the “amount of information” obtained about one random variable through observing the other random

variable [50].

Formally, denote I as the set of all incident. For each monitor m , we could calculate the WMI between the alert signal s^m and all incidents, i.e., $I(s^m; I)$. One monitor is usually only effective in detecting a specific problem. However, there are many different types of incidents. Therefore, calculating the WMI of one monitor against all incidents is not appropriate in characterizing its effectiveness, especially given one incident type may have far more cases than another type. Yet, a minority incident type may be equally, if not more, important than a majority type.

We divide all incidents into different subtypes based on their owning team that handled this incident. We notice that, in a production organization, each team usually focuses on specific functionalities [17, 18, 30]. Therefore, we assume that all incidents handled by the same team are similar, and therefore, constitute a subtype of incidents. We use $i \subset I$ to denote the a subtype of incidents. Then, the WMI between s^m and i could be calculated in Eq. (1).

$$I(s^m; i) = \sum_{s^m} \sum_i w(s^m, i) \cdot P(s^m, i) \cdot \log \left(\frac{P(s^m, i)}{P(s^m)P(i)} \right) \quad (1)$$

Both s^m and i are series of events with $s^m, i \in \{0, 1\}$. Eq. (1) essentially elaborates all value combinations of the two variables and examines their inherent dependence. We divide historic data into windows in order to calculate Eq. (1). For instance, to derive the joint probability $P(s^m = 1, i = 1)$, we simply count the number of windows containing both events. This value is then divided by the total number of windows. Other joint and marginal probabilities could be derived in a similarly way. The coefficients $w(s^m, i)$ in Eq. (1) are used to assign different weights to different value combinations.

Once we have the WMI for every pair of monitor and incident subtype, we can calculate the sum of score for m by going through all incident subtypes. We use this score to rank the monitors and pick the top 150, which are most effective for incident detection. We will evaluate the number of selected monitors in Sec. 4.6.2. The alerts not reported by the selected monitors are ignored by our system.

3.2 Incident Detection

We formulate the incident detection problem as a binary classification problem. The input consists of alert signals in a time window. A classifier is trained offline based on the historic labelled samples. Then, we apply the trained model for online incident detection.

3.2.1 Feature Extraction

We identify the following features from alerts generated by selected monitors in a time window:

Alert signals: The first set of features characterize the alert signals. Each alert signal is a series of alerts generated by a certain monitor within the time window.

- Alert count. In the event of a malfunction, the alert signal is typically stronger than usual. As a result, we count the total number of alerts and the high-severe alerts for each monitor, respectively. Multiple services may start to report alerts, and we, therefore, count the number of alerts from each service. Besides, we count the total number of alerts, the total number of monitors reporting high-severe alerts, and the total number of services, respectively.
- Alert burst. We adopt a time window length of 3 hours¹. Our window size is large enough to accommodate related alerts. However, under certain conditions, alerts erupt only in a small time and space. For instance, a partial power failure may hit only a few racks in a datacenter. To capture this feature, we calculate the max number of monitors reporting alerts and the max number of high-severity alerts in any datacenter, respectively. Likewise, in the temporal dimension, we calculate the two features for all child sliding windows of 10/30/60 minutes in length, respectively.

Engineer activities: Engineers leave their footprints when they are working on alerts in IcM. The second set of features characterize the intensiveness of engineer activities. Engineers could post their diagnosis logs on the alert page. They could also launch a bridge meeting for online discussion. The bridge meetings are hosted by IcM and attached to the alerts. If people in one service want to reach out to another service, they could use the notification tool in IcM which automatically routes them to the on-call team in the other service. Though private communications (via personal phone calls or IM apps) still exist, most traffic today is through IcM.

- Diagnosis log count. The engineers tend to leave diagnosis logs on the alert web pages as well as in the bridge meetings. We count the number of discussion posts for

¹According to our empirical study, over 80% alerts are triggered within 3 hours after the impact start time.

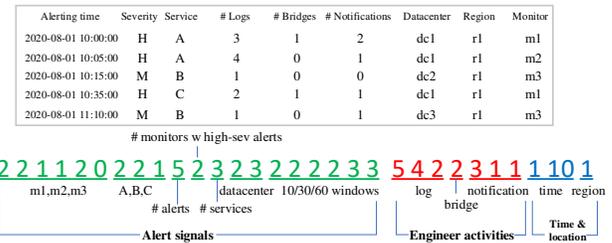

Figure 7: An example of feature extraction with 5 alerts in the time window generated by 3 monitors from 3 services. One feature vector is constructed for each time window.

each alert and the number of concurrent bridge meetings in IcM, respectively.

- Notification count. Notifications are sent to initiate cross-team collaborations. We thus count the number of notifications within the time window.

In addition to the aforementioned features, we also include features about time (day and hour) and location (Region ID). We illustrate the process of feature extraction using a dummy example of 5 alerts in Fig. 7. We show a few example columns of the derived feature vector.

3.2.2 Model Construction

We construct data samples using alert data with a sliding window to training an incident detection model. The window size is set to 3 hours as discussed in the previous section. The window is sliding with a stride length of 5 minutes, which is small enough in order not to miss any significant changes. The label of the sliding windows overlapping with incidents is positive; otherwise, negative. The labeling methodology is illustrated in Fig. 8. The two vertical bars represent the impact starting time and the mitigation time of the incident, respectively. The example sliding window (i.e., the shadowed rectangle) in Fig. 8 is thus labeled as positive. The 5-minute stride length is only used for offline model construction. For online usage, Warden runs once every minute. More details could be found in Sec. 3.4.

Not all alert signals in the window are part of the incident. In Fig. 8, only the alerts marked by the dashed curve are symptoms of the incident. This group of alert signals is $\hat{\mathcal{A}}_t$ according to our definition in Sec. 2.2. In our evaluation, we use the links between alerts to obtain the relationship between an incident and its related alerts. The links were manually labelled by on-call engineers or the incident commander during the incident mitigation process. We note that the related alerts are only available for historic data. For online detection, this information is unknown (or partially unknown).

Once we have the extracted features and the labels, we train a model and apply it for online incident detection. In our

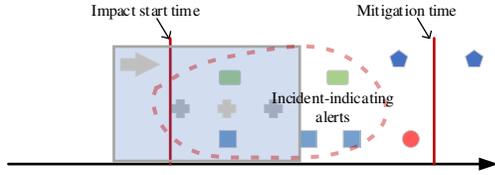

Figure 8: The sliding window is labelled as positive if any incident impact start time falls into it. Those time windows with no overlap with incident impact time ranges (from impact start to mitigation) are labelled as negative.

context, the number of incidents is much smaller than that of alerts. We therefore choose the BRF [37] classifier because of its robustness to noise and ability to handle imbalanced data. Warden is a generic framework, and any model could be plugged in for the classification task. More details about the model selection are presented in Sec. 4.6.1.

The output of the model is the probability $P_t \in [0.0, 1.0]$. We use a confidence threshold as discussed in our problem formulation in Sec. 2.2. If the confidence is higher than the threshold, we believe a potential incident is happening.

3.3 Identifying the Incident-indicating Alerts

We need to inform the right people when a potential incident is detected, and otherwise, it is non-actionable. In other words, we need to find out which alerts in the window are related to the detected incident, as illustrated in Fig. 8. After we identify these incident-indicating alerts, we notify their responsible on-call engineers.

It is a non-trivial task given many concurrent alert signals in the window. We propose a novel approach inspired by two intuitions: first, the target alert signals must be a group of correlated alert signals due to the same reason; second, the target alert signals should contribute significantly to the detection result. Such a group of correlated alerts is indicative to the detected incident.

Our approach has two steps. We first group alert signals that are likely related to each other into signal groups. Then, we interpret the incident detection model on a group basis.

3.3.1 Alert signal grouping

Correlated alert signals could be identified based on statistics on their co-occurrence history. We put two alert signals into the same group under one of the two conditions: (1) they co-occur frequently in history; (2) they fire from the same cluster.

An alert signal is a series of events. We thus first characterize the correlation between a pair of alert signals as we did for monitor selection in Sec. 3.1. We use a threshold to tell if one is strongly correlated with another. In addition, we

conduct statistics on related alerts for historic incidents. For each incident, people manually link related alerts. If two alert signals are frequently linked in history (more than 3 times), we believe that they are correlated if they present in the same time window.

Then, if two alert signals fire in the same cluster, we believe that they are correlated. In a large-scale cloud computing platform like Azure, a cluster is usually dedicated for a certain functionality (e.g., for storage, compute, or database). If two alert signals emerge from the same cluster in a short time frame, they are inherently related in a high probability.

We apply the aforementioned rules to group alert signals in the current time window. After grouping, the alert signals are divided into corresponding groups, as illustrated in Fig. 6.

3.3.2 Group-based Model Interpretation

We now discuss how to obtain the incident-indicating alerts. The basic idea is to rank the signal groups according to their contribution to the prediction result of the detection model. Then, we pick the top group of alert signals.

For this purpose, we develop a novel algorithm called Group Shapely Value (GSV). GSV is heavily inspired by the Shapely Value method [47] which is a model-agnostic interpreter.

Algorithm 1 Group Shapely Value (GSV)

Require:

- The classification model, M ;
- A testing window, \mathcal{W}_t ;
- The alert signal groups set associated with \mathcal{W}_t , \mathcal{G}_t ;
- The target group, $g \in \mathcal{G}_t$;
- Background training data, B
- Sampling rounds, n

Ensure:

- The Shapely Value c for target group g ;
 - 1: $\phi = 0$
 - 2: **for** 1 to n **do**
 - 3: Randomly select a subset \mathcal{G}' , $\mathcal{G}' \subseteq \mathcal{G}_t$
 - 4: $\mathcal{G}_{other} = \mathcal{G}_t \setminus (g \cup \mathcal{G}')$
 - 5: Randomly select a sample $x_b \in B$
 - 6: $b_1 = x_t(\mathcal{G}_{other}) \vee x_t(g) \vee x_b(\mathcal{G}')$
 - 7: $b_2 = x_t(\mathcal{G}_{other}) \vee x_b(g) \vee x_b(\mathcal{G}')$
 - 8: $\phi = \phi + M(b_1) - M(b_2)$
 - 9: **end for**
 - 10: $c = \frac{\phi}{n}$
-

The original Shapely Value method only estimates the importance for each feature value. In contrast, GSV is able to interpret the model for each alert signal group.

The intuition behind GSV is that we assemble combinations of alert signal groups to evaluate the contribution from each individual group. We leverage the Monte Carlo approximation method [47] to overcome the combination explosion

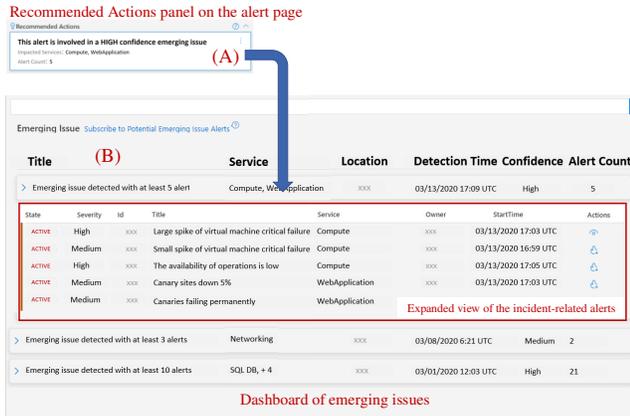

Figure 9: Web-based UI of Warden in IcM. (A) shows the “Recommended Actions” panel and (B) shows the “Emerging Issues” dashboard.

problem. The details of GSV can be referred in Algorithm 1. The input of the algorithm are the model M and the set of alert signal groups in the time window denoted as G_t obtained in the previous grouping step. GSV requires a set of background data B , which is randomly sampled from the training data. n is a hyper-parameter which is typically set to several hundred.

In Algorithm 1, we construct two synthetic samples b_1 and b_2 in each iteration, as shown in Line 6 and Line 7, respectively. Then, we calculate their difference in prediction probabilities by the model M . The operator $x(\cdot)$ retains only the feature values from a subset of alert signal groups of the testing sample x . Intuitively, the difference between b_1 and b_2 indicates the significance of the current value of g (i.e., $x_t(g)$) given a background sample $x_b \in B$. The iteration continues for n rounds and the accumulated ϕ is normalized to c . We use c as the score for the group g . We pick the group with the highest score as the incident-indicating alert signals.

3.4 Using Warden in Practice

To facilitate using Warden in practice, we develop a Web-based UI as shown in Fig. 9. The UI consists of two parts: (A) a “Recommended Action” panel located on each alert page, and (B) a dashboard of “Emerging Issues” for all detected incidents. Each detected incident is with a list of incident-indicating alerts.

Warden runs periodically at a fixed interval (in our practice, Warden runs once every minute, and the main task takes around 20 seconds). When Warden detects a potential incident, a notification is pushed to the “Recommended Action” panels of all identified incident-indicating alerts. Our notification is basically saying: *this alert is of high priority and it may be part of an emerging incident. Please check other alerts are likely triggered by the same issue as well.* When the engineer sees the notification pops up in the “Recommended Action” panel, she or he could click to jump to the dashboard for

more details. The list of related alerts on the dashboard helps the engineers to understand the big picture, prioritize their work, and initiate cross-team collaboration. We will describe real-world cases in Sec. 4.7.

4 Experimentation

In our evaluation, we aim to answer the following research questions:

- RQ1: How effective is Warden in detecting incidents?
- RQ2: How fast can Warden detect incidents compared with human?
- RQ3: How accurate can Warden extract incident-indicating alert signals?
- RQ4: What is the impact of key system settings on incident detection performance?

4.1 Dataset

To evaluate Warden, we collect alert data ($\sim 240G$) from the IcM of Azure within a 18-month-length period, starting from Oct.2018. We carefully selected 26 major services of Azure, including the Big5. Hundreds of people in dozens of teams are behind each service. The total number of incidents reported by the 26 services accounts for $\sim 72\%$ of all incidents in Azure. The dataset includes over 10 million alerts. We use the data in the last two month for testing and the previous months for training. Our training and testing data contain around 82% and 18% of all incidents, respectively. We organize our dataset into sliding windows and conduct data labeling as discussed in Sec. 3.2.2. The positive-to-negative ratio is around 1:25. More details about our dataset could be found in Table 1.

	Training	Testing
Low-severity alert	31.4%	7.8%
Med-severity alert	51.6%	6.3%
High-severity alert	2.6%	0.3%
Incident	82.2%	17.8%

Table 1: Details about the dataset for experimentation.

4.2 Evaluation Metrics

Warden runs on a fixed interval. Once a potential incident is inferred, Warden notifies related on-call engineers. The metric we care most about is the accuracy of incident detection and incident-indicating alert identification. For incident detection, we calculate the precision, recall, and F1-score. Precision measures the ratio of the sliding windows identified by Warden are truly containing incidents. Recall measures

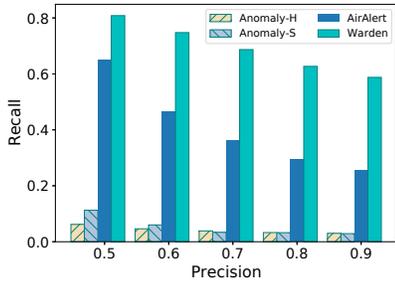

Figure 10: The recall of Warden and three baselines recorded with precision from 0.5 to 0.9.

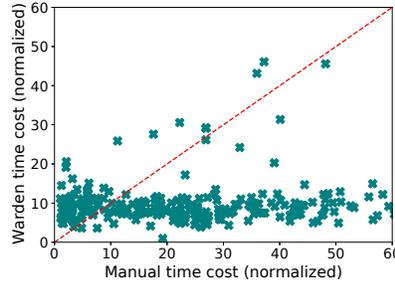

Figure 11: The time taken by manual incident declaration versus that by Warden.

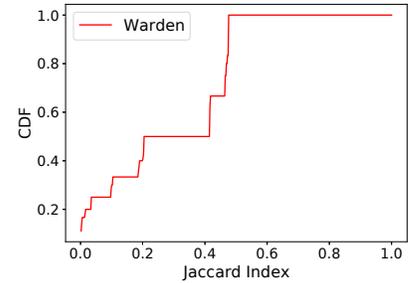

Figure 12: The CDF of Jaccard index between the owning services of the identified alerts and the actual impacted services.

the ratio of positively labeled windows recognized by Warden. F1-score is the harmonic mean of precision and recall. We also calculated AUC-PR in model selection, which is the area under the precision-recall curve. For incident-indicating alerts identification, we use Jaccard Index [33] to measure the difference between the identified group of alerts versus the manually linked alerts.

4.3 RQ1: Incident Detection Effectiveness

To our best knowledge, Warden is the only deployed system for incident detection based on monitor reported alerts in large-scale cloud systems. To better evaluate the effectiveness of incident detection, we compare Warden with the following baselines:

Anomaly detection Anomaly detection is a widely used approach to discover system faults. An incident is detected if the actual number of alerts is significantly higher than the prediction. We implement our baselines based on Prophet [49] from Facebook, which is widely adopted for time-series forecasting. The first baseline, namely **anomaly-H**, is evaluated on high-severity incidents; the second, namely **anomaly-S**, is evaluated on incidents reported by our selected monitors.

AirAlert AirAlert [23] uses a XGBoost [20] model to predict outages with only the alert count features from each monitor. We implemented AirAlert with input from our selected monitors.

The comparison results of Warden with the three baselines are presented in Fig. 10. There is a trade-off between precision and recall for a certain model. As discussed in Sec. 3.2.2, we use a confidence threshold to tune our model. In Fig. 10, we tune the models to change their precision to different values (0.5 ~ 0.9) and record the corresponding recall values. The x-axis of Fig. 10 is the precision and the bar charts show the corresponding recall values. The results show that Warden is effective and outperforms the baseline methods.

The anomaly detection based approaches achieve very low recall. The key reason is that an incident does not necessarily cause a spike, especially given the large volume of alerts. Only those incidents with extremely large impact (usually referred to as outages) could lead to high peaks. The anomaly-S achieves slightly higher recall than anomaly-H, which demonstrates the effectiveness of our monitor selection. AirAlert achieves better performance than the anomaly detection based approaches. As discussed in Sec. 3.2.1, we identified more features in addition to alert count. With the full set of features, Warden significantly outperforms AirAlert. This evaluation result justifies the effectiveness of feature engineering.

False alarms could be annoying to deal with in real-world scenario, as they can cause incorrect task prioritization or unnecessary communication. To avoid spamming the engineering team with false alarms, we ensure a precision of above 90%, which corresponds to a recall of ~ 58%. The achieved F1-score is 0.71.

4.4 RQ2: Fast Incident Detection

We compare the detection time using Warden and the manual incident declaration time for incidents in our test dataset. For all successfully detected incidents, Warden is able to perform detection faster than human in ~ 68% of cases. The time saving for an incident is measured between the notification time reported by Warden and the incident declaration time reported by the on-call engineers. The median time saving for these cases is 21.8 NTUs, which accounts for ~ 15% of the whole time-to-mitigate for these incidents. The readers could use the public incident reports [8, 10, 11] as a reference for incident mitigation time.

Figure 11 compares the time taken by manual incident declaration and that by Warden. Each cross in the figure represents one case in our testing dataset. It is clear Warden beats human for majority of cases. Moreover, we can see that Warden can particularly help reduce the incident detection time for those cases performed poorly by human. In practice, for those cases when Warden falls behind human, we simply

ignore them without sending notifications. To make the figure more compact, we only show data points within 60 NTUs.

4.5 RQ3: Accuracy of Extracting Incident-indicating Alert Signals

It is tricky to evaluate how accurately can Warden extract the incident-indicating alert signals from the current time window. Our ground truth is based on manually linked alerts in incidents. As discussed in Sec. 2.1, the incident commander and on-call engineers manually link related alerts to the primary alert of an incident. Since this is done manually, it is easy to miss some related alerts. According to our empirical study, usually, only partial alerts are linked during a failure event. Therefore, it is infeasible to rely on the manual links for evaluation. However, we discovered that the impacted services are more reliable. When an incident occurs, more than one alert usually gets triggered for each impacted service. People usually selectively pick one or a few alerts and add to the primary alert, which are used to track the health status of that service. As a result, we use only the group of impacted services, instead of the linked alert signals, for evaluation.

We extract the incident-indicating alerts from the current time window as described in Sec. 3.3. For evaluation, we compare the owning services of the identified alert signals with the actual impacted services. Figure 12 shows the CDF of the Jaccard indices for the cases recalled by Warden in our testing dataset. First of all, we can see that Warden achieves a perfect alignment with the ground truth for 53% cases. For 78% cases, the Jaccard index is above or equal to 50%. Moreover, the curve in Fig. 12 is constantly above 0, which means that Warden can find at least one impacted service when incidents have been detected. In general, Warden can accurately find the impacted services inside the current time window.

4.6 RQ4: The Impact of Key System Settings

So far we have evaluated our system with a fixed set of settings. We now address the question of how different system settings affect the performance. Specifically, we examine three sub-questions: (1) What is the impact of different classification models on incident detection? (2) how many monitors should we select? and (3) how much data and how often is required to train our model?

4.6.1 Classification Model Selection

Warden uses a classification model for incident detection. We evaluated a few popular candidates, namely Penalized Linear Regression (PLR) [23], SVM [24], Balanced Random Forest (BRF) [37], and LightGBM [36]. To account for data imbalance, we assign different class weights to positive/negative samples for PLR, SVM, and LightGBM; for BRF, we adjust

the sampling rate. These settings are all tuned with grid search using validation data. The results are shown in Table 2.

Model	F1	Recall	Precision	AUC-PR
PLR	0.505	0.361	0.840	0.64
SVM	0.604	0.655	0.561	-
LightGBM	0.680	0.658	0.704	0.71
BRF	0.704	0.658	0.757	0.73

Table 2: The comparison results of different models.

We mainly use the AUC-PR for comparison. Since AUC-PR does not apply for SVM, we also record the F1-score and the corresponding precision and recall. BRF achieves the highest AUC-PR of 0.73 compared with PLR and LightGBM. For BRF and SVM, we could see BRF achieves higher precision and recall. In conclusion, BRF outperforms the other candidates, and therefore we adopt BRF in our system.

4.6.2 Alert signal selection

In Sec. 3.1, we have derived a score for each monitor and ranked all monitors accordingly. One remaining question is how many monitors should be selected. Intuitively, selecting more monitors will improve the coverage by detecting more incidents. However, more monitors also increase the complexity of the model as well as the data volume. Therefore, we try to find the minimum set of monitors while achieving satisfactory precision and recall.

We measure the recall at different precision values (0.6, 0.7, and 0.8) varying the number of monitors. The results are presented in Fig. 13, where the x-axis denotes the number of monitors and the y-axis shows the recall. The three curves are the recall values with different precision values, respectively. The number of monitors is ranging from 25 to 300.

We can see that the recall rises significantly for all three curves, when the number of monitors increases from 25 to 150, which is in line with our expectation. This observation indicates that a moderate fraction of incidents could be detected with a relatively small number of monitors. Then, increasing the number (when exceeds 150) would not increase the coverage as the newly-added monitors become less indicative of incidents. On the other hand, adding more monitors will increase the number of alerts to process. As a result, we set the number of selected monitors to 150 in our system.

4.6.3 Training data and frequency

We also evaluate our model with different training data lengths. Specifically, we keep the later two months in our dataset for testing and vary the length of training data from 1 to 16 months. For each round, we record the F1 score and the result is shown in Fig. 14.

The x-axis shows the length of training data from 1 to 16 months, and the y-axis is the F1 score. We can see that F1 rises

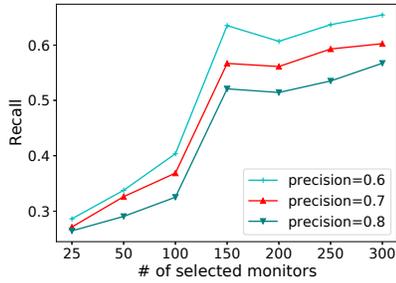

Figure 13: The recall at different precision values with different number of selected monitors.

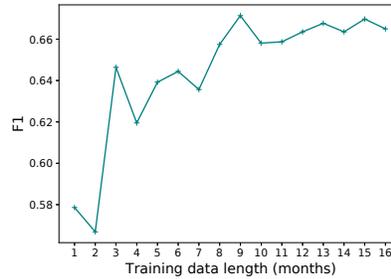

Figure 14: The F1 value with training data length from 1 to 16 months.

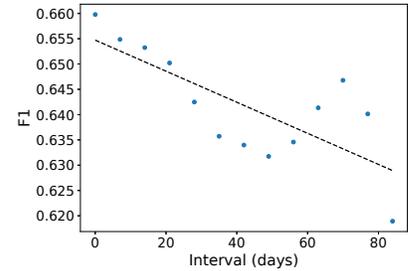

Figure 15: The F1-score with different training and testing data interleaving intervals.

with more training data. However, the gain becomes minor with the training data length exceeding 9 months. Therefore, for production usage, we collect data from the last 12 months for training, which is sufficient to reach optimal performance.

Another question is how often we need to retrain the model. We use 9 months of data for training and 2 months for testing. We interleave the training and testing data by m days, where m ranges from 0 to 80. We record the F1 scores with different interleaving intervals. Fig. 15 shows the result where the x-axis is the interleaving days and the y-axis is the mean F1 score. The dashed line is the regression fit which clearly shows a decreasing trend.

We can see a decline in performance as the data evolves (e.g., newly added monitors as shown in Fig. 4). In our system, we retrain our model on a weekly basis to capture incremental data changes. Our training is conducted on a node with 48 cores and 512 G memory. The training process with a 12-month dataset takes 16 cores and ~ 8 G memory, and costs ~ 1.2 hours.

4.7 Case Studies

Warden has been deployed online in IcM of Azure for around 3 months till May 2020. In this section, we describe two real-world cases.

Case 1: power failure incident The first case is an incident caused by a datacenter power failure. Counterintuitively, not all incidents caused by power issues are easy to detect. Few power issues lead to real incidents due to resource redundancy. In this case, the region of the datacenter was hit by an ice storm, resulting in a large-scale power failure. The affected racks lost power when their supporting UPS units drained. It took tens of minutes before running out of power supply.

Multiple services got affected gradually during this incident. Warden sent out an initial notification at receiving alerts from the Compute service. The alerts were about “Compute Manager QoS degradation”. Our notification immediately attracted the attention of the on-call engineer. When the engineer was investigating the problem, Warden gradually identi-

fied more than 10 alert signals (including “Virtual machines unexpected reboot”, “Web Application probe alert”, “TOR dead event”, “Too many partition load failures”, “API Unexpected Failures”, etc.) in following time intervals. Not only the inference confidence of the model was raised substantially, but also more on-call engineers from multiple teams were engaged. They were on the same page, and a bridge meeting was set up for collaborative problem-solving. Without Warden, the engineers in different service teams would have to run individual diagnoses and discuss back-and-forth for a prolonged time until they realized that they were impacted by a power failure.

Case 2: networking incident The second case is an incident caused by TOR (top-of-rack router) down. When the TOR device is down, a VM will lose the connection to its storage, resulting in an unexpected reboot. Meanwhile, the issue of VM unexpected reboot could also be caused by storage problems such as disk failures. The current practice is that on-call engineers run diagnostic tools to find out the root cause [51]. This diagnosis is time-consuming and requires cross-team collaboration.

In this case, a VIP customer’s service was impacted and timely root cause analysis (RCA) was required. When the TOR down alert was received, Warden notified the Networking on-call engineer immediately. Several minutes later, the alert from the Compute service arrived, and Warden correlated the two alerts together. When the RCA request came to the Compute team, it was immediately concluded the incident was caused by the networking issue. Timely RCA helped increase our customer’s confidence.

5 Discussions

Why can incidents be detected? Incidents can be caused by one-off issues like code bugs or flawed configurations. Once these issues get fixed, they might never happen again. However, the detection is not based on the root causes, but on symptoms (the triggered alerts) which indeed exhibits

certain repetitive patterns. In addition, some root cause issues indeed happen again and again, like hardware failures. For example, we examined the incidents caused by cluster-level partial power failures in history. The consequential impact vary slightly from one case to another. Therefore, it is also non-trivial to detect based on manually crafted rules. In conclusion, a data-driven approach is appropriate for incident detection.

Generalizability of the proposed approach Incident detection is a common problem for all cloud platforms. Different companies implement different incident response processes. For example, Azure has a 4-step incident management process as discussed in [17]. The steps are detection, triage, mitigation, and resolution. GCP employs a very similar 4-step process as described in [1], with more detailed child processes in each step. NIST proposed a high level of abstraction for incident response with similar steps in [5]. Warden relies on the monitoring system which is a key building block to ensure service reliability. Therefore, our proposed approach could be extended to all these incident response platforms.

Trade-off in detection accuracy and delay Warden aims to detect the incidents as early as possible. However, there is a trade-off between the accuracy and the delay. We can wait for long enough until the alerts accumulate so that we can accurately detect incidents. On the other hand, we can make detection with only early weak signals, which will save time but also lower our confidence. So far, the primary audience of our system are the on-call engineers. Therefore, we conducted user studies to understand their practical concern. We conclude a precision above 90% is satisfactory for real usage, and we then tune our system accordingly.

Difference between incident-indicating alert identification and model interpretation Identifying the incident-indicating alerts is not solely a model interpretation problem [43]. Algorithms, such as SHAP or LIME [40, 41, 45], rank the input features based on their contribution to the prediction result, without considering the inherent relationship between the features. In our system, the features are constructed from the alert signals and we want to understand the contribution of each alert signal, instead of individual features.

5.1 Threats to Validity

Subject system: We have limited our evaluations to 26 major services on Azure, which produce the majority of incidents. The services we pick are representative of large-scale cloud computing platforms. For example, the Compute, Networking, and Storage are the three most fundamental services. We also include SQL DB, Web Application, Backup, Data Pipeline, etc., which are common services provided by all platforms such as AWS, Azure, and GCP. The incidents in our dataset

are caused by a variety of common reasons. The top 5 deterministic reasons are code bug, network hardware issue, configuration, code defect, and design flaw. In our future plan, we will extend our evaluations with more services.

Label quality: We rely on manually linked alerts in our evaluation in Sec. 4.5. In practice, usually, only part of related alerts are linked correctly. The major problem is the missing links. Instead of manually linking all related alerts, the on-call engineers often only selectively link one alert for one service to track the cause-effect relationship. As a result, we have to evaluate the correctness of our extracted alerts on a service basis. Sometimes, people may even fail to involve a truly impacted service or add wrong links between irrelevant alerts. We incorporated experts from IcM to verify our label data and made a number of corrections. The label quality problem is thus greatly mitigated.

6 Related Work

Fault Detection and Localization: A significant amount of work [14, 28, 29, 31, 32, 34, 42, 44, 48, 51] exists on failure detection in cloud environments. Researchers [28, 31, 44] have advocated the scenario where minor failures from low-level services may cause large-scale impact to dependent services, which actually motivates our work of using alerts from multiple services to detect incidents. Some work [13, 25, 35, 42, 51] leverages the service dependency graph or API invocation chain to localize the root cause. Other work [14, 29, 32] proposes to use agents in distributed systems for failure detection and localization. In this work, we lay our foundation on top of the existing failure monitoring infrastructure built by individual services. We do not assume that we know the hierarchical dependency among components, which we believe is challenging for a large-scale dynamically changing cloud computing platform.

Time-Series Anomaly Detection: We notice that there is a body of work on anomaly detection and root cause localization for multi-dimensional time-series data [16, 38, 52]. There are plenty of commercial anomaly detection frameworks [7, 9, 12] offered by companies. In contrast, our work is based on alert data produced by cloud monitors. The alert data (described in Sec. 2.1) is very different from time-series metric data or console logs, and is commonly seen in cloud systems. Besides, our approach can not only detect the occurrence of cross-service incidents but also identify the incident-indicating alerts. We propose a novel algorithm called GSV for extracting the incident-indicating alerts. Finally, we target incidents that require cross-team collaboration (i.e., cross-service incidents). Therefore, we believe our work is novel and significantly different from the related work on time-series anomaly detection.

Incident Management: Haryadi et al. [27] analyze hundreds of officially published outages. Recently, there are also increasing interests in incident triage [17, 18, 39, 46, 56]. Jun-

jie et al. [19] use deep learning to find low severity incidents that represent self-healing or transient issues. Yujun et al. [22] study the problem of grouping different incidents with intrinsic relationships. Incident detection or prediction has gained increasing interest in recent years. A few recent work leverages customer feedback [55], tweets [15], or alerts with rich textual information [54] to detect real-time issues for online systems. They focus on extracting effective indicators from textual information. However, in our system, the alerts carry only machine generated texts as shown in Fig. 9 which is different from natural languages. Our previous work AirAlert [23] uses monitor generated alerts to predict several specific types of outages. In this work, Warden is designed for generic incident detection. We compare the performance of Warden with AirAlert in Sec. 4.3.

7 Conclusion and Future Work

In this work, we propose Warden, a framework to automatically detect incidents. We train an inference model based on historic failure patterns with input from a set of carefully selected monitors. Upon detecting potential incidents, Warden extracts a set of related alert signals and notifies relevant on-call engineers. This information assists the on-call engineers to prioritize their tasks and initiate cross-team collaboration. We have evaluated Warden using data collected from 26 major services on Azure. The evaluation results confirm the effectiveness of Warden. Furthermore, Warden has been successfully deployed in production.

We notice that not all incidents are covered by the monitoring system. Therefore, in our future work, we plan to exploit more signals such as the customer submitted support cases and social streams for incident detection.

Acknowledgement

We thank Kiran-Kumar Muniswamy-Reddy, our shepherd, and the anonymous reviewers for their tremendous feedback and comments. We also thank our partners Januelle Roldan, Sai Ramani, Navendu Jain, Irfan Mohiuddin, Andrew Edwards Douglas Phillips, Rakesh Namineni, David Wilson, Paul Lorimer, Victor Rühle, Jim Kleewein, Perry Clarke, Alex Dong, Wesley Miao, Andrew Zhou, Robert Gu, Yining Wei, Yingnong Dang, and Murali Chintalapati in the production teams for their valuable feedback on this work and using our system. Abstract

Deep learning researchers and practitioners usually leverage GPUs to help train their deep neural networks (DNNs) faster. However, choosing *which* GPU to use is challenging both because (i) there are many options, and (ii) users grapple with competing concerns: maximizing compute performance while minimizing costs. In this work, we present a new practical technique to help users make informed and cost-efficient GPU selections: make performance *predictions* with the help of a GPU that the user already has. Our technique exploits the observation that, because DNN training consists of repetitive compute steps, predicting the execution time of a single iteration is usually enough to characterize the performance of an entire training process. We make predictions by scaling the execution time of each operation in a training iteration from one GPU to another using either (i) wave scaling, a technique based on a GPU’s execution model, or (ii) pre-trained multilayer perceptrons. We implement our technique into a Python library called Habitat and find that it makes accurate iteration execution time predictions (with an average error of 11.8%) on ResNet-50, Inception v3, the Transformer, GNMT, and DCGAN across six different GPU architectures. Habitat supports PyTorch, is easy to use, and is open source.¹

1 Introduction

Over the past decade, deep neural networks (DNNs) have seen incredible success across many machine learning tasks [26, 37, 39, 50, 93, 96, 99]—leading them to become widely used throughout academia and industry. However, despite their popularity, DNNs are not always straightforward to use in practice because they can be extremely computationally-expensive to train [23, 53, 95, 109]. This is why, over the past few years, there has been a significant and ongoing effort to bring *hardware acceleration* to DNN training [10, 16, 35, 36, 45, 78, 80].

As a result of this effort, today there is a vast array of hardware options for deep learning users to choose from for

training. These options range from desktop and server-class GPUs (e.g., 2080Ti [70] and A100 [78]) all the way to specialized accelerators such as the TPU [45], AWS Trainium [10], Gaudi [36], IPU [35], and Cerebras WSE [16]. Having all these options offers flexibility to users, but at the same time can also lead to a paradox of choice: which hardware option should a researcher or practitioner use to train their DNNs?

A natural way to start answering this question is to first consider CUDA-enabled GPUs. This is because they (i) are commonly used in deep learning; (ii) are supported by all major deep learning software frameworks (PyTorch [86], TensorFlow [1], and MXNet [19]); (iii) have mature tooling support (e.g., CUPTI [76]); and (iv) are readily available for rent *and* purchase. In particular, when considering GPUs, we find that there are many situations where a deep learning user needs to *choose* a specific GPU to use for training:

- **Choosing between different hardware tiers.** In both academia and industry, deep learning users often have access to several *tiers* of hardware: (i) a workstation with a GPU used for development (e.g., 2080Ti), (ii) a private GPU cluster that is shared within their organization (e.g., RTX6000 [84]), and (iii) GPUs that they can rent in the cloud (e.g., V100 [66]). Each tier offers a different *cost*, *availability*, and *performance* trade-off. For example, a private cluster might be “free” (in monetary cost) to use, but jobs may be queued because the cluster is also shared among other users. In contrast, cloud GPUs can be rented on-demand for exclusive use.
- **Deciding on which GPU to rent or purchase.** Cloud providers make many different GPUs available for rent (e.g., P100 [62], V100, T4 [71], and A100 [78]), each with different performance at different prices. Similarly, a wide variety of GPUs are available for purchase (e.g., 2080Ti, 3090 [82]) both individually and as a part of pre-built workstations [52]. These GPUs can vary up to $6\times$ in price [98] and $6\times$ in peak performance [79].
- **Determining how to schedule a job in a heterogeneous**

¹Habitat is available on GitHub: github.com/geoffxy/habitat [105, 106]

GPU cluster. A compute cluster (e.g., operated by a cloud provider [8,32,58]) may have multiple types of GPUs available that can handle a training workload. Deciding which GPU to use for a job will typically depend on the job’s priority and performance on the GPU being considered [18,61].

- **Selecting alternative GPUs.** When a desired GPU is unavailable (e.g., due to capacity constraints in the cloud), a user may want to select a different GPU with a comparable cost-normalized performance. For example, when training ResNet-50 [37] on Google Cloud [31], we find that both the P100 and V100 have similar cost-normalized throughputs (differing by just 0.8%). If the V100 were to be unavailable,² a user may decide to use the P100 instead since the total training cost would be similar.

What makes these situations interesting is that there is not necessarily a *single* “correct” choice. Users make GPU selections based on whether the performance benefits of the chosen configuration are *worth* the cost to train their DNNs. But making these selections in an informed way is not easy, as performance depends on many factors simultaneously: (i) the DNN being considered, (ii) the GPU being used, and (iii) the underlying software libraries used during training (e.g., cuDNN [74], cuBLAS [77]).

To do this performance analysis today, the common wisdom is to either (i) directly measure the computational performance (e.g., throughput) by actually running the training job on the GPU, or (ii) consult existing benchmarks (e.g., MLPerf [53]) published by the community to get a “ballpark estimate.” While convenient, these approaches also have their own limitations. Making measurements requires users to already have access to the GPUs they are considering; this may not be the case if a user is deciding whether or not to *buy* or *rent* that GPU in the first place. Secondly, benchmarks are usually only available for a subset of GPUs (e.g., the V100 and T4) and only for common “benchmark” models (e.g., ResNet-50 [37] and the Transformer [99]). They are not as helpful if you need an accurate estimate of the performance of a *custom* DNN on a specific GPU (a common scenario when doing deep learning research).

In this work, we make the case for a third complementary approach: making performance *predictions*. Although predicting the performance of general compute workloads can be prohibitively difficult due to the large number of possible program phases, we observe that DNN training workloads are special because they contain *repetitive computation*. DNN training consists of repetitions of the same (relatively short) training iteration, which means that the performance of an entire training process can be characterized by just a few training iterations.

We leverage this observation to build a new technique that *predicts* a DNN’s training iteration execution time for a given

²In our experience, we often ran into situations where the V100 was unavailable for rent because the cloud provider had an insufficient supply.

```
import habitat

tracker = habitat.OperationTracker(
    origin_device=habitat.Device.RTX2070,
)

with tracker.track():
    run_my_training_iteration()

trace = tracker.get_tracked_trace()
print("Pred. iter. exec. time: {:.2f} ms".format(
    trace.to_device(habitat.Device.V100).run_time_ms,
))
```

Listing 1: An example of how Habitat can be used to make iteration execution time predictions.

batch size and GPU using both *runtime information* and *hardware characteristics*. We make predictions in two steps: (i) we measure the execution time of a training iteration on an *existing* GPU, and then (ii) we scale the measured execution times of each individual operation onto a *different* GPU using either wave scaling or pre-trained multilayer perceptrons (MLPs) [29]. Wave scaling is a technique that applies *scaling factors* to the GPU kernels in an operation, based on a mix of the ratios between the two GPUs’ memory bandwidth and compute units. We use MLPs for certain operations (e.g., convolution) where the kernels used differ between the two GPUs; we describe this phenomenon and the MLPs in more detail in Sections 3.2 and 3.4. We believe that using an existing GPU to make operation execution time predictions for a different GPU is reasonable because deep learning users often already have a local GPU that they use for development.

We implement our technique into a Python library that we call Habitat, and evaluate its prediction accuracy on five DNNs that have applications in image classification, machine translation, and image generation: (i) ResNet-50, (ii) Inception v3 [97] (iii) the Transformer, (iv) GNMT [102], and (v) DCGAN [89]. We use Habitat to make iteration execution time predictions across six different GPUs and find that it makes accurate predictions with an average error of 11.8%. Additionally, we present two case studies to show how Habitat can be used to help users make accurate cost-efficient GPU selections according to their needs (Section 5.3).

We designed Habitat to be easy and practical to use (see Listing 1). Habitat currently supports PyTorch [86] and is open source: github.com/geoffxy/habitat [105, 106].

In summary, this work makes the following contributions:

- Wave scaling: a new technique that scales the execution time of a kernel measured on one GPU to a different GPU by using scaled ratios between the (i) number of compute units on each GPU, and (ii) their memory bandwidths.
- The implementation and evaluation of Habitat: a new library that uses wave scaling along with pre-trained MLPs to predict the execution time of DNN training iterations on different GPUs.

2 Why Predict the Computational Training Performance of DNNs on Different GPUs?

This work presents a new practical technique for predicting the execution time of a DNN training iteration on different GPUs, with the goal of helping deep learning users make informed cost-efficient GPU selections. However, a common first question is to ask why we need to make these performance predictions in the first place. Could other performance comparison approaches (e.g., simple heuristics or measurements) be used instead? In this section, after providing some background about DNN training, we outline the problems with these alternative approaches to further motivate the need for practical performance predictions.

2.1 Background on DNN Training

DNNs, at their heart, are mathematical functions that produce predictions given an input and a set of *learned* parameters, also known as *weights* [29]. They are built by combining together a series of different *layers*, each of which may contain weights. The layers map to mathematical operations. For example, a fully connected layer is implemented using matrix multiplication [29]. To produce predictions, a DNN takes a tensor (an n -dimensional array) as input and applies the operations associated with each layer in sequence.

Training. A DNN learns its weights in an *iterative* process called training. Each training iteration operates on a batch of labelled inputs and consists of a *forward* pass, *backward* pass (using backpropagation [90]), and *weight update*. The forward and backward passes compute gradients for the weights, which are then used by an optimization algorithm (e.g., stochastic gradient descent [12] or Adam [49]) to update the weights so that the DNN produces better predictions. These steps are *repeated* until the DNN makes acceptably accurate predictions.

Computational performance. Although conceptually simple, prior work has shown that DNN training can be an extremely time-consuming process [23, 53, 95, 109]. There are two primary factors that influence the time it takes a DNN to reach an acceptable accuracy during training [59]: (i) statistical efficiency, and (ii) hardware efficiency. Statistical efficiency governs the *number* of training iterations (i.e., weight updates) required to reach a target test accuracy whereas hardware efficiency governs how *quickly* a training iteration runs. In this work, we focus on helping deep learning users make informed cost-efficient hardware configuration selections to improve their DNN’s *hardware efficiency*. As a result, we compare the performance of different GPUs when training a DNN using the *time it takes a training iteration to run*. This metric equivalently captures the training throughput for that particular DNN.

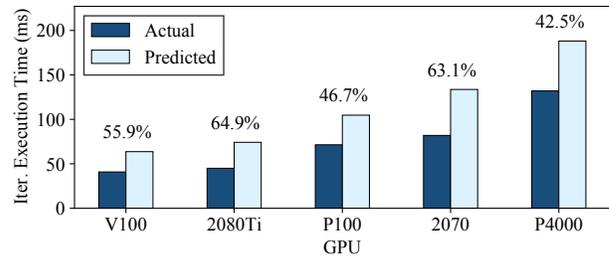

Figure 1: DCGAN iteration execution time predictions, and their errors, made from the T4 using peak FLOPS ratios between the devices. Using simple heuristics can lead to high prediction errors.

2.2 Why Not Measure Performance Directly?

Perhaps the most straightforward approach to compare the performance of different GPUs is to just measure the iteration execution time (and hence, throughput) on each GPU when training a given DNN. However, this approach also has a straightforward downside: it requires the user to actually have access to the GPU(s) being considered in the first place. If a user is looking to buy or rent a cost-efficient GPU, they would ideally want to know its performance on their DNNs *before* spending money to get access to the GPU.

2.3 Why Not Apply Heuristics?

Another approach is to use heuristics based on the hardware specifications published by the manufacturer. For example, one could use the ratio between the peak floating point operations per second (FLOPS) of two GPUs or the ratio between the number of CUDA cores on each GPU. The problem with this approach is that these heuristics do not always work. Heuristics often assume that a DNN training workload can exhaust all the computational resources on a GPU, which is not true in general [109].

To show an example of when simple heuristics do not work well, we use a GPU’s peak FLOPS to make iteration execution time predictions. We measure the execution time of a DCGAN training iteration on the T4³ and then use this measurement to predict the iteration execution time on *different* GPUs by multiplying by the ratio between the devices’ peak FLOPS. Figure 1 shows the measured and predicted execution times on each GPU, along with the prediction error as a percentage. The main takeaway from this figure is that using simple heuristics can lead to high prediction errors; the highest prediction error in this experiment is 64.9%, and all the prediction errors are at least 42.5%. In contrast, Habitat can make these exact same predictions with an average error of 10.2% (maximum 21.8%).

³We use a batch size of 128 LSUN [104] synthetic inputs. See Section 5.1 for details about our methodology.

2.4 Why Not Use Benchmarks?

A third potential approach is to consult published benchmarking results [23,53,81,109]. However, the problem with relying on benchmarking results is that they are limited to a set of “common” DNNs (e.g., ResNet-50 or BERT [26]) and are usually only available for a small selection of GPUs (e.g., the T4, V100, and A100). Moreover, benchmarking results also vary widely among different models and GPUs [53,81,109]. Therefore if no results exist for the GPU(s) a user is considering, or if a user is working with a new DNN architecture, there will be no benchmark results for them to consult.

2.5 Why Not Always Use the “Best” GPU?

Finally, a fourth approach is to always use the most “powerful” GPU available with the assumption that GPUs are already priced based on their performance. Why make performance predictions when the cost-efficiency of popular GPUs should be the same? However, this assumption is a misconception. Prior work has already shown examples where the performance benefits of different GPUs changes depending on the model [18,61,109]. In this work, we also show additional examples in our case studies (Section 5.3) where (i) cost-efficiency leads to selecting a different GPU, and (ii) where the V100 does not offer significant performance benefits over a common desktop-class GPU (the 2080Ti).

Summary. Straightforward approaches that users might consider to make GPU selections all have their own downsides. In particular, existing approaches either require access to the GPUs themselves or are only applicable for common DNNs and GPUs. Therefore there is a need for a complementary approach: making performance predictions—something that we explore in this work.

3 Habitat

Our approach to performance predictions is powered by three key observations. In this section, after describing these observations, we outline the key ideas behind Habitat.

3.1 Key Observations

Observation 1: Repetitive computation. While training a DNN to an acceptable accuracy can take on the order of hours to days [23,53,109], a single training iteration takes on the order of hundreds of *milliseconds*. This observation improves the predictability of DNN training as we can characterize the performance of an entire DNN training session using the performance of a single iteration.

Observation 2: Common building blocks among DNNs. Although DNNs can consist of hundreds of operations, they are built using a relatively *small* set of unique operations. For

example, convolutional neural networks typically comprise convolutional, pooling, fully connected, and batch normalization [42] layers. This observation reduces the problem of predicting the performance of an arbitrary DNN’s training iteration to developing prediction mechanisms for a small set of operations.

Observation 3: Runtime information available. When developing DNNs, users often have a GPU available for use in their workstations. These GPUs are used for development purposes and are not necessarily chosen for the highest performance (e.g., 1080Ti [64], TITAN Xp [68]). However, they can be used to provide valuable runtime information about the GPU kernels that are used to implement a given DNN. In Section 3.3, we describe how we can leverage this runtime information to predict the performance of the GPU kernels on different GPUs (e.g., from a desktop-class GPU such as the 2080Ti [70] to a server-class GPU such as the V100 [66,67]).

3.2 Habitat Overview

Habitat records information at runtime about a DNN training iteration for a specific batch size on a given GPU (*Observation 3*) and then uses that information to predict the training iteration execution time on a *different* GPU (for the same batch size). Predicting the iteration execution time is enough (*Observation 1*) to compute metrics about the entire training *process* on different GPUs. These predicted metrics, such as the training throughput and cost-normalized throughput, are then used by end-users (e.g., deep learning researchers) to make informed hardware selections.

To actually make these predictions for a different GPU, Habitat predicts the new execution time of each individual operation in a training iteration. Habitat then adds these predicted times together to arrive at an execution time prediction for the entire iteration. For an individual operation, Habitat makes predictions using either (i) wave scaling (Section 3.3), or (ii) pre-trained MLPs (Section 3.4).

The reason why Habitat uses two techniques together is that wave scaling assumes that the *same* GPU kernels are used to implement a given DNN operation on each GPU. However, some DNN operations are implemented using *different* GPU kernels on different GPUs (e.g., convolutions, recurrent layers). This is done for performance reasons as these operations are typically implemented using proprietary kernel libraries that leverage GPU architecture-specific kernels (e.g., cuDNN [21], cuBLAS [77]). We refer to these operations as *kernel-varying*, and scale their execution times to different GPUs using pre-trained MLPs. Habitat uses wave scaling for the rest of the operations, which we call *kernel-alike*.

3.3 Wave Scaling

Wave scaling works by scaling the execution times of the *kernels* used to implement a kernel-alike DNN operation. The

computation performed by a GPU kernel is partitioned into groups of threads called *thread blocks* [28], which typically execute in concurrent groups, resulting in *waves* of execution. The key idea behind wave scaling is to compute the number of *thread block waves* in a kernel and scale the wave execution time using *ratios* between the origin and destination GPUs.

We describe wave scaling formally in Equation 1. Let T_i represent the execution time of the kernel on GPU i , B the number of thread blocks in the kernel, W_i the number of thread blocks in a wave on GPU i , D_i the memory bandwidth on GPU i , and C_i the clock frequency on GPU i . Here we let $i \in \{o, d\}$ to represent the origin and destination GPUs. By measuring T_o (*Observation 3*), wave scaling predicts T_d using

$$T_d = \left\lceil \frac{B}{W_d} \right\rceil \left(\frac{D_o W_d}{D_d W_o} \right)^\gamma \left(\frac{C_o}{C_d} \right)^{1-\gamma} \left\lceil \frac{B}{W_o} \right\rceil^{-1} T_o \quad (1)$$

where $\gamma \in [0, 1]$ represents the “memory bandwidth bound-ness” of the kernel. Habitat selects γ by measuring the kernel’s arithmetic intensity and then leveraging the roofline model [101] (see Section 4.2).

As shown in Equation 1, wave scaling uses the ratios between the GPUs’ (i) memory bandwidths, (ii) clock frequencies, and (iii) the size of a wave on each GPU. The intuition behind factors (i) and (iii) is that a higher relative memory bandwidth allows more memory requests to be served in parallel whereas having more thread blocks in a wave results in more memory requests being made. Thus, everything else held constant, waves in memory bandwidth bound kernels (i.e., large γ) should see speedups on GPUs with more memory bandwidth. The intuition behind factor (ii) is that higher clock frequencies may benefit waves in compute bound kernels (i.e., small γ).⁴

For large $\lceil B/W_i \rceil$ (i.e., when there are a large number of waves) we get that $\lceil B/W_i \rceil \approx B/W_i$. In this case, Equation 1 simplifies to

$$T_d = \left(\frac{D_o}{D_d} \right)^\gamma \left(\frac{W_o}{W_d} \right)^{1-\gamma} \left(\frac{C_o}{C_d} \right)^{1-\gamma} T_o \quad (2)$$

Habitat uses Equation 2 to predict kernel execution times because we find that in practice, most kernels are composed of many thread blocks.

Habitat computes W_i for each kernel and GPU using the thread block occupancy calculator that is provided as part of the CUDA Toolkit [80]. We obtain C_i from each GPU’s specifications, and we obtain D_i by measuring the achieved bandwidth on each GPU ahead of time. Note that we make these measurements once and then distribute them in a configuration file with Habitat.

⁴The clock’s impact on execution time depends on other factors too (e.g., the GPU’s instruction set architecture). Wave scaling aims to be a simple and understandable model and therefore does not model these complex effects.

3.4 MLP Predictors

To handle kernel-varying operations, Habitat uses pre-trained MLPs to make execution time predictions. We treat this prediction task as a regression problem: given a series of input features about the operation and a target GPU (described below), predict the operation’s execution time on that target GPU. We learn an MLP for each kernel-varying operation that Habitat currently supports: (i) convolutions (2-dimensional), (ii) LSTMs [38], (iii) batched matrix multiplies, and (iv) linear layers (matrix multiply with an optional bias term). As we show in Section 5, relatively few DNN operations are kernel-varying⁵ and so training separate MLPs for each of these operations is a feasible approach. Furthermore, these MLPs can be used for many different DNNs as these operations are common “building blocks” used in DNNs (*Observation 2*).

Input features. Each operation-specific MLP takes as input: (i) layer dimensions (e.g., the number of input and output channels in a convolution); (ii) the memory capacity and bandwidth on the target GPU; (iii) the number of streaming multiprocessors (SMs) on the target GPU; and (iv) the peak FLOPS of the target GPU, specified by the manufacturer.

Model architecture. Each MLP comprises an input layer, eight hidden layers, and an output layer that produces a single real number—the predicted execution time (this includes the forward and backward pass) for the MLP’s associated operation. We use ReLU activation functions in each layer and we use 1024 units in each hidden layer. We outline the details behind our datasets and how these MLPs are trained in Section 4.3.

4 Implementation Details

Habitat is built to work with PyTorch [86]. However, the ideas behind Habitat are general and straightforward to implement in other frameworks as well. Habitat performs its analysis using a DNN’s computation graph, which is also available in other frameworks (e.g., TensorFlow [1] and MXNet [19]).

4.1 Extracting Runtime Metadata

Habitat extracts runtime metadata in a training iteration by “monkey patching” PyTorch operations with special wrappers. These wrappers allow Habitat to intercept and keep track of all the operations that run in one training iteration, as they are executed. As shown in Listing 1, users explicitly indicate to Habitat when to start and stop tracking the operations in a DNN by calling `track()`.

Execution time. To measure the execution time of each operation, Habitat re-runs each operation independently with

⁵This is, in part, because implementing performant architecture-specific kernels for each kernel-varying operation takes significant engineering effort.

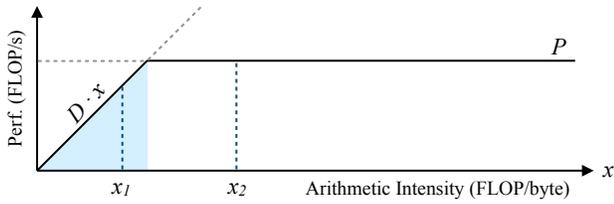

Figure 2: An example roofline model. If a kernel’s arithmetic intensity falls in the shaded region, it is considered memory bandwidth bound (x_1); otherwise, it is considered compute bound (x_2).

the same inputs as recorded when the operation was intercepted. Habitat also measures the execution time associated with the operation’s backward pass, if applicable. The reason why Habitat makes measurements by re-running the individual operations is that the operations could be very short (in execution time). Thus, Habitat needs to run them multiple times to make accurate measurements. Habitat uses CUDA events [73] to make these timing measurements.

Kernel metadata and metrics. Habitat uses CUPTI [76] to record execution times and metrics (see Section 4.2) for the kernels used to implement each operation in the DNN. This information is used by wave scaling.

4.2 Selecting Gamma (γ)

Recall from Section 3.3 that wave scaling scales its ratios using γ , a factor that represents the “memory bandwidth boundedness” of a kernel. In this section, we describe in more detail how Habitat automatically selects γ for each kernel.

Roofline model. Habitat uses the roofline model [101] to estimate a kernel’s memory boundedness. Figure 2 shows an example roofline model. The roofline model introduces the notion of a kernel’s arithmetic intensity: the number of floating point operations it performs per byte of data read or written to memory (represented by x in Figure 2).

A key idea behind the roofline model is that it models a kernel’s peak performance as the minimum of either the hardware’s peak performance (P) or the hardware’s memory bandwidth times the kernel’s arithmetic intensity ($D \cdot x$) [101]. This minimum is shown by the solid line in Figure 2. The arithmetic intensity where these two limits meet is called the “ridge point” (R), where $R = P/D$. The model considers a kernel with an arithmetic intensity of x to be memory bandwidth bound if $x < R$ and compute bound otherwise. For example, in Figure 2, a kernel with an arithmetic intensity of x_1 would be considered memory bandwidth bound whereas a kernel with an intensity of x_2 would be considered compute bound.

Wave scaling leverages the observation that a kernel’s arithmetic intensity is fixed across GPUs (i.e., arithmetic intensity only depends on the kernel’s code). R changes across GPUs

because P and D vary among GPUs, but can be computed using a GPU’s performance specifications. Therefore, if Habitat computes a kernel’s arithmetic intensity, it can use the arithmetic intensity’s distance from the destination GPU’s ridge point to estimate the kernel’s memory bandwidth boundedness (on the destination GPU).

Selecting γ . When profiling each kernel, Habitat gathers metrics that allow it to empirically calculate the kernel’s arithmetic intensity (floating point efficiency, number of bytes read and written to DRAM). If we let x be the kernel’s measured arithmetic intensity and $R = P/D$ for the destination GPU (using the notation presented above), Habitat sets γ using

$$\gamma = \begin{cases} (-0.5/R)x + 1 & \text{if } x < R \\ 0.5R/x & \text{otherwise} \end{cases} \quad (3)$$

This equation means that γ decreases linearly from 1 to 0.5 as x increases toward R . After passing R , γ approaches 0 as x approaches infinity.

Practical optimizations. In practice, gathering metrics on GPUs is a slow process because the kernels need to be replayed multiple times to capture all the needed performance counters. To address this challenge, we make two optimizations: (i) we cache measured metrics, keyed by the kernel’s name and its launch configuration (number of thread blocks and block size); and (ii) we only measure metrics for operations that contribute significantly to the training iteration’s execution time (e.g., with execution times at or above the 99.5th percentile). Consequently, when metrics are unavailable for a particular kernel, we set $\gamma = 1$. We believe that this is a reasonable approximation because kernel-alike operations tend to be very simple (e.g., element-wise operations) and are therefore usually memory bandwidth bound.

4.3 MLPs: Data and Training

In this section, we describe the details behind Habitat’s MLPs: how we (i) collect training data, (ii) preprocess the data, and (iii) train the MLPs.

4.3.1 Data Collection

We gather training data by measuring the forward and backward pass execution times of kernel-varying operations at randomly sampled *input configurations*. An input configuration is a setting of an operation’s parameters (e.g., batch size and number of channels in a convolution). We use predefined ranges for each operation’s parameters, as described in more detail below, and ignore any configurations that result in running out of memory. We make these measurements for all six of the GPUs listed in Section 5.1. We use the same seed when sampling on different GPUs to ensure we have measurements for the same random input configurations across all the GPUs.

Table 1: A summary of the datasets used for our MLPs.

Operation	Features	Dataset Size
2D Convolution	7+4	91,138 × 6
LSTM	7+4	124,176 × 6
Batched Matrix Multiply	4+4	131,022 × 6
Linear Layer	4+4	155,596 × 6

We create the final dataset by joining data entries that have the same operation and configuration, but with different GPUs.

2D convolutions. For convolutions, we vary the (i) batch size (1 – 64), (ii) number of input (3 – 2048) and output channels (16 – 2048), (iii) kernel size (1 – 11), (iv) padding (0 – 3), (v) stride (1 – 4), (vi) image size (1 – 256), and (vii) whether or not there is a bias weight. We only sample configurations with square images and kernel sizes. During sampling, we ignore any configurations that result in invalid arguments (e.g., a kernel size larger than the image). We selected these parameter ranges by surveying the convolutional neural networks included in PyTorch’s torchvision package [24].

LSTMs. For LSTMs, we vary the (i) batch size (1 – 128), (ii) number of input features (1 – 1280), (iii) number of hidden features (1 – 1280), (iv) sequence length (1 – 64), (v) number of stacked layers (1 – 6), (vi) whether or not the LSTM is bidirectional, and (vii) whether or not there is a bias weight.

Batched matrix multiply (bmm). For a batched matrix multiply of $A \times B$ where $A \in \mathbb{R}^{n \times l \times m}$ and $B \in \mathbb{R}^{n \times m \times r}$, we vary the (i) batch size (n) (1 – 128), and (ii) the l , m , and r dimensions (1 – 1024).

Linear layers. For linear layers, we vary the (i) batch size (1 – 3500), (ii) input features (1 – 32768), (iii) output features (1 – 32768), and (iv) whether or not there is a bias weight.

4.3.2 Data Preprocessing

After collecting data on the GPUs, we build one dataset per operation by (i) adding the forward and backward execution times to arrive at a single execution time for each operation instance on a particular GPU, and (ii) attaching additional GPU hardware features to each of these data points. We attach the GPU’s (i) memory capacity and bandwidth; (ii) number of streaming multiprocessors (SMs); and (iii) peak FLOPS, as specified by the GPU manufacturer.

We present the characteristics of the final datasets in Table 1. We add four to the number of features to account for the four GPU features (described above) that we add to each data point. Similarly, in the dataset size column we show the total number of unique operation configurations that we sample. We multiply by six because we make measurements on six different GPUs.

Table 2: The GPUs we use in our evaluation.

GPU	Generation	Mem.	Mem. Type	SMs	Rental Cost ⁶
P4000 [65]	Pascal [63]	8 GB	GDDR5 [56]	14	–
P100 [62]		16 GB	HBM2 [4]	56	\$1.46/hr
V100 [66]	Volta [67]	16 GB	HBM2	80	\$2.48/hr
2070 [69]	Turing [72]	8 GB	GDDR6 [57]	36	–
2080Ti [70]		11 GB	GDDR6	68	–
T4 [71]		16 GB	GDDR6	40	\$0.35/hr

4.3.3 Training

We implement our MLPs using PyTorch. We train each MLP for 80 epochs using the Adam optimizer [49] with a learning rate of 5×10^{-4} , weight decay of 10^{-4} , and a batch size of 512 samples. We reduce the learning rate to 10^{-4} after 40 epochs. We use the mean absolute percentage error as our loss function:

$$L = \frac{1}{n} \sum_{i=1}^n \left| \frac{\text{predicted}_i - \text{measured}_i}{\text{measured}_i} \right|$$

We assign 80% of our data samples to the training set and the rest to our test set. None of the configurations that we test on in Section 5 appear in our training sets. We normalize the inputs by subtracting by the mean and dividing by the standard deviation of the input features in our training set.

5 Evaluation

Habitat is meant to be used by deep learning researchers and practitioners to predict the *potential compute performance* of a given GPU so that they can make *informed* cost-efficient choices when selecting GPUs for training. Consequently, in our evaluation our goals are to determine (i) how *accurately* Habitat can predict the training iteration execution time on GPUs with different architectures, and (ii) whether Habitat can correctly predict the relative cost-efficiency of different GPUs when used to train a given model. Overall, we find that Habitat makes iteration execution time predictions across pairs of *six* different GPUs with an average error of 11.8% on ResNet-50 [37], Inception v3 [97], the Transformer [99], GNMT [102], and DCGAN [89].

5.1 Methodology

Hardware. In our experiments, we use the GPUs listed in Table 2. For the P4000, 2070, and 2080Ti we use machines whose configurations are listed in Table 3. For the T4 and V100, we use g4dn.xlarge and p3.2xlarge instances on AWS respectively [7]. For the P100, we use Google Cloud’s

⁶Google Cloud pricing in us-central1, as of June 2021.

Table 3: The machines we use in our evaluation.

CPU	Freq.	Cores	Main Mem.	GPU
Xeon E5-2680 v4 [41]	2.4 GHz	14	128 GB	P4000
Ryzen TR 1950X [5]	3.4 GHz	16	16 GB	2070
EPYC 7371 [6]	3.1 GHz	16	128 GB	2080Ti

Table 4: The DNNs and training configurations we use.

Application	Model	Arch. Type	Dataset
Image Classif.	ResNet-50 [37]	Convolution	ImageNet [91]
	Inception v3 [97]		
Machine Transl.	GNMT [102]	Recurrent	WMT’16 [11] (EN-DE)
	Transformer [99]	Attention	
Image Gen.	DCGAN [89]	Convolution	LSUN [104]

n1-standard instances [30] with 4 vCPUs and 15 GB of system memory.

Runtime environment. We run our experiments inside Docker containers [27]. Our container image uses Ubuntu 18.04 [15], CUDA 10.1 [80], and cuDNN 7 [74]. On cloud instances, we use the NVIDIA GPU Cloud Image, version 20.06.3 [83]. We use PyTorch 1.4.0 [86] for all experiments.

Models and datasets. We evaluate Habitat by predicting the training iteration execution time for the models listed in Table 4 on different GPUs. For ResNet-50 and Inception v3 we use stochastic gradient descent [12]. We use Adam [49] for the rest of the models. We use synthetic data (sampled from a normal distribution) of the *same size* as samples from each dataset.⁷ For the machine translation models, we use a fixed sequence length of 50—the longest sentence length typically used—to show how Habitat can make predictions for a lower bound on the computational performance.

Metrics. In our experiments, we measure and predict the *training iteration execution time*—the wall clock time it takes to perform one training step on a batch of inputs. We use the training iteration execution time to compute the training *throughput* and *cost-normalized throughput* for our analysis. The training throughput is the batch size divided by the iteration execution time. The cost-normalized throughput is the throughput divided by the hourly cost of renting the hardware.

Measurements. We use CUDA events to measure the execution time of training iterations and DNN operations. We run 3 warm up repetitions, which we discard, and then record the average execution time over 3 further repetitions. We use CUPTI [76] to measure a kernel’s execution time.

⁷We verified that the training computation time does not depend on the values of the data itself.

5.2 How Accurate are Habitat’s Predictions?

To evaluate Habitat’s prediction accuracy, we use it to make training iteration execution time predictions for ResNet-50, Inception v3, the Transformer, GNMT, and DCGAN on all six GPUs listed in Section 5.1. Recall that Habitat makes execution time predictions by *scaling* the execution time of a model and specific batch size measured on one GPU (the “origin” GPU) to another (the “destination” GPU). As a result, we use all 30 possible (origin, destination) pairs of these six GPUs in our evaluation.

5.2.1 End-to-End Prediction Accuracy

Figure 3 shows Habitat’s prediction errors for these aforementioned end-to-end predictions. Each subfigure shows the predictions for all five models on a specific destination GPU. We make predictions for three different batch sizes (shown on the figures) and plot both the predicted and measured iteration execution times. Since we consider all possible pairs of our six GPUs, for each destination GPU we plot the average predicted execution times among the five origin GPUs. Similarly, we show the average prediction error above each bar. From these figures, we can draw three major conclusions.

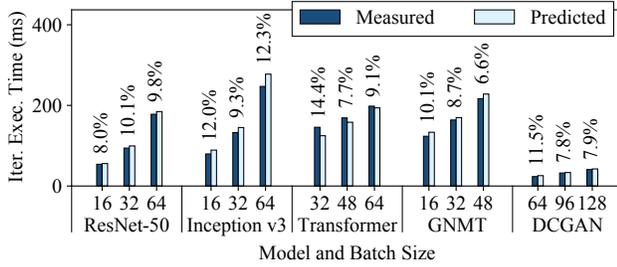

First, Habitat makes accurate end-to-end iteration execution time predictions since the average prediction error across all GPUs and models is 11.8%. The average prediction error across all ResNet-50, Inception v3, Transformer, GNMT, and DCGAN configurations are 13.4%, 9.5%, 12.6%, 11.2%, and 12.3% respectively.

Second, Habitat can predict the iteration execution time across GPU *generations*, which have different architectures, and across *classes* of GPUs. The GPUs we use span three generations (Pascal [63], Volta [67], and Turing [72]) and include desktop, professional workstation, and server-class GPUs.

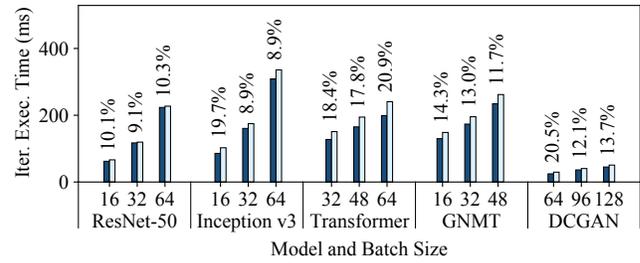

Third, Habitat is *general* since it supports different types of DNN architectures. Habitat works with convolutional neural networks (e.g., ResNet-50, Inception v3, DCGAN), recurrent neural networks (e.g., GNMT), and other neural network architectures such as the attention-based Transformer. In particular, Habitat makes accurate predictions for ResNet, Inception, and DCGAN despite the significant differences in their architectures; ResNet has a “straight-line” computational graph, Inception has a large “fanout” in its graph, and DCGAN is a generative-adversarial model.

5.2.2 Prediction Error Breakdown

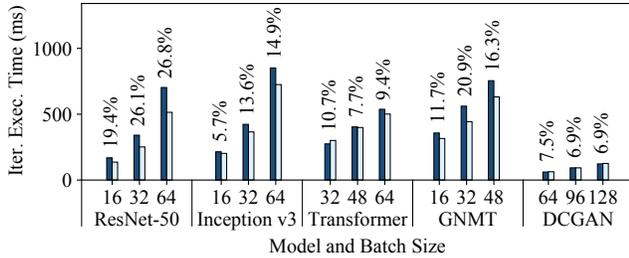

Figure 4 shows a breakdown of the prediction errors for the execution time of individual operations, which are listed on the *x*-axis. The operations predicted using the MLP predictors are shown on the left (conv2d, lstm, bmm, and linear). Wave scaling is used to predict the rest of the operations. Above each bar, we also show the *importance* of each operation as

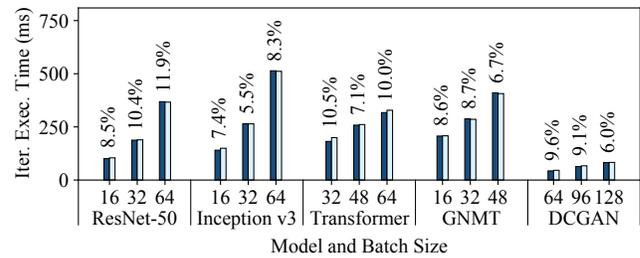

(a) Predictions onto the V100

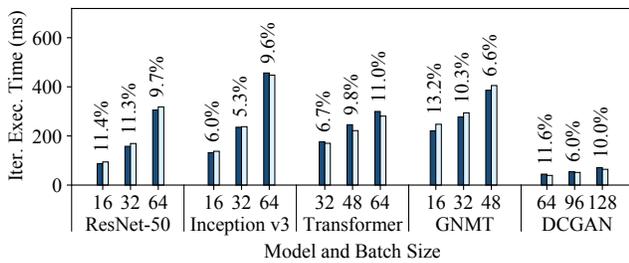

(b) Predictions onto the 2080Ti

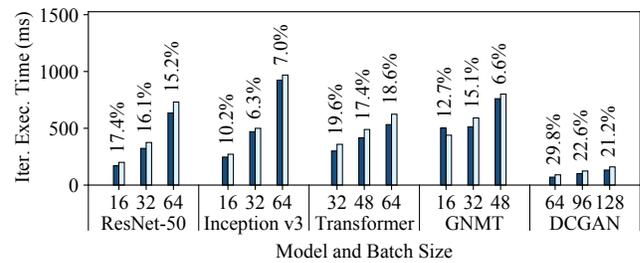

(c) Predictions onto the T4

(d) Predictions onto the 2070

(e) Predictions onto the P100

(f) Predictions onto the P4000

Figure 3: Iteration execution time predictions averaged across all other “origin” GPUs we evaluate.

a percentage of the iteration execution time, averaged across all five DNNs. The prediction errors are averaged among all pairs of the six GPUs that we evaluate and among ResNet-50, Inception v3, the Transformer, GNMT, and DCGAN. From this figure, we can draw two major conclusions.

First, MLP predictors can be used to make accurate predictions for kernel-varying operations as the average error among all the conv2d, lstm, bmm, and linear operations is 18.0%. Second, wave scaling can make accurate predictions for important operations; the average error for wave scaling predictions is 29.8%. Although wave scaling’s predictions for some operations (e.g., `__add__`, `scatter`) have high errors, these operations do not make up a significant proportion of the training iteration execution time (having an overall importance of at most 0.3%).

5.2.3 Prediction Contribution Breakdown

We also examine how wave scaling and the MLPs each contribute to making Habitat’s end-to-end predictions. In our

evaluation, Habitat uses wave scaling for 95% of the unique operations; it uses MLPs for the other 5%. In contrast, when looking at execution time, Habitat uses wave scaling to predict 46% of an iteration’s execution time on average; it uses MLPs for the other 54%.

These breakdowns show that *both* wave scaling and the MLPs contribute non-trivially to Habitat’s predictions—each is responsible for roughly half of an iteration’s execution time. Additionally, the unique operation breakdown shows that most operations are predicted using wave scaling. This observation highlights a strength of Habitat’s hybrid approach of using both wave scaling and MLPs: most operations can be automatically predicted using wave scaling; MLPs only need to be trained for a few kernel-varying operations.

5.2.4 MLPs: How Many Layers?

In all our MLPs, we use eight hidden layers, each of size 1024. To better understand how the number of layers affects the MLPs’ prediction accuracy, we also conduct a sensitivity

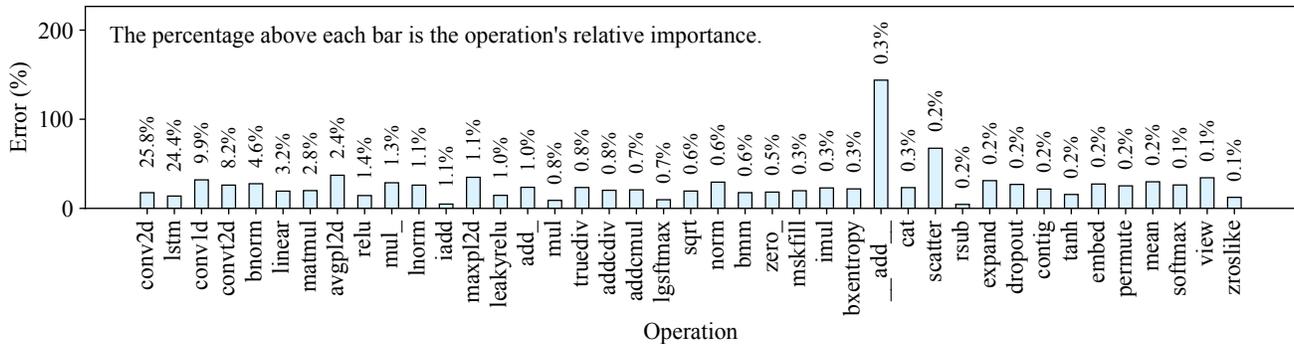

Figure 4: Operation execution time prediction errors, with importance on top of each bar, averaged across all pairs of evaluated GPUs and models. The operation names have been shortened and we only show operations with an importance of at least 0.1%.

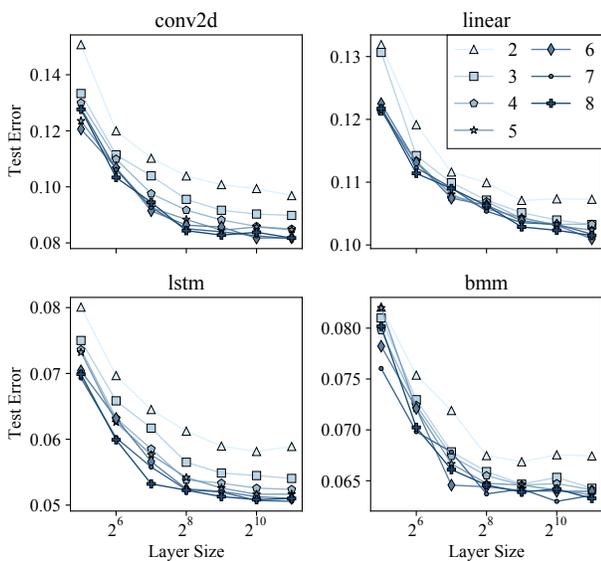

Figure 5: Test error as we vary the number of layers and their sizes in each MLP. The x -axis is in a logarithmic scale.

study where we vary the number of hidden layers in each MLP (2 to 8) along with their size (powers of two: 2^5 to 2^{11}). Figure 5 shows each MLP’s test mean absolute percentage error after being trained for 80 epochs. From this figure we can draw two major conclusions.

First, increasing the number of layers and their sizes leads to lower test errors. Increasing the size of each layer beyond 2^9 seems to lead to diminishing returns on each operation. Second, the MLPs for all four operations appear to follow a similar test error trend. Based on these results, we can also conclude that using eight hidden layers is a reasonable choice.

5.3 Does Habitat Lead to Correct Decisions?

One of Habitat’s primary use cases is to help deep learning users make *informed* and *cost-efficient* GPU selections. In the following two case studies, we demonstrate how Habitat can

make cost-efficiency predictions that empower users to make correct selections according to their needs.

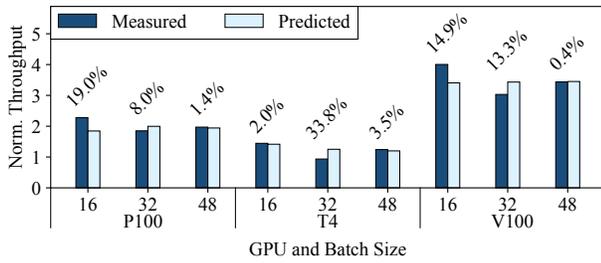

5.3.1 Case Study 1: Should I Rent a Cloud GPU?

As mentioned in Section 1, one scenario a deep learning user may face is deciding whether to rent GPUs in the cloud for training or to stick with a GPU they already have locally (e.g., in their desktop). For example, suppose a user has a P4000 in their workstation and they want to decide whether to rent a P100, T4, or V100 in the cloud to train GNMT.

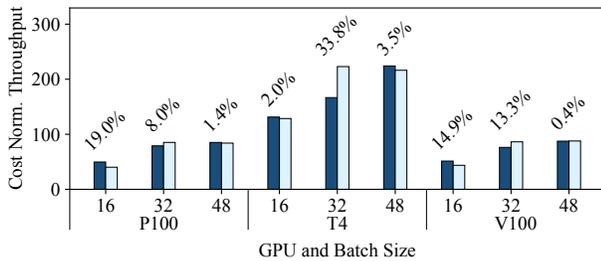

With Habitat, they can use their P4000 to make *predictions* about the computational performance of each cloud GPU to help them make this decision in an informed way. Figure 6a shows Habitat’s throughput predictions for GNMT for the P100, T4, and V100 normalized to the training throughput on the P4000. Additionally, Figure 6b shows Habitat’s predicted training throughputs normalized by each cloud GPU’s rental costs on Google Cloud as shown in Table 2. Note that (i) we make all these predictions with the P4000 as the origin device, (ii) we make our ground truth measurements on Google Cloud instances, and (iii) one can also use Habitat for a similar analysis for other cloud providers. From these results, the user can make two observations.

First, both the P100 and V100 offer training throughput speedups over the P4000 (up to $2.3\times$ and $4.0\times$ respectively) whereas the T4 offers marginal throughput speedups (up to $1.4\times$). However, second, the user would also discover that the T4 is more *cost-efficient* to rent when compared to the P100 and V100 as it has a higher cost-normalized throughput. Therefore, if the user wanted to optimize for maximum computational performance, they would likely choose the V100. But if they were not critically constrained by time and wanted to optimize for cost, sticking with the P4000 or renting a T4 would be a better choice.

Habitat makes these predictions accurately, with an average error of 10.7%. We also note that despite any prediction errors, Habitat still *correctly* predicts the relative ordering of these three GPUs in terms of their throughput and cost-normalized

(a) GNMT training throughput normalized to the P4000

(b) GNMT cost normalized throughput

Figure 6: Habitat’s GNMT training throughput predictions for cloud GPUs, made using a P4000. The percentage error is shown above each prediction.

throughput. For example, in Figure 6b, Habitat correctly predicts that the T4 offers the best cost-normalized throughput on all three batch sizes. These predictions therefore allow users to make correct decisions based on their needs (optimizing for cost or pure performance).

5.3.2 Case Study 2: Is the V100 Always Better?

In the previous case study, Habitat correctly predicts that the V100 provides the best performance despite not being the most cost-efficient to rent. This conclusion may lead a naïve user to believe that the V100 always provides better training throughput over other GPUs, given that it is the most advanced and expensive GPU available in the cloud to rent.⁸ In this case study, we show how Habitat can help a user recognize when the V100 does not offer significant performance benefits for their model.

Suppose a user wants to train DCGAN and already has a 2080Ti that they can use. They want to find out if they should use a different GPU to get better computational performance (training throughput). They can use Habitat to predict the training throughput on other GPUs. Figure 7 shows Habitat’s throughput predictions along with the measured throughput, normalized to the 2080Ti’s training throughput. Note that we use a batch size of 64 as it is the default batch size in the

⁸This is true except for the new A100s, which have only recently become publicly available in the cloud.

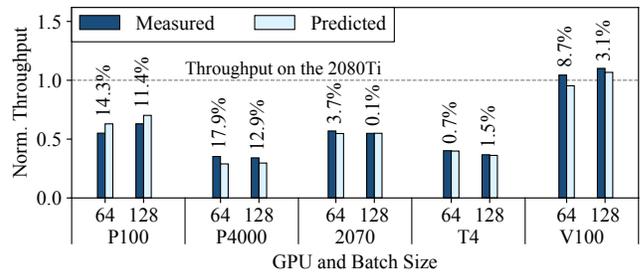

Figure 7: Predicted and measured DCGAN training throughput normalized to the 2080Ti, with prediction errors above each bar. Habitat correctly predicts that the V100’s performance is not significantly better than the 2080Ti.

DCGAN reference implementation [22] and 128 because it is the size reported by the authors in their paper [89].

From this figure, the user would conclude that they should stick to using their 2080Ti as the V100 would not be worth renting. The V100 offers marginal throughput improvements over the 2080Ti (1.1×) while the P100, P4000, 2070, and T4 all do not offer throughput improvements at all. The reason the V100 does not offer any significant benefits over the 2080Ti despite having more computational resources (Table 2) is that DCGAN is a “computationally lighter” model compared to GNMT and so it does not really benefit from a more powerful GPU. Habitat makes these predictions accurately, with an average error of 7.7%.

Summary. These case studies show examples of situations where (i) the GPU offering the highest training throughput is *not* the same as the most cost-efficient GPU, and where (ii) the V100 does *not* offer significantly better performance when compared to a desktop-class GPU (the 2080Ti). Notably, in both case studies, Habitat *correctly* predicts each of these findings. As a result, deep learning researchers and practitioners can rely on Habitat to help them make correct cost-efficient GPU selections according to their needs.

6 Discussion

In this section, we discuss how Habitat can be extended to support additional (i) training setups, and (ii) deep learning frameworks. In doing so, we also highlight opportunities for future work and describe some challenges and opportunities associated with supporting additional hardware accelerators.

6.1 Additional Training Setups

Habitat is designed to make accurate cross-GPU execution time predictions for DNN training. However, users may also face situations where they need performance predictions for more complex training setups such as (i) distributed training [25], (ii) mixed precision training [55], or (iii) needing

predictions for batch sizes larger than what can fit on the origin GPU. In this subsection, we outline how Habitat could be extended to support these setups.

6.1.1 Distributed Training

Predicting the execution time of a distributed training iteration generally reduces to predicting (i) the computation time on the cluster’s GPUs, (ii) the communication time among the GPUs and/or nodes, and (iii) how the communication overlaps with the computation. For data parallel training [25], several prior works present techniques for predicting the data parallel iteration execution time given the execution time on a single GPU [87, 88, 110] (i.e., tasks (ii) and (iii)). Habitat’s computation predictions (task (i)) could be used as an input to these existing techniques.

For more complex distribution schemes such as model parallel [25] and pipeline parallel training [40, 60], Habitat could still be used for task (i), but the user would need to split up their model based on the distributed partitioning scheme before profiling it with Habitat. However, for tasks (ii) and (iii), new prediction techniques would need to be developed. This is something we leave to future work.

6.1.2 Mixed Precision Training

The Daydream paper [110] presents a technique for predicting the performance benefits of switching from single to mixed precision training on the *same* fixed GPU. If users want to know about the performance benefits of mixed precision training on a *different* GPU, they can use Daydream’s technique in conjunction with Habitat.

To show that this combined approach can work in practice, we use a P4000 to predict the execution time of a ResNet-50 mixed precision training iteration on the 2070 and 2080Ti.⁹ On the P4000, we first use Habitat to predict the single precision iteration execution time on the 2070 and 2080Ti. Then, we apply Daydream’s technique to translate these predicted single precision execution times into mixed precision execution times. We also repeat this experiment between the 2070 and 2080Ti. Overall, we find that this approach has an average error of 16.1% for predictions onto the 2070 and 2080Ti.

To distinguish between the errors introduced by Habitat versus Daydream, we also apply Daydream’s technique to the measured (i.e., ground truth) single precision iteration execution times. We find that Daydream’s technique alone has an average error of 10.7% for the 2070 and 2080Ti. Thus we believe the additional error introduced by also using Habitat is reasonable, given the extra functionality. So overall, we conclude that Habitat with Daydream should be able to effectively support mixed precision predictions on other GPUs.

⁹We use the same experimental setup and batch sizes as described and shown in Section 5.1 and Figure 3. We compare our iteration execution time predictions against training iterations performed using PyTorch’s automatic mixed precision module.

6.1.3 Larger Batch Sizes

Recall that Habitat’s iteration execution time predictions are for a model and a specific batch size. This means that the origin GPU must be able to run a training iteration with the desired batch size (for Habitat’s profiling pass).

One potential approach to making predictions for batch sizes larger than what can run on the origin GPU is as follows. First, use Habitat to make iteration execution time predictions for multiple (e.g., three) different batch sizes that *do* fit on the origin GPU. Then, build a linear regression model on these predicted values to *extrapolate* to larger batch sizes. This approach is based on our prior work, where we observed an often linear relationship between the iteration execution time and batch size [107]. We leave the handling of models where only one batch size fits on the origin GPU to future work.

6.2 Additional Deep Learning Frameworks

Recall that Habitat predicts the execution time of operations using either (i) wave scaling or (ii) pre-trained MLPs, depending on whether the operation is kernel-alike or kernel-varying. Therefore, as long as Habitat has information about a DNN’s operations and their parameters (e.g., batch size, number of channels), Habitat will be able to apply its techniques to make execution time predictions for a different GPU. Ultimately this means that adding support for other deep learning frameworks (e.g., TensorFlow or MXNet) boils down to extracting the underlying operations that run during a training iteration and sending the operations to Habitat (i.e., extracting the computation graph). Since the other major deep learning frameworks (TensorFlow and MXNet) both already use computation graphs internally [1, 19], we believe that adding support for them would be straightforward to implement.

6.3 Additional Hardware Accelerators

As described in Section 1, there are also other hardware options available beyond GPUs that can be used for training (e.g., the TPU [45], AWS Trainium [10], and Gaudi [36]). Therefore, a natural opportunity for future work is to explore execution time predictions for these other hardware accelerators. We outline two challenges that arise when going beyond GPUs, as well as two examples of ways that Habitat’s guiding principles can be applied to these prediction tasks.

Challenges. First, specialized deep learning accelerators may have a different hardware architecture when compared to GPUs—necessitating different performance modeling techniques. For example, the TPU uses a systolic array [14, 45] whereas GPUs are general-purpose SMT processors [85]. Second, accelerators such as the TPU rely on *tensor compilers* (e.g., XLA [34] or JAX [13]) to produce executable code from the high-level DNN model code written by an end-user. The compiler may apply optimizations that change the oper-

ations. These changes make the high-level operation-based analysis that Habitat performs more difficult to realize.

Opportunities. Despite these challenges, we believe that there are also opportunities to apply Habitat’s key idea of leveraging runtime-based information from one accelerator to predict the execution time on a different accelerator. For example, as of June 2021, Google makes two versions of the TPU available for rent (v2 and v3) [33] and has announced the v4 [51]. Execution times measured on the TPU v2 could potentially be used to make execution time predictions on the v3 and v4 and vice-versa. Similarly, assuming that the AWS Trainium also uses a systolic array,¹⁰ it may also be possible to leverage execution time measurements on the TPU to make execution time predictions for the Trainium and vice-versa.

7 Related Work

The key difference between Habitat and existing DNN performance modeling techniques for GPUs [46, 87, 88] is in how Habitat makes execution time predictions. Habitat takes a hybrid *runtime-based approach*; it uses information recorded at runtime on one GPU along with hardware characteristics to *scale* the measured kernel execution times onto different GPUs through either (i) wave scaling, or (ii) pre-trained MLPs. In contrast, existing techniques use analytical models [87, 88] or rely *entirely* on machine learning techniques [46]. The key advantage of Habitat’s hybrid scaling approach is that wave scaling works “out of the box” for all kernel-alike operations (i.e., operations implemented using the same kernels on different GPUs). Ultimately, this advantage means that new analytical or machine learning models do not have to be developed each time a new kernel-alike operation is introduced.

DNN performance models for different hardware. There exists prior work on performance models for DNN training on GPUs [46, 87, 88], CPUs [100], and TPUs [47]. As described above, Habitat is fundamentally different from these works because it takes a hybrid *runtime-based approach* when making execution time predictions. For example, Paleo [88] (i) makes DNN operation execution time predictions using *analytical models* based on the number of floating point operations (FLOPs) in a DNN operation, and (ii) uses heuristics to select the kernels used to implement kernel-varying operations (e.g., convolution). However, an operation’s execution time is not solely determined by its number of FLOPs, and using heuristics to select an analytical model cannot always capture kernel-varying operations correctly. This is because proprietary closed-source kernel libraries (e.g., cuDNN [21, 74], cuBLAS [77]) may select different kernel(s) to use by running benchmarks on the target GPU [44, 75].

Performance models for compilers. A complementary body of work on performance modeling is motivated by the

¹⁰The AWS Inferentia [9, 108], a related accelerator, uses a systolic array architecture [92]. So we believe that this is a reasonable assumption to make.

needs of compilers: predicting how *different implementations* of some high-level functionality perform on the *same hardware*. These models were developed to aid in compiling high-performance (i) graphics pipelines [2], (ii) CPU code [54], and (iii) tensor operators for deep learning accelerators [20, 47]. These models have fundamentally different goals compared to Habitat, which is a technique that predicts the performance of *different GPUs* running the *same high-level code*.

General scalability predictions. Wave scaling is similar in spirit to ESTIMA [17], since both use the idea of making measurements on one system to make performance predictions for a different system. However, ESTIMA is a scalability predictor for CPU programs. Wave scaling instead targets GPU kernels, which run under a different execution model when compared to CPU programs.

Repetitiveness of DNN training. Prior work leverages the repetitiveness of DNN training computation to optimize distributed training [43, 48, 60], schedule jobs in a cluster [18, 61, 103], and to apply DNN compiler optimizations [94]. The key difference between these works and Habitat is that they apply optimizations on the *same* hardware configuration. Habitat exploits the repetitiveness of DNN training to make performance predictions on *different* hardware configurations.

DNN benchmarking. A body of prior work focuses on benchmarking DNN training [3, 23, 53, 109]. While these works provide DNN training performance insights, they do so only for a *fixed* set of DNNs and hardware configurations. In contrast, Habitat analyzes DNNs in *general* and provides performance *predictions* on different GPUs to help users make informed GPU selections.

8 Conclusion

We present *Habitat*: a new runtime-based library that uses wave scaling and MLPs as execution time predictors to help deep learning researchers and practitioners make *informed cost-efficient* decisions when selecting a GPU for DNN training. The key idea behind Habitat is to leverage information collected at runtime on one GPU to help predict the execution time of a DNN training iteration on a different GPU. We evaluate Habitat and find that it makes cross-GPU iteration execution time predictions with an overall average error of 11.8% on ResNet-50, Inception v3, the Transformer, GNMT, and DCGAN. Finally, we present two case studies where Habitat correctly predicts that (i) optimizing for cost-efficiency would lead to selecting a different GPU for GNMT, and (ii) that the V100 does not offer significant performance benefits over a common desktop-class GPU (the 2080Ti) for DCGAN. We have also open sourced Habitat (github.com/geoffxy/habitat) to benefit both the deep learning and systems communities [105, 106].

Abstract

GPUs are the workhorse in modern server infrastructure fueling advances in a number of compute-intensive workloads such as deep neural network (DNN) training. Several recent works propose solutions on sharing GPU resources across multiple concurrent DNN training jobs, but none of them address rapidly increasing memory footprint introduced by such job co-locations, which greatly limit the effectiveness of sharing GPU resources. In this paper, we present Zico, the first DNN system that aims at reducing the system-wide memory consumption for concurrent training. Zico keeps track of the memory usage pattern of individual training job by monitoring its progress on GPU computations and makes memory reclaimed from the job globally sharable. Based on this memory management scheme, Zico automatically decides a strategy to share memory among concurrent jobs with minimum delay on training while not exceeding a given memory budget such as GPU memory capacity. Our evaluation shows that Zico outperforms existing GPU sharing approaches and delivers benefits over a variety of job co-location scenarios.

1 Introduction

Recent advances in deep neural networks (DNNs) have made tremendous progress on a wide range of applications, including object detection [24], language model [11, 47], translation [40], and speech recognition [27]. As a number of new DNN models are being explored, developers take advantage of hardware accelerators to train the models, such as TPU [22] and GPU, which is the most popular choice. GPUs are the workhorse in server infrastructure and yet becoming highly contended resources at the same time [20, 43].

To utilize expensive GPU resources, efficient GPU sharing mechanisms have become indispensable. Prior work focuses on either *temporally* multiplexing GPU in its entirety [26, 43, 44] or *spatially* sharing compute units [10]. The temporal sharing is a software mechanism that dedicates both compute cores and memory in GPU solely to single training

for a time quantum (e.g., 1 minute). Despite the good flexibility, this approach often cannot efficiently utilize GPU resources. For example, most compute resources are left idle for common translation models such as GNMT [42] and language models such as RHN [47]. These training algorithms include a number of RNN modules [28], such as LSTM [12] and GRU [8] networks, which exhibit a small degree of data parallelism to GPU, causing under-utilization of GPU resources. As a different approach, the spatial sharing can provide better throughput than the temporal sharing as long as a single training job does not fully saturate GPU compute resources [44]. However, a limitation in applying the spatial sharing is the working set size of concurrent jobs, which grows substantially with the job co-location. If the working set does not fit in GPU memory, the system has to kill a job or swap GPU memory to the host, which overshadows the performance benefit of the spatial sharing. Therefore, to make the spatial sharing widely applicable, it is essential to reduce the memory footprint of co-located training jobs.

We observe that sharing intermediate data generated during co-located training jobs significantly reduces the total memory footprint. Training is a highly iterative procedure first navigating layers in order (forward pass) and then the same layers in *reverse* order (backward pass) for each batch of input data. During the training procedure, intermediate outputs from model layers called *feature maps* dominate memory footprint [18, 32]. Feature maps are generated in each layer during the forward pass and later consumed in the backward pass to update the layer. Due to the regular bi-directional execution, memory consumption in a single training job commonly exhibits a *cyclic pattern* — memory consumption gradually increases in the forward pass and then decreases in the backward pass. Thus, a simple yet effective strategy to save memory consumption is creating a large GPU memory pool and elastically sharing the memory pool for concurrent training jobs. To increase sharing opportunity, coordination of concurrent training jobs is needed to make them run different passes, e.g., forward pass for job A (increasing its working set) and backward pass for job B (decreasing its working set). This

approach results in memory allocations of a job to happen simultaneously with memory deallocations of the other job, efficiently reducing the *system-wide* memory footprint.

Despite that the sharing idea is plausible, the way today's DNN frameworks execute training on GPU poses significant challenges. Current frameworks are mainly designed for a *solo training* case. Following dataflow dependency, they allocate the memory required for each DNN kernel computation ahead of time and issue as many kernels as possible to the GPU stream, i.e., work queue per job for its GPU computations, in order to saturate the GPU's internal compute resources. This leads to GPU computations *asynchronous* and in parallel with CPU processing. Thus, the platforms are *unaware* of progress on the GPU computations and when memory is indeed consumed by GPU. Without proper handling of the asynchrony, shared memory does not guarantee correctness such as preventing memory corruptions in shared untapped memory of a waiting kernel by other training jobs.

In this paper, we propose Zico, a DNN platform that enables efficient memory sharing for concurrent training. Zico retrofits a widely used DNN platform, TensorFlow, to maximize the overall throughput of concurrent training. The goal of Zico is finding the best coordinated executions of concurrent training to fully utilize GPU computational and memory resources. To achieve the goal, (i) Zico accurately monitors computational progress of training jobs. Based on that, Zico allocates and deallocates memory for DNN kernels, informing memory usage patterns closer to GPU's view. (ii) Zico incorporates runtime information (e.g., iteration times, memory usage patterns, and GPU memory limit) and executes a job scheduler, called *scrooge scheduler*, to efficiently steer concurrent jobs to utilize the shared memory pool. (iii) Zico efficiently organizes the entire GPU space as an elastic shared memory pool to support scrooge scheduler.

To detect computational progress of asynchronous kernels, Zico leverages a specific kernel called CUDA event, which notifies progress of GPU kernels. Zico uses CUDA event to identify allocation and release time of memory used by a GPU kernel. Based on the information, Zico executes our novel scrooge scheduler to forecast the memory consumption trend of concurrent training at the iteration boundary and introduces the minimum stall time on each iteration. Nevertheless, the memory usage trend of the co-scheduled jobs varies according to how they interfere each other in the use of GPU compute units. To apply their dynamic behaviors, scrooge scheduler refines decisions based on feedback collected at runtime.

Zico organizes the memory pool as a collection of chunks called *regions* and separates their uses based on data characteristics. DNN training generates several types of data as tensors, categorized mainly as *ephemeral* tensors with high occurrences and *long-lived* tensors like feature maps which constitute the most memory footprint. By separating regions by type, Zico ensures that memory stored with feature maps does not interfere with other transient data while making their

demands follow the cyclic pattern of training iteration. This design choice allows our scheduling decisions to be applied with little disruption without losing sharing opportunity.

Being prototyped on a popular DNN framework, TensorFlow, we evaluate Zico experimentally using six models ranging from translation to object detection on V100 and RTX 2080 Ti GPUs. The results show that Zico enables effective memory sharing over a wide range of memory consumption trends. For high memory footprint, Zico is up to 8.3x and 1.6x faster than traditional spatial sharing and temporal sharing approaches, respectively, especially when concurrently training non-identical models. Furthermore, for low memory footprint, where no stall on concurrent training is needed, Zico behaves similarly to traditional spatial sharing and is up to 1.6x faster than temporal sharing. Overall, Zico achieves speedups, regardless of whether concurrent training is based on the same or distinct models.

2 Background

2.1 Deep Neural Network Training

The training process typically relies on iterative optimization methods like stochastic gradient descent (SGD) [13], Momentum [39], and Adam [23]. In each *iteration*, *forward pass* (FP) is followed by *backward pass* (BP) on a *batch* of training dataset. During FP, by computing on the layer's input, weights, and bias, each layer outputs *feature maps* to be used as an input to the next downstream layer. At the end of FP, the last layer produces a loss representing the accuracy of the current model on the input batch. Using the loss value, BP computes the gradients by flowing the layers in reverse order and aggregates the gradient values to update model *parameters* (i.e., layers' *weights* and *bias*). On finishing BP, the training repeats FP and BP on the next batch. As the batch size is usually fixed, the computation load and the memory usage characteristic are usually very similar across iterations [15, 43].

It is widely known that model parameters occupy only a small fraction of memory, and the majority is consumed to store feature maps generated in the FP computation [18, 32, 43]. BP needs feature maps to calculate the gradients at each layer. Hence, unless recomputed [6, 14, 19], feature maps are usually kept on memory for a long time until they are no longer accessed in BP. The amount of memory consumption is determined by several factors, such as the number of layers, layer size and type, input batch size, etc. There is also other intermediate data training iteration creates, e.g., *gradient maps* that represent the output of each layer during BP, local data local in each kernel, etc. They are *all* ephemeral as memory is released soon after its allocation [18, 32]. For brevity, we assume all memory allocations in DNN training are based on *tensors*.

2.2 GPU Sharing Use Cases

Users run training either on shared GPU clusters or on dedicated servers. For both cases, GPU sharing is becoming a fundamental technique to better utilize GPU resources. In this subsection, we introduce two specific scenarios that can take advantage of sharing GPUs.

Hyperparameter tuning (inter-job). With the increasing popularity of applications fueled by DNN, a number of new models are being developed by DNN practitioners every day. A model for developing exposes many high-level properties, e.g., learning rate and momentum, as hyperparameters that need to be optimized. This task is known as *hyperparameter tuning* [3]. As hyperparameters constitute a large search space, there are several popular tools such as Hyperdrive [35] and HyperOpt [4] that automate hyperparameter optimization and construct a new model with the best (or desired) quality for users. These tools usually generate a large number of closely related training jobs (as much as 100s [26, 43]) that explore a different set of hyperparameters for the same reference model. Nevertheless, spatial GPU sharing has greater performance potential for this workload, as discussed in Section 7.

Hyperparameter tuning jobs dominate training workloads run atop shared GPU clusters [20, 26, 43]. To get them timely done on heavily contended GPUs, prior works propose several techniques such as temporal and spatiotemporal sharing to apportion a single GPU over multiple training jobs [43, 44].

Gradient accumulation (intra-job). Gradient accumulation is a promising method to speed up model convergence when hyperparameters other than batch size are stabilized. It runs a set of consecutive mini-batches and accumulates the gradients of those mini-batches before updating model parameters. The essential goal is to give an illusion of training on a large batch that better improves convergence without oversubscribing GPU memory by using small mini-batches. A common practice has been to process these mini-batches sequentially.

Nonetheless, efficient spatial GPU sharing can offer sharing incentive to concurrent training on mini-batches. One might wonder whether spatial sharing on this training is indeed plausible. Based on our observation, translation or speech recognition models (e.g., GNMT [42]) often underutilize GPU compute resources, making it beneficial to share GPU computes. On top of it, our system supports highly effective sharing of GPU memory, enabling in concurrent training each to use a mini-batch size slightly smaller, if not the same, than the original mini-batch size. Altogether, our system opens up a new opportunity to speed up training for gradient accumulation, which we will discuss in Section 7.

2.3 Spatial GPU Sharing

NVIDIA has developed Multi-Process Service (MPS) [10], an alternative way to share GPU among multiple CUDA processes. With MPS, NVIDIA V100 GPU supports up to 48 pro-

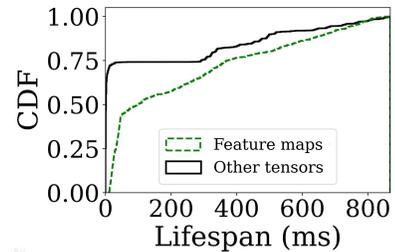

Figure 1: Cumulative distribution of NASNet tensor lifespan.

cesses to run concurrently on a single GPU, with each process assigned with separate GPU compute resources, i.e., SMs [10]. In NVIDIA A100 [29], a newer generation, GPU sharing architecture further partitions HW paths in the memory system, e.g., memory controllers and address buses, to prevent the concurrent processes from interfering with each other when demands for memory bandwidth are high. NVIDIA’s GPU sharing mechanisms have two commonalities. First, they are mainly designed for sharing “compute resources” spatially. Second, they attribute GPU sharing to demands for protection among untrusted users requiring strong isolation.

Since not all use cases require strong isolation among training jobs, e.g., hyperparameter tuning driven by a single user [26], recent work supports a spatial GPU sharing similar to MPS in a single process domain [44]. Regardless of protection level, the underlying mechanism enabling spatial sharing within GPU is very similar, if not the same — and so is the resulting performance.

3 Challenges for Memory Sharing

GPU has a limited amount of HW resources, requiring it to be used in high efficiency. As GPU’s compute and memory resources are shared to run concurrent training limiting per-training resource capacity, it is crucial to thoroughly understand the current practices in DNN frameworks and uncover challenges for spatial GPU training. In this section, we discuss three major challenges to address in Zico.

3.1 Memory Bloating

Major DNN frameworks [1, 5, 31] typically maintain feature maps in memory until they are no longer accessed. As discussed earlier, feature maps have a relatively longer lifespan between the first access and the last access, making the most of in-use memory consumed to store the feature maps. Figure 1 compares cumulative distributions of lifespans for feature maps and other data in NASNet training. As the figure shows, feature maps exhibit longer lifespans with 134ms on average and 234ms as median value as opposed to 18ms on average and 2ms as median value in the other data. We further investigate cumulative distributions of tensor sizes of the two data types, showing that feature maps are larger. In consequence, as shown in Figure 2, feature maps lead to the peak

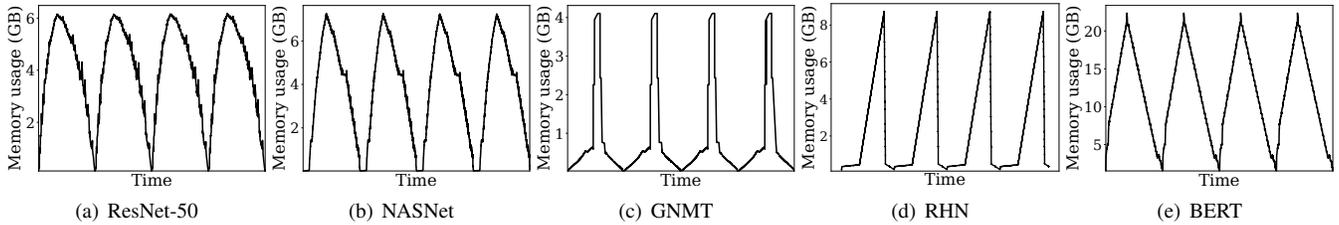

Figure 2: Memory usage patterns for different DNN models over time.

memory consumption substantially higher than the minimum that corresponds to the model size in each iteration. We call this issue *memory bloating*.

Traditional spatial GPU sharing mechanisms are vulnerable to memory bloating. DNN frameworks like TensorFlow do not tend to be designed for memory sharing with internal memory manager maintaining a *local pool* of memory for single training. Thus, no memory release to GPU happens. This results in peak memory usages from concurrent training, all adding up and consequently saturating GPU memory even in the modest memory footprint for individual training. To illustrate, let us consider concurrent training of two identical models, with each demanding more than half of GPU memory as an example. In this case, the memory demand across the two local memory pools exceeds GPU memory capacity, beginning to take advantage of CPU-side memory as a swap space. To facilitate this, recent NVIDIA GPUs, including V100, provide a feature known as Unified Virtual Memory (UVM), which is transparent to DNN platforms.

We found that using UVM for DNN training is currently costly and severely affects overall performance despite great flexibility. To confirm the effect, we compare throughput between solo training versus concurrent training for ResNet-50 using NVIDIA V100 when a training job occupies 70% GPU memory. To make the comparison fair, we configure a single training job to use 50% GPU resources set by MPS. There is a dramatic throughput degradation in concurrent training (i.e., 8 times slower) as it suffers from GPU memory oversubscription. Therefore, we should decrease the risk of GPU memory being used up during concurrent training.

3.2 Workload Variability

As an additional challenge, we explain a workload characteristic that makes memory optimization for spatial GPU sharing fundamentally complicated. Although all models follow a cyclic pattern in memory usage, as shown in Figure 2, memory usage patterns are inherently different across models. For example, ResNet-50 has a beefy shape in which memory bloating appears for a fairly large time duration. In contrast, GNMT has a lean shape in which peak memory appears for a short period and quickly disappears. Therefore, such variability must be taken into account in designing a scheduling policy for concurrent training.

Nonetheless, we take advantage of an observation that a

similar memory usage pattern repeats over iterations for a single model. DNN frameworks require that computation kernels be ordered in a specific way, e.g., following topological sort, thus keeping the corresponding memory operations ordered across iterations [32]. So, we believe this determinism is prevalent in most of the training tasks.

3.3 Asynchrony with GPU Processing

CPU processing in DNN frameworks is in parallel with GPU computations. Before issuing a kernel to a GPU stream, the memory manager in the platform allocates tensors required for the kernel computation. After issuing the kernel and returning immediately, CPU processing brings back its control and can do any subsequent task asynchronously with GPU computations. Meanwhile, GPU may or may not execute the issued kernel depending on whether earlier kernels are still pending or not.

Driven by this GPU-specific property, DNN frameworks produce a static schedule of DNN kernels mainly customized for single training, in which kernel operations are *ordered* based on dependencies every iteration. DNN frameworks usually allocate the memory required for kernel operations in sequence *ahead of time* while issuing *as many kernels as possible* to the stream to saturate GPU. This way of exercising GPU for single training has been common because there is no concern regarding correctness in memory allocations. Specifically, suppose we use a released tensor memory from a kernel to allocate it for the next kernel, even though the earlier kernel is not completed by GPU yet. In that case, memory corruption does not occur since kernels in the GPU stream are processed sequentially.

However, it is critical to make the CPU process keep track of GPU memory usage trends precisely to enable memory sharing for concurrent training. To illustrate the current limitation concretely, let us show effective memory observed in TensorFlow during training ResNet-50 in Figure 3. In the figure, training exhibits a cyclic pattern for a short period followed by a long pause due to kernels pending on GPU during an iteration. Unlike the CPU’s view, the actual memory usage trend from GPU’s view appears in Figure 2(a), which perfectly follows a continuous cycling pattern.

In summary, for concurrent training with multiple GPU streams, today’s approaches that make memory sharing decisions based on CPU’s view are vulnerable to memory cor-

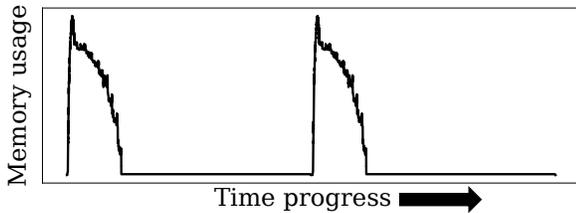

Figure 3: GPU memory usage from CPU view (ResNet-50).

ruption led by simultaneous accesses on the same memory address. This issue is the last challenge to address.

4 Design Overview

Zico aims at providing efficient spatial GPU sharing by enabling coordinated job scheduling and GPU memory management for concurrent training. As a system currently built on TensorFlow, the framework keeps tracking the lifespans of memory used in each training and produces a schedule of concurrent training executions to avoid GPU memory oversubscription. We seek to achieve the following goals in the design of Zico:

- **High performance.** A single iteration runs for a short time duration from tens to hundreds of milliseconds. Thus, a modest overhead with memory sharing in each iteration can manifest as a long delay in the entire training. We should attempt to minimize such overhead and achieve high performance.
- **Wide model support.** Section 3.2 demonstrates a wide range of patterns in memory demand across models during training. Our memory sharing strategy should be general, not restricted to specific memory patterns. The concurrent training may not even expose similar or the identical models.
- **Common approach.** Our approaches are mainly compatible with DNN platforms that express a job execution as a computation graph ahead of time, e.g., TensorFlow [1], Caffe [21], and MXNet [5]. The other platforms are based on imperative programming and train a model without constructing a computation graph, namely, the eager mode. The memory-aware scheduler in Zico makes decisions based only on observed memory demands at runtime, making it also applicable to the eager mode.

Zico has two key system modules as shown in Figure 4: (i) *scrooge scheduler*, a processing unit that orchestrates executions of concurrent training driven by memory demand patterns; and (ii) *memory manager*, a unified memory allocator that handles both inter- and intra-training memory requests.

Scrooge scheduler. Zico monitors GPU progress to capture precise memory usage in GPU for each training over time. On observing memory usage, Zico schedules concurrent jobs to achieve the best possible performance in training while putting the total memory consumption within a predefined budget, which does not exceed GPU memory capacity. This is a sophisticated problem to which a naive strategy rarely

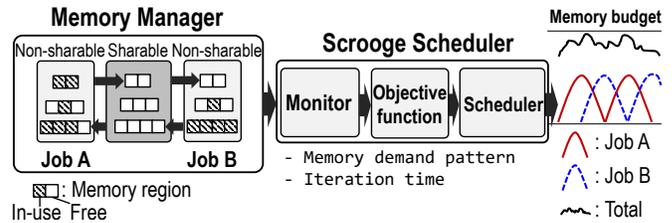

Figure 4: System architecture in Zico.

works. When memory is sufficient for running concurrent training without sharing, no coordination among jobs might be necessary. In contrast, when memory is tight, we need a schedule of concurrent training in order not to exceed the given memory budget. A simple approach towards saving memory consumption can be coordinating training jobs in such a way that forward pass execution (i.e., memory allocation phase) is overlapped with backward pass execution (i.e., memory deallocation phase) as much as possible. However, when memory demand patterns are beefy such as in Figure 2(a), the system-wide memory usage can blow up because the memory demand in the forward pass grows fast while the backward pass shrinks its memory demand relatively slowly.

To provide concrete guidance for memory sharing, we devise *scrooge scheduler* that facilitates an objective function helping forecast the system-wide memory demand in the future. Before starting a new iteration, the scheduler takes into account the lifespans of in-use memory regions, which are sharable memory units in Zico. Then, the scheduler predicts whether allowing the iteration immediately will consume memory less than the memory budget. If this is nearly impossible, the scheduler estimates the minimum stall time to be applied on the new iteration so that memory allocations in the forward pass to be issued later are safely fulfilled when more memory is available. It is essential to maintain precise region lifespan in order to make a correct decision in the scheduling. To meet this goal, Zico iteratively refines region lifespan based on feedback collected from prior iterations at runtime.

Scrooge scheduler is agnostic to programming model in DNN platforms and only relies on information on memory demand patterns. For this reason, Zico is able to perform spatial memory sharing as long as memory requests are appropriately clustered on regions and their lifespans can be estimated. As explained next, we facilitate tensor types to constitute regions for sharing, but many different ways are indeed possible — e.g., classification based on tensor access time intervals in eager mode [2].

Memory manager. Zico organizes the entire GPU memory space into a collection of *regions*, which is a contiguous memory space that stores a set of tensors in the same type. Using regions is a natural choice for us to mitigate the sharing overhead and to keep memory stored with feature maps not contended with other tensor data. Using regions further assists job scheduling decision to be made promptly. Scrooge scheduler makes use of memory demand pattern that changes dynami-

cally within an iteration. If we consider memory changes at the granularity of tensor, we may need to investigate too many time points along the way, putting a strain on the scheduler. Details will be discussed in Section 5.

The memory manager separates memory space into two areas, *sharable* and *non-sharable*. The sharable area represents currently unused memory that can be granted to any in-flight training in need of more space (mainly for feature maps), whereas the non-sharable area constitutes job-local memory pools. Zico analyzes the computational graph and extracts type information on tensors at runtime. During training iterations, allocation requests for feature map tensors are always served from their own regions first in the local memory pool. If regions in the local memory pool are used up, the memory manager assigns a new region from the sharable area. In general, feature maps demand the most regions in the system and these regions are mainly shared across concurrent training jobs.

The current design of Zico limits two training jobs to share a common memory area since many models we observe, including models in Figure 2, exhibit rather beefy memory demand patterns or high GPU utilization. For co-locating more than two jobs, a feasible approach is to organize the jobs into a group of pairs and schedule each pair independently with its own memory budget. This is a natural extension to Zico, so we leave it as a future work.

Protection level. We provide Zico as a single framework instance mainly for performance reason. Existing multi-process solutions such as MPS do not promise good performance for elastic memory space sharing across different processes. For example, to grant memory across two MPS processes, we require invoking CUDA APIs such as `cudaMalloc` and `cudaFree` quite frequently at each training iteration. Among these API, `cudaFree` is known to stall GPU’s pipelined execution upon invoked [9], making itself harmful if recklessly used. Our measurement also reveals that a single ResNet-50 training that allocates memory using these APIs becomes 7x slower than the training that allocates memory locally.

Note that key scenarios discussed in Section 2.2 are enough to train models in the same protection domain. Apart from it, we design Zico to be useful for a variety of scenarios as long as isolation is not a primary concern, e.g., the same tenancy with trusting users in a shared GPU cluster.

5 Scheduling Algorithm

In this section, we formalize the scheduling problem for concurrent training and introduce the *scrooge scheduler*. All related implementation details on how to obtain memory usage patterns are explained in Section 6.

5.1 Problem Definition

We make use of memory consumption at the region level to shape the memory pattern of a job. Despite the coarser-grained leveling of memory utilized by tensors, using regions still provides meaningful information to compute memory sharing potential. Since regions allocated for feature maps are the main target for sharing, in the problem formulation, we assume all regions for a job have the lifetime that spans the forward-backward passes for a single iteration.

Formally, we denote M regions required for an iteration of a training job as $\{R_i : 1 \leq i \leq M\}$ following the *allocation order*, with region R_i having two parameters to indicate its *lifespan*: $Time(R_i(a))$ for the allocation time and $Time(R_i(d))$ for the deallocation time. Assume at time moment T that there are K active regions in the system that indicate the sum of memory footprint of the concurrent jobs. To achieve efficient GPU memory provisioning, we need to *minimize the time delay* to be applied on each training iteration without overcommitting the system-wide memory budget C . This objective turns into the following formulation:

$$\underset{TimeShift}{\operatorname{argmin}} (Time(R_1(d)) - Time(R_1(a)) + TimeShift) \quad (1)$$

subject to

$$\sum_{i=1}^K Size(\hat{R}_i) \leq C \quad (2)$$

at any time T over a training iteration, where $\{Size(\hat{R}_i) : 1 \leq i \leq K\}$ are the sizes of active regions in the system.

Intuitively, Equation 1 represents that an iteration, whose duration corresponds to $Time(R_1(d)) - Time(R_1(a))$, must be delayed by the minimum *Timeshift*. Note that there are other costs such as model synchronization in distributed training that affect training time. They are mostly static [15, 25, 37, 45] and can be easily factored in.

5.2 Time Shift Model

From the perspective of memory sharing, the worst case possible is having forward passes of all training jobs run simultaneously. This may lead to no memory sharing opportunity as regions being freed out in the backward pass of a job may not be used by the other training job. Therefore, when it comes to exceeding the memory budget C , scrooge scheduler adds a time delay driven by the *TimeShift* parameter to a training iteration appropriately to ensure that memory allocations during the forward pass occur when enough memory is available.

Since DNN training is highly periodic and deterministic, when training on an apportioned GPU compute capacity is stabilized, we see almost no variations on the region lifespans over iterations. Moreover, for each iteration, allocation times for adjacent regions exhibit strong temporal dependency. In other words, the time interval between $Time(R_{i(a)})$ and

$Time(R_{i+1}(a))$ for a job is almost static and does not change drastically over iterations. Similarly, deallocations of any two consecutive regions have such strong temporal dependency. This observation suggests that *TimeShift* is the most effective when applied to the entire iteration, not an individual region. Suppose we postpone the allocation of an arbitrary region R_i by *TimeShift*. In that case, deallocations of the regions between R_1 and R_i will be all postponed by *TimeShift*, because allocations for the regions subsequent to R_i get delayed by *TimeShift* and temporal dependencies during deallocations are still preserved. This results in increasing overall memory usage for the iteration unnecessarily.

5.3 Memory Sharing Algorithm

Now, we explain how scrooge scheduler works to enable spatial memory sharing. Scrooge scheduler optimizes for the minimum possible iteration time based on Equation 1 at run-time. To solve the problem, the scheduling algorithm must address two challenges: C-1) The lifespan of the region, $L(R_i)$, changes according to how two training jobs execute under co-location; C-2) While $L(R_i)$ is changing, the schedule has to find an optimal *TimeShift* in Equation 1. Scrooge scheduler performs iterative searching steps to reach the goal. For C-1, scrooge scheduler introduces a feedback-driven online process in which the scheduler monitors lifespans of all R_i during the current step and updates them to use in the next step. For C-2, at each step, scrooge scheduler decides *TimeShift* of the co-located training jobs toward minimizing their iteration times. After several steps, the lifespans are adjusted enough and stabilized. *TimeShift* should be estimated in an iteration basis to determine when the current iteration has to start.

Profiling phase (The first search step). When a new training job is issued, scrooge scheduler initiates *profiling phase* during which it collects basic information on the new job. In particular, the scheduler runs the first iteration of the new job in an isolated manner. During this profile phase, scrooge scheduler identifies regions by type and obtains lifespan for each feature map region in the solo run¹.

Informed phase. After the profile phase, scrooge scheduler knows useful information for co-locating jobs. In this informed phase, for a new iteration to be started for a job (e.g., job A) with $TimeShift = 0$, the scheduler navigates through time progress using lifespan information and predicts if the memory constraint in Equation 2 is violated or not. If violated, the scheduler waits for time T , which leads to $TimeShift += T$, and does the prediction again. This time-shifting continues until the scheduler meets the memory constraint — this is guaranteed as the other co-located job (e.g., job B) will ultimately release all regions at the end of its backward pass.

To illustrate, for job A's forward pass, $Time(R_2^{Job A}(a)) - Time(R_1^{Job A}(a))$ indicates the time duration in which the

job A uses $Size(R_1^{Job A}(a))$ amount of memory, which corresponds to the allocation of the first region $R_1^{Job A}$. Likewise, $Time(R_N^{Job A}(a)) - Time(R_1^{Job A}(a))$ indicates the time taken for the entire forward pass in which job A gradually demands more memory by allocating regions from $R_1^{Job A}$ to $R_N^{Job A}$. In this way, scrooge scheduler can forecast the memory demand trend for job A's forward pass and similarly the trend for its backward pass.

To fulfill the condition in Equation 2, scrooge scheduler also needs to know the memory demand trend of the co-located job B. Assume that job B deallocates its R_{i+1} , i.e., $R_{i+1}^{Job B}$, when the scheduler attempts to schedule job A's forward pass. Then, scrooge scheduler knows that during $Time(R_{i-1}^{Job B}(d)) - Time(R_i^{Job B}(d))$, job B will use $\sum_i^i Size(R_i^{Job B})$ amount of memory. As such, as job B gradually deallocates its in-use regions from $R_i^{Job B}$ to $R_1^{Job B}$ in order over time, job B will ultimately release $\sum_i^i Size(R_i^{Job B})$ amount of memory after $Time(R_1^{Job B}(d)) - Time(R_i^{Job B}(d))$.

With this memory trend information on job A and job B, scrooge scheduler can decide during Job B's backward pass, if Job A can start by computing 1) the amount of memory required by Job A as time progresses and 2) the amount of memory released by job B as time progresses in terms of regions. This brings out the system-wide active regions as time progresses, which scrooge scheduler uses to predict if memory consumption will always fit in the defined memory budget, i.e., if Equation 2 is satisfied.

In the informed phase, we first use a memory budget which is lower than the actual memory budget C to calculate region lifespans under a conservative schedule that incurs a smaller interference among jobs and thus a less aggressive memory sharing. At this time, the execution of concurrent training is far from optimal, i.e., having long time shifts. From this point, scrooge scheduler iteratively optimizes the objective function. The scheduler gradually increases the lowered memory budget to allow more interference over time and keeps updating region lifespans until it reaches back the memory budget C . It is necessary to calculate region lifespans under co-location with such adaptation because co-scheduling jobs that together have >100% compute demands than the GPU's capacity will inadvertently interfere with the lifespan calculations.

Note that scrooge scheduler works regardless of training two heterogeneous models or when forward passes of the two jobs overlap. Although scheduling is a per-iteration process, it operates at a low cost as memory patterns are already discretized into region level (the scheduling overhead will be discussed in Section 7.4). In reality, the slowdown for each training is very predictable when two training jobs exhibit very similar GPU compute demands. A rare but challenging case is when a beefy model is trained along with a lean model which suddenly suffers from a dramatic slowdown from co-location. This case results in memory not being released from the lean model for a long time while the beefy model keeps allocating memory, leading to the system-wide

¹This profiling can also be done offline to reduce online profiling cost.

memory usage going over GPU memory capacity. In this case, Zico gives up an attempt on spatial GPU sharing and falls back to time-multiplexing.

Deadlock potential. With concurrent jobs in phases of increasing memory allocation, the deadlock could happen when there is insufficient memory to allocate to these in-flight jobs. Scrooge scheduler does not start the current iteration of a training job if global memory consumption would go beyond the memory budget during its forward-backward passes. In the worst case, scrooge scheduler will schedule the current iteration when the co-located job finishes its iteration (releasing all memory), guaranteeing training progress similar to temporal sharing and thus preventing the deadlock. Such planned execution should be accompanied by tracking of memory used by GPU, which we will explain in the next section.

6 Memory Management with Concurrency

We discuss how to track GPU memory usage for sharing, classify tensors according to usage type, and manage GPU memory for tensors of different types using regions.

6.1 Tracking Memory Usage in GPU

Most of existing DNN platforms are mainly customized for single-job training and unaware of memory sharing among concurrent training jobs. As described in Section 3.3, inherent asynchrony between CPU and GPU does not incur any correctness issue for memory operations when there is only one job to run on the platform. However, for concurrent training with each job assigned with its own GPU stream, we should not make memory released by CPU readily available for the co-located jobs, since kernel computations to be launched on the multiple GPU streams are independent and unordered. In essence, the memory corruption could occur because there is no dependency among kernels in different GPU streams. We apply two techniques to support efficient memory sharing without the corruption.

Memory deallocation. For memory deallocation, rather than immediately releasing the memory based on CPU point of view, we must wait until GPU actually completes the corresponding kernel execution. Zico facilitates *CUDA event* to meet this requirement. *CUDA event* is a specific kernel that can be inserted into the GPU stream and monitored by CPU for its completion. Once GPU reaches a *CUDA event*, it is guaranteed that kernels launched before the detected *CUDA event* have finished the execution. Hence, tensors of those kernels can be safely released if no longer accessed. Tracking in-use memory with *CUDA event* is not cost-free, requiring CPU cycles. To reduce the overhead, Zico inserts *CUDA event* periodically at a certain memory allocation granularity (currently, 8 MB for CNNs and 256 MB for RNNs). We discuss the sensitivity of the granularity in Section 7.4.

Memory allocation. The memory tracking brings out another issue, namely, *early memory allocation*. Although deallocation of memory occurs after the actual kernel completion as a result of the memory tracking, its allocation occurs by CPU when the kernel is issued to the GPU stream. Thus, the allocation time is typically earlier than the time the kernel actually starts its execution, accesses the memory, and completes the execution within GPU. It is always desirable to maintain a small number of in-flight kernels (i.e., kernels pending on GPU stream), since this way would narrow the above time gap and ultimately avoid unnecessary pre-allocations of memory by CPU: otherwise, the system makes memory allocations too early compared to the actual time the memory is utilized by GPU kernels. Oftentimes, we found memory consumption *soars up* due to a number of in-flight kernels issued at full CPU speed. To address this issue, Zico limits the number of in-flight kernels to a certain level just sufficient to keep GPU busy. Currently, the right number is obtained via offline profiling for each model while not causing a loss in overall training performance. It can be also easily found online by running a few iterations over varying numbers of in-flight kernels to be limited in the GPU.

6.2 Tensor Classification

With a computation graph constructed for training, Zico differentiates the tensors used by GPU kernel operators forming the graph. In general, we classify the current tensors into three types: feature map tensors, gradient map tensors, and temporary tensors, where temporary tensors are neither feature maps nor gradient maps. A temporary tensor is mostly created by an operator and used internally, not later accessed by other operators. To correctly classify tensors in this way, we exploit three pieces of information available for a tensor: by considering the operator creating the tensor as the *source* operator, (i) whether the source belongs to the forward pass; (ii) whether there is any *destination* operator accessing the tensor outside the source; and (iii) whether the destination belongs to the backward pass. Feature map tensors will meet all three conditions while gradient map tensors are distinguished from complying with (ii) and (iii) only. The remaining tensors are all sorted into temporary tensors.

For the proposed tensor classification, we need to identify whether a computation kernel is involved in the forward pass or the backward pass. Memory manager in Zico pinpoints the peak memory as the starting point of the backward pass. This method exploits the fundamental property of DNN training that a forward pass is a memory allocation phase and a backward pass is a memory deallocation phase. This method is a simple but generic approach that does not depend on DNN implementation and does not belong to a specific framework.

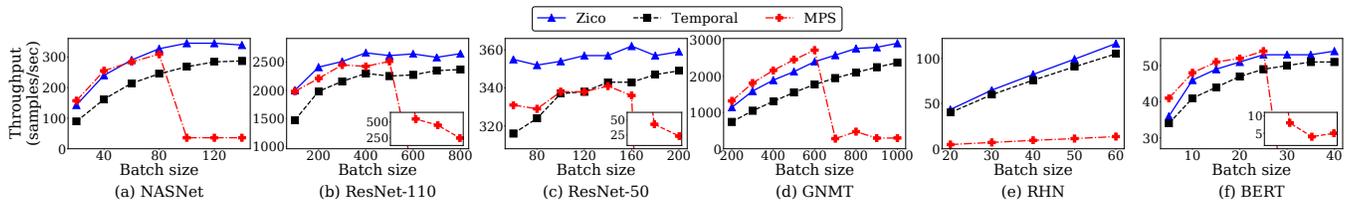

Figure 5: Throughput in training the same models. ResNet-50 and BERT are run on Machine 1 and NASNet, ResNet-110, GNMT, and RHN are on Machine 2 considering their model sizes.

6.3 Managing Memory Regions

Based on the tensor classification, the memory manager in Zico accepts the tensor type as parameter and then allocates the tensor on a region according to the type. The region-based memory management is a basic mechanism in TensorFlow and we extend it to build our own memory sharing system.

The essential goal of Zico’s memory management policy is to promote spatial sharing with low interference between co-scheduled training jobs. Based on separating sharable regions (global) from non-sharable regions (job-local), we assure no contention occurs when non-sharable regions are enough to allocate new tensors for the local job. Further, within the local regions, temporary tensors are stored exclusively on a few regions managed by their own free block lists which manage empty memory space for allocating new tensors. Temporary tensors are small in size and frequently allocated and soon deallocated, thus contending with other types of tensors for accessing free block lists unless managed separately.

The size of the sharable and non-sharable area changes elastically depending on runtime demands. As a region stores tensors in the same type, for feature map tensors the demand will increase and decrease within each iteration. Thus, during forward pass, the local memory manager will continuously request regions from the sharable area and then during the backward pass, these regions will be returned back to the sharable area. The free regions in the sharable area are shared through a free list for which updates are synchronized by a lock. To prevent the potential contention on the lock, the granularity of the regions needs to be chosen carefully. We experimentally validated different region sizes over diverse training jobs. From the sensitivity study, we chose the region size to be at least tens of MB to minimize lock contention. The results of the sensitivity study can be found in Section 7.4.

7 Evaluation

Experimental setup. We implement Zico in TensorFlow 1.13.1 and compare it with spatial sharing using MPS (MPS)² and temporal sharing with no job switching overhead (Temporal), which is similar to the approach taken

²Spatial sharing within a single framework exhibits similar limitations to MPS, i.e., performance degradation with memory oversubscription.

in the state-of-the-art [44]. We select six training benchmarks across different DNN tasks including NASNet [48], ResNet-110 [16], ResNet-50 [16], GNMT [42], RHN [47], and BERT [11]. All models use the stochastic gradient descent (SGD) optimizer.

The evaluation is performed on two machines. Machine1 has an NVIDIA Tesla V100 GPU with 32 GB GPU memory, 3.8 GHz Intel Xeon(R) Gold 5222 4 CPU cores and 64 GB of host memory. Machine2 has an NVIDIA RTX 2080 Ti GPU with 11 GB GPU memory, 3.8 GHz Intel Xeon(R) Gold 5222 4 CPU cores and 64 GB of host memory. Both machines run Ubuntu 16.04. We use Machine1 and Machine2 to evaluate large models and small models, respectively.

7.1 Training Same Models

We first compare Zico, MPS, and Temporal when two identical models are concurrently trained. The memory budget in Zico is configured as GPU memory capacity.

Figure 5 shows the throughput of the six models when training over different input batch sizes (i.e., number of samples) in x-axis. For each model, some of the batch sizes are chosen to have MPS exceed GPU memory capacity to show how effective Zico is in such cases. The figure shows that as compared to temporal sharing, Zico achieves higher throughput across all batch sizes in all models. In particular, Zico outperforms Temporal by on average 35% for NASNet and 37% for GNMT across the batch sizes. These results are rather surprising as the largest batch size in each model results in memory consumption in solo training that reaches close to the GPU memory limit. Even in such an extreme memory usage scenario, Zico finds an optimal time point to start the forward pass of a job while the backward pass of the other job is in progress. Therefore, Zico does not have any model being completely time-multiplexed, making it co-schedule the jobs more efficiently than Temporal.

Zico achieves comparable throughput with MPS from small to modest batch sizes for each model. MPS is sometimes slightly better than Zico. This is not because MPS provides a better schedule for concurrent training but mainly because the underlying setup is different: Zico runs on a single framework and MPS runs two training jobs on different framework instances and processes. Nonetheless, throughput in MPS drops significantly when models are trained on large batch sizes.

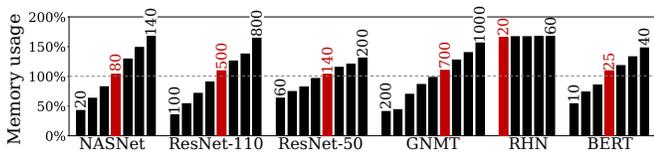

Figure 6: Aggregated memory usage for training the same models. For each model, bars are sorted by the batch sizes as used in Figure 5. The red bars indicate the batch sizes of aggregated memory usage beyond GPU memory capacity.

On training large batches, MPS suffers from GPU memory oversubscription that accompanies UVM overhead. Subsequently, as compared to MPS, Zico is up to 4.7 times faster across models. Note that the solo training of RHN incurs high memory usage even with small batch sizes, causing memory oversubscription for MPS across all batch sizes. Figure 6 presents the system-side memory usage (which sums up the memory usage of the two co-located jobs) to reveal the degree of GPU memory oversubscription handled by Zico.

In Figure 7, we show how memory usage patterns are coordinated in Zico to reduce the system-wide memory footprint. For the space reason, we select only two models, ResNet-110 and BERT, for which concurrent training is scheduled slightly differently. In ResNet-110, almost no delay on each iteration occurs, i.e., $TimeShift \approx 0$, making it behave similar to the non-coordinated spatial GPU sharing. On the contrary, in each scheduling interval of BERT, there is a slight delay applied to every iteration to keep memory consumption within the budget. It is worth noting that for training the same models, the memory-aware schedules across iterations for a job are very regular, making scheduling decisions across the co-located jobs rather deterministic. We also found out training the same models entails an almost similar, if not the same, slowdown for each job. Hence, scrooge scheduler can quickly stabilize its memory-aware scheduling across jobs even without beginning from a low memory budget during the informed phase.

In general, Zico delivers more benefit to less computation-intensive models such as GNMT. Over GPU generations, GPU compute capacity scales faster than GPU memory capacity does, keeping the bottleneck pushed towards GPU memory capacity. With this trend continued, the advantage of Zico over temporal sharing is likely to grow in the future.

7.2 Training Non-identical Models

Now, we use two distinct models in concurrent training. In this experiment, we select five models to make combinations based on different GPU compute demands: GNMT (low), RHN (low), NASNet (high), ResNet-110 (high), and BERT (high). Figure 8 shows the throughput normalized by Temporal over diverse co-location combinations which all oversubscribe GPU memory capacity. In the figure, we put the memory demand of individual training in the parenthesis, computed as the percentage of GPU memory capacity, which

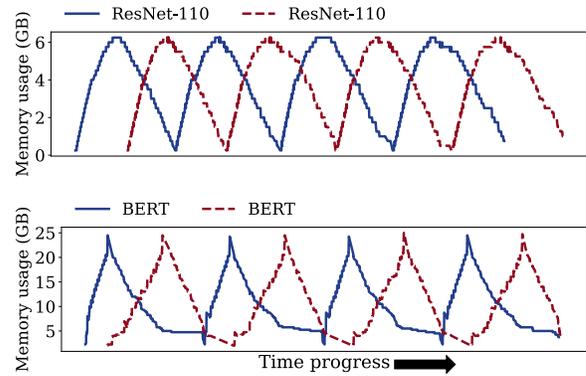

Figure 7: Memory usage over time for training the same models. ResNet-110 and BERT are shown as an example.

is obtained by varying batch sizes for the model.

For training non-identical models, we organize co-location combinations into three scenarios: (i) including both models with low GPU utilization (i.e., RH+GT), (ii) including one model with low GPU utilization (i.e., NN+GT and BT+GT), and (iii) including both models with high GPU utilization (i.e., NN+RN). First, Figure 8 shows that Zico significantly outperforms MPS regardless of GPU utilization between the co-located jobs. Zico is around 5.7x faster than MPS on average, specifically faster up to 5.1x in RH+GT, 8.3x in NN+GT, 6x in BT+GT, and 6.5x in NN+RN. Our conclusion repeats: MPS experiences significant performance degradation under GPU memory oversubscription.

In comparison to Temporal, Zico achieves higher throughput by 42% in RH+GT, 46% in NN+GT, 27% in BT+GT, and 15% in NN+RN on average. That is, Zico favors scenario (i) and (ii) over (iii) because ample GPU cycles are available by running a model with low compute demand. Nonetheless, in Zico, since any of co-located jobs starts training once memory constraint is met, no fair use of compute resources is guaranteed. As a result, in the NN(30%)+GT(90%), Zico obtains a great throughput improvement for GT over Temporal but slightly worse performance for NN due to a bit fewer iterations scheduled within a time duration as opposed to Temporal. We leave balancing individual job throughput on top of increasing the aggregated throughput as future work.

It is also worth noting that Zico achieves different scheduling ratio for the co-located jobs depending on their memory usage patterns. To illustrate, we show memory usage patterns in RN+NN in Figure 9, where ResNet-110 has relatively shorter iteration time compared to NASNet. On the given memory budget, Zico decides to schedule executions of the two jobs in such a way that ResNet-110 runs its iterations more frequently than NASNet does — Zico keeps scheduling ResNet-110 during time periods with low-to-moderate memory usages in NASNet to maximize GPU memory utilization.

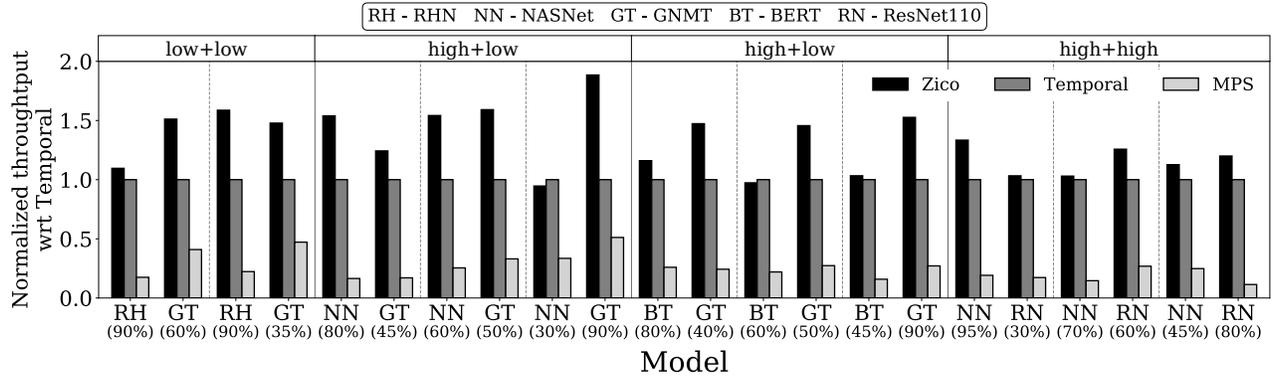

Figure 8: Throughput in training the distinct models concurrently. All co-locations are run on Machine 2.

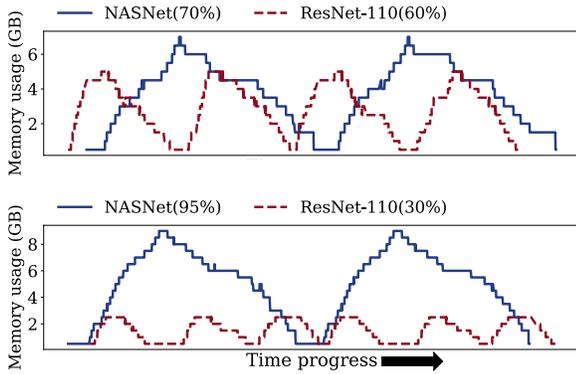

Figure 9: Memory usage over time for training NASNet and ResNet-110 concurrently. This co-location incurs different scheduling ratios for having different memory demands.

7.3 Dynamic Memory Budget Change

Recall that for co-locating more than two jobs, e.g., four jobs, we propose to organize the jobs into a group of pairs and schedule each pair independently with a lower memory budget. Then, when some of the jobs depart, the system would have fewer pairs and need to make a schedule based on the increased memory budget. Therefore, adapting to the memory budget change is a fundamental functionality required in Zico to deal with the dynamic workload. In this section, we evaluate Zico scheduling decisions when several continuous changes are made on the memory budget.

Figure 10 shows how Zico schedules two NASNet training jobs while decreasing the memory budget and then increasing it back. Before the first change, the two jobs run concurrently with zero delay by virtue of scrooge scheduler between consecutive iteration executions of a job under the budget set as 70% GPU memory. Around A time point, the memory budget is set down to 50% and Zico begins to schedule the co-located jobs more conservatively. During this period, each job exhibits a wider gap (140 ms) between consecutive iterations. Around B time point, the memory budget returns back to 70% and Zico now takes a more aggressive schedule on memory sharing. At this moment, we attempt to further increase the

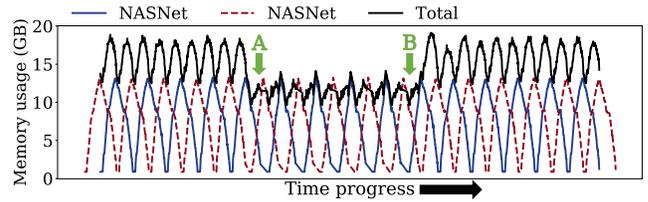

Figure 10: Memory usage patterns on dynamic memory budget changes. The budget is decreased from 70% GPU memory to 50% at time A and then increased back to 70% at time B.

memory budget to fully utilize GPU memory, but we do not see any change in both throughput and memory footprint. The reason is that 70% GPU memory is already enough to make an ideal scheduling decision for Zico with no TimeShift. That is, Zico does not overuse GPU memory unnecessarily.

7.4 Design Validation

GPU memory tracking. As explained in Section 6.1, tracking in-use memory is essential to share memory with the correctness between multiple GPU streams. Table 1 shows the sensitivity of memory tracking granularity. If CUDA event is inserted too frequently, it imposes overhead on CPU and leads to delaying training iteration. For instance, inserting CUDA event for every GPU kernel launch slows down the training up to more than 50% in GNMT. To mitigate this overhead, CUDA event is inserted periodically in Zico. For models which use CPU intensively like GNMT, due to the significant number of light-weight kernels to issue, coarse-grained tracking is required to avoid this overhead. On the

GPU tracking	NN	RN-110	RN-50	GNMT	RHN	BERT
All	78%	91%	97%	44%	94%	97%
Fine-grained	100%	100%	100%	89%	99%	99%
Coarse-grained	100%	100%	100%	97%	99%	100%

Table 1: Throughput with memory tracking (normalized to the throughput with no memory tracking). All, Fine-grained, and Coarse-grained track GPU memory for every kernel launch, 8 MB allocation, and 256 MB allocation, respectively.

Granularity	NN	RN-110	RN-50	GNMT	RHN	BERT
Tensor	94%	99%	98%	90%	96%	94%
Small region	94%	99%	100%	97%	99%	99%

Table 2: Throughput with different sharing granularity (normalized to sharing granularity of 64 MB region size).

other hand, for models which use CPU less like CNN models and BERT, even fine-grained tracking does not bring out the actual delay of the training iteration. Zico chooses the right memory tracking granularity, minimizing the overhead.

Sharing granularity. As mentioned in Section 6.3, if the sharing granularity is too fine-grained, e.g., tensor granularity, the contention of shared lock becomes non-negligible. Table 2 shows the sensitivity of different sharing granularity choices, where the size of small region is set to 512 KB. The table presents the normalized throughput with respect to using our default region size (64 MB) for memory sharing. The tensor-level sharing could introduce up to 10% of throughput degradation as shown in GNMT.

Scheduling. Making a scheduling decision in our scrooge scheduler takes $O(n)$ time complexity, where n is a small number of regions exercised by co-located jobs. The observed overhead is only a few hundreds of nanoseconds, and hence scrooge scheduler has nearly zero scheduling overhead. Moreover, the scheduling process of one job does not interfere with the scheduling process of counterpart co-located job, since each job has a dedicated CPU thread.

8 Related Work

Temporal/Spatial GPU sharing. Temporal GPU sharing represents software-based techniques that time-share GPU for DNN workloads. Gandiva [43] proposes a GPU time-slicing mechanism for the first time to mainly accelerate hyperparameter tuning jobs. It initiates job switching at iteration boundary to reduce CPU-GPU communication overhead. Salus [44] tries to remove the switching overhead by making model parameters of a job resident in GPU memory even when the job is inactive. It further integrates a spatial sharing mechanism to harness underutilized memory in a similar way to MPS [10]. We faithfully compare Zico with both temporal and spatial sharing in Section 7.

Tensor swapping/recomputation. Prior works make use of host memory as a swap storage for DNN training to mitigate memory footprint in GPU [17,32,36]. vDNN [36] predictively swaps tensors ahead of time to overlap CPU-GPU communication with GPU computation during training. It mainly focuses on swapping the inputs of convolutional layers as they tend to have long lifespans in CNN models. SwapAdvisor [17] considers memory allocation and operator scheduling to jointly optimize for swapping decisions. Capuchin [32] proposes a computational graph agnostic technique that estimates

the costs of tensor swapping and recomputation to make the best choice between the two.

Other prior works study dropping tensors created in forward pass and recomputing them in backward pass [6, 19, 41]. SuperNeurons [41] introduces a cost-aware recomputation technique to remove tensors from convolution layer, which are cheap to recompute. Checkmate [19] formulates tensor recomputation into an optimization problem and provides an approximation algorithm to recompute tensors timely. Similar to tensor swapping, tensor recomputation reduces memory footprint for a single training. The goal of Zico is different; Zico reduces global memory footprint for concurrent training.

Compression. Many approaches were invented to reduce memory footprint of DNN training, including HW-based compression techniques [7, 30]. There are also a few SW-based memory compression techniques. Gist [18] proposes a series of layer-specific encoding techniques to compress tensors including feature maps. Echo [46] proposes a compression technique more effective on LSTM RNN training driven by internal operator dependencies. Zico is complementary and can be combined with tensor compression techniques.

9 Concluding Remarks

We present our attempt on realizing GPU memory sharing across concurrent training. The proposed system, Zico, is the first introducing a memory-aware scheduler that coordinates training iterations among co-located jobs with minimum stall times. Zico works generally for co-locating both identical models or non-identical models regardless of the iteration time and the memory pattern of each model. Our experimental results show that Zico outperforms existing GPU sharing approaches. With growing model sizes, very large models such as GPT family [33,34,38] are preferred to run with model parallelism or data parallelism to accommodate intermediate tensors on GPU memory. Despite diverse parallelism in use, we believe Zico benefits both cases as we still see increasing and decreasing memory usage within an iteration.

Abstract

Data augmentation is a widely adopted technique for improving the generalization of deep learning models. It provides additional diversity to the training samples by applying random transformations. Although it is useful, data augmentation often suffers from heavy CPU overhead, which can degrade the training speed. To solve this problem, we propose data refurbishing, a novel sample reuse mechanism that accelerates deep neural network training while preserving model generalization. Instead of considering data augmentation as a black-box operation, data refurbishing splits it into the partial and final augmentation. It reuses partially augmented samples to reduce CPU computation while further transforming them with the final augmentation to preserve the sample diversity obtained by data augmentation. We design and implement a new data loading system, Revamper, to realize data refurbishing. It maximizes the overlap between CPU and deep learning accelerators by keeping the CPU processing time of each training step constant. Our evaluation shows that Revamper can accelerate the training of computer vision models by $1.03\times$ – $2.04\times$ while maintaining comparable accuracy.

1 Introduction

Deep learning (DL) is at the heart of modern AI-based applications, enabling various services such as computer vision [19, 20, 33, 34], automatic speech recognition [38], and natural language processing [17, 35]. DL models are trained by repeatedly adjusting the parameters of the models in order to minimize their loss with regard to training samples. The trained models must ensure generalization, the ability to appropriately process previously unseen input data.

Recently, *data augmentation* has been widely used in deep neural network (DNN) training to improve generalization of DL models including image classification [14, 15, 36, 39], object detection [15, 36], and automatic speech recognition [29]. By applying several transformations on training samples in

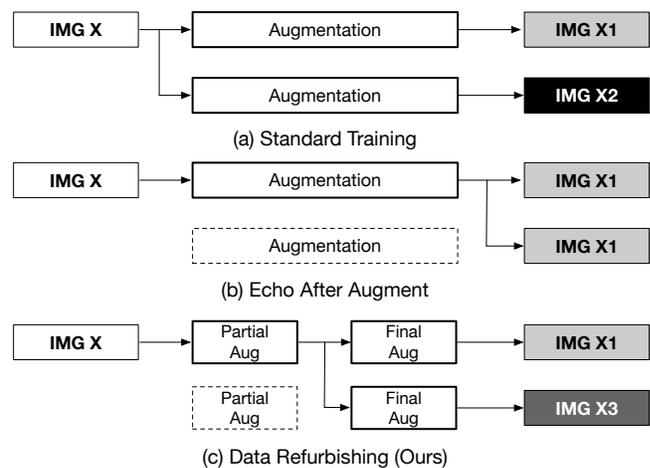

Figure 1: A high-level introduction of (a) standard training, (b) data echoing [9, 13] after augment, and (c) data refurbishing (ours). The dotted rectangles indicate computation saved by sample reuse.

a random manner [14, 15, 29], data augmentation provides additional samples to model training and thus helps improve model generalization. Because data augmentation is a stochastic process, every augmented sample is unique (Figure 1 (a)). Better model generalization from data augmentation, however, comes at the cost of expensive CPU operations. This CPU overhead often causes data augmentation to become a performance bottleneck of DNN training [4, 9, 13, 30].

To address the CPU overhead from data augmentation, recent works such as NVIDIA DALI [4] and TrainBox [30] utilize hardware accelerators such as GPUs and FPGAs for optimizing data augmentation. However, the stochastic nature of data augmentation makes it difficult to exploit accelerators that are optimized for parallel execution of homogeneous operations. Data echoing [9, 13], on the other hand, tries to reduce the amount of computation by splitting training pipelines into the upstream and downstream pipelines, and reusing previously prepared samples from the upstream pipeline in the

*Corresponding author.

downstream pipeline. However, it considers augmentation as a black-box operation and splits the DNN training pipeline to only before or after the augmentation. If the pipeline is split before data augmentation, the overhead from data augmentation remains unchanged. However, with the other option, the augmented samples are reused multiple times without further transformations as shown in Figure 1 (b). This decreases the number of unique samples generated from data augmentation—the sample diversity—to a great degree and degrades the accuracy of trained models.

To solve this problem, we propose data refurbishing, a novel sample reuse mechanism for fast DNN training data preparation. Data refurbishing splits the original data augmentation pipeline into the *partial augmentation* and *final augmentation* according to the given split policy, and reuses the intermediate results generated from the partial augmentation (Figure 1(c)). The *partially augmented samples* produced from the partial augmentation are cached, reused for a designated number of times, and renewed to preserve the diversity of augmented samples. The final augmentation applies the remaining portion of the full augmentation pipeline to the cached samples and produces fully augmented samples to be used for gradient computation.

Although reused, each partially augmented sample undergoes the final augmentation to produce a diverse set of augmented samples to be used for gradient computation. The number of unique samples, thus, remains almost the same, preserving the original sample diversity and model generalization. As such, data refurbishing is able to reduce CPU overhead from data augmentation with little generalization loss. Reducing computation overhead while maintaining enough sample diversity, this approach provides better trade-offs between training speed and model generalization than data echoing. We demonstrate these benefits both mathematically and empirically. Such characteristics make data refurbishing especially useful for exploration tasks, such as hyperparameter optimization [10, 27], which requires much DNN training with various configurations.

We design Revamper, a new caching and data loading system, to realize data refurbishing. Revamper shares similarity with systems that adopt intermediate data caching [18, 37], but it differs from such systems in that Revamper addresses new challenges that are specific to the context of DNN training. Because with data refurbishing a mixture of cached and non-cached samples is used for gradient computation, the CPU processing time may fluctuate depending on the number of cache misses in each step, which can deteriorate computation overlap between the CPU and DL accelerators. Revamper maintains a constant CPU computation overhead across epochs with the balanced eviction and within each epoch with the cache-aware shuffle, where an epoch denotes a complete pass on the entire dataset. The balanced eviction resolves the inter-epoch computation skew by evicting cached samples in a way that the number of cache misses is evenly distributed

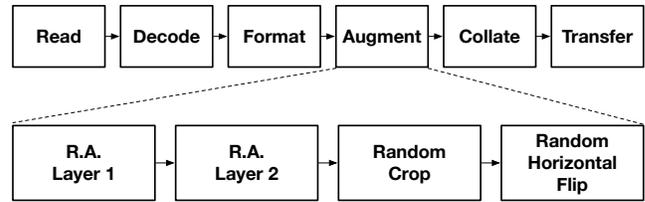

Figure 2: An illustration of a RandAugment [15] augmentation pipeline in a typical data preparation pipeline. R.A. Layer stands for a RandAugment layer.

across epochs. To address the intra-epoch computation skew, the cache-aware shuffle utilizes information from the cache store to prepare training samples for each step to make the number of cache misses uniform over training steps.

Revamper is implemented on PyTorch 1.6 [31], a widely used DL framework for DNN training. Its interface overrides the existing PyTorch dataloader so that users can utilize Revamper by giving a few additional parameters such as how to split the given augmentation pipeline and how many times to reuse each cached sample. Our evaluations on various computer vision models and datasets demonstrate that Revamper can reduce training time for DNN models by $1.03\times$ – $2.04\times$ while maintaining comparable top-1 validation accuracy. Although we focused on evaluating Revamper on vision tasks where data augmentation is most widely used, it is notable that Revamper can also be applied to other domains such as speech [29] and language tasks [32], when augmentation pipelines can be split into multiple transformations.

2 Background

2.1 DNN Training

DNN training "trains" a DL model to perform a certain task by repeatedly adjusting the model weights with regard to the given set of training samples. Broadly speaking, training DNNs consists of two steps: data preparation and gradient computation. Until a certain termination condition is satisfied (e.g. target validation accuracy is met), the two steps are repeated for multiple epochs.

Data Preparation The data preparation step prepares training data to be fed to the DL model. Figure 2 describes a typical data preparation procedure, which is generally performed on CPU [8, 31]. The process starts with reading in the training data residing on a local or a remote storage in a random order in order to give randomness for each epoch. In general, each training data entry is a tuple of (x_i, y_i) , where x_i represents the training sample at index i (e.g. an image, an audio clip, and a text snippet) and y_i the corresponding target of x_i (e.g. class and original text). The loaded training data are decoded and formatted into tensors, multi-dimensional arrays of numbers used in gradient computation.

Often, training data undergo random transformations called *data augmentation* (§ 2.2) in the next step. This optional step gives greater variation in the training set and helps train a more generalized DL model. The decoded and transformed data are collated into mini-batches before being sent to DL accelerators such as GPU and TPU. This mini-batching is necessary to perform stochastic gradient descent or its variants.

Gradient Computation The gradient computation step actually trains a DL model by adjusting the model parameters with regard to the gradients computed from the training data. This is done via forward computation and backward propagation. Forward computation calculates the loss, or the deviation of the produced result from the target value, for the given mini-batch of training samples. Backward propagation traverses the model in a reverse order and recursively computes the gradient of each layer with respect to the loss. The model parameters are then adjusted proportional to the gradients to minimize the loss.

It is important to note that the data preparation and the gradient computation steps can be overlapped, as they are typically executed on different hardware. Thus, ideally the processing time of data preparation can be hidden by that of gradient computation, and so the former has not been considered to have a significant impact on the speed of DNN training. However, recent development of specialized hardware accelerators [2, 3] has dramatically reduced the processing time required for the gradient computation step. Accordingly, the data preparation step is becoming the bottleneck of DNN training as pointed out in the recent works [9, 13, 30].

2.2 Data Augmentation

During the data preparation step, several random distortions, referred to as transformations, are applied to increase the effective number of training samples and thus to improve the generalization of DL models. These data transformation steps are collectively called data augmentation. Data augmentation is a common technique in many domains of DL, including computer vision [14, 15, 36, 39], automatic speech recognition [29] and natural language processing [12, 32].

A data augmentation pipeline is usually a sequence of multiple transformations. Here, each transformation is referred to as a layer. For example, RandAugment [15] consists of a sequence of RandAugment layers (Figure 2), each of which randomly applies one of the 14 distortions (e.g., shear, rotate, and solarize) to each sample. AutoAugment [14] searches a set of effective transformation sequences before training, and applies a sequence randomly selected from the set in every training step. As an example of an extreme use of data augmentation, Karas et al. [23] deployed at most 18 consecutive transformation layers when training generative adversarial network (GAN) models with limited data.

Multi-layered augmentations can also be seen in other do-

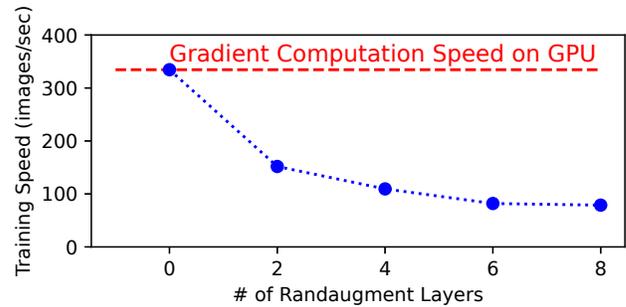

Figure 3: ResNet-50 training speed on ImageNet varying the number of RandAugment layers. The horizontal line indicates the gradient computation speed on GPU.

ains. For example, SpecAugment [29], an augmentation method for automatic speech recognition tasks, can be decomposed into three transformation layers (time warp, frequency masking, and time masking). Such transformations are known to be computationally expensive, which is why popular speech recognition frameworks such as DeepSpeech provides an option that caches and reuses previously augmented samples [7]. Another example is CoSDA-ML [32] in natural language processing, which translates N random tokens into different languages. CoSDA-ML can be decomposed into N consecutive random transformation layers, each of which selects a token and translates it to a token in a randomly chosen language.

3 Motivation

3.1 Overhead of Data Augmentation

Data augmentation improves model generality, but it is often a bottleneck in DNN training due to its heavy CPU overhead from the multiple layers of transformations. To analyze the overhead of data augmentation, we measure the training throughput of ResNet-50 [19] model, a widely-used DL model for image classification, using the ImageNet [16] dataset with an example data preparation pipeline. As for data augmentation, we apply varying number of RandAugment [15] layers along with the random crop and random horizontal flip transformations. The number of RandAugment layers (N) is adjusted from zero to eight to investigate the CPU overhead from various loads of data augmentation. When N is zero, only the random crop and random horizontal flip are applied to training samples. We employ one NVIDIA V100 GPU and four physical CPU cores for the training, which is similar to an Amazon Web Service (AWS) p3.2xlarge instance, a standard cloud virtual machine used for DNN training.

Figure 3 plots the measured throughput of data preparation pipelines with different number of data augmentation layers. When only the random crop and flip are applied ($N = 0$), the

throughput of data preparation exceed that of gradient computation on GPU, making the data preparation step completely overlap with GPU operations. On the other hand, when the number of RandAugment layers is set to 2, which is known to produce the highest validation accuracy when training ResNet-50 on the ImageNet dataset [15], the DNN training process is bottlenecked by the data preparation. This problem becomes more severe as the number of data augmentation increases and the CPU overhead from data augmentation becomes heavier. From the result, we observe that the CPU overhead from data augmentation can be too large to be fully overlapped with the gradient computation, and thus data augmentation can be the main bottleneck in DNN training process.

3.2 Limitations of Existing Approaches

As the data preparation step is becoming the bottleneck for DNN training, there has been effort to reduce this overhead. However, due to the stochastic nature of data augmentation, such effort has failed to efficiently reduce the CPU overhead introduced by data augmentation pipelines.

Utilizing Hardware Accelerators Recent works such as NVIDIA DALI [4] and TrainBox [30] leverage hardware accelerators like GPUs and FPGAs for data augmentation. Unlike the gradient computation, which applies identical and deterministic computations to each training sample, data augmentation applies stochastic operations to each sample in a random fashion. Hence, it is difficult for data augmentation to efficiently utilize such hardware accelerators, which are optimized for massive parallel execution of homogeneous operations [9]. In addition, because such accelerators are frequently used for gradient computation, this approach may make the data preparation and gradient computation not overlapped.

Data Echoing Data echoing [9, 13] splits DNN training pipelines into the upstream and downstream pipelines, and reuses previously produced samples from the upstream pipeline in the downstream. For example, if we split the pipeline in Figure 2 between Format and Augment operations, the upstream pipeline would be Read-Decode-Format and the downstream pipeline would be Augment-Collate-Transfer. This approach is useful when the deterministic part of the data preparation pipeline, such as I/O from a remote storage, is the bottleneck. However, data echoing becomes less effective when stochastic data augmentation is the slowest part. With data echoing, the entire data augmentation pipeline is considered as a black-box operation, and so the samples are reused either before or after the augmentation process. If a sample is reused before the data augmentation, the reused sample needs to be re-augmented, and thus the overhead from data augmentation remains the same. Or, when fully augmented samples are simply reused for gradient computation, the number of unique augmented samples significantly decreases. As a result, data echoing fails

to reduce the CPU overhead from data augmentation without severely harming the generalization of trained models. We further demonstrate this limitation in § 7.

Our observation suggests that it is necessary to devise a mechanism to reduce the computation overhead of CPU-heavy data augmentation techniques, while preserving generalization of the model obtained by data augmentation.

4 Data Refurbishing

We propose **data refurbishing**, a simple and effective sample reuse mechanism for input pipelines of DNN training that alleviates CPU computation for data augmentation while preserving the generalization of trained models. Data Refurbishing caches and reuses partially augmented samples generated from the *partial augmentation*, which consists of the first few transformations in the full augmentation pipeline. The rest of the augmentation pipeline—the *final augmentation*—is applied to the partially augmented samples from the cache in order to produce fully augmented samples. Reusing partially augmented samples reduce CPU computation while further transforming them with the final augmentation maintains the sample diversity obtained by data augmentation.

Data refurbishing introduces two additional configurations, the *reuse factor* and the *split policy*. The reuse factor represents how many times to reuse each cached sample, and the split policy determines how to split the full augmentation pipeline into the partial and final augmentations. Note that configuring Revamper is simple since its configuration space is small. The reuse factor is an integer that is typically smaller than five, and the number of split strategies, which is identical to the number of augmentation layers, does not exceed twenty even in extreme cases [23]. Applying data augmentation without reusing data—the *standard data augmentation*—and data echoing are both special cases of data refurbishing, as will be explained later in this section.

Data refurbishing can reduce the CPU computation required for data augmentation with minimal loss of the generalization of the trained model, given that the final augmentation provides enough sample diversity. In the rest of this section, we mathematically explain how data refurbishing preserves the sample diversity produced from the standard data augmentation.

Problem Formulation Let \mathcal{X} and \mathcal{X}' denote the sample space before and after augmentation, respectively. An augmentation A can then be represented as a finite set of functions such that $A := \{f_1, f_2, \dots, f_{|A|}\}$ for $\forall_i f_i: \mathcal{X} \rightarrow \mathcal{X}'$. Note that, in the standard data augmentation, we randomly choose $f_i \in A$ and produce an augmented sample $f_i(x)$ for a given input sample $x \in \mathcal{X}$ in every epoch. Then, the partial augmentation A_P and the final augmentation A_F of A can also be represented as some augmentations that satisfy $\{f_F \circ f_P | f_P \in A_P, f_F \in A_F\} = A$. In the rest of this section, we make the following assumptions to simplify our analysis.

Assumption 1. Discrete Uniform Distribution

For an augmentation A , the probability of choosing $f \in A$ is uniform.

$$\forall f \in A \ P(f) = \frac{1}{|A|}$$

Assumption 2. Balanced Eviction

All the cached samples are reused exactly r times before being evicted from the cache.

Assumption 3. Uniqueness of Composed Augmentation

Any composition of partial and final augmentation functions always produces a unique fully augmented sample.

$$\begin{aligned} & \forall f_P, g_P \in A_P \ \forall f_F, g_F \in A_F \ \forall x \in \mathcal{X} \\ & ((f_P \neq g_P) \text{ or } (f_F \neq g_F)) \rightarrow (f_F \circ f_P)(x) \neq (g_F \circ g_P)(x) \end{aligned}$$

Now let $A(x)$ denote the set of all possible augmented samples produced by an augmentation A given an input sample x . Then, Assumption 3 implies that $A(x) = \{f_1(x), f_2(x), \dots, f_{|A|}(x)\}$ and $|A_P| \times |A_F| = |A| = |A(x)|$.

Under the above formulation, applying data refurbishing for k epochs with reuse factor r to an augmentation A for an input sample $x \in \mathcal{X}$ can be represented as a sampling process such that the samples are taken r times from $A_F(y)$ for every y sampled $\frac{k}{r}$ times from $A_P(x)$, respectively. Given k , data refurbishing can have any $1 \leq r \leq k$ by the definition. Note that data echoing and the standard data augmentation are both the special cases of data refurbishing, since data echoing is equivalent to data refurbishing with $((A_F = \{I\})$ and $(r > 1))$, and the standard data augmentation is equivalent to data refurbishing with $((A_F = A)$ or $(r = 1))$, where I denotes the identity function.

Therefore, the following theorem holds:

Theorem 1. Expectation of Unique Samples

$$\mathbb{E}(U) = |A| \left(1 - \left(1 - \frac{|A_F|}{|A|} + \frac{|A_F|}{|A|} \left(1 - \frac{1}{|A_F|} \right)^r \right)^{\frac{k}{r}} \right)$$

where U denotes the number of unique samples produced by applying data refurbishing to A given a single input sample.

The proof is given in the supplemental material.

In Theorem 1, $\mathbb{E}(U)$ is maximized when the standard data augmentation ($r = 1$ or $|A_F| = |A|$) is applied, and minimized when data echoing ($r > 1$ and $|A_F| = 1$) is applied. The expected number of unique samples of data refurbishing lies between the two.

Figure 4 visualizes the impact of r and $\frac{\log|A_F|}{\log|A|}$ to $\frac{\mathbb{E}(U)}{\mathbb{E}(U^*)}$ where $\mathbb{E}(U^*)$ denotes the expected number of unique samples of the standard data augmentation. In this figure, we assumed the same data augmentation pipeline used in our evaluation (§ 7), which consists of two RandAugment layers followed by a random crop and a random horizontal flip layers. Intuitively, $\log|A|$ means the number of transformations comprising the

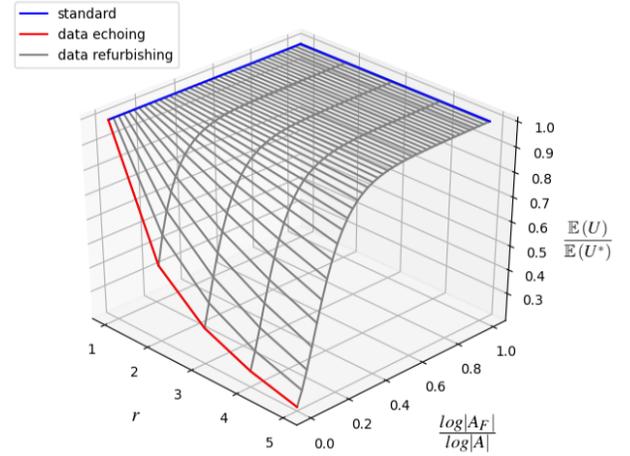

Figure 4: The normalized expected number of unique samples. The x-axis represents reuse factor r , y-axis $\frac{\log|A_F|}{\log|A|}$, and z-axis the normalized expected number of unique samples with respect to that of the standard data augmentation, $\mathbb{E}(U^*)$. Intuitively, the y-axis means the ratio of the number of transformations of final augmentation to that of full augmentation pipeline.

data augmentation pipeline, since $|A|$ grows exponentially as the number of transformations increases. Therefore, the y-axis means the ratio of the number of transformations of final augmentation to that of full augmentation pipeline, assuming each transformation can produce the same number of unique outputs from a given input.

As the figure shows, data refurbishing is robust to the growth of reuse factor r given that $\frac{\log|A_F|}{\log|A|}$ is greater than 0.4. However, when $\frac{\log|A_F|}{\log|A|}$ decreases below 0.4, the expected number of unique samples decreases sharply as r grows. This suggests that we can save computation without significant loss of the model generalization as long as the final augmentation provides sufficient sample diversity.

Based on the above analysis, the goal of a good split policy is to find a split where the final augmentation provides sufficient sample diversity above some threshold with the minimal amount of computation. To do so, it is most desirable for the final augmentation to consist of the transformations that provide high sample diversity with little computation. In our evaluation setup in § 7, for example, one RandAugment layer is computationally heavy but can produce only 14 possible augmented samples from an input sample; on the other hand, random crop ($padding = 3$) along with random horizontal flip can produce a total of 98 augmented samples from an input sample with fewer CPU cycles.

However, if this property does not hold (i.e., the last few layers do not provide sufficient diversity or are computationally heavy), achieving both fast training speed and high accuracy

with data refurbishing might be difficult. In this case, one can consider reordering transformations inside the augmentation pipeline given that the transformations are interchangeable or such reordering puts negligible effect on augmented samples.

5 Revamper Design

We design Revamper, a new data loading system that efficiently implements data refurbishing. It incorporates data refurbishing to existing data preparation procedures of DL frameworks such as PyTorch [31] and TensorFlow [8] by replacing existing data loading systems such as PyTorch dataloader and tf.data [28].

In traditional data loading systems, all the samples in each epoch and step undergo the same data-preparation pipeline. However, with data refurbishing, a mixture of cached and non-cached samples are used to prepare fully augmented samples for the gradient computation. Because cached samples only need the final augmentation to be further applied whereas non-cached samples require both partial and final augmentation, the amount of computation needed for each step and epoch may fluctuate with the number of cache misses. This then causes fluctuation in the CPU processing time. However, the gradient computation time on DL accelerators is consistent throughout the training process, both with and without data refurbishing. For this reason, the CPU processing time may not be effectively overlapped with the DL accelerator processing time when data refurbishing is implemented in a naïve fashion.

Revamper overcomes this challenge by keeping the number of cache misses constant both across epochs and within each epoch, which effectively makes the CPU processing time for each mini-batch consistent throughout the training. First, the **balanced eviction** strategy evenly distributes the number of cache misses across epochs while ensuring that every cached sample is used for gradient computation for the same number of times. Within an epoch, the **cache-aware shuffle** leverages the cache information to choose training samples for mini-batches in order to keep the CPU computation time constant for each step.

We explain broader contexts where Revamper can be used. Revamper is applicable to both local (i.e., only one DL accelerator is used) and distributed (i.e., multiple DL accelerator or machines are used) training environments, because independent Revamper processes are created for each DL accelerator or machine. However, it assumes that training data is accessible from the local disk of each machine, which requires the size of training data that are assigned to each machine to be smaller than the capacity of its local disks. Hence, Revamper currently does not consider network overhead from fetching training data from a shared cloud storage. For such environments, one can consider using distributed caching systems for DNN training [25] along with Revamper.

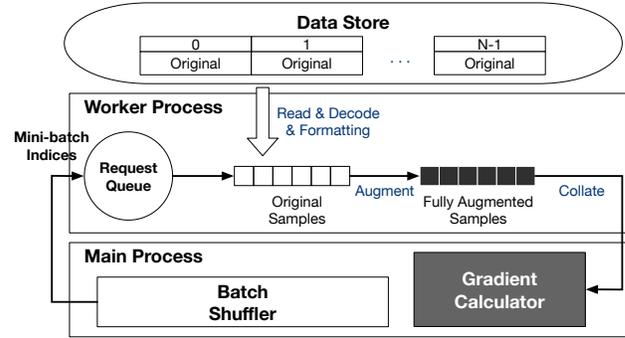

Figure 5: The architecture of a traditional data loading system (PyTorch dataloader).

5.1 Revamper Overview

Before going into Revamper, we briefly explain the existing data loading systems with the architecture of PyTorch dataloader as an example. Figure 5 explains the architecture of PyTorch dataloader, which consists of one main process and one or more worker processes. Each training sample is typically represented with a sequential integer spanning from 0 to $N - 1$, where N denotes the total number of samples. The order of training samples within each epoch is decided by the batch shuffler, which randomly chooses the sample indices for mini-batches. The mini-batch indices are transferred to a worker process. After receiving them, the worker process reads, decodes, and formats the corresponding training samples from the data store. The read samples are then augmented following the user-given augmentation pipeline, making fully augmented samples. The augmented samples are then collated to make a batched sample and transferred to DL accelerators for gradient computation.

The architecture of Revamper (Figure 6) differs from those of traditional data loading systems, mainly in that (1) it has a cache store that stores partially augmented samples in memory or on disk and (2) its main process maintains a separate shuffler that selects the indices to be evicted from the cache. In addition, Revamper adopts the balanced eviction and cache-aware shuffle to stabilize the data preparation time of each mini-batch. Even with such modifications, the epoch boundaries are still intact, meaning that all the original training samples are used exactly once within each epoch of DNN training.

Data Preparation Procedure Figure 6 illustrates the end-to-end data preparation procedure of Revamper in detail. (1) Before starting each training epoch, the evict shuffler selects the samples that need to be evicted from the cache store, following the balanced eviction strategy. By doing so, Revamper balances the number of non-cached samples across epochs while ensuring that each cached sample is reused for the same number of times. (2) The cache store then invalidates the selected samples. (3) After the eviction, the main process

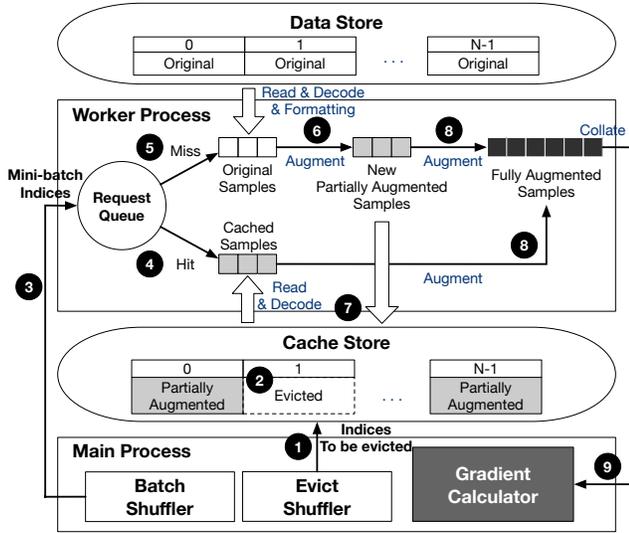

Figure 6: The architecture of Revamper and its end-to-end data preparation procedures.

allocates mini-batch indices to each worker sampled from the batch shuffler. When sampling mini-batch indices, the batch shuffler adopts the cache-aware shuffle in order to make the CPU processing time of each mini-batch stable. (4) Each worker process fetches mini-batch indices from the request queue and reads the corresponding cached samples from the cache store. (5) For the missed samples, the worker process reads the original training samples from the data store and (6) applies the partial augmentation. (7) The worker process then stores the new partially augmented samples in the cache store in order to reuse them in the future epochs. (8) Once all the partially augmented samples for the requested indices are ready, the worker process applies the final augmentation to them. (9) Finally, the fully augmented samples are collated and transferred for the gradient computation.

Cache Store The cache store provides an interface similar to that of key-value stores. It supports `get(I)`, `put(I, S)`, and `remove(I)` methods, where `I` denotes an index and `S` denotes a partially augmented sample to be cached. Partially augmented samples are either stored in memory or on disk according to the user-given `store_disk`. If the `store_disk` is turned off, partially augmented samples are stored in an in-memory hash map that maps indices and the corresponding cached samples. Hash maps are appropriate for DNN training, because it provides $O(1)$ data access by sacrificing performance of range access (i.e., reading all the indices from k_1 to k_2), which is not necessary during DNN training.

Storing partially augmented data on disk is useful when training models with a large dataset whose size exceeds a hundred of GBs [16]. Revamper performs disk I/O in one of the following two ways depending on the size of partially augmented samples. If the size of each sample is below threshold

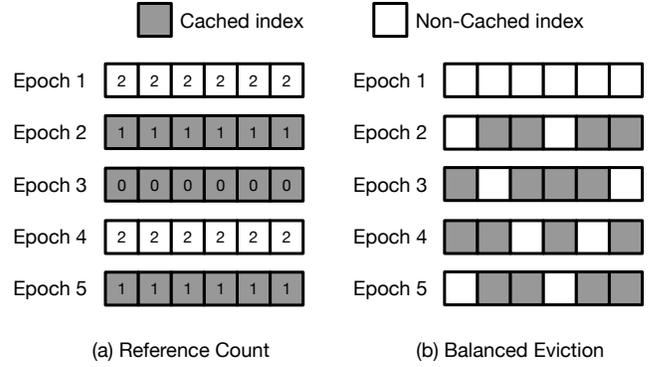

Figure 7: An example distribution of cache misses with (a) reference count algorithm and (b) the balanced eviction.

(16KB by default), Revamper batches multiple I/O requests to reduce system call overhead. To batch write requests, the cached samples are firstly written to in-memory write buffers and flushed to shared log files when the buffers are full. Revamper also batches multiple sample reads within a mini-batch by packing multiple read requests into a single system call using the AIO library of Linux [26]. The cache store periodically clears up invalidated data through background compaction [5], which makes new log files that contain only the valid samples. If the size of each sample is large enough, on the other hand, system call overhead becomes negligible. In this case, Revamper stores each sample in a separate encoded file in order to avoid compaction overhead.

5.2 Balanced Eviction

The balanced eviction is a cache eviction policy that maintains an even spread of computation overhead across the training epochs as well as ensures that each sample is reused for the same number of times. Preparing data from the non-cached samples requires more computation than doing so from the cached samples, because the former needs both the partial and final augmentations to be applied. The computation overhead of each epoch may thus vary depending on the number of cache misses in the epoch when a naïve design of data refurbishing such as the reference count algorithm is used. The reference count algorithm maintains the remaining reference for each cached data and evicts the cached data when a sample’s corresponding reference becomes zero. Although this algorithm ensures that each sample is reused for the same number of times, this approach results in uneven distribution of computation overhead across epochs. As shown in Figure 7 (a), some epochs need to prepare a large number of non-cached samples while others do not, because the remaining references of all the indices decrease at the same rate and become zero at the same time. Such uneven distribution of non-cached samples increases the blocking time between CPU and DL accelerators. Because computation required for

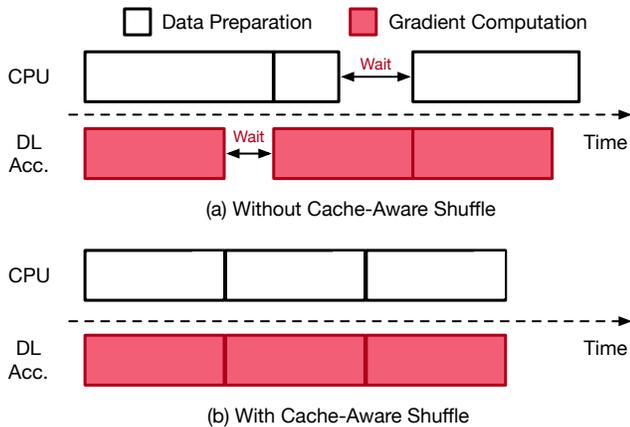

Figure 8: An example illustration of CPU and DL accelerator utilization with and without the cache-aware shuffle. The bidirectional arrow blocking time caused by uneven mini-batch processing time. Each block represents the computation time for corresponding batches.

data augmentation is skewed to a small number of epochs, DL accelerators may wait CPU in such epochs and vice versa in the other epochs.

To solve this problem, we propose the balanced eviction. At the start of each training epoch, the evict shuffler samples $\frac{N}{r}$ indices to be evicted, where N denotes the number of training samples and r denotes the reuse factor. In addition, the shuffler samples the indices without replacement and repeats the same sampling order until the end of training process. By adopting this strategy, the balanced eviction evenly distributes the computation overhead across epochs after the first epoch, by evicting the same number of partially augmented samples in each epoch. It also ensures that except for the the first r epochs, each cached sample is reused exactly r times. Figure 7 (b) illustrates an example of the data loading procedure with $N = 6$ and $r = 3$. After the first epoch, two ($N/r = 2$) samples are evicted from the cache and replaced with new partially augmented samples. All the cached samples are also evicted every three ($r = 3$) epochs, because the evict shuffler always selects indices in a same order.

5.3 Cache-Aware Shuffle

While the balanced eviction effectively addresses the inter-epoch computation skew, the intra-epoch computation skew may still slow down the training speed. Figure 8 (a) illustrates a worst-case example that can happen when the batch shuffler does not adopt the cache-aware shuffle. The non-cached indices are skewed to the first and the third mini-batch, whereas the second batch only contains cached indices. Because the processing time of the data preparation fluctuates while that of the gradient computation remains the same, this results in unnecessary blocking between CPU and DL accelerators.

The cache-aware shuffle solves this problem by leveraging cache information when deciding the indices of the samples for each mini-batch. Because cached samples are evicted only before starting each training epoch, Revamper knows the indices of the evicted samples by the beginning of each epoch. By utilizing this knowledge, the cache-aware shuffle prepares mini-batches in a way that each mini-batch has the same ratio of cached to non-cached samples. Figure 8 (b) shows that the cache-aware shuffle makes the processing time for all mini-batches stable and helps avoid blocking time between CPU and DL accelerators. We ensure the randomness of the mini-batch indices by randomly sampling from both non-cached indices and cached indices. This does not adversely affect the validation accuracy of trained models as shown in § 7.4, because the training order has little impact on the model accuracy as long as it is random [25].

6 Implementation

We implement Revamper with 2000+ lines of code based on PyTorch 1.6 [31] with Python 3.7. Revamper overrides the existing PyTorch dataloader with almost identical interface except for additional parameters such as the reuse factor, the final and partial augmentation, and whether to store cached samples to disk or not. To use Revamper, users only need to override the existing `torch.utils.data` package with our code.

Due to the global interpreter lock (GIL) of Python [11], Revamper workers are executed on separate processes, which makes it hard to share cached samples among the workers if the samples are stored in memory. As a workaround, Revamper puts cached samples inside the main process and transfers them to necessary workers. Such inter-process tensor transfer may cause frequent shared memory allocation, because PyTorch’s `multiprocessing.queue` puts tensors inside the shared memory region when they are transferred between processes. To avoid this problem, Revamper preallocates buffers in the shared memory region and reuses those buffers for inter-process communications.

7 Evaluation

Environment We perform our evaluation on a dedicated training server equipped with 2×Intel Xeon E5-2695v4 CPU (18 cores, 2.10GHz, 45MB Cache), 256GB DRAM, a NVIDIA V100 GPU, and a Samsung 970 Pro 1TB NVMe SSD. We adjust the ratio of the number of CPU cores to the number of GPUs by setting different numbers of CPU cores using a docker container [6] and fixing the number of GPUs to one. By default, we set the CPU-GPU ratio to four, which effectively emulates the ratio in AWS P3 instances [1], but we also evaluate Revamper on different CPU-GPU ratios. Our evaluation is done on PyTorch 1.6. We replace PyTorch

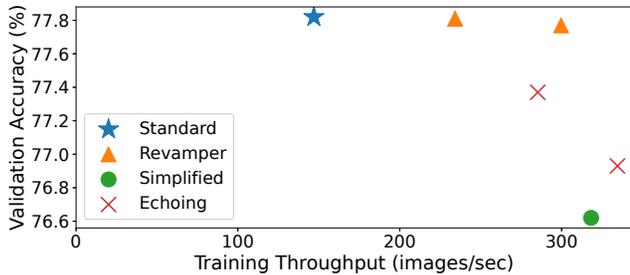

Figure 9: Training throughput and model validation accuracy of ResNet50 trained on ImageNet with diverse settings using RandAugment. Different points of the same setting represent the results under different reuse factors (2 or 3).

dataloader with Revamper for data preparation.

DNN Models and Datasets We evaluate Revamper on several DNN models for image recognition and on two datasets, ImageNet [16] and CIFAR-10 [24], which represent large and small datasets respectively. We train ResNET-50 [19] on ImageNet. On CIFAR-10, we train VGG-16 [33], ResNET-18 [19], MobileNet [20], and EfficientNet-B0 [34].

Baselines We evaluate data refurbishing implemented in Revamper against the following baselines.

- **Standard:** The standard setting represents the canonical DNN training with full augmentation without any reuse mechanism. The accuracy of the model trained under this setting serves as the target accuracy for the other data reusing mechanisms.
- **Data Echoing:** We evaluate data echoing [9, 13] with `echo-after-augment` strategy, in which each fully augmented sample is reused r times, where r denotes the user-given reuse factor. We do not evaluate the other two strategies, `echo-before-augment` and `echo-after-batch`, since they are less relevant and/or not a good baseline. When the training data resides in local SSDs, data echoing with `echo-before-augment` strategy is almost identical to the standard setting with additional encoding and disk write. `echo-after-batch` is reported to result in a lower accuracy with little training throughput improvement [13]. To make a fair comparison, we keep the size of the cache store for data echoing equal to that of Revamper.
- **Simplified:** In this setting DNN models are trained with no reuse mechanism but with fewer transformation layers compared to those of the standard setting. This approach is a baseline optimization for reducing the computation overhead of data augmentation by simply removing one or more transformations.

We use the identical model hyperparameters (e.g., the number of training epochs, learning rate, batch size, and optimizer) for each setting.

We do not evaluate a baseline without augmentation, since random crop and random flip are considered as the norm for training computer vision models. Such baseline only results in a lower accuracy with little improvement on training throughput compared to the simplified setting, as training models without augmentation has been reported to result in a significantly lower accuracy [30], and the simplified setting already makes training throughput bounded by GPUs.

Augmentation and Split Policy We apply RandAugment [15] and AutoAugment [14], the two state-of-the-art data augmentation techniques, accompanied with the random crop and random horizontal flip. After § 7.2, we use RandAugment for the data augmentation methodology.

In most of the experiments except for § 7.2, we use a single split policy: RandAugment or AutoAugment layers for the partial augmentation, and the rest of augmentation (i.e., random crop and random horizontal flip) for final augmentation.

7.1 Comparison with Baselines

ImageNet Training with RandAugment We first evaluate the training throughput and the top-1 accuracy of ResNet-50 trained on ImageNet dataset with RandAugment using Revamper and the other baselines. We follow the model hyperparameters (or configurations) from [15]. We set the number of RandAugment layers (N) to 2 and the distortion magnitude (M) to 9. Then we have a total of four transformation layers, including random crop and flip layers. We also follow the original paper when configuring other hyperparameters, such as the learning rate per batch size, the optimizer and its configurations, and the number of total epochs. We evaluate Revamper and data echoing with two different reuse factors, 2 and 3. For the simplified setting, we use a simpler data augmentation pipeline consisting of a random crop and a random horizontal flip layers. We execute three runs for each point and report the averaged results.

As shown in Figure 9 (a), when training ResNet-50, Revamper achieves top-1 accuracy comparable to the accuracy of 77.82% under the standard setting with better training throughput. With the reuse factor of 2, 77.81% accuracy is achieved with $1.59\times$ training speed-up. With the reuse factor increased to 3, the training throughput improves by $2.04\times$ while maintaining a comparable accuracy of 77.77%. On the other hand, data echoing fails to achieve comparable validation accuracy, having only 77.37% and 76.93% top-1 accuracy for the reuse factor of 2 and 3, respectively. The result demonstrates that Revamper is beneficial over data echoing in that Revamper can maintain comparable accuracy to that of the standard setting, whereas data echoing cannot avoid accuracy degradation even with the smallest reuse factor 2. For example, Revamper with the reuse factor 3 provides 0.84% validation accuracy improvement compared to data echoing with the same reuse factor.

The result also shows that Revamper provides better trade-

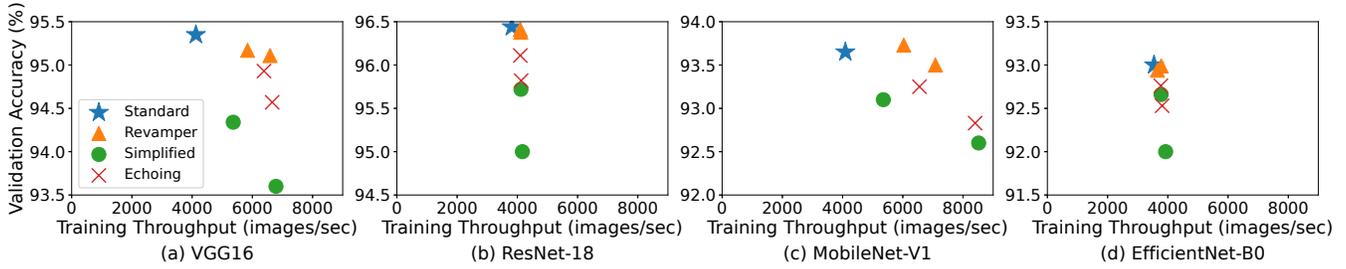

Figure 10: Training throughput and top-1 validation accuracy of DNN models trained on CIFAR-10 using RandAugment. Different points of the same setting represent measurements under different reuse factors (2 or 3) for Revamper and data echoing and under different numbers of removed transformation layers (1 or 2) for the simplified setting.

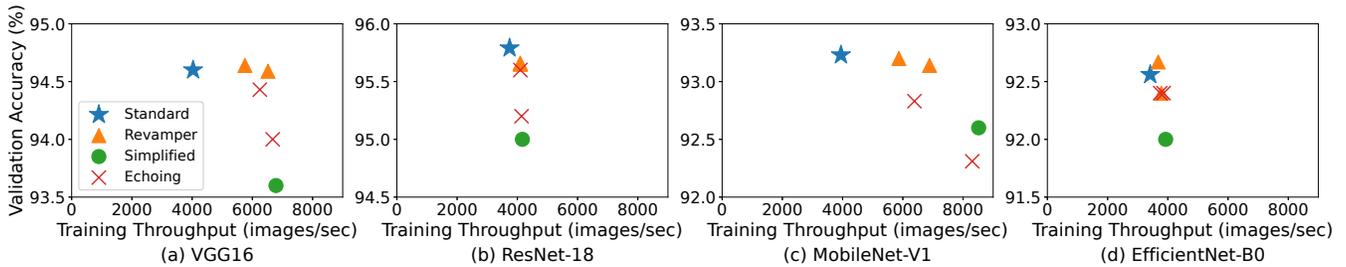

Figure 11: Training throughput and top-1 validation accuracy of DNN models trained on CIFAR-10 using AutoAugment. Different points of the same setting represent the results under different reuse factors (2 or 3).

off points between training throughput and accuracy than data echoing. For example in ResNet-50, compared to data echoing with the reuse factor 2, Revamper with the reuse factor 3 provides faster training throughput ($299.66images/sec$ vs. $285.25images/sec$) and better validation accuracy ($77.77%$ vs. $77.37%$).

The simplified setting achieves the worst validation accuracy with the training throughput similar to that of Revamper with the reuse factor 3, demonstrating that naïvely removing transformations from the pipeline does not provide a good trade-off between training throughput and accuracy.

CIFAR-10 Training with RandAugment Next, we present the performance of our evaluation of training models on a small dataset. We set the number of RandAugment layers (N) to 2 and the distortion magnitude (M) to 10. Same as ImageNet training, we evaluate data refurbishing and data echoing with two reuse factors, 2 and 3. For the simplified setting, we evaluate two different augmentations: one with random crop and random horizontal flip and the other with an additional RandAugment layer. We execute three runs for each point and report the averaged results.

The evaluation results are summarized in Figure 10. For VGG-16 (Figure 10 (a)) and MobileNet-V1 (Figure 10 (c)), Revamper achieves $1.42\times-1.73\times$ speed-up while maintaining validation accuracy comparable to the standard setting. However, for ResNet-18 (Figure 10 (b)) and EfficientNet-B0 (Figure 10 (d)), Revamper does not show significant train-

ing throughput improvement, exhibiting only $1.03\times-1.08\times$ speed-up. This is because these models require more GPU computation time for the gradient computation, and so the training process is bottlenecked by the GPUs rather than the CPUs. Such results suggest that Revamper is beneficial only when DNN training tasks are CPU-bound, but we predict that more training tasks will benefit from Revamper in near future considering rapid performance improvement of DL accelerators [2, 3].

Although data echoing and the simplified setting show an improved training throughput, their validation accuracy deviates much from that of the standard setting. Figure 10 also shows that at many points Revamper demonstrates both higher accuracy and faster training throughput compared to those of data echoing and the simplified setting. Likewise, Revamper provides better trade-offs between training throughput and accuracy than the other baselines.

CIFAR-10 Training with AutoAugment We then evaluate DNN models trained with AutoAugment [14] on CIFAR-10. We use the same configuration we used in the RandAugment evaluation except for the augmentation method. For the simplified setting, we evaluate a data augmentation pipeline with random crop and random horizontal flip, since we cannot manually adjust the number of layers once the policy is found by AutoAugment. We execute three runs for each point and report the averaged results.

Figure 11 demonstrates the results. Compared to the stan-

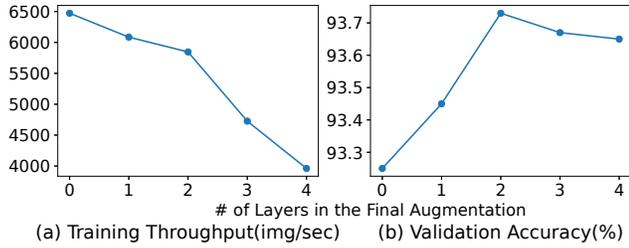

Figure 12: The training throughput and the top-1 validation accuracy for different split policies (MobileNet-V1 on CIFAR-10).

standard setting, Revamper shows $1.08\times-1.75\times$ speed-up while achieving comparable top-1 accuracy within $\pm 0.16\%$ range. Similar to the RandAugment evaluation, models that require less GPU computation (VGG16, MobileNet) has shown greater training throughput gain compared to the models (ResNet-18, EfficientNet-B0) that need heavy GPU computation. Revamper again has better trade-off points between training throughput and accuracy compared to data echoing and the simplified setting.

7.2 Augmentation Split Policy

We evaluate and analyze the trade-offs between training throughput and accuracy for different split policies. The final augmentation contains the last one to three transformation layers of the RandAugment pipeline from Figure 2. Figure 12 summarizes how the number of final augmentation layers affects training throughput and accuracy. Training throughput decreases as the number of the transformations in the final augmentation increases due to heavier CPU overhead. On the other hand, the top-1 accuracy peaks when the final augmentation consists of two transformations and does not increase with additional transformations. This is because the final augmentation with two transformations provides enough sample diversity. As we describe in § 4, once enough sample diversity has been achieved, further providing sample diversity does not significantly improve the model generalization but only degrades the training throughput.

7.3 CPU-GPU Ratio

We evaluate the training throughput change of training MobileNet-V1 on the CIFAR-10 dataset and ResNet50 on the ImageNet dataset with CPU-GPU ratios varying from two to six. As summarized in Figure 13, the training throughput of Revamper scales well upon the increasing number of CPUs, as long as it is not bottlenecked by DL accelerators. Also, the performance gain from Revamper is maximized in training environments with fewer CPUs.

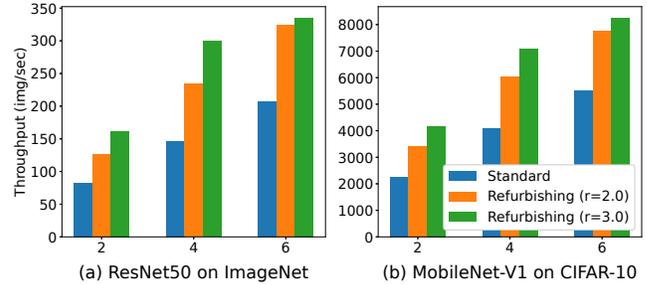

Figure 13: The training throughput of ResNet50 on ImageNet and MobileNet-V1 on CIFAR-10 for varying CPU-GPU ratios.

	Balanced + CAS	Naïve	Standard
VGG-16	5839.08	4746.91	4125.07
ResNet18	4098.36	3884.40	3813.30

Table 1: The comparison of the throughput (*images/sec*) of data refurbishing with and without Revamper’s key features, balanced eviction and cache-aware-shuffle (CAS).

7.4 Revamper Key Design Features

Revamper provides distinctive features—the balanced eviction and cache-aware shuffle—in order to efficiently support data refurbishing. We evaluate how these features further improve the DNN training throughput compared to the naïve approach with the reference count algorithm and the random shuffle. As Table 1 shows, the naïve approach provides $1.15\times$ faster training throughput for VGG-16 training on CIFAR-10 than the standard data loading system, but with the balanced eviction and cache-aware shuffle, the speed-up gain can be as much as $1.42\times$ compared to the standard one. For ResNet18, however, there is no evident additional speed-up gain with the balanced eviction and the cache-aware shuffle. Since the heavy GPU computation needed for ResNet18 training causes the gradient computation to be the main bottleneck, data refurbishing itself has no significant improvement in the training throughput. In summary, the balanced eviction and the cache-aware shuffle of Revamper contributes much to training throughput improvement whenever the DL accelerator is not the main bottleneck. Cache-aware shuffle, although it adjusts the sample order when preparing each mini-batch, does not adversely affect the accuracy of the model, as evidenced in Figure 14. As such, the balanced eviction strategy and cache-aware shuffle help Revamper support data refurbishing efficiently without negatively affecting the model generalization.

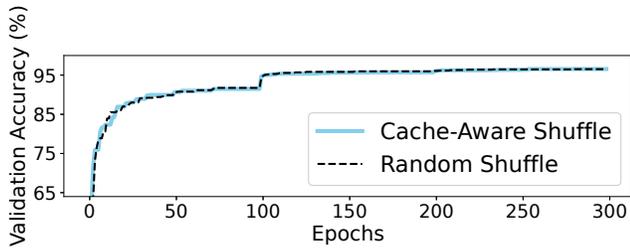

Figure 14: The change in validation accuracy over training epochs of ResNet18 trained on CIFAR-10 with different shuffle strategies.

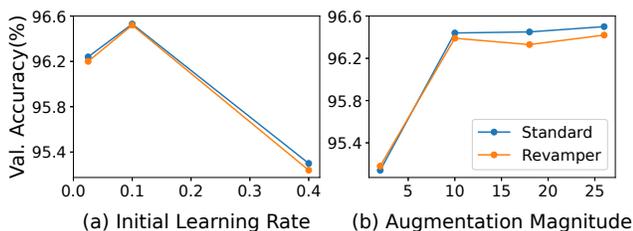

Figure 15: The top-1 validation accuracy of ResNet18 trained with different hyperparameter configurations.

7.5 Robustness to Hyperparameter Change

In this evaluation, we show that Revamper preserves the model accuracy of the standard setting under various hyperparameters. We have varied two hyperparameters—the initial learning rate and the distortion magnitude of RandAugment. As shown in Figure 15, the accuracy of the model trained with Revamper is well aligned with the one trained with the standard setting. This indicates that Revamper can achieve the validation accuracy comparable to that of the standard setting on various hyperparameter configurations.

8 Related Work

We discussed the limitations of existing approaches that accelerate data augmentation in § 3.2. In this section, we introduce other works that are closely related to our system.

Accelerating Data Preparation Quiver [25] proposes a caching system between local and remote storage shared by multiple DNN training jobs, in order to optimize slow data read from remote storage with limited cache. To achieve this goal, it leverages internal information of DL frameworks to optimize cache loading and eviction. Quiver and Revamper differ in that Quiver focuses on sharing cached training data among multiple tasks while ensuring randomness of training order, whereas Revamper focuses on reusing partially augmented data while keeping sample diversity obtained from data augmentation. OneAccess [21] proposes to use a shared data preparation pipeline to train multiple DNN models with

the same dataset. Revamper, on the other hand, focuses on optimizing data augmentation within a single DNN training task. SMOL [22] dynamically adjusts the fidelity of input data to avoid data preparation bottleneck at inference time. Unlike SMOL, Revamper focuses on fast DNN training with data augmentation rather than DNN inference.

Intermediate Data Caching Many data processing systems such as Spark [37] and Nectar [18] adopts intermediate data caching, which caches and reuses frequently used intermediate results in order to reduce computation overhead. Similarly, Revamper reuses intermediate results in the augmentation pipeline but instead handles stochastic data. In the context of DL pipelines, it is necessary to consider new aspects that have not yet been considered in previous work, such as maintaining the diversity of augmented samples and maximizing computation overlap between CPU and DL accelerators. In this work, we propose complete system design and implementation that address these new challenges.

9 Conclusion

In this paper, we present data refurbishing, a novel sample reuse mechanism that accelerates DL training while maintaining model generalization. We realize this idea by designing and implementing Revamper, a new caching and data loading system that solves system-side challenges from caching partially augmented data. Revamper has shown $1.03\times-2.04\times$ speed-up in DNN training while maintaining comparable accuracy. We hope that this work will encourage further research to rethink well-studied topics like caching in systems in the new context of deep learning.

Abstract

Large-scale model training has been a playing ground for a limited few users, because it often requires complex model refactoring and access to prohibitively expensive GPU clusters. ZeRO-Offload changes the large model training landscape by making large model training accessible to nearly everyone. It can train models with over 13 billion parameters on a single GPU, a 10x increase in size compared to popular framework such as PyTorch, and it does so without requiring any model change from data scientists or sacrificing computational efficiency.

ZeRO-Offload enables large model training by offloading data and compute to CPU. To preserve compute efficiency, it is designed to minimize data movement to/from GPU, and reduce CPU compute time while maximizing memory savings on GPU. As a result, ZeRO-Offload can achieve 40 TFlop-s/GPU on a single NVIDIA V100 GPU for 10B parameter model, compared to 30TF using PyTorch alone for a 1.4B parameter model, the largest that can be trained without running out of memory on GPU. ZeRO-Offload is also designed to scale on multiple-GPUs when available, offering near-linear speedup on up to 128 GPUs. Additionally, it can work together with model parallelism to train models with over 70 billion parameters on a single DGX-2 box, a 4.5x increase in model size compared to using model parallelism alone.

By combining compute and memory efficiency with ease-of-use, ZeRO-Offload democratizes large-scale model training making it accessible to even data scientists with access to just a single GPU.

1 Introduction

Since the advent of the attention-based deep learning (DL) models in 2017, we have seen an exponential growth in DL model size, fueled by substantial quality gains that these attention based models can offer with the increase in the number of parameters. For example, the largest language model in literature had less than 100M parameters in 2017. It grew to over 300M with BERT [6] in 2018, and increased to tens of billions in 2019 with models such as GPT-2 [3], T5 [20], Megatron-LM [28] and Turing-NLG [25]. Today, the largest

language model GPT-3 [2] has a staggering number of 175B parameters. With the three orders of magnitude growth in model size since 2017, the model accuracy continues to improve with the model size [12]. Recent studies in fact show that larger models are more resource-efficient to train than smaller ones [12] for a given accuracy target. As a result, we expect the model size to continue growing in the future.

However, accessibility to large model training is severely limited by the nature of state-of-art system technologies. Those technologies make entry into the large model training space prohibitively expensive. To be more specific, distributed parallel DL training technologies such as pipeline parallelism [10], model parallelism [28], and ZeRO [21] (Zero Redundancy Optimizer) allow transcending the memory boundaries of single GPU/accelerator device by splitting the model states (parameters, gradients and optimizer states) across multiple GPU devices, enabling massive models that would otherwise simply not fit in a single GPU memory. All record-breaking large models such as GPT-2, Megatron-LM, Turing-NLG, and GPT-3, were trained using a combination of the aforementioned technologies. However, all of these DL parallel technologies require having enough GPU devices such that the aggregated GPU memory can hold the model states required for the training. For example, training a 10B parameter model efficiently requires a DGX-2 equivalent node with 16 NVIDIA V100 cards, which costs over 100K, beyond the reach of many data scientists, and even many academic and industrial institutions.

Heterogeneous DL training is a promising approach to reduce GPU memory requirement by exploiting CPU memory. Many efforts have been made in this direction [8, 9, 11, 17, 23, 23, 24, 32–34]. Nearly all of them target CNN based models, where activation memory is the memory bottleneck, and model size is fairly small (less than 500M). However, the primary memory bottleneck for recent attention based large model training are the model states, instead of activation memory. There is an absence in literature studying these workloads for heterogeneous DL training. Additionally, existing efforts on heterogeneous training are further limited in two major ways: i) nearly all of them exploit CPU memory, but not CPU compute, which we show can be used to significantly reduce the CPU-GPU communication overhead, and

ii) they are mostly designed for and evaluated on single GPU [9, 11, 23, 34], without a clear path to scaling efficiently on multiple GPUs, which is crucial for large model training.

Addressing the aforementioned limitation, we attempt to democratize large model training by developing ZeRO-Offload, a novel heterogeneous DL training technology designed specifically for large model training. ZeRO-Offload exploits both CPU memory and compute for offloading, while offering a clear path towards efficiently scaling on multiple GPUs by working with ZeRO-powered data parallelism [21]. Additionally, our first principle analysis shows that ZeRO-Offload provides an optimal and the only optimal solution in maximizing memory saving while minimizing communication overhead and CPU compute overhead for large model training.

ZeRO-Offload is designed around three main pillars: i) Efficiency, ii) Scalability, and iii) Usability.

Efficiency: The offload strategy in ZeRO-Offload is designed with the goal of achieving comparable compute efficiency to the state-of-art non-offload strategies but for significantly larger models. To achieve this goal, we rely on first principle analysis to identify a *unique optimal* computation and data partitioning strategy between CPU and GPU devices. This strategy is optimal in three key aspects: i) it requires orders-of-magnitude fewer computation on CPU compared to GPU, preventing the CPU compute from becoming a performance bottleneck, ii) it minimizes the communication volume between CPU and GPU preventing communication from becoming a bottleneck, and iii) it provably maximizes memory savings on GPU while achieving minimum communication volume.

Our analysis shows that to be optimal in the aforementioned regards, we must offload the gradients, optimizer states and optimizer computation to CPU, while keeping the parameters and forward and backward computation on GPU. This strategy enables a 10x increase in model size, with minimum communication and limited CPU computation, which allows us to train 13B parameters on a single NVIDIA V100 GPU at 40 TFLOPS, compared to 30 TFLOPS on the same GPU with 1.2B parameters, the largest model that can be trained without any CPU offloading.

Offloading optimizer computation requires CPU to perform $O(M)$ computation compared to $O(MB)$ on GPU where M and B are the model size and batch sizes respectively. In most cases, the batch size is large, and CPU computation is not a bottleneck, but for small batch sizes, the CPU compute can be a bottleneck. We address this using two optimizations: i) an efficient *CPU optimizer* that is up to 6x faster than the-state-of-art, and ii) One-step *delayed parameter update* that allows overlapping the CPU optimizer step with GPU compute, while preserving accuracy. Together, they preserve efficiency for ZeRO-Offload even with small batch sizes.

Scalability: Good scalability is crucial to take advantage of multiple GPUs that may be available to some data scientists. In the DL community, data parallelism is generally

```
import torch
...
model = BuildModel(config)
optimizer = Optimizer(model)
...
for batch in batches:
    loss = model(batch)
    loss.backward()
    optimizer.step()

import torch
import deepspeed
...
model = BuildModel(config)
optimizer = Optimizer(model)
model = deepspeed.initialize(
    model, optimizer)
...
for batch in batches:
    loss = model(batch)
    model.backward(loss)
    model.step()
```

Figure 1: ZeRO-Offload can be enabled with a few lines of change. The code on left shows a standard training pipeline, while the right shows the same pipeline with ZeRO-Offload enabled.

used as the de facto standard to scale DL training to multiple GPUs [5, 26, 35]. However, it is not designed to work with heterogeneous training and presents scalability challenges because of the replication of data and computation in data parallel training. Data parallel training replicates all the model states such as optimizer states, parameters, and gradients, and it also replicates the optimizer computation on each GPU. Therefore, offloading model states or optimizer computation to CPU in combination with data parallelism will result in significant replication of communication and CPU compute: increase the CPU memory requirement proportionally to the data parallelism degree while limiting throughput scalability due to the increased communication.

To address these challenges, ZeRO-Offload combines unique optimal offload strategy with ZeRO [21] powered data parallelism instead of traditional data parallelism. The symbiosis allows ZeRO-Offload to maintain a single copy of the optimizer states on the CPU memory regardless of the data parallel degree. Furthermore, it keeps the aggregate communication volume between GPU and CPU, as well as the aggregate CPU computation a constant regardless of data parallelism, allowing ZeRO-Offload to effectively utilize the linear increase in CPU compute with the increase in the data parallelism degree. As a result, ZeRO-Offload achieves excellent scalability on up to 128 GPUs.

In addition to working with ZeRO powered data parallelism, ZeRO-Offload can be combined with model parallelism [27, 28] to achieve higher memory savings, when multiple GPUs are available.

Usability: ZeRO-Offload is available as part of an Open-Source PyTorch library, DeepSpeed (www.deepspeed.ai). Unlike most strategies discussed in Section 2, ZeRO-Offload does not require model refactoring to work. In fact, PyTorch users can enable ZeRO-Offload with few lines of code change to their existing training pipeline as shown in Figure 1, allowing to train 10x larger models easily.

Contributions. To the best of our knowledge, ZeRO-Offload is the first fully distributed all-reduced based training framework using CPU memory and computation resources to train large-scale models. We summarize contributions as follows:

- A unique optimal offload strategy for heterogeneous large model training on GPU + CPU system that enables 10x larger model on a single GPU without sacrificing efficiency (Sec. 3 and Sec. 4.1).
- Highly scalable multi-GPU design through i) a symbiotic combination of offload strategy with ZeRO powered data parallelism (Sec. 4.2), allowing ZeRO-Offload to achieve near-linear scalability, and ii) seamless integration with model-parallel training [28], enabling even larger models than using ZeRO-Offload or model parallelism alone (Sec. 4.2).
- Open-source implementation of ZeRO-Offload in PyTorch.
- Extensive evaluation demonstrating i) *Model Scale*: 10x increase in model size with up to 13B on a single GPU and 4x increase in model size over model parallelism with up to 70B parameters on a DGX-2 node. ii) *Efficiency*: Over 40 TFlops for a 10B parameters on a single NVIDIA V100, compared to 30 TFLOPS on the same GPU with 1.4B parameters, the largest model that can be trained without any CPU offloading; Outperform two state-of-the-art heterogeneous DL training frameworks by 22% and 37% respectively on a single GPU. iii) *Scalability*: Near-perfect linear scalability for a 10B parameter model on up to 128 GPUs. iv) CPU overhead reduction with our ADAM implementation with 6x speedup over PyTorch optimizer and up to 1.5X improvement in end-to-end throughput with delayed parameter update optimizations (Sec. 6).

2 Background and Related Work

Memory consumption in large model training. The full spectrum of memory consumption during DL model training can be classified into two parts: i) model states and ii) residual states [21]. Model states include parameters, gradients, and optimizer states (such as momentum and variances in Adam [13]); Residual states include activations, temporary buffers, and unusable fragmented memory.

Model states are the primary source of memory bottleneck in large model training. We consider the memory consumption due to model states for large transformer models such as Megatron-LM (8 billion) [28], T5 (11 billion) [20], and Turing-NLG [25] (17.2 billion). They are trained with float-16 mixed precision training [16] and Adam optimizer [13].

Mixed precision training often keeps two copies of the parameters, one in float-16 (fp16) and the other in float-32 (fp32). The gradients are stored in fp16. In addition to the parameters and gradients, the Adam optimizer keeps track of the momentum and variance of the gradients. These optimizer states are stored in fp32. Therefore, training a model in mixed precision with the Adam optimizer requires at least 2 bytes of memory for each fp16 parameter and gradient, and 4 byte of memory for each fp32 parameter, and the momentum and variance of each gradient. In total, a model with M parameters requires $16 \times M$ bytes of memory. Therefore, the model states

for Megatron-LM, T5 and Turing-NLG require 128 GB, 176 GB and 284 GB, respectively, which are clearly beyond the memory capacity of even the current flagship NVIDIA A100 GPU with 80 GB of memory.

Significant amount of work has been done in the recent years to enable large model training, which requires more memory than what is available on a single GPU to fit these model and residual states. These efforts can be classified broadly into two categories: i) scale-out training and ii) scale-up training based approaches. We discuss them as follows.

Scale out large model training. Scale-out training uses aggregate memory of multiple GPUs to satisfy the memory requirement for large model training. Two prominent examples of scale out training is model parallelism [5, 28] and pipeline parallelism [7, 10], both partitioning the model states and the residual states across multiple GPUs. Model parallelism [5, 28] partitions the model vertically and distributes the model partitions to multiple GPU devices in order to train large models. Pipeline parallelism [7, 10] on the other hand parallelizes model training by partitioning the model horizontally across layers. Both of these approaches must change the user model to work, therefore can limit usability.

A recent work, ZeRO [21], provides an alternative to model and pipeline parallelisms to train large models. ZeRO splits the training batch across multiple GPUs similar to data parallel training [5, 26, 35], but unlike data parallel training which replicates all the model states on each GPU, ZeRO partitions them across all GPUs, and uses communication collectives to gather individual parameters as needed during the training. ZeRO does not require changes to the user model to work, making it more generic than model or pipeline parallel training. It also offers better compute efficiency and scalability.

Despite the ability of model and pipeline parallelisms, and ZeRO to train large models, they all require multiple GPUs such that the aggregate GPU memory can hold the model and residual states for training large models. In contrast, ZeRO-Offload is designed to fit a larger model by offloading model states to CPU memory and can train a 10x larger model on a single GPU without sacrificing efficiency. When multiple GPUs are available, ZeRO-Offload is designed to work together with ZeRO to offer excellent scalability, or in conjunction with model parallelism to fit even larger model sizes that is not possible with ZeRO-Offload or model parallelism alone.

Scale up large model training. Existing work scales up model size in a single GPU through three major approaches. The first approach trades computation for memory saving from activations (residual memory) by recomputing from checkpoints [4]. The second approach uses compression techniques such as using low or mixed precision [16] for model training, saving on both model states and activations. The third approach uses an external memory such as the CPU memory as an extension of GPU memory to increase memory capacity during training [8, 9, 11, 17, 23, 24, 33].

Our work, ZeRO-Offload falls under the third approach.

Unlike ZeRO-Offload, the above efforts only offload data to CPU but not compute, and they use smaller models training. Furthermore, none of the above works is communication optimal, leading to extra communication between CPU and GPU and hurting training throughput. In contrast, a recent work called L2L [18] can enable multi-billion parameter training by managing memory usage in GPU layer by layer. In particular, L2L synchronously moves tensors needed in the upcoming layer into GPU memory for computation and keeps the rest of tensors into CPU memory for memory saving. In comparison to ZeRO-Offload, it offers limited efficiency due to extra communication overhead, does not offer a way to scale out across devices, and requires model refactoring, making it difficult to use.

ZeRO powered data parallel training. ZeRO-Offload works with ZeRO to scale DL training to multiple GPUs. ZeRO has three stages, ZeRO-1, ZeRO-2 and ZeRO-3 corresponding to the partitioning of the three different model states, optimizer states, gradients and parameters, respectively. ZeRO-1 partitions the optimizer states only, while ZeRO-2 partitions gradients in addition to optimizer states, and ZeRO-3 partitions all model states. ZeRO-Offload works symbiotically with ZeRO-2, and therefore we discuss it further.

In ZeRO-2, each GPU stores a replica of all the parameters, but only updates a mutually exclusive portion of it during the parameter update at the end of each training step. As each GPU only updates a portion of the parameters, they only store optimizer states and gradients required to make that update. After the update, each GPU sends its portion of the updated parameters to all the other GPUs using an `all-gather` communication collective. ZeRO-2 computation and communication schedule is described below:

During the forward pass, each GPU computes the loss with respect to a different mini-batch. During the backward propagation, as each gradient is computed, it is averaged using a `reduce` operator at the GPU/GPUs that owns the gradient or part of the gradient. After the backward pass, each GPU updates its portion of the parameters and optimizer states using the averaged gradients corresponding to that portion. After this, an `all-gather` is performed to receive the rest of the parameter update computed on other GPUs.

3 Unique Optimal Offload Strategy

ZeRO-Offload is designed to enable efficient large model training on a single or multiple GPUs by offloading some of the model states from GPU to CPU memory during training. As discussed in Sec. 2, model states: parameters, gradients, and the optimizer states, are the primary source of memory bottleneck in large model training. By offloading some of these model states to CPU, ZeRO-Offload can enable training of significantly larger models ¹. However, identifying the

¹ZeRO-Offload only offloads model states. Offloading secondary sources of memory bottleneck such as activation memory is beyond scope of our

optimal offloading strategy is non-trivial. There are numerous ways to offload model states to CPU memory, each with a different trade-off in terms of CPU computation, and GPU-CPU communication, both of which can limit the training efficiency.

To identify the optimal offload strategy, ZeRO-Offload models the DL training as data-flow graph and uses first principle analysis to efficiently partition this graph between CPU and GPU devices. ZeRO-Offload partitions the graph in a way that is *optimal* in three key aspects: i) it requires orders-of-magnitude fewer computation on CPU compared to GPU, which prevents CPU from becoming a performance bottleneck (Sec. 3.1), ii) it guarantees the minimization of communication volume between CPU and GPU memory (Sec. 3.3), and iii) it provably maximizes the memory savings while achieving minimum communication volume (Sec. 3.4). In fact, ZeRO-Offload can achieve high efficiency during training that is comparable to non-offload training and it is *unique optimal*, meaning no other solution can offer better memory savings without increasing the communication volume or increasing CPU computation.

In this section, we discuss the derivation of our unique optimal offload strategy. Our strategy is specifically designed for *mixed precision training with Adam optimizer* which is the de facto training recipe for large model training.

3.1 DL Training as a Data-Flow Graph

The DL training workload can be represented as a weighted directed graph of data and computation, as shown in Figure 2, where the circular nodes represents model states (parameter16, gradient16, parameter32, momentum32, variance32), and the rectangular nodes represents computation (forward, backward, param update). The edges in the graph represents the data flow between the nodes, and the weight of an edge is the total data volume in bytes that flows through it during any given training iteration. For a model with M parameters, the weight of the edges in this graph is either $2M$ where the source node produces fp16 model states, or $4M$ where the source node produces fp32 model states.

An offload strategy between GPU and CPU can be represented using a two-way partitioning of this graph, such that computation nodes in a partition would be executed on the device that owns the partition, and the data nodes in the partition will be stored on device that owns the partition. The total data volume that must be communicated between GPU and CPU is given by the weight of edges running across two partitions.

There are numerous ways to partition this graph. In the following sections, we use first principles to simplify the data

offload strategy. Given that they are significantly smaller than model states, we ignore them for the purpose of our analysis. Furthermore, the first and second approaches described in Sec. 2 can be used in conjunction with ZeRO-Offload to reduce activation memory

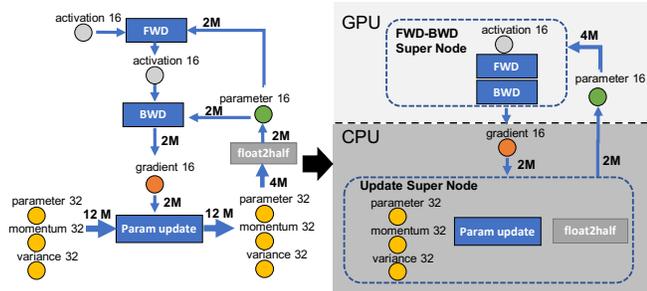

Figure 2: The dataflow of fully connected neural networks with M parameters. We use activation checkpoint to reduce activation memory to avoid activation migration between CPU and GPU.

flow graph to reduce the number of possible choices based on three different efficiency metric: i) CPU computation overhead, ii) communication overhead, and iii) memory savings.

3.2 Limiting CPU Computation

The CPU computation throughput is multiple orders of magnitude slower than the GPU computation throughput. Therefore, offloading large computation graph to CPU will severely limit training efficiency. As such, we must avoid offloading compute intensive components to the CPU.

The compute complexity of DL training per iteration is generally given by $O(MB)$, where M is the model size and B is the effective batch size. To avoid CPU computation from becoming a bottleneck, only those computations that have a compute complexity lower than $O(MB)$ should be offloaded to CPU. This means that the forward propagation and backward propagation both of which have a compute complexity of $O(MB)$ must be done on GPU, while remaining computations such as norm calculations, weight updates etc that have a complexity of $O(M)$ may be offloaded to CPU.

Based on this simple observation we fuse the forward and backward nodes in our data flow graph into a single super-node (FWD-BWD) and assign it to GPU.

3.3 Minimizing Communication Volume

The CPU memory bandwidth is at least an order of magnitude faster than the PCI-E bandwidth between CPU and GPU, while the GPU memory is another order of magnitude faster than even the CPU memory. Therefore, we must minimize the communication volume between CPU and GPU memory to prevent the PCI-E bandwidth from becoming a training performance bottleneck. To do so we must first identify the theoretical minimum communication volume for a model-state offload strategy.

The minimum communication volume for any model-state offload strategy is given by $4M^2$. Note that after fusing the

²Please note that it is possible to reduce the communication volume further by only offloading partial model states. For simplification, we assume

forward and backward into a single super-node as discussed in Sec. 3.2, each node in our data flow graph is part of a cycle. Therefore, any partitioning of this graph would require cutting at least two edges, each of which has a edge weight of at least $2M$, resulting in a total communication of at least $4M$.

If we choose to limit the communication volume to this bare minimum, we can greatly simplify our data-flow graph and reduce the number of partitioning strategies to a handful:

Creating fp32 super-node. Notice that any partitioning strategy that does not co-locate the fp32 model states with their producer and consumer nodes cannot achieve the minimum communication volume of $4M$. Such a partition must cut at least one edge with a weight of $4M$, and the other with at least $2M$, resulting in a communication volume of at least $6M$. Therefore, to achieve the minimum communication volume, all offload strategies must co-locate fp32 model states with their producer and consumer operators, i.e., the fp32 model states (momentum32, variance32 and parameter32) must be co-located with the *Param Update* and the *float2half* computation.

This constraint allows us to treat all the aforementioned fp32 data and compute nodes in the data flow graph as a single super-node that we refer to as *Update Super*. We show this reduced data flow graph in Figure 2, consisting of only four nodes: *FWD-BWD Super* node, *p16* data node, *g16* data node, and *Update Super* node.

p16 assignment. To achieve the minimum communication volume, *p16* must be co-located with *FWD-BWD Super* because the edge weight between these two nodes is $4M$. Separating these two nodes, would increase the communication volume to $6M$ (i.e., $4M + 2M$). Since, we have already assigned node *FWD-BWD Super* to GPU to limit computation on CPU, *p16* must also be assigned to GPU.

3.4 Maximizing Memory Savings

After simplifying the data flow graph to minimize communication volume, only *g16* and *Update Super* remain to be assigned. Notice that at this point, all partitions will result in minimum communication volume, so we can prune the choices further to maximize the memory savings on GPU. Table 1 shows the memory savings of all valid partitioning strategies that minimize the communication volume. The maximum memory savings of 8x can be achieved by offloading both *g16* and *Update Super* to CPU.

Table 1: Memory savings for offload strategies that minimize communication volume compared to the baseline.

FWD-BWD	p16	g16	Update	Memory	Reduction
gpu	gpu	gpu	gpu	16M	1x (baseline)
gpu	gpu	cpu	gpu	14M	1.14x
gpu	gpu	gpu	cpu	4M	4x
gpu	gpu	cpu	cpu	4M	8x

that an offload of a model state implies that we offload the entire model state. Our analysis on the memory savings per communication volume, still holds even if we offload partial model states

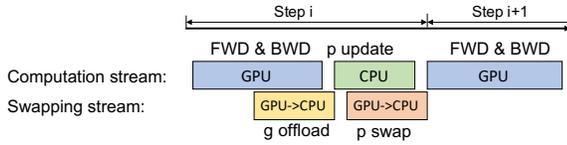

Figure 3: ZeRO-Offload training process on a single GPU.

3.5 A Unique and Optimal Offload Strategy

ZeRO-Offload allocates all the fp32 model states along with the fp16 gradients on the CPU memory, and it also computes the parameter updates on CPU. The fp16 parameters are kept on GPU and the forward and backward computations are also done on GPU.

We arrive at this offload strategy by simplifying our data flow graph and eliminating all other partitioning strategies as they do not limit CPU computation, minimize communication volume, or maximize memory savings. Therefore, ZeRO-Offload is not only optimal in terms of the aforementioned metrics, it is also unique; there can be no other strategy that can offer more memory savings than ZeRO-Offload without increasing the compute complexity on the CPU or incur additional GPU-CPU communication volume.

4 ZeRO-Offload Schedule

In this section, we discuss the concrete computation and communication schedule for implementing ZeRO-Offload on a single GPU system based on our offload strategy. We then show how we extend this schedule to work effectively on multi-GPU systems by combining our offload strategy with ZeRO data parallelism and model parallelism.

4.1 Single GPU Schedule

As discussed in Sec. 3, ZeRO-Offload partitions the data such that the fp16 parameters are stored in GPU while the fp16 gradients, and all the optimizer states such as fp32 momentum, variance and parameters are stored in CPU.

During the training, we begin by computing the loss via the forward propagation. Since the fp16 parameters are already presented on GPU, no CPU communication is required for this part of the computation. During the backward propagation on the loss, the gradient for different parameters are computed at different point in the backward schedule. ZeRO-Offload can transfer these gradients for each parameter individually or in small groups to the CPU memory immediately after they are computed. Therefore, only a small amount of memory is required to temporarily hold the gradients on the GPU memory before they are transferred to CPU memory. Furthermore, each gradient transfer can be overlapped with the backpropagation on the remainder of the backward graph, allowing ZeRO-Offload to hide a significant portion of the communication cost.

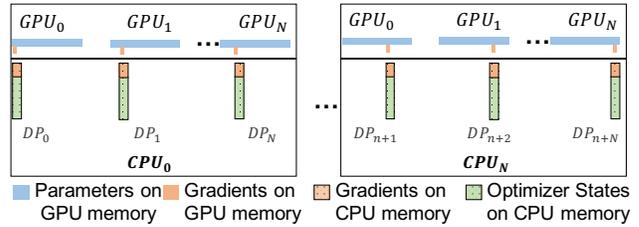

Figure 4: ZeRO-Offload data placement with multiple GPUs

After the backward propagation, ZeRO-Offload updates the fp32 parameters and the remaining optimizer states (such as momentum and variance) directly on CPU, and copies the updated fp32 parameters from the CPU memory to the fp16 parameters on the GPU memory. Figure 3 shows the computation and communication in each step of ZeRO-Offload diagrammatically, and Figure 5 shows the concrete schedule as a pseudo-code.

4.2 Scaling to Multi-GPUs

ZeRO-Offload in its entirety is a symbiotic integration of ZeRO-Offload strategy described in Sec. 3 and ZeRO-powered data parallelism discussed in Sec. 2, which allows ZeRO-Offload to scale to hundreds of GPUs efficiently. ZeRO-Offload preserves the model state partitioning strategy of ZeRO Stage-2 (optimizer state and gradient partitioning), while offloading the partitioned gradients, optimizer states and the corresponding parameter updates to CPU.

The key benefit of doing this partitioning before offloading is that for systems with more than 1 GPU, each data parallel process is only responsible for updating a subset of the parameters. The aggregated communication volume from all the data parallel GPUs to CPU remains constant, and CPU resources are used in parallel to jointly compute a single weight update. As a result, the total CPU update time decreases with increased data parallelism, since the CPU compute resources increase linearly with the increase in the number of compute nodes. This allows ZeRO-Offload to achieve very good scalability, as the overhead of communication across GPUs is offset by the reduction in the CPU optimizer step.

ZeRO-Offload partitions gradients and optimizer states among different GPUs, and each GPU offloads the partition it owns to the CPU memory and keeps it there for the entire training. During the backward propagation, gradients are computed and averaged using reduce-scatter on the GPU, and each GPU only offloads the averaged gradients belonging to its partition to the CPU memory. Once the gradients are available on the CPU, optimizer state partitions are updated in parallel by each data parallel process directly on the CPU. After the update, parameter partitions are moved back to GPU followed by an all-gather operation on the GPU similar to ZeRO-2 to gather all the parameters. Figure 4 shows the data

placement model parameters, gradients and optimizer states for ZeRO-Offload and the details of the ZeRO-Offload data parallel schedule is presented in Figure 5. The all gather operation described above is shown as a sequence of broadcast operations in the Figure.

Model Parallel training ZeRO-Offload can also work together with tensor-slicing based model parallelism (MP) frameworks such as Megatron-LM [28]. It does so by offloading the gradients, optimizer states and the optimizer computation corresponding to each MP process allowing ZeRO-Offload to train significantly larger models than possible than using model parallelism alone. Sec. 6 provides more details.

5 Optimized CPU Execution

We speedup the CPU execution time for the parameter updates with two optimizations. First, we implement a fast CPU Adam optimizer using high performance computing techniques offering significant speedup over state-of-art Pytorch implementation. Second, we develop a one-step delayed parameter update schedule that overlaps the CPU parameter update computation with the forward and backward computation on the GPU, hiding the CPU execution time when enabled.

5.1 Implementing the CPU Optimizer

We use three levels of parallelism for improving the performance of the CPU optimizer. 1) SIMD vector instruction [15] for fully exploiting the hardware parallelism supported on CPU architectures. 2) Loop unrolling [31], an effective technique for increasing instruction level parallelism that is crucial for better memory bandwidth utilization. 3) OMP multithreading for effective utilization of multiple cores and threads on the CPU in parallel. Using these technique, we present a significantly faster implementation of Adam optimizer compared to state-of-art PyTorch implementation.

Mixed Precision Training with Adam ADAM is an optimization algorithm used for deep-learning training, which takes the loss gradients together with their first and second momentums to update the parameters. Therefore, in addition to the model parameters, ADAM requires two more matrices of the same size (M) saved during the training. In the mixed precision training mode, there are two versions of the parameters stored in memory: one in fp16 (parameter16) used for computing the activations in the forward pass (on GPU), and one master copy in fp32 (parameter32) which is updated by the optimizer (on CPU). The p16 is updated with the parameter32 through *float2half* casting, at each training step. Moreover, the momentum and variance of the gradients are saved in fp32 (on CPU), to prevent the precision loss for updating the parameters. Please refer to [13] for further detail on ADAM’s algorithm.

Figure 5: Code representing ZeRO-Offload that combines unique optimal CPU offload strategy with ZeRO-powered data parallelism.

Optimized Implementation Algorithm 1 elaborates the ADAM’s implementation detail using SIMD operations. As shown, the Adam function receives the optimizer parameters such as β_1 , β_2 , and α , and the gradient, momentum, variance and master copy of parameters (parameter32) as the input. We also use some parameters specific to the implementation, like the *simd_width* and *unroll_width*. The Adam optimizer sends back the updated variance, momentum, and parameter in both fp16 (to GPU) and fp32 (to CPU) .

We firstly read the data, including parameter, gradient, momentum and variance, into the vector registers (line 7). Then, we use several fused multiply-add (*FMA*) vector operations to preform the main execution pipeline which is repeated by the unrolling width. Note that the rest of operations, such as multiply, division, and sqrt, also run in vector mode. For the best performance we use AVX512 simd instruction set and an *unroll_width* of 8 based on auto-tuning results.

In addition to the CPU-Adam optimizer, we implement

Algorithm 2 CPU-ADAM Optimizer

```

the CPU-to-GPU fp16 parameter-copy in a tiled manner (line 15). We overlap the CPU and GPU execution by parallelizing the Adam computation and copying the parameters over to GPU. As we process Adam computation of the current tile of data on CPU, we write the parameters back to GPU for the previously processed tile. This way, we reduce the idle time of GPU to start the processing of the next training step.

5.2 One-Step Delayed Parameter Update

Despite using a highly optimized CPU optimizer, the CPU computation overhead can become a bottleneck during training with very small batch sizes, when the GPU computation time is not much larger than CPU compute. For such limited cases, we develop one-step delayed parameter update (DPU) that overlaps CPU and GPU compute to hide the CPU computation overhead by delaying the parameter update by a single step. We verify that DPU does not impact the final accuracy of training in the evaluation.

DPU training schedule Figure 6 shows the workflow of ZeRO-Offload training process with delayed parameter update. ❶ The first $N - 1$ steps, are trained without DPU to avoid destabilizing the training during the early stages where gradients change rapidly. ❷ On step N , we obtain the gradients from the GPU, but we skip the CPU optimizer step, and do not update the fp16 parameters on the GPU either. ❸ At step $N + 1$, we compute the parameter updates on the CPU using gradients from step N , while computing the forward and backward pass on the GPU in parallel using parameters updated at step $N - 1$. From this step onwards, the model at $(i + 1)^{th}$ step will be trained using the parameters updated with gradients from $(i - 1)^{th}$ step instead of parameters updated at i^{th} step, overlapping CPU compute with GPU compute.

Accuracy trade-off. Since DPU changes the semantics of the training, it is reasonable to ask if there is a trade-off between model accuracy and training efficiency. To answer this

Table 2: Hardware overview of experimental system.

question, we evaluated DPU on multiple training workloads and found that DPU does not hurt convergence if we introduce DPU after a few dozen iterations instead of introducing it at the beginning. Our evaluation result in Sec. 6 shows that compared with training with ZeRO-Offload only, training with delayed parameter update achieves same model training accuracy with higher training throughput.

6 Evaluation

This section seeks to answer the following questions, in comparison to the state-of-the-art:

- (i) How does ZeRO-Offload scale the trainable model size compared to existing multi-billion parameter training solutions on a single GPU/DGX-2 node?
- (ii) What is the training throughput of ZeRO-Offload on single GPU/DGX-2 node?
- (iii) How does the throughput of ZeRO-Offload scale on up to 128 GPUs?
- (iv) What is the impact of our CPU-Adam and delay parameter update (DPU) on improving throughput, and does DPU change model convergence?

6.1 Evaluation Methodology

Testbed. For the evaluation of model scale and throughput, we conduct our experiments on a single DGX-2 node, whose details are shown in Table 2. For the evaluation of throughput scalability, we conduct experiments on 8 Nvidia DGX-2 nodes connected together with InfiniBand using a 648-port Mellanox MLNX-OS CS7500 switch.

Workloads. For the performance evaluation, we focus on evaluating GPT-2 [19] like Transformer based models [30]. We vary the hidden dimension and the number of Transformer blocks to obtain models with a different number of parameters. Note that scaling the depth alone is often not sufficient because it would make training more difficult [12]. Table 3 shows the configuration parameters used in our experiments.

For convergence analysis, such as the delayed parameter update, we use GPT-2 [19] and BERT [6], both of which are commonly used as pre-trained language models and have demonstrated superior performance in many NLP tasks (e.g., natural language understanding and inference) than recurrent neural networks or convolutional neural networks. We use BERT-large, same as the one from [6], which has 24-layer, 1024-hidden, 16-heads, and 336M parameters. Similar

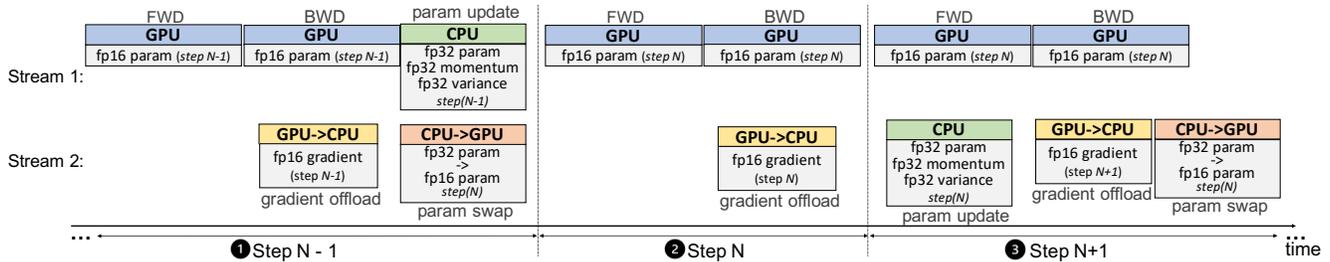

Figure 6: Delayed parameter update during the training process.

Table 3: Model configuration in evaluation.

# params	batch size per GPU	MP setting in ZeRO-Offload	# layer	hidden size
1, 2 billion	32	1	20, 40	2048

70 billion	8	8	69	9216

to [21, 28], we fine-tune BERT on the Stanford Question Answering Dataset (SQuAD) [1], which is one of the most widely used reading comprehension benchmark [22]. Unless otherwise stated, we follow the same training procedure and hyperparameter settings as in [6, 19].

Baseline. We compare the effectiveness of ZeRO-Offload with state-of-arts multi-billion parameter training solutions:

- PyTorch DDP: This is the existing PyTorch Transformer implementation using DistributedDataParallel [14].
- Megatron [28]: One of the current state-of-the-art multi-billion parameter model training solutions, which employs model parallelism to train up to 8.3B parameter models using 512 GPUs.
- SwapAdvisor [9]: SwapAdvisor explores a genetic algorithm to guide model-agnostic tensor swapping between GPU and CPU memory for GPU memory saving.
- L2L [18]: L2L enables training of deep Transformer networks by keeping one Transformer block at a time in GPU memory and only moves tensors in the upcoming Transformer block into GPU memory when needed.
- ZeRO-2 [21]: ZeRO extends data parallelism by eliminating memory redundancies across multiple GPUs, allowing to train models up to 170B parameters with high training throughput using 25 DGX-2 nodes. ZeRO-2 achieves the SOTA results for large model training and is a strong baseline.

6.2 Experimental Results

6.2.1 Model Scale

As an important step toward democratizing large model training, in this part, we first test the largest trainable models on a

single GPU as well as 16 GPUs in a single DGX-2 node.

Single GPU. The largest model can be trained using PyTorch DDP on a single GPU with 32GB memory is 1.4B, before running out of memory, as shown in figure 7. Both Megatron and ZeRO-2 do not increase the trainable model size on a single GPU in comparison to PyTorch, because they both utilize the aggregated GPU memory to fit larger models. In contrast, ZeRO-Offload enables 13B model training on a single GPU, which is more than 9X larger than using PyTorch, Megatron, and ZeRO-2. This is mainly because of ZeRO-Offload’s strategy for maximizing the memory savings on GPU by offloading expensive states such as optimizer states and the majority of gradients to CPU memory. The largest model can be trained with SwapAdvisor on a single GPU is 8B, which is 38% smaller than the model can be trained with ZeRO-Offload. SwapAdvisor relies on a black-box approach and uses a simulator to predict which tensors are more frequently used in order to keep them in GPU memory to maximize training throughput. The prediction can not be fully accurate, and therefore SwapAdvisor keeps more tensors in GPU memory than ZeRO-Offload does. On the other hand, L2L is able to train even larger models (e.g., 17B) on a single GPU by frequently moving weights from unused layers to CPU memory. However, the largest model size does not increase when training L2L with multiple GPUs, which is discussed next.

Multi-GPU in single DGX-2. We further perform model scale tests with 4 and 16 GPUs in a single DGX-2 node, respectively. As shown in Figure 7, the maximum trainable model size stays the same for PyTorch, L2L and SwapAdvisor, because all of them do not handle memory redundancies in data parallelism. As a result, their scalability is bounded by the model scale on a single GPU. Both Megatron and ZeRO-2 support large model training with more GPUs, but they cannot scale efficiently beyond 15B parameters, even with 16 GPUs. Megatron supports larger models than ZeRO-2, because ZeRO-2 still incurs memory redundancies on model weights. On the other hand, ZeRO-Offload easily enables training of up to 70B parameter models by partitioning and offloading optimizer states and gradients to CPU memory

combined with model parallelism. Overall, ZeRO-Offload increases the model scale on a single DGX-2 node by 50X, 4.5X, 7.8X, and 4.2X than using PyTorch, Megatron, ZeRO-2, and L2L, respectively.

6.2.2 Training Throughput

Single GPU. Next, we compare the training throughput of SwapAdvisor, L2L and ZeRO-Offload, for models with billion-scale parameters, on a single GPU. We do not include Megatron and ZeRO-2 in this comparison, because both of them cannot train models bigger than 1.4B parameters due to OOM. We evaluate SwapAdvisor, L2L and ZeRO-Offload with the same training batch size (e.g., 512) and same micro-batch sizes (shown in table 3), with gradient accumulation enabled. We also disable delayed parameter update in this experiment so that the comparison is only from the system efficiency perspective. We evaluate the performance improvement and its impact on the convergence of delayed parameter update in Section 6.2.4.

Figure 8 shows that ZeRO-Offload outperforms SwapAdvisor by 23% (up to 37%) in training throughput. SwapAdvisor relies on genetic algorithm to make tensor swapping decision, which takes hours to find an optimal tensor swapping solution in terms of maximizing the overlapping of computation and tensor swapping. Before getting the optimal tensor swapping solution, SwapAdvisor tries random tensor swapping solutions and hurts training performance.

Figure 8 shows that ZeRO-Offload outperforms L2L by 14% on average (up to 22%) in throughput (TFLOPS). The performance benefit of ZeRO-Offload comes from the following two aspects. First, ZeRO-Offload has a lower communication cost between CPU and GPU than L2L. For a model with M parameters, L2L requires $28M$ data communication volume between GPU and CPU, which is a sum of the weights, gradients, and optimizer states of each layer of the model. As analyzed in Sec. 4.1, the communication volume between CPU and GPU memory in ZeRO-Offload is $4M$, which is 7x smaller than L2L. The reduced communication volume significantly mitigates the bottleneck from CPU-GPU communication. Second, compared with L2L, the parameter update of ZeRO-Offload happens on CPU instead of GPU, but our optimized CPU-Adam implementation achieves a quite comparable parameter update performance than the PyTorch Adam implementation on GPU (evaluated in Sec. 6.2.4). Therefore, although the optimizer update on GPU in L2L is slightly faster than the optimizer update on CPU in ZeRO-Offload, the communication overhead introduced by L2L leads to an overall slower throughput than ZeRO-Offload.

Multi-GPU in single DGX-2. Next, we compare the training throughput of PyTorch, ZeRO-2, Megatron, ZeRO-Offload without model parallelism (w/o MP), and ZeRO-Offload with model parallelism (w/ MP) in one DGX-2 node. When using MP, we use a MP degree that gives the best performance

for both baseline and ZeRO-Offload. We use a total batch size of 512 for all the experiments using a combination of micro-batch per GPU and gradient accumulation. To get the best performance for each configuration, we use the largest micro batch that it can support without OOM. We exclude L2L [29] in this test because its implementation does not support multi-GPU training.

Figure 10 shows the throughput per GPU results when training on multiple GPUs. We make the following observations:

- For 1B to 15B models, ZeRO-Offload achieves the highest throughput and has up to 1.33X, 1.11X, 1.64X higher speeds than PyTorch, ZeRO-2, and Megatron, respectively. By offloading all the optimizer states to CPU with low overhead, ZeRO-Offload can train with larger micro-batch sizes giving higher throughput.
- ZeRO-2 runs out of memory once the model size is beyond 8B due to lack of enough aggregated GPU memory to store the model states on 16 GPUs. Instead, ZeRO-Offload scales to 13B, without model parallelism because it offloads optimizer states and the majority of gradients to CPU memory.
- When combined with model parallelism, ZeRO-Offload enables training up to 70B parameter models with more than 30 TFLOPS throughput per GPU. In contrast, Megatron supports only up to 15B parameter models before running out of memory, using just model parallelism.
- Compared ZeRO-Offload with ZeRO-2 and Megatron, ZeRO-Offload outperforms ZeRO-2 and Megatron in throughput for 1–8B and 1–13B parameter models, respectively. ZeRO-Offload is faster than Megatron, because it eliminates frequent communication between different GPUs and can train with larger micro batch sizes. ZeRO-Offload outperforms ZeRO-2 also due to larger micro batch sizes.

6.2.3 Throughput Scalability

We compare the throughput scalability of ZeRO-2 and ZeRO-Offload³ on up to 128 GPUs in Figure 11 and make the following key observations: First, ZeRO-Offload achieves near perfect linear speedup in terms of aggregated throughput (green line) running at over 30 TFlops per GPU (blue bars). Second, from 1 to 16 GPUs, while ZeRO-2 runs out of memory, ZeRO-Offload can effectively train the model, turning the model training from infeasible to feasible. Third, with 32 GPUs, ZeRO-Offload slightly outperforms ZeRO-2 in throughput. The improvement comes from additional memory savings on GPU from ZeRO-Offload, which allows training the model with larger batch sizes that lead to increased GPU computation efficiency. Fourth, with more GPUs (such as 64

³We do not include comparison against Megatron because it consistently performs worse than ZeRO-Offload, as shown in Figure 10. Given the communication overhead added by model parallelism, scaling out Megatron training can not achieve higher throughput than ZeRO-Offload even with linear scalability.

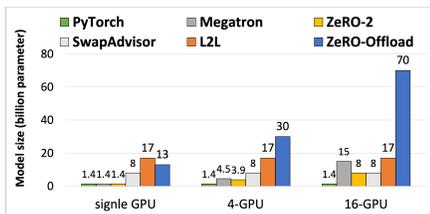

Figure 7: The size of the biggest model that can be trained on single GPU, 4 and 16 GPUs (one DGX-2 node).

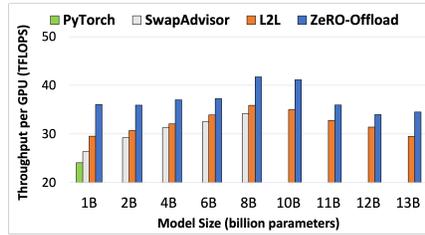

Figure 8: The training throughput with PyTorch, L2L, SwapAdvisor and ZeRO-Offload on a single GPU with a batch size of 512.

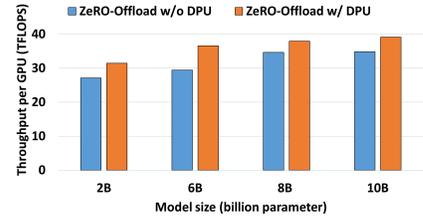

Figure 9: The training throughput is compared for w/o DPU and w/ DPU to GPT-2. Batch size is set to 8.

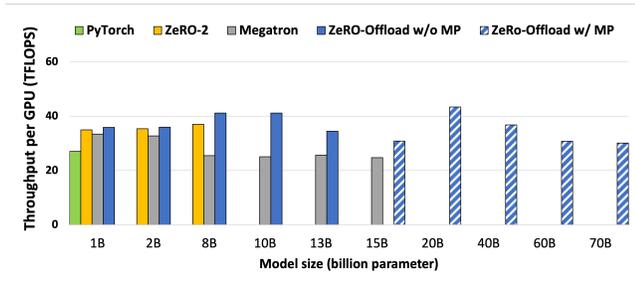

Figure 10: Training throughput with PyTorch, ZeRO-2, MegatronLM, ZeRO-Offload without model parallelism and ZeRO-Offload with model parallelism.

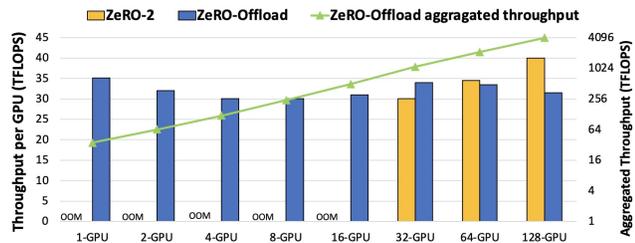

Figure 11: Comparison of training throughput between ZeRO-Offload and ZeRO-2 using 1–128 GPUs for a 10B parameter GPT2.

and 128), ZeRO-2 starts to outperform ZeRO-Offload, because both can now run similar batch sizes, achieving similar computation efficiency, whereas ZeRO-2 does not suffer from the additional overhead of CPU-GPU communication. In summary, ZeRO-Offload complements ZeRO-2 and enables large model training from a single device to thousands of devices with good computation efficiency.

6.2.4 Optimized CPU Execution

A. CPU-Adam efficiency. In this part, we evaluate our Adam implementation against the PyTorch Adam on CPU. Table 4 shows the optimizer execution time of the two implementations for model parameters from 1 to 10 billion. Compared to PyTorch (PT-CPU), CPU-Adam reduces the execution time by over 5X for all the configurations and 6.4X

for the case with 1B parameters. The CPU-Adam optimizer achieves high speedups by exploiting the instruction-level parallelism, thread-level parallelism, and the tile-based data copy scheme (as shown in line 15 of Algorithm 1). Meanwhile, although CPU-Adam has a slower speed than the PyTorch Adam implementation on GPU (PT-GPU), the performance gap is not very huge, and the CPU computation is not a bottleneck of the training throughput.

B. One-step Delayed parameter update (DPU). Figure 9 shows the comparison of the training throughput of GPT-2 with and without DPU. As shown, with DPU enabled, the training achieves 1.12–1.59, updated times higher throughput than without it, for a wide range of model sizes for a small micro batch size of 8. This is expected because DPU allows the optimizer updates to overlap with the next forward computation such that the GPU does not have to be slowed down by the CPU computation and CPU-GPU communication. But, what about accuracy?

Convergence impact We study the convergence impact of DPU on both GPT-2 and BERT. Figure 12 shows the pre-training loss curves over 100K training iterations using PyTorch (unmodified GPT-2), and Figure 13 shows the loss curves of fine-tuning Bert-large model on SQuAD using ZeRO-Offload without DPU, and ZeRO-Offload with DPU. In both cases, DPU is enabled after 40 iterations allowing the training to stabilize in its early stage before introducing DPU.

We observe that the training curves of the unmodified GPT-2 and ZeRO-Offload w/o DPU are exactly overlapped, because ZeRO-Offload w/o DPU performs only system optimizations and does not alter training dynamics. On the other hand, the training curve from ZeRO-Offload with DPU converges slightly slower at the very beginning of the training (e.g., barely can be seen at 2K-5K iterations) and quickly catches up after 5K iterations. For the remaining of the training, the training loss matches the original training until the model converges.

For Bert-Large fine-tuning, we can see that although the training losses are not exactly the same, they converge in the same trend and are largely overlapped. Without changing any hyperparameters, ZeRO-Offload + DPU achieves the same

Table 4: Adam latency (s) for PyTorch (PT) and CPU-Adam.

#Parameter	CPU-Adam	PT-CPU	PT-GPU (L2L)
1 billion	0.22	1.39	0.10
2 billion	0.51	2.75	0.26
4 billion	1.03	5.71	0.64
8 billion	2.41	11.93	0.87
10 billion	2.57	14.76	1.00

final F1 score (92.8) as the baseline. From these results on both GPT-2 pretraining, and Bert-Large fine-tuning, we empirically verify that DPU is an effective technique to improve the training throughput of ZeRO-Offload without hurting model convergence and accuracy. The 1-step staleness introduced by DPU is well tolerated by the iterative training process once the model has passed the initial training phase.

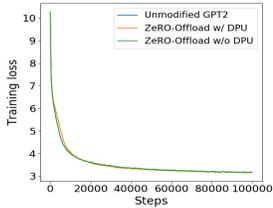

Figure 12: The training loss curve of unmodified GPT-2, ZeRO-Offload w/o DPU and ZeRO-Offload with DPU.

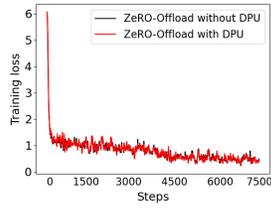

Figure 13: The fine-tuning loss curve of BERT, ZeRO-Offload w/o DPU and ZeRO-Offload with DPU.

6.2.5 Performance Breakdown and Analysis

To better understand the performance benefit from offload strategies and optimization techniques in ZeRO-Offload, we evaluate the training throughput of PyTorch, ZeRO-Offload with PT-CPU, ZeRO-Offload with CPU-Adam (refer as ZeRO-Offload), and ZeRO-Offload with DPU. We perform the evaluation with various batch sizes with 1-billion GPT-2 model on a single GPU. Figure 14 shows the result.

From batch size 1 to 8, PyTorch outperforms ZeRO-Offload with PT-CPU by 16% on average. This is because when the model can fit on GPU memory, PyTorch does not incur any communication overhead. Meanwhile, PyTorch adopts PyTorch GPU Adam (PT-GPU) for optimizer computation on GPU. To reduce the performance loss because of communication and optimizer computation on CPU, ZeRO-Offload optimizes execution on CPU. (1) By optimizing CPU optimizer, ZeRO-Offload implements CPU-Adam and improves the performance by up to 10% compared with using offload strategy only (i.e., ZeRO-Offload with PT-CPU). (2) PyTorch outperforms ZeRO-Offload by 8% on average when the model can fit on GPU memory. As shown in table 4, the performance gap between CPU-Adam and PT-GPU is not very large. Therefore, the performance degradation from PyTorch

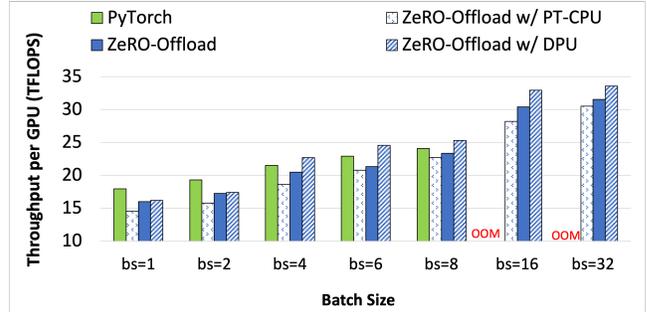

Figure 14: Comparison of training throughput with enabling offload strategies and optimization techniques step-by-step in ZeRO-Offload.

to ZeRO-Offload in Figure 14 are mainly coming from tensor migration overhead between GPU and CPU memory. (3) ZeRO-Offload further introduces one-step delayed parameter update, which overlaps computation on CPU with computation on GPU and improves performance by 7% compared with using ZeRO-Offload without DPU. In summary, leveraging optimized CPU execution, ZeRO-Offload has similar performance as PyTorch when ZeRO-Offload and PyTorch training with the same batch size on GPU.

As the batch size increases, out-of-memory on GPU memory happens in training with PyTorch. The training throughput increases in ZeRO-Offload as the batch size increasing. With unique optimal offload strategy, ZeRO-Offload outperforms PyTorch by 39% for the maximum training throughput that can be achieved on a single GPU with 1-billion model.

7 Conclusions

We presented ZeRO-Offload, a powerful GPU-CPU hybrid DL training technology with high compute efficiency and near linear throughput scalability, that can allow data scientists to train models with multi-billion parameter models even on a single GPU, without requiring any model refactoring. We open-sourced ZeRO-Offload as part of the DeepSpeed library (www.deepspeed.ai) with the hope to democratize large model training, allowing data scientist everywhere to harness the potential of truly massive DL models.

Hashing Linearity Enables Relative Path Control in Data Centers

Zhehui Zhang¹, Haiyang Zheng², Jiayao Hu², Xiangning Yu², Chenchen Qi², Xuemei Shi², Guohui Wang²
¹University of California, Los Angeles, ²Alibaba Group

Abstract

A data center network is an environment with rich path diversity, where a large number of paths are available between end-host pairs across multiple tiers of switches. Traffic is split among these paths using ECMP (Equal-Cost Multi-Path routing) for load balancing and failure handling. Although it has been well studied that ECMP has its limitations in traffic polarization and path ambiguity, it remains the most popular multi-path routing mechanism in data centers because it is stateless, simple, and easy to implement in switch ASICs.

In this paper, we analyze the ECMP hash algorithms used in today's data center switch ASICs, aiming for lightweight path control solutions that can address the ECMP limitations without any changes to existing data center routing and transport protocols. Contrary to common perceptions about the randomness of ECMP hashing, we reveal the linear property in the hash algorithms (e.g. XOR and CRC) used in widely deployed switch ASICs in data centers. Based on the hashing linearity, we propose relative path control (RePaC), a new lightweight, and easy-to-deploy path control mechanism that can perform on-demand flow migration with deterministic path offsets. We use a few case studies to show that RePaC can be used to achieve orders of magnitude faster failover and better path planning with up to 3 times link utilization gain in hyper-scale data centers.

1 Introduction

To support the high bandwidth and high availability requirements of cloud and big data applications, data center networks are often designed with rich path diversity. Typical data center network topologies, such as FatTree [1], Clos [10], or Hyper-Cube [16], offer hundreds of paths across multiple tiers of switches between any pair of servers. In such a multi-path network, managing a large number of paths among all end-point pairs is challenging. The path selection mechanism is always a key part of data center network design to fully utilize the high bandwidth from these paths and achieve good traffic load balance and fault-tolerance properties.

The multi-path IP routing protocol (e.g. BGP [27]) with ECMP [20] is the most common routing scheme in many production data centers [13, 26]. In such networks, reachable network prefixes and available paths are propagated to all the switches using BGP, and each switch uses ECMP to select a next hop based on the hash value from specified packet header fields. To understand the performance of ECMP-based routing, much research has been done. A common perception is that ECMP offers reasonable load balancing and fault tolerance among a large number of uniform flows, however, it is difficult to perform any explicit path control on ECMP because it is stateless, and its hashing calculation is random [18, 21, 46]. Besides, ECMP suffers from traffic polarization because it performs static load balancing based on header fields without considering flow sizes [2].

Many alternative path control mechanisms, such as Hedera [2], XPath [21] and Multi-path TCP [36, 37], have proposed to redesign routing and transport layers to better leverage the path diversity. However, these proposals often require a redesign in either the server network stack or routing protocol of data center switches. As a result, although these proposals offer many advantages over ECMP on dynamic load balancing and precise path control, they have seen very limited deployment in today's production data centers. For the path selection mechanism, ECMP remains the common practice because it is stateless, simple, and easy to implement in switch ASICs.

In this work, we take a different approach to address the ECMP limitations in load balancing and failure handling. Given the wide deployment of BGP with ECMP routing, we look for solutions that require minimal changes to server software stack and data center routing protocols. Instead of treating ECMP as a random path selection black-box, we analyze the ECMP path selection process and investigate typical hash algorithms used in the most popular data center switch ASICs on the market. Our study reveals that most widely-deployed switches use XOR, CRC or their variants for ECMP hashing. These hash algorithms hold a linear property ($ECMP(a) \oplus ECMP(b) = ECMP(a \oplus b) \oplus ECMP(0)$),

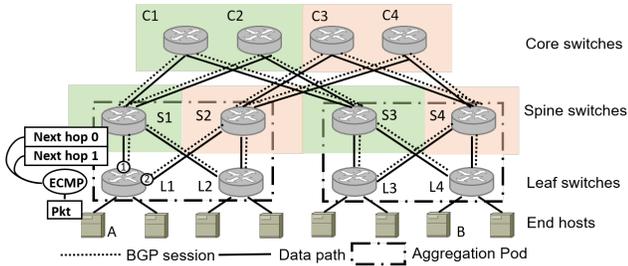

Figure 1: A Clos-based data center network topology

which guarantees a deterministic mapping between packet header changes and path changes. We analyze how hashing linearity affects traffic load balance and how the hashing linearity can be used to control the flow paths to better leverage the path diversity.

We propose a relative path control (RePaC) scheme, which uses the deterministic mapping between the header change and path change to perform on-demand flow migration for failure handling and load balancing. We validate the hashing linearity and relative path control scheme on a testbed with the same ECMP configuration as our production data centers. Our evaluation shows that RePaC can achieve fast failover and better traffic engineering for TCP and RDMA applications. With RePaC, failover speeds up by orders of magnitude compared with existing in-network failover approaches. RePaC also outperforms MPTCP with 2(4) subflows in recovery success rate by 36%(21%). In addition, RePaC-based traffic engineering reduces flow completion time by up to 25% and improves link utilization by up to three times. Proven to be simple and effective, RePaC can be readily deployed in production data centers with no changes required in the routing and transport protocols.

As far as we know, our work is the first study that investigates the linear property of ECMP hash algorithms and discusses its applications to data center path control. We show the feasibility of leveraging the hash algorithm properties to develop flexible path control algorithms for load balancing and failure handling, which contradicts the common perception about the randomness and ambiguity of ECMP path selection. The resulting solution RePaC is lightweight, easy to deploy in production data centers, and easy to integrate with a large spectrum of applications. Our work sheds light on a new perspective of multi-path routing, traffic engineering and application design in data centers.

2 Background and Motivation

2.1 Data Center Networking Primer

Most data center networks adopt some variant of a multi-rooted tree topology. Figure 1 shows an example of a Clos-structured data center network with three tiers of switches, which provides abundant paths between any pair of servers to

achieve high aggregated bandwidth and tolerate potential link and device failures. To better utilize the available paths in the network, multi-path routing is the key part of the data center network design, with load balancing and fault tolerance as two primary design goals.

Multi-path BGP with ECMP is the most common multi-path routing design in hyperscale data centers [27]. In this design, switches establish BGP sessions among each other over the connected links and choose next hops based on BGP routing information. Multiple equal-cost next hops are grouped as ECMP groups when routes are installed into the routing table in the switch ASIC. When a packet reaches a switch, a random next hop will be selected in the ECMP group, so flows can be evenly distributed among parallel links for load balancing. As shown in Figure 1, if a packet is being sent to switch L3 via switch L1, the BGP session running on L1 will first decide all equal-cost next hops, S1 and S2. In ECMP, each switch distributes packets based on a hashing value calculated from specific packet header fields. ECMP would select one from S1 and S2. If ECMP distributes flows to S1 and S2 evenly, load balancing is fulfilled. To support failover, the in-network BGP sessions send keepalive messages to detect whether the link is still available. In case of failure, BGP tears down the session of the malfunctioning link, and the corresponding next hop is removed from ECMP. Therefore ECMP is critical for both load balancing and failure handling in data center networks.

2.2 The Limitations of ECMP

Many previous studies have shown that ECMP has several key limitations in practice. First, ECMP fails to leverage the path diversity in a lot of scenarios. Hedera [2] shows ECMP may cause significant bandwidth loss when flows are not evenly distributed. The situation becomes worse when large and long-lived flows co-exist. Second, ECMP distributes traffic using random hash algorithms, which makes it difficult to perform precise path control. A lot of fine-grained flow scheduling and traffic engineering mechanisms cannot be done in data center networks over ECMP [5, 21].

Due to the aforementioned limitations, a common perception of ECMP is that ECMP provides decent load balancing among a large number of flows evenly distributed across a large header space. However, ECMP works under strong assumptions about traffic patterns, and it may fail in many cases with traffic polarization, slow failover, and under-utilized links. And it is difficult to perform deterministic path control because ECMP path selection is random.

Several previous studies have proposed alternative solutions to address the limitations of ECMP from both routing and transport layers. For example, Hedera [2] is proposed to perform dynamic flow scheduling based on a traffic matrix using OpenFlow. XPath [21] proposes to enable explicit path control for data center applications using pre-installed routes. FUSO [8] proposes a multi-path loss recovery mechanism

on MPTCP to enable fast failure recovery in data centers. However, these solutions require major redesigns of the data center routing protocol or server network stacks. And major redesigns of routing and transport protocols have huge impacts on the data center applications and daily network operations. As a result, these solutions still have very limited deployment in today’s production data centers.

ECMP still has wide deployment in many production data centers for multi-path routing, however, the implementation of the ECMP hashing mechanism remains a mystery for the research community. There isn’t a thorough analysis of the details of the ECMP mechanism on popular data center switch ASICs. Volur [47] is the only study we have seen, which tries to model ECMP as a deterministic mapping from headers to paths. It aggregates all the mappings from all switches and uses model replay to predict ECMP path selection. However, Volur still treats ECMP as a black-box model, and a full network model replay incurs too much overhead for real-time traffic engineering and path control in large data centers.

This dilemma of path control in data centers motivates us to dig into the black-box of ECMP implementation of widely-deployed data center switches and look for lightweight solutions to address the ECMP limitations. Such solutions can be incrementally deployed to a large volume of existing data centers and benefit data center applications without a major redesign of the network. We explore the factors that affect ECMP path selection and reveal an interesting property, linearity of hash algorithms used by most merchandise switch ASICs, which could be used to enable a new relative path control scheme.

3 Demystifying ECMP Path Selection

Our analysis of ECMP path selection is based on the ECMP implementation of popular switch ASICs available on the data center switch market. We look into the publicly available open source repositories and documents about the ECMP implementation on widely deployed switch ASICs [6, 12, 31, 33]. We also investigate the ECMP configurations from the widely-adopted open switch abstraction interface (SAI) [34], which is supported by most switch ASIC vendors, such as Broadcom, Barefoot, CISCO, Mellanox, and Marvell [29]. We consider the variations of ECMP implementations [20, 32, 38] and validate our analysis with commercial switches. Specifically, our validation covers Broadcom Tomahawk series, Trident series, and Barefoot Tofino series [7].

3.1 Modeling ECMP Path Selection

ECMP is typically implemented as part of the routing table matching stage in the switch ASIC pipeline. When multiple routes are available for a given network prefix, equal-cost next hops are added into an ECMP group in the routing table. When a routing table entry is matched for an incoming

packet, the packet will be forwarded to one of the next hops in its ECMP group, based on the hashing of the packet header fields [33].

Figure 2 shows a general ECMP processing model from typical switch ASICs. The input of ECMP is header fields, and the output is a next hop ID. There are four stages in ECMP processing: pre-processing, hashing, post-processing, and bucket mapping. We use the following functions to denote the ECMP stages: $Pre_proc()$, $Hash()$, $Post_proc()$, $Bucket_B^N()$. The overall ECMP processing can be described as:

$$ECMP(h) = Bucket_B^N(Post_proc(Hash(Pre_proc(h)))) \quad (1)$$

where the hash function plays a key role in path selection.

In the $Pre_proc(h)$ stage, the H -bit input packet header fields h , with range $\{0, 1\}^H$, together with a configurable hash seed are processed using bit-wise operations, such as AND, XOR, shifting and masking. For example, if we use source and destination IP addresses and port numbers as input, H would be 96. Then $Hash()$ denotes the hash function from $\{0, 1\}^I$ to $\{0, 1\}^O$, where I is the length of the pre-processed input and O is the length of the output hash result, both in number of bits. O is usually 32 or 16 since most switches use 32-bit or 16-bit values to represent hash results [12, 31]. In the $Post_proc()$ stage, the hash result is further shuffled using bit-wise operations. Then $Bucket_B^N()$ performs modulo operations to map the post-processed hash result $\{0, 1\}^O$ to one of the next hops in the ECMP group $\{0, \dots, N - 1\}$ placed in B hash buckets, where N is the number of next hops. The entire ECMP process is a mapping from $\{0, 1\}^H$ to a number in $\{0, \dots, N - 1\}$.

3.2 The Linearity of ECMP Process

In this section, we discuss the linear property of the most common ECMP hash functions, and how linearity impacts the path selection.

Hash functions overview: The commercial switch ASICs support various hash functions for ECMP, such as random, XOR, CRC and Pearson hashing [11, 24, 31]. Among them, CRC and XOR are two popular hash algorithms defined in SAI [34], and supported by most switch vendors [29]. There are two reasons that CRC and XOR are widely adopted. These two algorithms have been used in communication systems with mature and efficient ASIC implementation, which includes plenty of circuit optimization [31, 42, 45]. In addition, previous analysis has shown that CRC and XOR algorithms have good load balancing performance given a uniform distribution of flows [49].

The SAI [34] also cites the random hash algorithm, but it is not commonly used in the ECMP implementation of modern switches. The reasons are twofold. First, packet-level random path selection will result in a nightmare in network monitoring

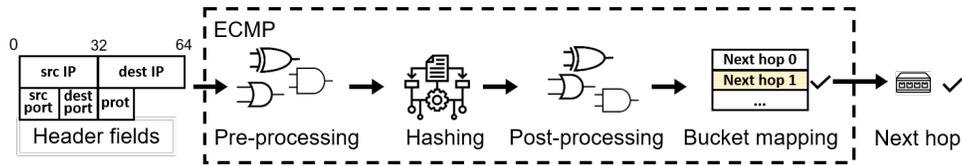

Figure 2: An example of an ECMP packet processing pipeline: pre-process certain header fields, hash and post-process the hash results to get bucket number two, then refer to the bucket for the next hop ID

and troubleshooting. Second, packets from the same flow need to be hashed onto the same path to avoid the out-of-order issues that affect end-to-end transport performance. There are other hash algorithms that are not included in SAI, such as Pearson hashing, which are proprietary of a specific switch ASIC vendor. In this paper, we will focus on the properties of the most common hash functions using CRC and XOR.

The linearity of hash functions: We define the hashing linearity as follows: a hash function is linear, if

$$\text{Hash}(h_i) \oplus \text{Hash}(h_j) = \text{Hash}(h_i \oplus h_j) \oplus \text{Hash}(0) \quad (2)$$

where h_i and h_j are arbitrary packet headers, and $\text{Hash}(0)$ is the hash result for a packet with all 0's, which is a constant given the initial hashing seed. Both XOR and CRC hashing satisfy hashing linearity. The detailed proof of CRC/XOR hash linearity can be found in supplemental materials [48].

Insight: If the linear hash function is fixed, for any packet header h_i , the hash value after a relative change Δ on the original header fields is deterministic, i.e. $\text{Hash}(h_i \oplus \Delta) = \text{Hash}(h_i) \oplus \text{Hash}(\Delta) \oplus \text{Hash}(0)$. In other words, as long as we know the mapping from Δ to $\text{Hash}(\Delta)$ and $\text{Hash}(0)$, we can predict the relative hash value change.

The linearity of $\text{ECMP}()$: We prove the linearity of ECMP by proving the linearity of the other three procedures $\text{Pre_proc}()$, $\text{Post_proc}()$, and $\text{Bucket}_B^N()$. The pre-processing and post-processing functions are bit-wise operations used to shuffle certain fields of the packet header or hash result to cope with hash polarization [20, 24, 31]. Hash polarization would cause load imbalance when hashing results favor certain buckets over others. Pre-processing usually uses bit-wise operations such as AND, XOR, bit shifting and masking. Post-processing uses XOR-folding of 32-bit hash results to get a 16-bit result [38]. Our analysis shows that these bit-wise operations in pre-processing and post-processing functions do not affect the linear property of ECMP path selection. The detailed proof can be found in supplemental materials [48].

Linearity also holds for the $\text{Bucket}_B^N()$ function if N and B are both powers of two, which is expected if a fat-tree topology is used. Then the modulo operation is equivalent to a bit-wise shifting, which is proved to be linear. There are two scenarios in which linearity does not apply for ECMP. The first scenario is that the next hop ID of the Bucket is randomized. However, we can reorder buckets based on the next hop ID after bucket mapping updates, which is commonly adopted for consistent hashing. The second scenario is that the number of buckets is not a power of two 2^k , where k is an integer. The number of buckets depends on the topology.

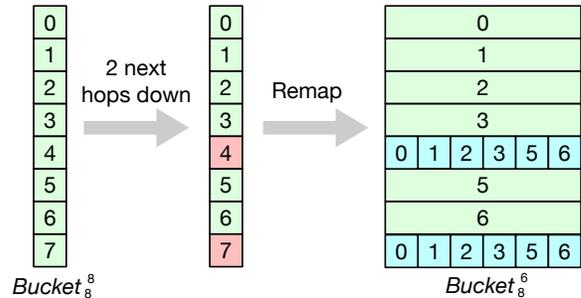

Figure 3: Consistent bucket mapping upon 2 link failures. Buckets of failed hops are remapped to 6 virtual entries.

Table 1: Probability of different failure scenarios with various # of failed links and probability that linearity holds (\mathbb{P}) under various link failure ratios σ ($B = 8$)

# failed links	0	1	2	3	\mathbb{P}
$\sigma=1\%$	92.2%	7.45%	0.26%	0.005%	99.68%
$\sigma=0.1\%$	99.2%	0.79%	0.003%	$< 10^{-9}$	99.90%
$\sigma=0.01\%$	99.9%	0.08%	$< 10^{-6}$	$< 10^{-10}$	99.99%

If a fat-tree topology is used, the number of buckets is 2^k . If the data center adopts a variation of a fat-tree topology, each switch can enable consistent hashing by adding virtual nodes to make the bucket number as 2^k [33].

Thus we have

$$\text{ECMP}(h_j \oplus \Delta) = \text{ECMP}(h_i) \oplus \text{ECMP}(\Delta) \oplus \text{ECMP}(0) \quad (3)$$

where h_i and h_j are arbitrary packet headers, $\text{ECMP}(0)$ is the output given an all 0's header, a constant for a given ECMP configuration.

Linearity upon link and device failures: In the case of link and device failures, the number of next hops N varies and may not always be a power of two, which breaks the linearity of the whole ECMP process. We leverage consistent hashing and bucket remapping to guarantee linearity for most links in the ECMP group. We illustrate our ideas with an example with two link failures. In the case of failures, for example both next hop 4 and 7 fail as shown in Figure 3, removing two buckets (Bucket_6^8) will break linearity since 6 is not a power of two. If we keep these two buckets and simply adopt consistent hashing to remap these two buckets to two random available next hops, the load is imbalanced given 8 buckets are mapped to 6 hops. We thus remap these two buckets to 6 virtual entries and map these entries to available next hops uniformly as shown in Figure 3. Therefore, we can still

preserve the linearity for available links by fixing the hash bucket B as a power of two. The load balancing performance is equivalent to an ECMP table with size of the least common multiples of B and N . And the $Bucket_B^N()$ function can be modeled as follows:

$$Bucket_B^N() = Bucket_B^B() \text{ is down? } Bucket_N^N() : Bucket_B^B() \quad (4)$$

where $Bucket_B^B()$ holds linearity as B is a power of two. And the non-linear function $Bucket_N^N()$ is a modulo operation over N followed by a mapping from $\{0, \dots, N-1\}$ to all available next hop IDs.

As stated in [15], links and devices inside data center networks usually have four 9's of high availability. Before BGP updates bucket mapping upon the first link failure, linearity still holds since the output of $Bucket()$ remains the same. The linearity-based path control might fail upon more failures, but the probability is low. For example, the probability that more than 1 failure happens in the same ECMP group is only 41% [15]. We analyzed the probability that linearity holds under various link failure ratios as shown in Table 1. We consider the probability of occurrence with various numbers of failed links under different link failure ratios. Given F next hops removed due to failure links, $Bucket_B^N()$ holds linearity with a probability of $1 - F/B$. Based on our observation of 1%-0.01% failure rate σ in our production data centers of more than 1500 links, the probability that linearity holds is more than 99% even when link failures are considered. Here we assume link failures are independent. If we assume the probability of link failures under the same ECMP group is positively correlated, the probability of recovery decreases. However, according to previous studies [15] and our observations in our own data centers, the probability of concurrent failures in one ECMP group is low.

Validation: We validate linearity in commercial switches by checking whether Equation 3 holds. We configure the switch with 8 next hops. First, we generate 1 million packet headers with random IP addresses, port numbers, protocol field and reserved fields. For each header, we record the output of ECMP before and after adding the offset Δ , which are denoted as $ECMP(h_i)$ and $ECMP(h_i \oplus \Delta)$, where h_i are random packet headers and Δ ranges from 0 to $2^k - 1$ for a k bit field. We do the same for another random packet header h_j . Finally, as shown in Figure 4, by comparing whether $ECMP(h_i) \oplus ECMP(h_i \oplus \Delta) = ECMP(h_j) \oplus ECMP(h_j \oplus \Delta), \forall i, j$ holds, we verify that switches from Broadcom and Barefoot all satisfy the linearity. We also compare with different hashing seed configurations. The results show that linearity holds for different seed settings from 0 to $2^{32} - 1$. Linearity holds for validated vendors under XOR hashing, CRC hashing, and variants of XOR/CRC hashing (e.g. optimized hashing by concatenating COR hashing results and CRC hashing results). Besides the Broadcom and Barefoot switches that we validated in the paper, switches from 100+ platforms with SAI also support linear hashing [29, 34].

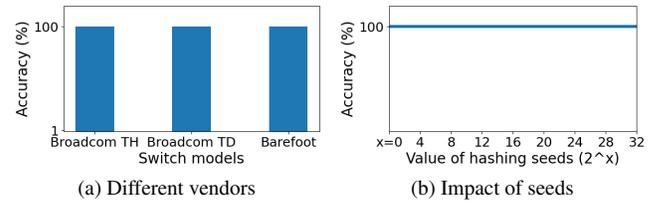

Figure 4: Validation with commercial switches. Accuracy of ECMP linearity-based prediction is 100% in different vendors and under selection of different seeds.

3.3 The Path Linearity

Our previous analysis has demonstrated the linearity of ECMP path selection at a single switch. In this section, we analyze the linearity behavior of ECMP in the multi-hop environment and discuss how the linearity can be used for path control.

Multihop linearity: In the multihop environment, a path is defined as a list of end hosts and switches, for example, $(A \rightarrow L1 \rightarrow S2 \rightarrow C3 \rightarrow S4 \rightarrow L4 \rightarrow B)$ is a path from the end host A to the end host B in Figure 1. In general, a path is modeled as $(sender, s_1, \dots, s_X, receiver), s_i \in \{0, \dots, N_i - 1\}$, where X is the number of hops, N_i is the number of equal-cost next hops at hop i , and s_i is the next hop ID chosen by hop $i - 1$. There can be one or more links between the end host and leaf switches.¹

We compile the path as the concatenation of the binary representation of next hop selections $Path(h) = s_1 \cdot s_2 \cdot \dots \cdot s_X$, where the sender and receiver are omitted. In a typical three-tier data center network, X is 5 for inter-pod traffic and 3 for intra-pod traffic, where a pod is an aggregation of leaf and spine switches as shown in Figure 1. Since ECMP decides the next hop at each switch, we have $s_i = ECMP_{s_{i-1}}(h), i = 1, \dots, X$. In order to calculate a path, we need the ECMP functions of all switches along the path. However, since we are only interested in the linearity, we aim to calculate $Path(h \oplus \Delta)$. As our analysis shows, the linearity $ECMP(h)$ holds at a single hop. For two hops $s_1 \cdot s_2$, concatenation of $s_1 = ECMP_{sender}(h)$ and $s_2 = ECMP_{s_1}(h)$ still satisfies $ECMP_{sender}(h \oplus \Delta) \cdot ECMP_{s_1}(h \oplus \Delta) = (ECMP_{sender}(h) \cdot ECMP_{s_1}(h)) \oplus (ECMP_{sender}(\Delta) \cdot ECMP_{s_1}(\Delta)) \oplus (ECMP_{sender}(0) \cdot ECMP_{s_1}(0))$ under the assumption that the selection of s_1 will not affect $ECMP_{s_1}(\Delta)$ and $ECMP_{s_1}(0)$. Note this assumption holds as long as switches in the same ECMP group are configured with the same hashing configuration. By the same methodology, we can prove the linearity for the concatenation of the entire path. Then we have

$$Path(h \oplus \Delta) = Path(h) \oplus Path(\Delta) \oplus Path(0) \quad (5)$$

¹ If there are several leaf switches to choose, the end host usually adopts Link Aggregation Control Protocol (LACP) to choose the next hop based on the hashing result of packet header fields like ECMP [4, 9]. Our analysis on ECMP linearity applies to LACP.

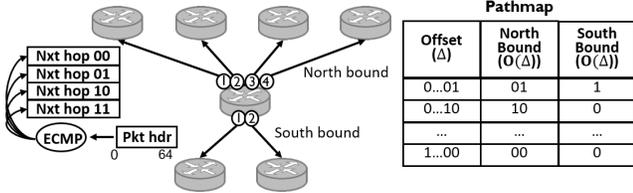

Figure 5: Illustration of pathmap. There are 64 offsets for a header space with 64 bits. Each row represents the path change $O(\Delta)$ for northbound and southbound with offset Δ .

Pathmap: Equation 5 suggests that with the linearity of ECMP path, given a relative change to an arbitrary packet header ($h \oplus \Delta$), we can predict the corresponding ECMP path change as $Path(h \oplus \Delta) = Path(h) \oplus O(\Delta)$, where $O(\Delta) = Path(\Delta) \oplus Path(0)$. This mapping relationship from Δ to $O(\Delta)$ can be modeled with a pathmap structure. As shown in Figure 5, we use a $K \times 2$ table to represent the pathmap of a single switch, where K is the number of bits used for path control, and each column corresponds with the northbound and southbound path offset $O(\Delta)$ for corresponding header offset Δ . If there are N hops, we need a $K \times N$ table. Here we use K entries since we can represent the entire header space by XORing Δ , where Δ are headers $0...010...0$ with only one significant bit. With this model, we compress the ECMP model exponentially from the header space 2^K . In most well-defined packet headers, the number of bits that can be used for path control is limited, which restricts the size of the pathmap.

Insights: Given the proven linearity, we can control the relative path change by changing certain header fields. This is feasible since hashing linearity is a built-in property for linear hashing algorithms. To extend hashing linearity to path linearity and improve accuracy upon link failure, we also need to adopt several ECMP hashing configurations, i.e. consistent hashing, bucket remapping and the same hashing configuration for the same ECMP group².

4 Relative Path Control

4.1 Design

Our analysis of the ECMP hash linearity suggests a deterministic mapping between the packet header changes and path changes. It provides a powerful tool to predict the relative path offset $O(\Delta)$ based on a packet header offset Δ .

We propose a relative path control algorithm, RePaC, based on the insight from hashing linearity. RePaC has two parts: offline pathmap collection and online path control. The offline pathmap collection module acquires the mapping from relative header change to the relative path change based on the static configuration of the network. The online module

²Supplemental materials [48] discuss a solution with relaxed requirements that allow different hashing seeds.

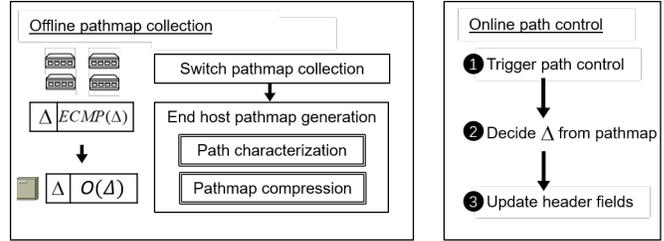

Figure 6: Relative Path Control Process

decides the header change accordingly and alters packets to navigate certain flows to a different path with deterministic offset. The overall procedure is shown in Figure 6.

Offline pathmap collection: In order to collect the pathmap for a switch as shown in Figure 5, we need to send the packets with reference headers with different offsets Δ to northbound and southbound egress ports on the switch. As introduced in Section 3.3, Δ is $0...010...0$ with a single significant bit, and the position of the significant bit ranges from 1 to K , where K is the number of controllable bits in the packet header. The pathmap of a switch depends on the static ECMP hash configuration. So to collect the pathmap for a whole data center network, we need to consider different hashing algorithms (e.g. XOR, CRC with different polynomials) and different hashing seeds. In production data centers, the switches in the same tiers of the network are often designed to use the same ECMP configurations for the simplicity of network management and operations. Then we only need to collect pathmaps for three types of ECMP hash configurations for a typical data center network in a 3-tier Clos topology. Note if the hashing algorithm is fixed, the mapping between the hashing seed and pathmap is deterministic, which reduces the overhead of collecting pathmaps from switches with different hashing seeds. The offline pathmap collection can be easily done on today's network management systems.

Online path control: The online path control module has two parts, the triggering function and the decision function. The triggering function is triggered when path control is needed, for example, upon failures. The decision function decides the path header offset. Users can design the decision function based on application requirements. We define a utility function $util(\Delta)$ for path control. The target of path control is $\hat{\Delta} = argmax(util(\Delta))$. For example, if the target is to change the path, we define $util(\Delta) = Path_changed(\Delta)$, where $Path_changed(\Delta)$ is a function to check whether applying header offset Δ could change the path. We showcase how to design the utility function in Section 4.2.

Based on the designed utility function, the pathmap can be reconstructed in different formats to facilitate searching for an offset for a specified relative path change. For example, a pathmap can be compressed into a hashmap with keys as desired path changes and values as all possible header offsets. For solutions that are not sensitive to the value of relative path change, for example, a failover solution that aims to use

a specific path change, the pathmap can be compressed to a list of desired header offsets that can lead to the desired path change. The structure of the pathmap is decided by the granularity of path control required by applications.

Another key question is which header fields to use for path control. Options depend on what user-defined fields are configured for ECMP hashing. By default, switches might only configure IP addresses and port numbers for ECMP hashing. Based on [28], SAI-supported switches can configure all header fields for hashing. Among all the fields, the high significant bits of TTL fields (8 bits) are typically usable since the number of hops in data centers is small. If switches do not support user-defined fields, the source port number (16 bits) can be leveraged though it might require changes of the port allocation. Besides, the source IP address can be controlled with certain flexibility in incast scenarios if there is a configurable DHCP server inside the pod to assign IP addresses dynamically.

4.2 The Applications of Relative Path Control

In this section, we present two case studies to demonstrate the applications of relative path control.

4.2.1 RePaC for fast failover

Leveraging relative path control, we design a lightweight and fast failover mechanism to detect path failures at the transport layer and update the packet headers to migrate the traffic from the failed path. Our approach relates to the previous end-host-based failure recovery [19, 23] but gives strong guarantees on path control with the ECMP hashing linearity and does not require any changes to the network protocols and switch hardware. We demonstrate a failover mechanism with TCP traffic as an example. The RePaC-based failover mechanism generally applies to any network transport layer protocol with a retransmission mechanism.

The RePaC-based fast failover involves retransmission-triggered failure detection and failure recovery by altering packet headers. It works as shown in Algorithm 1. Our algorithm detects the second retransmission of each flow to trigger failure recovery, then every packet in that flow will be marked for path control. We choose the higher four bits of TTL fields and TCP five tuples as input for $ECMP()$. In this case, we can vary the higher four bits of TTL fields, so Δ is in $\{0001, 0010, 0100, 1000\}$.

After failure recovery is triggered, we mark the reserved bits with a different value to reroute this packet to a different path. In theory, if the path offset $O(\Delta)$ is non-zero at each hop, we can ensure the new path $Path(h \oplus \Delta)$ has no overlapping links or devices with $Path(h)$, where h is the packet header of the flow affected by the failure. With RePaC, we can generate a path mapping table from all marking values to the

Algorithm 1 Failure recovery

Input: Packet p and corresponding flow f
Output: Packet p with $f.mark$ within path marking period.
 Otherwise, original packet p

- 1: **if** p is a repeated retransmission **then**
- 2: Update $f.mark = \text{SelectNextMark}(p)$
- 3: Begin path marking period
- 4: **end if**

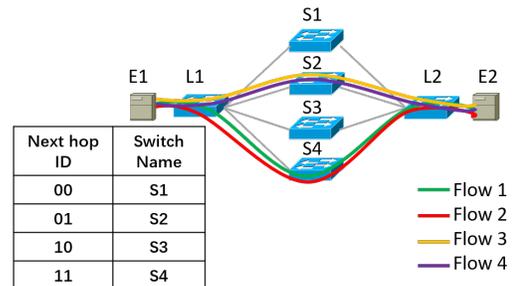

Figure 7: Example network. Flow polarization causes under-utilization of paths.

network path change, as illustrated in Figure 5. And we design the utility function as $util(\Delta) = Path_changed(\Delta)$, where $Path_changed(\Delta)$ is a simple function to check whether $O(\Delta)$ is non-zero for each hop, which indicates that the next hop selected at each hop would be different from the previous path. Then we use a subset of eligible Δ as marking values for fast failover purposes. If we cannot find an $O(\Delta)$ with all hops changed, we select the one with the most changes. RePaC will stop path marking after a configurable timer. We set the timer as the failure detection time in BGP. Path marking will be triggered again if BGP fails to recover the failure.

4.2.2 RePaC for traffic engineering

Given the multi-path nature of data center networks, traffic engineering, the ability to schedule traffic on many non-overlapped paths to better leverage the network bandwidth, has been a key part of data center network design [2, 5, 30, 37]. Compared to existing proposals, such as Hedera [2], MicroTE [5], and XPath [21], RePaC provides a lightweight tool for us to plan and distribute flows in data center networks for traffic engineering without any changes to the switch hardware and routing protocols.

Path planning using RePaC: Given the topology and ECMP configurations of the network, we derive the pathmap M , a map between each path offset $O(\Delta)$ and the corresponding header offset Δ , by sending probing packets with different Δ . Here we show an example for the network in Figure 7. We consider the lower 6 bits of src_port is controllable and probe every switch L1 for $O(\Delta)$ to get Table 2. Table 2 shows how changing a bit in src_port changes the selected hop ID. XORing all possible hop ID changes results in four different path offsets.

Table 2: Probed results. Six controllable bits generate six headers Δ , each with one significant bit. Then RePaC uses six headers to get $O(\Delta)$.

Δ	000001	000010	000100	001000	010000	100000
$O(\Delta)$	00	00	01	00	01	10

Table 3: Calculated $M = (O(\Delta), \Delta)$ for path planning. For each $\Delta = 0, \dots, 63$, RePaC calculates the Path ID.

$O(\Delta)$	0	1	2	3
Δ	0-3, 8-11, 20-23, 28-31	4-7, 12-19, 24-27	32-35,40- 43, 52-55, 60-63	36-39, 44-51, 56-59

We then derive all the possible header changes for each path offset $O(\Delta)$. For example, $\Delta = 000100 \oplus 100000$ is mapped to path offset $01 \oplus 10 = 11$. We index these path offsets as Path IDs to differentiate paths for path planning. Finally, We get the pathmap M as shown in Table 3, which is a map from Path ID $O(\Delta)$ to a set of Δ sharing the same path offset $O(\Delta)$.

From Table 3, we can observe that the selected Path IDs are limited to two choices for src_port values from 0 to 31. This means if E1 sends flows with src_port ranges from 0 to 31, ECMP will select only half of the next hops. We conjecture that only a subset of bits in the hash results are selected by the post-processing function for final ECMP resolution. This suggests that the default ECMP path selection could result in only half of the paths being utilized in the example scenario. Based on the pathmap M in Table 3, we can assign src_port values (e.g. $i, i \oplus 4, i \oplus 32, i \oplus 36$) for those 4 flows to ensure that all four possible paths are utilized.

Based on the analysis in Section 3.3, we can infer the path offset between two flows by looking up the Δ of their packet headers in the pathmap. Therefore, we can use a valid packet header h_{ref} as a reference, then for each $flow_i$, look up the desired path offset in the pathmap for unused Δ and assign $h_{ref} \oplus \Delta$ as packet header h_i . We plan the paths for all flows based on estimated loads as shown in Algorithm 2. In the example network of Figure 7, flows might conflict with each other according to default ECMP. With our algorithm, flows are evenly distributed on diverse paths. Note we can extend the algorithm to consider both the request load and the response load. The pathmap at the receiver can predict the path for response load.

5 Evaluation

5.1 Implementation and Test-Bed Setup

We implement RePaC as a library on the servers to perform on-demand path control. There are three components in the implementation, a pathmap collector that generates a pathmap database given a network, a module that monitors all outgoing

Algorithm 2 Load based path planning

Input: Pathmap M as illustrated in Table 3,

Output: assign a packet header h_i for $flow_i$ to minimize the deviation of bandwidth utilization L_p for each path

- 1: $h_{ref} \leftarrow$ a random valid packet header; $L_p \leftarrow 0$ for all paths
- 2: **for** $flow_i$; in all flows **do**
- 3: Find $\Delta \in M$ for Path ID p with the minimum load L_p
- 4: $h_i = h_{ref} \oplus \Delta$
- 5: $L_p +=$ estimated bandwidth utilization for $flow_i$
- 6: **end for**

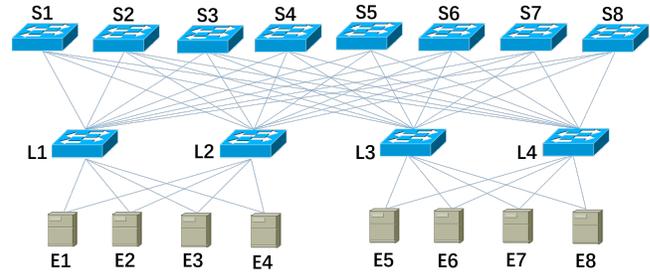

Figure 8: Test topology

traffic on servers to perform TCP failover, and a path planner application that generates the best paths for applications. We implement flow monitoring with the VNIC, which maintains a soft stateful flow table. For each TCP flow, RePaC checks for packet retransmissions and marks packets to perform traffic failover as discussed in Algorithm 1. The total software modules are implemented in 1066 lines of C code. The RePaC library is a lightweight software module that can be easily installed on servers.

We evaluate the performance of RePaC in a fat-tree topology as shown in Figure 8. In this testbed, all the links are 25Gbps. 8 spine switches (Broadcom Trident 3) interconnect 4 leaf switches (Broadcom Tomahawk 3). We run SONiC [35] (an open-source network operating system) on all switches and adopt different ECMP configurations at each tier to avoid traffic polarization. Four physical servers are connected to leaf switches L1 & L2, and another four are connected to L3 & L4. With each server connected to two switches, the server can still connect to another leaf switch if one fails. Each server is equipped with Linux 3.10 or Linux 4.19 and TCP NewReno. These settings are consistent with our production data center networks.

5.2 Effectiveness and Overhead

Path control upon link and device failures: We first evaluate the accuracy of path control under various failure scenarios. Link and device failures are injected based on failure statistics collected in production data centers during one week. We gauge the accuracy of path control by calculating the percentage that the selected path is the expected path. We test with various numbers of spine switches to validate the perfor-

Table 4: Accuracy of path control under failures

# of spine switches	4	8	16	32
RePaC w\o failures	100.0%	100.0%	100.0%	100.0%
RePaC w\ failures	97.0%	98.5%	99.24%	99.62%
Random w\o failures	25%	12.5%	6.3%	3.1%

mance under different network scales. As shown in Table 4, the accuracy increases with the number of spine switches since the proportion of failed links of total links decreases. As discusses in Section 3.1, RePaC can provide accurate path control for the first link failure if RePaC is triggered before BGP changes the bucket. But RePaC might not work at the first attempt if there are two and more link failures in the same ECMP group. Table 4 shows RePaC provides >97.0% accuracy while the random path selection can only provide <25% .

Overhead: We test the CPU overhead and the memory cost of RePaC with 1 thousand to 1 million concurrent connections. The average CPU cost on a 64-core processor is about 0.01% for 1k connections and 0.05% for 1m connections. Note that the performance of RePaC is independent of the kernel version because RePaC is lightweight and implemented in a portable VNIC module. At each server, we allocate about 64 bytes of extra memory for each connection to keep track of its state. We also evaluate whether RePaC reduces packet processing speed. RePaC looks up the flow table on every packet, checks packet sequence number, and updates the flow state accordingly. These bring a few extra memory accesses to the data path. We observe no degradation in packet processing speed with different workloads.

5.3 RePaC for Failover Evaluation

Experiment methodology: We study the failover performance of RePaC by measuring throughput and downtime under common failure scenarios. We run a high-priority application on the VNIC interface to collect throughput measurements at a 20ms interval, which also helps us determine the downtime upon failure. We consider two failure scenarios, silent drop failures and link failures. We simulate silent drop failures by configuring an ACL rule to discard the data traffic. We simulate link failures by issuing `ifconfig down` command to deactivate one of the interfaces from receiving and sending data from switch CLI. There are many existing studies on failover [19, 23, 43, 44, 50]. Among them, MPTCP is a fair baseline as an end-host-based mechanism. MPTCP employs a group of subflows with random paths for failover without adding any centralized controller or advanced hardware. We use MPTCP v0.90 with the redundant scheduler for comparison with RePaC. We test MPTCP with the redundant scheduler over the default scheduler since it provides better fault tolerance by sending redundant copies through all subflows.

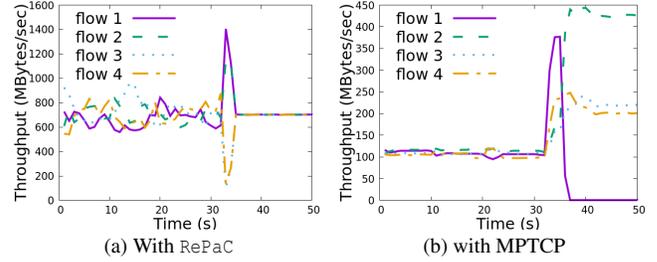

Figure 9: Throughput during failure

Failure recovery performance: We compare RePaC with both end-to-end and in-network failover design. Compared with end-to-end failover MPTCP, which recovers with a random backup path, RePaC provides better recoverability. Compared with in-network failover approaches, RePaC covers more failure types and reduces downtime by orders of magnitude.

We first compare RePaC with MPTCP in Figure 9. Figure 9a shows an example trace the silent drop on leaf switch L1 get recovered after silent drop failure with RePaC. Flow 3 and flow 4 are forwarded to L1 by ECMP and hence dropped by ACL. Both flows experience around 1 second of disruption and then are re-routed to switch L2. Flow 1 and flow 2 forwarded by switch L2 only experience oscillation. During the oscillation, the throughput of flow 1 and flow 2 first doubles when the other two flows stop transmission, then returns to similar throughput as before. All flows eventually share the bandwidth of the bottleneck link fairly with congestion control. Note that the bottleneck is the L3-E5 link, so the throughput before and after the failover are similar. In comparison, Figure 9b shows that MPTCP failover performance is unsatisfactory. We configure each flow with 4 subflows to increase the path diversity. Figure 9b shows that MPTCP can recover all affected flows except flow 1 because all subflows of flow 1 are dropped. The throughput of flows 2-4 increases after flow 1 is deactivated. Overall throughput performance with MPTCP is worse than RePaC since MPTCP with the redundant scheduler copies packets on all available subflows.

We further compare the failure recovery ratio between RePaC and MPTCP with different numbers of subflows for MPTCP. We define the recovery ratio as the probability that a flow affected by failure is recovered. As shown in Figure 10, MPTCP offers a higher recovery ratio with more subflows. Although MPTCP provides a reasonable recovery ratio with the redundant scheduler, RePaC performs better by leveraging path diversity with the pathmap. RePaC outperforms MPTCP with 2(4) subflows by 36%(21%). RePaC outperforms MPTCP because MPTCP cannot guarantee there exists at least a subflow unaffected by the failure.

We also compare RePaC with in-network failover mechanisms under various failure scenarios. As shown in Figure 11a, we start a single TCP flow from E1 to E5 and measure the downtime after simulating a device failure at L1. We simulate the device failure by deactivating all the interfaces. In prac-

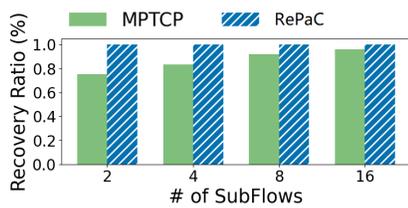

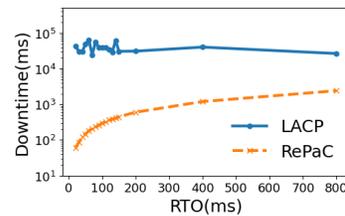

Figure 10: Recoverability comparison between RePaC and MPTCP.

tice, device failures might be triggered by hardware failure, unexpected reboot, or power loss. Although this type of failure can be detected by Link Aggregation Control Protocol (LACP) using heartbeat signals, it takes up to 90 seconds. In comparison, RePaC significantly reduces the downtime by orders of magnitude. Note the recovery Algorithm 1 initiates path control after the second TCP retransmission. Our solution performs better with a smaller minimum RTO. RePaC reacts to failures in around 60ms with a 20ms minimum RTO. Theoretically, RePaC can provide sub-ms recovery if the end hosts adopt high-resolution timers.

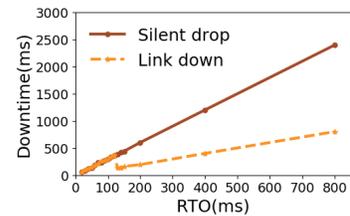

In Figure 11b, we evaluate how our solution can cooperate with the existing in-network failover approaches used in data centers, such as link scan, Bidirectional Forwarding Detection (BFD), LACP, and BGP. We compare the downtime caused by two types of failures, silent drop failures and link down events. For silent drop failures, our design can recover affected flows within three times of RTO, as shown in the solid line in Figure 11b. After a link down failure is injected, RePaC is triggered faster than in-network approaches when the second retransmission is triggered before the shortest in-network failover timers (130 ms for the link scan function). Note RePaC kicks in after around the triple of the minimum RTO. When the minimum RTO increases, RePaC will not be triggered since the link scan function would recover failures faster. In summary, Figure 11 proves RePaC can cooperate well with existing failover mechanisms and help to reduce the flow downtime.

5.4 RePaC for Traffic Engineering Evaluation

Experiment methodology: We gauge the performance of load balancing and flow completion time of RePaC compared with random path selection, precise path control via XPath [21], and in-network load balancing via CONGA [3]. We evaluate RePaC for load balancing under two scenarios: one-to-one flows and many-to-one incast flows. For one-to-one flows, we vary the *src_port* to vary the path selection of these parallel flows. For many-to-one incast flows, we vary *src_ip* and *src_port* for four servers under the same rack. We assume the source port number is flexible for traffic engineering applications. For many-to-one flows, we assume the source IP address is also assignable. We vary the least signifi-

Figure 11: Downtime comparison under various minimum RTOs

cant 8 bits of *src_ip* inside a cluster to improve path diversity. We test with three representative traffic patterns, same-size flows, webserver flows, and Hadoop flows. Webserver flows follow a uniform size distribution, and Hadoop flows follow a skewed size distribution [40].

Load balance performance: In Figure 12, we compare the bandwidth utilization of RePaC path planning with random path planning. The bandwidth utilization is measured using the average utilization ratio of the links in the network. For one-to-one flows, as seen in Figure 12a, RePaC increases the bandwidth utilization by up to 3 times when the total number of flows is 16. For many-to-one connection, Figure 12b shows the bandwidth utilization of links when flows of the same size from different sources are sent to a single destination. Our solution can evenly distribute the flows across different paths, achieving well-balanced bandwidth utilization. For the webserver case, as shown in Figure 12c, the bandwidth utilization increases from 0.54 to 0.99 using RePaC, compared to 0.34 to 0.85 with random selection as the number of flows increases from 16 to 4096. Figure 12d shows the bandwidth utilization for Hadoop with skewed flow size distribution. Both algorithms show low bandwidth utilization when the number of flows is small. When more flows join, RePaC can 20% to 50% better bandwidth utilization.

In Figure 13, we compare our solution with random path selection by measuring the load on each path when the number of concurrent flows increases from 16 up to 4096. Here we calculate the load at each path and plot the standard deviation over mean in Figure 13. As the number of flows increases, RePaC provides much better performance. For webserver traffic, the std./mean reduce by 58% to 97% as shown in Figure 13a. Our design tends to select a path with the least load for each flow. In Figure 13b, when the number of flows is greater than 64, the std./mean is reduced by more than 41%.

For time-sensitive applications, such as distributed file systems (DFS), flow completion time is crucial. We simulate DFS by sending 100GB of data from one host to another. We compare the completion time of all concurrent flows between RePaC and random path selection. RePaC can plan paths based on the traffic load, so elephant flows are distributed to separate paths. We notice that the average completion time of our solution is considerably less than the random path selection as shown in Figure 14a. When there are 16 flows, the comple-

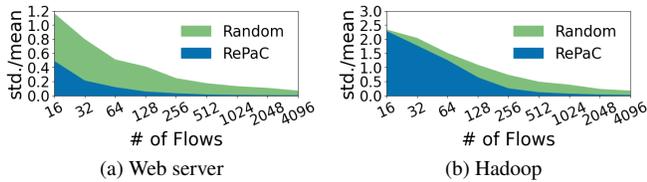

Figure 13: Load balance of path planning. The shading area shows the std./mean. of load on each switch. Larger shading area means load is more unbalanced.

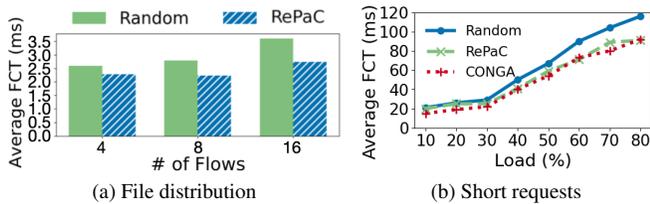

Figure 14: Flow completion time.

tion time reduces by 25% from 3.6 seconds to 2.7 seconds. Besides large file distribution, we also simulate short requests and gauge the flow completion time compared with random path selection and CONGA [3]. We use simulation since CONGA requires advanced hardware. Each host will inject flows with empirical traffic distributions of short requests into different queues based on the given path selection algorithm. CONGA will measure the queuing time of each path and choose the path with the least queuing time to send flowlets, thus performs best. RePaC tends to select the path with the least number of concurrent flows. As shown in Figure 14b, RePaC’s performance is comparable with CONGA.

Load balance performance under topology updates: The network topology might change if network devices are removed for maintenance or upgrade. In Figure 15, we compare the load balance performance between random path selection, RePaC, and XPath [21] when the network topology changes. Since XPath is based on source routing, which limits its deployment on our testbed, we use simulation with the same testbed topology. We simulate multiple concurrent flows between end-hosts and compare load balance by the standard deviation of the load on each available path. XPath relies on a centralized controller to perform topology updates, which, we assume, can provide accurate path estimation. As shown in Figure 15a, without topology updates, both RePaC and XPath distribute the flows evenly. After removing a spine

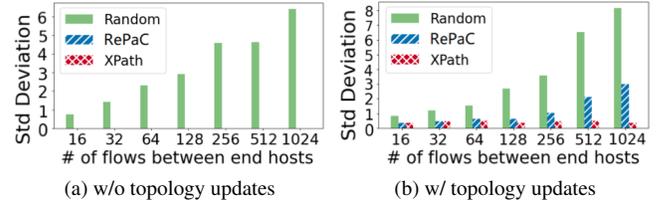

Figure 15: Load balance performance when topology changes

switch, as shown in Figure 15b, XPath can still balance the flows using accurate path information. RePaC can distribute most flows evenly on the unchanged paths using outdated pathmaps. In conclusion, XPath has the best performance leveraging pre-installed routes and real-time path information updates. RePaC degrades because of the outdated pathmap. However, both outperform the random path selection significantly. Compared with XPath, RePaC is a lightweight solution that significantly outperforms the random scheme without redesigning the routing protocols .

6 Discussion

Our work is the first study that performs a detailed analysis on the ECMP hashing linearity and its applications to path control in data centers. More work could be done to further explore the design of multi-path hashing mechanisms and their implications to data center networks.

ECMP configuration optimization: Our analysis has demonstrated that the properties of ECMP hashing algorithms have significant impacts on traffic engineering and failover in data center networks. However, ECMP configurations in today’s production data centers are still done by operators using ad-hoc approaches. Future investigations of ECMP might reveal other interesting properties rather than linearity, which could facilitate the data center network optimization and result in a more scientific approach to network-wide configuration optimization.

Flow analysis based on hash simulation: Analysis of the ECMP path selection algorithm also sheds insights on how flows are distributed. Using real-time network topology information, network operators could build a lightweight simulation network with the model of ECMP hashing behaviors. The simulation network can answer many what-if questions about the network performance and flow distributions, such as how many flows will be affected by certain failure events

or a congested link.

Programmable hashing on switch ASICs: Today’s data center switch ASICs provide limited interfaces to configure ECMP hash algorithms and parameters. Even on programmable switch ASICs (e.g. Tofino), where users can program the packet processing pipeline with network programming languages, there is still limited programmability to define ECMP hashing behaviors. Given that the hash algorithm could significantly impact the overall networking performance, a programmable interface that allows users to redesign the hash algorithms could lead to more innovations in this space.

RePaC capable applications: RePaC provides a lightweight mechanism for applications to predict and control the paths of packet flows in the network, without the requirements for deploying any new protocols, centralized controllers, or advanced hardware. Many applications can benefit from path diversity. For example, network probing tools, such as PingMesh [17], can guarantee full network coverage while minimizing the probing overhead with the help of pathmap. The same benefits apply to applications with low latency and high throughput requirements, such as distributed file systems or AI training clusters. RePaC provides a powerful tool for the applications to schedule flows to avoid traffic congestion and disruption.

RePaC and future ECMP: RePaC requires hashing linearity, which is a built-in feature for linear hashing algorithms. For future hashing algorithms, there is no conclusion on whether linear hashing is preferred or non-linear hashing. Existing ASICs combine XOR and CRC to improve hashing while keeping linearity [33]. We are not aware of any studies on the possible tradeoff between linearity and hashing performance. It is still unclear whether non-linear hashing definitely outperforms all variants of linear hashing. Lightweight path control for future variants of hashing algorithms remains an interesting research problem. In order to support RePaC, ECMP can only adopt linear hashing algorithms. We expect future standardizations of ECMP to include linearity as another metric to consider besides hashing performance.

7 Related Work

RePaC is related to several prior lines of work:

End-host based path control: There are two spectrums of end-host-based path control. The first spectrum of approaches gets rid of ECMP and redesigns the routing protocols in the network [21, 22, 39, 41]. XPath is the most recent work, which identifies and pre-installs routes on switches [21]. Though XPath reduces the routing table storage with compression algorithms, the communication between end-hosts and the path manager under topology changes and link failures incurs too much overhead. MPLS is the common practice for traffic engineering in core networks [39, 41]. However, MPLS is not suitable for data centers since it can only support a limited

number of tunnels. The OpenFlow-based solution relies on on-chip forwarding rules and compresses forwarding rules with a tiny flow table [22]. However, this approach does not apply to data centers due to too many flows. Fundamentally, these approaches require excessive routing/forwarding tables because of the large scale of header space and the variability of paths.

Another spectrum still keeps ECMP as the path selection in switches but extracts the path selection model. Volur [47] attempts to provide path control with a centralized controller that aggregates routing information from in-network switches and disseminates routing information to end-hosts. However, the path selection model incurs too much overhead since it uses a mapping from the entire header space to all possible paths. The header space grows exponentially to the number of bits in header fields used by ECMP. We argue that explicit path control is not necessary so that we can reduce the complexity of the path selection model. Compared with this spectrum of work, we leverage the linearity of ECMP path selection and reduce the model complexity significantly.

Failover and traffic engineering: While our work is closely related to prior studies on failover [14, 19, 23, 25, 43, 44, 50] and traffic engineering [2, 3, 5], it is also fundamentally different. First, RePaC enables path control, which is different from the random path selection scheme in [19, 23, 44]. Second, RePaC is lightweight and easy to deploy, while existing approaches rely on advanced programmable switches [3, 14, 19, 43, 44, 50], switch redesigning (e.g. installing Openflow) [5], or a centralized scheduler to get path information [2]. Third, RePaC enables data traffic based path discovery, which outperforms traceroute traffic based approach [25] since the header fields in original data traffic and traceroute traffic are different.

8 Conclusion

In this paper, we analyze the ECMP hash algorithms used in today’s data center switch ASICs. Our analysis shows that the hash algorithms (e.g. XOR and CRC) used in the most popular switch ASICs on the market maintain linearity. We analyze how linearity sheds insights on relative path control. We design RePaC to leverage linear property and show that RePaC can be used in two representative applications, faster failover and traffic engineering. Through extensive evaluation in production data centers, we show that RePaC is easy to deploy and benefits failover and traffic engineering.

Abstract

We introduce Express-Lane (X-Lane), a novel system for mitigating interference in data center infrastructure to improve the liveness of coordination services. X-Lane follows a novel design from the ground up to achieve interactions with ultra-low latency in the single-digit microsecond range and jitter in the nanosecond range, while the remaining interaction is treated as usual. To show X-Lane’s applicability and generality we implemented and evaluated two services atop it on commodity hardware in a production environment of SAP SE: a failure detector (X-FD) with detection time under 10 μ s and a Raft implementation (X-Raft) with latencies under 20 μ s. We further show the smooth integrability of X-Lane services by replacing the replication protocol of Redis with X-Raft, making it strongly consistent while improving latency 18 \times and write throughput 1.5 \times .

1 Introduction

In the last decade, a tremendous increase in Internet connectivity and the need for more computational performance changed the way we conceive applications. Today, most new applications are conceived as distributed, and in particular cloud-based, applications. The design of data centers and middleware layers then has to take into account all requirements for distributed coordination, including performance, fault-tolerance, and consistency [16] — a hard task.

Interference in distributed systems. Most distributed system designs treat the underlying infrastructure as a generic communication system. One of the main issues with this abstraction is the longstanding problem of interference of concurrent interactions and thus unpredictable latency of commodity networks and hosts [19]. Many distributed systems suffer from jitter induced by interference, manifesting through packets that may be arbitrarily delayed in the network (as well as reordered or dropped), and unbounded processing times.

Many applications and components have been designed to cope with the unpredictability of the infrastructure by making weak synchrony assumptions to guarantee a safe execution of their protocol. Yet, they rely on upper bounds for the latency of their interactions to ensure liveness, by way of timeouts, and as thus benefit strongly from interactions with low latency and bounded jitter. This is especially the case for coordination tasks [52] whose use is widespread in practice. Types of systems using the ZooKeeper [28] coordination service based on the popular Paxos [37] protocol by default or as option for coordination/fault tolerance include resource management (e.g., Mesos [25], YARN [54]), key-value and wide-column stores (e.g., Accumulo [20], HBase [1], etcd [4], TiKV [10]), data analytics (e.g., Hadoop [12], Spark [58]), or distributed filesystems (e.g., HDFS [13]) to only name few.

X-Lane. The research question underlying this work is whether interference in data center commodity systems can be mitigated to greatly accelerate coordination tasks lying at the core of distributed systems.

Prior works on low latency communication (e.g., [14,24,41,44,48,50]) focus on reducing 99th percentile latency where packets may be sacrificed (dropped) to maintain a good performance in most cases (e.g., fitting a given service-level objective (SLO) for 99% of the packets). Our goal is to address not only fast but also *timely sensitive interactions* for tasks that exhibit severe performance degradation upon delayed message delivery (e.g., when timeouts trigger). To this end, we aim at reducing maximum jitter to a point where it becomes so small relative to an already very low latency, that, in practice, it can be assumed to be bounded. Moreover, we include *endhost response times*, and only provide bounded jitter to applications that rely on it (e.g., for coordination). Thus we introduce with Express-Lane — X-Lane for short — an interference-free environment for select interactions with ultra low latency in the *single-digit microsecond range* and bounded jitter in *nanosecond range*. The remaining interactions follow common design principles. While being more generic in design compared to prior work on minimizing av-

erage latency, and also considering endhosts, X-Lane delivers significantly tighter bounds for latency and jitter for commodity hardware (HW) and software (SW).

In short, X-Lane isolates and prioritizes packets traversing it by using traffic engineering techniques to provision and monitor resources dedicated for X-Lane, and by neutralizing sources of interference inherent to data center infrastructures, i.e., interference present in endhosts/servers, switches, and links. X-Lane strives first and foremost to minimize jitter, and in the process also achieves unprecedented low latency.

Contributions and roadmap. This paper contributes:

- §2 Design of X-Lane atop commodity HW and SW, and for intelligent network devices (smartNICs) when available;
- §3 Traffic engineering approach incorporating residual jitter and queuing delay to perform packet-level latency analysis in X-Lane;
- §4 Implementation of X-Lane overcoming interference causing jitter on top of commodity HW and SW, as well as improvements and simplifications taking advantage of Netronome’s NFP-4000-based smartNICs [8];
- §5 Definition and implementation of two example asynchronous services using X-Lane: a failure detector dubbed X-FD, and a state machine replication protocol dubbed X-Raft adapted from Raft [45];
- §6 Evaluation of X-Lane in a production data center of SAP SE through the deployment of the two services. We measure median latency and maximum jitter of X-Lane on commodity HW and SW (Linux) (5.130 μ s latency and 655 ns jitter) and smartNICs (4.133 μ s latency, 152 ns jitter) *with heavy concomitant traffic over the course of 21 days*. Further comparisons display vast improvements over DPDK [21] (1.735 \times lower latency, 81,816 \times lower jitter), and QJump [24] (1.501 \times lower latency, 72,758 \times lower jitter), which greatly affect the coordination of distributed systems. We also show the applicability of X-Lane by integrating X-Raft into the Redis key-value store [9], making it strongly consistent while decreasing latency 18 \times and increasing write throughput 1.5 \times .

We compare X-Lane to related work in §7 before we draw the conclusions and discuss future work in §8. Additional material can be found on the project website [30].

2 X-Lane Design Overview

With X-Lane we propose an explicit express lane for timely sensitive interactions, following our original design outlined in Fig. 1. X-Lane is isolated from the “regular system” which follows common design principles. This architecture is reminiscent of earlier models of separate systems [55, 56], yet realizes them concretely, in a single infrastructure, with commodity HW and SW.

2.1 Communication Model

X-Lane’s novelty is characterized by an explicit upper-bound on the latency of all the messages sent by a given process p to another process q , i.e., X-Lane keeps the latency of every such message within $[\lambda_{\min}^{p,q}, \lambda_{\min}^{p,q} + \delta_{\max}^{p,q}]$, where $\lambda_{\min}^{p,q}$ is the best-case latency, and $\delta_{\max}^{p,q}$ is its concomitant maximum jitter. In the following, we denote jitter δ as a deviation from the best-case latency λ_{\min} .

We achieve bounded communication latency in X-Lane by implementing a *periodic unicast protocol* where a process p can send a message to a given process q with latency upper bound $\lambda_{\min}^{p,q} + \delta_{\max}^{p,q}$, but under two constraints: p can send only once during every period $\pi^{p,q}$, and the packet size may not exceed $\sigma^{p,q}$. In addition, we specifically address one-to-many communication patterns by a *periodic multicast protocol* that allows a process p to send a message to a *set of processes* Q with a common latency range $[\lambda_{\min}^{p,Q}, \lambda_{\min}^{p,Q} + \delta_{\max}^{p,Q}]$. A crucial requirement for both our protocols is that *all their parameters become known by the sending process at the protocol setup time*, i.e., before the first use, in order to allow services to adjust their internal timeouts for the best possible performance.

Note, purely bandwidth-oriented communication abstractions are *not* suitable for X-Lane, for they leave message size unspecified, while, clearly, no latency bound would hold uniformly for *every* message size, and queuing behind an arbitrarily large message leads to unbounded maximum jitter.

X-Lane is able to provide timely sensitive interaction that exhibits stable behavior as long as interconnecting devices function properly. Hence X-Lane is best used to improve the liveness of coordination tasks that assume an asynchronous communication model to guarantee safety properties.

Timely unicast and multicast serve as *backbone for all communication* between processes in X-Lane. In the following, “periodic protocol” refers to “unicast protocol or multicast protocol”. Bounding latency in the sending process is addressed in §2.4 and detailed in §4.

2.2 Components Overview

To achieve the properties provided by the two periodic protocols, X-Lane introduces a software-defined networking (SDN) controller that takes on two main orchestration responsibilities: 1) *resource allocation*, i.e., answering requests from services with the most suitable protocol parameters, subject to network capacity constraints; and 2) *resource tuning*, i.e., keeping overall usage of X-Lane low. Traffic engineering (TE) techniques that underpin this operation are presented in §3.

The X-Lane controller interacts with each endhost via a client integrated in the X-Lane (Linux) kernel module (X-KM) loaded on each endhost. The client exposes the controller API (cf. List. 1) to services forwarding requests and responses in both directions. It is important to note that only the bounded communication over X-Lane is managed by the X-Lane con-

```

// Service request parameters for X-Lane resources
struct request {
    int loadsize;           // max packet size (B)
    int period;            // packet period (μs)
    struct {
        uint32_t ip;       // MCast or UCast IPv4
        uint16_t port;     // service port
    } receiver;
};

// Resources approved by the X-Lane controller
static const int UNBOUNDED = -1;
struct resources {
    int loadsize;           // max packet size (B)
    int period;            // approved period (μs)
    int minLatency;        // minimum latency (ns)
    int maxJitter;         // maximum jitter (ns)
};

// Reason for resource modification
enum Reason { TE, BW_EXCEEDED, BW_UNUSED };
// Downcalls from services to controller
↓ resources requestBandwidth(request req);
↓ void releaseBandwidth();
↓ void changeBandwidth(request req);
// Upcalls from controller to applications
↑ void bandwidthChanged(resources res,
    Reason reason = TE);
↑ void bandwidthTerminated();

```

List. 1: Extract of the X-Lane controller C API used for resource allocation and tuning. Structure `resources` defines a timely periodic protocol. The first three methods are called by services the next two are upcalls/callbacks.

troller. The rest of the communication proceeds as usual and uses the remaining resources in the usual best-effort manner. If no requests are ever made to the X-Lane controller, no network resources are spared or lost.

2.3 Overview of Jitter Sources

To implement an express lane usable in practice for time-sensitive tasks, we need to mitigate the inherent interferences in data center computing. We expose and address numerous jitter sources in §4. In short, we identify the following causes:

- **Packet loss:** Packets can be lost, leading to retransmissions and thus uncertain latency. Besides intentional drops (e.g., for security), packet loss has two well-known causes:
 - **Bit flip errors:** Bits can get flipped in links, leading to packets being marked as corrupted and discarded (§4.1);
 - **Buffer overflows:** Packets are dropped when the finite resources on processing units are overloaded (§4.2).
- **Intrinsic jitter:** While commodity switching devices forward packets with little jitter (§4.2), endhosts and their commodity components have been becoming more complex, leading to many sources of jitter (§4.3) and motivating the need for moving the intelligence closer to network devices (§4.4). The lack of bounds on jitter further makes packet delay hard to distinguish from packet loss.

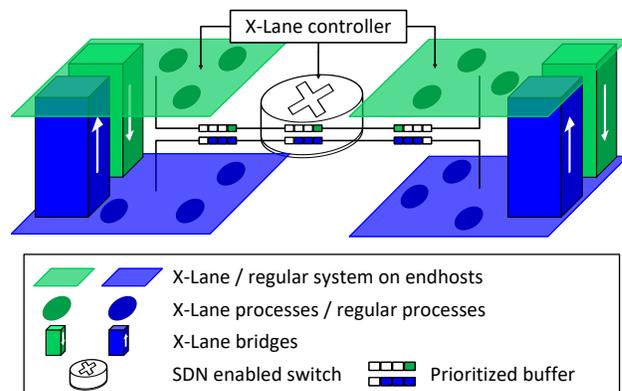

Figure 1: Separating the traffic of Express-Lane (X-Lane) and regular communication on switches to prioritize packets and prevent losses in the former. An SDN controller sets switches' rules to adapt buffer allocation and processing priority. X-Lane is interfaced to the regular system via its bridges.

2.4 X-Lane (Based) Services

X-Lane enables processes executing on the regular system to interact with the X-Lane services that may offer *timely* responses thanks to the unique timing properties of communications of X-Lane. There are a few intricacies to X-Lane that developers must take into account when interacting with and/or developing these services. First, applications and services, being in separate lanes, must use a specific interface to exchange data with each other. Second, X-Lane handles communications differently than in the regular system.

Building bridges between lanes. On endhosts, services must communicate with applications which have to deal with shared processor time. This resource sharing introduces unpredictable jitter for those processes while critical interactions need an upper bound for certain tasks. Hence X-Lane provides two sets of queues, called *bridges*, to establish the interface between processes in X-Lane and on the regular system.

Fig. 1 depicts the bridges. The express-to-regular (X-R) bridge (green cuboid) grants write access to X-Lane (green parallelogram) and read access to the regular system (blue parallelogram); inversely for the R-X bridge (blue cuboid).

Bridges are addressable using direct memory access (DMA) over PCIe (to minimize jitter, cf. §4.3) but are placed at different locations depending on the endhost HW configuration.

Using X-Lane services. Services are implemented as components of the X-KM (cf. §5 for already available services), and as thus have direct access to the client of the controller and to the network interface card (NIC) bridge, another X-KM component responsible for communication with the NIC. Each service has a dedicated queue in the R-X bridge where it

can receive (1) queries from applications wishing to start/stop using that service, and (2) queries and payloads specific to that service API. When an application starts using a service, the service requests network resources from the X-Lane controller and spawns a new queue in the X-R bridge dedicated to messages from this service to that application. The NIC bridge bundles up all the payloads from a service into packets and sends them over the wire at the allowed periodicity (cf. period in [List. 1](#)), and unpacks payloads on the receiver side. Like drivers, the bridge implementation varies between HWs.

Express communication on commodity HW. While commodity NICs rapidly process and copy packets to the main memory, they are not programmable. Procedures to send and receive packets must thus be executed by the CPU.

When handling packets that belong to X-Lane, guaranteeing minimal response time and tight timing bounds for these procedures is especially challenging on commodity HW. There is an abundance of sources of jitter within the CPU itself and in the communication path between the CPU and the NIC that prevents a jitter-free streamline flow of packets. As a response, we implemented a series of countermeasures to enable X-Lane on commodity HW, greatly improving the time bounds over the regular system, as detailed in [§4.3](#). On commodity HW, all bridges are in the main memory.

Express communication on smartNICs. Unlike commodity NICs, new generation NICs — so-called smartNICs — are highly programmable. Tasks can be offloaded from the CPU to the processing engine of a smartNIC, ranging from packet pre-processing to complex programs. The (relative) simplicity of the HW and SW stacks of smartNICs, over those of an endhost operated by a Linux kernel, and their proximity to the physical interface enable for packets to be processed on smartNICs with far lower latency and jitter (cf. [§6.2](#)). This makes smartNICs ideal to handle X-Lane services.

Processing for sending and receiving packets over X-Lane is confined within the smartNIC. This processing is mostly as with commodity HW, but with direct access to the packet processing pipeline and the ingress and egress buffers on the NIC (cf. [§4.4](#)). The X-R bridge is stored in the smartNIC’s memory while the R-X bridge is in the endhost main memory.

3 Traffic Engineering for Tunnel Trees

The key underlying mechanism of the controller are *latency-bounded fixed-bandwidth* tunnels, more precisely — tunnel trees (due to multicast), from sender to receiver processes.

3.1 Tunnel Allocation Model

The X-Lane controller relies on SDN for tunnel setup. In particular, by acting as an SDN controller, it gets access to

network-wide view in a form of a *network topology graph* G and the means to manage switches. For every link $(u, v) \in G$, the following information is used: bandwidth $\text{bw}(u, v)$, size of an egress queue $\text{qlen}(u, v)$, minimum delay $\lambda_{\min}(u, v)$, and maximum jitter $\delta_{\max}(u, v)$. Importantly, $\lambda_{\min}(u, v)$ and $\delta_{\max}(u, v)$ need only include processing and propagation delays, which are stable for switches and are made stable at endhosts by X-Lane’s endhost implementation (see [§4](#)).

A resource *allocation* is represented by a set \mathcal{T} of *tunnels*, where every $T \in \mathcal{T}$ is a *directed subtree* of the topology graph G with a sender source $\text{snd}(T)$ and a set of receiver sinks $\text{rcvs}(T)$. Tunnels are in one-to-one correspondence with allocated resources shown in [List. 1](#); hence, for every $T \in \mathcal{T}$, we have packet size $\sigma(T)$, period $\pi(T)$, minimum latency $\lambda_{\min}(T)$, and maximum jitter $\delta_{\max}(T)$. X-Lane further employs TE techniques [[26](#), [27](#), [31](#)] to guarantee channel availability. The particular TE algorithm used for X-Lane is close to B4’s state-of-the-art approach [[27](#)] (with worst-case estimation of available throughput) but is built upon a finer-grained network model to allow for packet-level latency bounds.

The X-Lane controller does not make any explicit resource reservations in the network but instead relies on *rate limiting* at the endhosts, forcing services to adhere to periodic protocol parameters. Thus, the traffic for a given tunnel T consists of packets of size $\sigma(T)$ entering node $\text{snd}(T)$ precisely every $\pi(T)$ with starting time chosen arbitrarily for each T . Once a packet p from T arrives at a node u , p is either delivered, if $u \in \text{rcvs}(T)$, or p is placed into u ’s egress queue(s) corresponding to next hop(s) in T , provided there is sufficient buffer space, if not — p is dropped. Switching and/or processing delays at u are incorporated into latency and jitter of incoming links. At the egress queue, p waits for its turn to be transmitted according to FIFO order, and after $\text{size}(p)/\text{bw}(u, v)$ seconds more p leaves the queue. It takes anywhere between $\lambda_{\min}(u, v)$ and $\lambda_{\min}(u, v) + \delta_{\max}(u, v)$ before p enters the next hop v accounting for the minimum residual jitter remaining after applying techniques described in [§4](#).

TE of X-Lane accounts for both the intrinsic uncertainties of the system and uncertainties arising from multiple services sharing network resources. Ultimately, TE ensures that allocation \mathcal{T} is *valid w.r.t.* topology G , meaning that no actual system behavior violates $\lambda_{\min}(T)$ and $\delta_{\max}(T)$ for $T \in \mathcal{T}$.

3.2 Two-Phase Allocation Approach

Resources in X-Lane are allocated reactively, upon concrete requests by services.

To bootstrap a periodic protocol, a service calls the `requestBandwidth` method of the controller API passing the desired packet size and periodicity in a request structure r . The controller handles r as follows: 1) a new tunnel T is allocated between the sender and receiver(s); 2) switches’ meter tables are updated for resource monitoring; 3) parameter adjustments for other affected tunnels in \mathcal{T} are communi-

cated to corresponding services using the `bandwidthChanged` callback; 4) the approved resources with periodicity adjusted according to the allocation are returned to the service. Naturally, the new tunnel T must *match* the request r , i.e., packet size $\sigma(T)$ is equal to $r.loadsize$, $\text{snd}(T)$ is the process that originated r , $\text{rcvs}(T)$ correspond to $r.receiver.ip$, and $\pi(T) \geq r.period$ (mind the adjustment). The returned structure reflects all the T 's parameters of a periodic protocol (cf. §2.1): latency range $[\lambda_{\min}(T), \lambda_{\min}(T) + \delta_{\max}(T)]$, periodicity $\pi(T)$, and load size $\sigma(T)$. The service frees the resources by using `releaseBandwidth`. For the X-Lane properties to be reliable, every `bandwidthChanged` callback invoked by the controller comes with a grace period, during which the service can send messages under the old periodic protocol guarantees.

A distinguishing feature of our setting is the inevitable interference between already established tunnels and the new tunnel. Trying to minimize such interference, we arrive to an optimization problem underlying steps 1) and 3) above.

Problem (X-TE). *Given a network G , an allocation \mathcal{T} , and a sequence of service requests r_1, \dots, r_k , find a sequence of new tunnels $\mathcal{T}' = T'_1, \dots, T'_k$ and adjust parameters of \mathcal{T} , s.t., T'_i matches r_i for $1 \leq i \leq k$, $\mathcal{T} \cup \mathcal{T}'$ is valid w.r.t. G , and $\sum_{T \in \mathcal{T} \cup \mathcal{T}'} (\lambda_{\min}(T) + \delta_{\max}(T))$ is minimized.*

Solving X-TE directly is challenging as deriving parameters (or even checking validity) for a general \mathcal{T} is highly non-trivial due to interdependency between arrival times for packets queuing behind each other. Hence to simplify the problem, we split the allocation into two phases: *optimization* and *adjustment*. The *optimization* phase takes as input a request sequence and decides on the matching sequence of tunnels. In the current implementation, we allocate trees one-by-one; each tree is allocated incrementally by greedily attaching receiver sinks while minimizing the current value of the X-TE's objective function. The *adjustment* phase alters the parameters of all tunnels so they become valid w.r.t. the network G . Each tree is adjusted independently using depth-first search traversal calculating worst-case parameters.

3.3 Resource Monitoring and Tuning

In addition to its resource allocation task, the X-Lane controller improves resource utilization by monitoring and refining the set of already allocated tunnels.

Controller oversight. For instance, if a service wants to adjust its `loadsize` and/or `period` without disrupting other services, the `requestBandwidth` and `releaseBandwidth` methods force it to establish a new periodic protocol first, migrate all clients there, and only then release the old resources. This two-phase approach incurs artificial delay, adds complexity, and wastes X-Lane's resources. The `changeBandwidth` method of the controller's API shortcuts the process by leveraging the `bandwidthChange` mechanism discussed earlier.

When a service attempts to use more resources than assigned, some of its packets get dropped at a rate limiter. X-Lane can do nothing to maintain timeliness for those packets, and neither should it as the service has violated the protocol. To ensure an already broken interaction does not waste resources, the controller decreases priority of that service's packets right after the drop, voiding their timing guarantees. Then, the jitter reduction is communicated to services sharing queues with the misbehaving one, and the latter is notified by `bandwidthChanged` with `resources.priority` set to `UNBOUNDED` and `reason` to `BW_EXCEEDED`. This service may recover later with `changeBandwidth`. Further, switches' meter tables are used to identify services that behave well but *underutilize* resources. The controller reclaims a portion of their bandwidth through the `bandwidthChanged` callback with higher period and `reason` set to `BW_UNUSED`.

In the extreme scenario when a service keeps violating the protocol and/or drives its bandwidth allocation to zero by not utilizing resources, the controller terminates the protocol unilaterally with `bandwidthTerminated`.

Fine-grained jitter control with sub-lanes. Earlier, we saw newly set up tunnels adding jitter to existing ones and vice versa, whose effect we incorporated in periodic protocol parameters. Certain combinations of services require a different approach. A low-traffic jitter-sensitive service (e.g., failure detection, cf. §5.1) and a throughput-oriented one needing a "small enough" latency bound (e.g., replication, cf. §5.2), affect each other in very unequal ways leading to suboptimal overall performance. The controller addresses this issue through virtual sub-lanes — virtual controller instances that use different priority levels for timely communication, isolating services in a higher-priority sub-lane from lower-priority sub-lanes. This separation needs only be reflected at the tunnel setup, where lower-priority tunnels must include jitter from higher-priority ones but not the other way around.

4 Overcoming Jitter in Data Centers

Comprehensive mitigation of jitter sources due to interference with the rest of the data center (outlined in §2.3) is key to achieving latency with tight bounds. In what follows we describe our technique and discuss implementation details.

4.1 Bit Flips Errors in Links

Most of the messages transmitted via X-Lane are expected to be much smaller than the MTU size. To reduce the data transmission overhead, X-Lane tries to pack multiple data chunks into a single physical packet. The increased chance of packet loss due to bit flip errors is mitigated by using two custom error correction schemata that provide the same mean time to fault packet acceptance as layer 2 headers (i.e., 10^6 years with

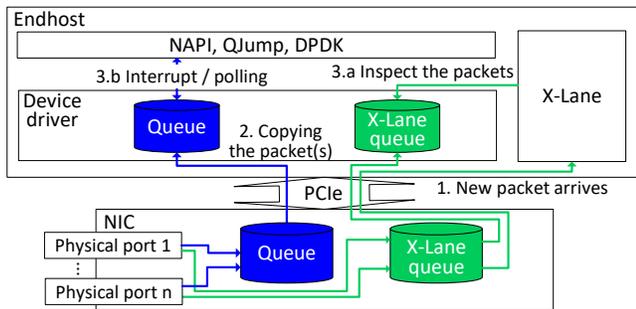

Figure 2: Overview of packet reception on commodity HW.

a bit error rate of 10^{-12}), while supporting either up to 55 chunks of 26 bytes per MTU or up to 40 chunks of 36 bytes (depending on the schema). Both schemata use a specific choice of cyclic redundancy code (CRC) polynomials.

4.2 Buffer Overflows and Jitter in Switches

Endhost NICs have a large amount of buffer memory available, allowing them to enqueue large numbers of packets before they are constrained to drop some. In contrast, commodity switching HW has a much smaller amount of (shared) buffer memory, that is commonly exceeded in the case of congestion, leading to packet losses ultimately hampering latency and jitter bounded communication. Commodity switches using an ASIC as forwarding processor can have their shared buffer split in multiple queues that are populated with packets from incoming traffic and are processed following a given scheduling strategy.

X-Lane uses a strict priority scheduler to realize the TE approach introduced in §3, to serve queues in order of priority, i.e., a non-empty queue is chosen over any other queue with lower priority. For each switch handling X-Lane’s flows, the X-Lane controller (cf. §2.2) dedicates the switch’s highest priority queues to X-Lane, and adapts the queues’ size to the expected load. X-Lane packets are therefore processed as fast as possible, reducing both jitter and the risk of packet drops since packets are processed before the queue is full. Furthermore, commodity switches are tailor-fitted to forward packets, they thus do so deterministically in the ns range [2].

4.3 Jitter in Endhost Commodity Hardware

While the standard network stack built upon endhost commodity HW can be used for throughput-oriented communication, the many sources of jitter it contains preclude X-Lane from using it for communication with bounded latency. Fig. 2 depicts how packets are handled when received on X-Lane (green) compared to the regular system (blue); X-Lane focuses on timestamping packets as early as possible to minimize stamping jitter, doing so even before their payload is inspected,

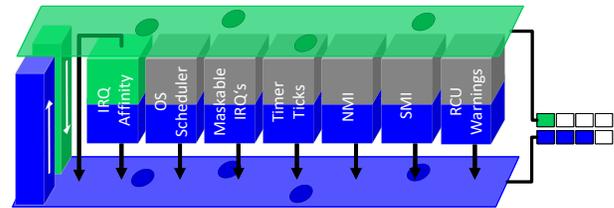

Figure 3: X-Lane is pinned to a dedicated core on which the sources of preemption (cuboids) are entirely (gray) or partly (green) disabled. The regular system is running on all other cores with all the side effects.

therefore performing *optimistic timestamping*. In the following, we give an overview of the measures implemented in X-Lane to drastically reduce jitter and latency of transmitting packets atop endhost commodity HW and SW.

First, at least a CPU core must remain available at all times for X-Lane services to promptly send and receive packets to/from other services running on other endhosts. To do so, X-Lane runs on a dedicated core (§4.3.1) and shunts preemption on it to minimize completion time of X-Lane services (§4.3.2). Second, packets must be copied between the CPU, for processing, and the NIC, for remote exchange, while avoiding jitter-prone kernel memory management (§4.3.3). Fig. 3 gives an overview of preemption sources X-Lane disables compared to a regular system.

4.3.1 Highly Responsive X-Lane Dedicated CPU Core

Execution slots on CPU cores are managed by the OS kernel scheduler which, typically, distributes these slots in a fair manner across all applications to avoid resource starvation. Timing-sensitive tasks are therefore regularly preempted to leave room for other tasks, increasing both latency and jitter for the former. Even earliest deadline first (EDF) schedulers [43] are affected by their jitter-prone environments and cannot guarantee the highest degree of responsiveness for such tasks. Furthermore, CPUs can switch between power consumption modes (i.e., C-states defined by the ACPI standard) to save energy when idle but need to wake up from an idle mode to execute a task, hampering response time [18].

X-Lane thus is *pinned* to a core, and isolates it from the scheduler to avoid task preemptions for a better response time. We call this core *X-Lane’s core* as it is (almost) exclusively managed by X-Lane. X-Lane’s core is isolated by including it in the `isolcpus` kernel boot parameter. To avoid costly wake-ups, X-Lane’s core remains in the highest active state by setting the following kernel boot parameters: `cpuidle.off=1`, `powersave=off`, `processor.max_cstate=0`.

4.3.2 X-Lane's Uninterrupted Execution

Interrupt request (IRQ) signals are generated by HW devices, e.g., I/O devices or CPU, to notify a core of an event to handle. The CPU preempts the task it is running to treat the received IRQ, which in effect increases the task's completion time and completion jitter due to the unpredictability of these IRQs.

We mitigate these delays by shielding X-Lane's core from as many IRQs as possible, as overviewed in Fig. 3. Those that cannot be ignored see their impact reduced (e.g., timer ticks).

IRQ affinity. On multi-core systems, IRQs can be distributed among cores statically — IRQs are always routed to the same core, or dynamically — IRQ affinity is set such that IRQs are handled by the core running the lowest priority task.

Most IRQs are routed away from X-Lane's core via a static distribution while other cores use a dynamic distribution, achieved by changing each IRQ's `smp_affinity` file in `/proc`.

IRQ masking. Some IRQs cannot be re-routed by setting their IRQ affinity, such as inter-processor interrupts (IPIs) that target a specific core. These IRQs can however be masked to prevent them from preempting the targeted core.

X-Lane uses the `local_irq_save(int state)` kernel function to mask IRQs before it executes an X-Lane service, and it restores the IRQ state afterwards using `local_irq_restore(int state)` with the same parameter. The masked IRQs are routed to other cores, by adapting their affinity, to preserve the correct operation of the system.

NMI watchdog. The Linux kernel integrates a watchdog timer that regularly sends non-maskable interrupts (NMIs) to each core to test for HW failures; it halts the system if the HW does not handle the NMI. There exists no standard kernel mechanisms to ignore the watchdog's NMIs.

X-Lane prevents these jitter-inducing NMIs by disabling the watchdog using the `nowatchdog` kernel boot parameter.

Timer ticks. Timer ticks are a special type of IRQs originating from CPU-local timers or external timers. They are used to run routines at a set frequency, typically between 100 and 1000 Hz, as configured in the kernel [46]. In our experiments, we have observed a substantial processing time for each of these interrupts, ranging from 1.5 μ s to 50 μ s.

X-Lane mitigates timer interrupts by configuring the kernel with the `CONFIG_NO_HZ_IDLE=y` option and adding X-Lane's core to the `nohz_full` kernel boot parameter, which sets the given core to adaptive-tick mode. While this mode does not completely oust interrupts, it greatly reduces their frequency to 1 Hz, offering significant timing improvements. For even greater improvements, X-Lane masks timer interrupts during the execution of its services. Masking these IRQs however does trigger warnings from the read, copy, update (RCU) stall detector that preempts the tasks on the masked cores.

RCU warnings. The RCU stall detector issues a warning if a core is looping (1) in an RCU read-side critical section or (2) with interrupts and preemptions disabled. The stall detector triggers these warnings, i.e., time-wise unpredictable offloadable callbacks, once its grace period is over.

The RCU stall detector issues warnings to X-Lane's core as a side-effect of masking timer (and other) interrupts on them. X-Lane thus offloads RCU callbacks to other cores by configuring the kernel with the `CONFIG_RCU_NOCB_CPU=y` option and adding X-Lane's core to the `rcu_nocbs` kernel boot parameter. Further, less callbacks are triggered and offloaded by increasing the grace period of the RCU stall detector set in the `rcu_cpu_stall_timeout` kernel boot parameter.

Unmaskable SMIs. System management interrupts (SMIs) are x86-specific unmaskable interrupts that force *all* cores to switch to system management mode to run safety-related tasks. These thus monopolize all cores for up to milliseconds, creating jitter. Some SMIs are critical to the safety of the system/HW such as the ones forcing cores throttling to prevent overheating and HW damage. These SMIs however are rare and typically do not happen in nominal scenarios.

To prevent SMIs and still protect system health, core throttling is disabled in the BIOS and X-Lane manages fans itself.

4.3.3 Packet Transfer Between X-Lane's Core and NIC

Sending and, in particular, receiving packets on an endhost is not a task as straightforward as on a switch. The complexity of this task lies within the memory management and device management modules of the Linux kernel that contain design decisions typically favoring fairness, i.e., reducing overall latencies, over prioritizing accesses for select applications.

To reduce latency and jitter, X-Lane optimizes (1) how packets are copied between X-Lane's core, that packs outgoing and unpacks incoming packets, and a NIC, that encodes/decodes packets to/from the wire, and how (2) these two devices notify one another that a packet is ready to be handled by the other.

Packet copy. When booting, the NIC's driver initializes a queue on the NIC for outgoing packets waiting to be sent (i.e., TX ring buffer), and two queues for received packets waiting to be processed by a CPU core (i.e., RX ring buffers): one on the NIC and one in the main memory. Queues hosted on the NIC are accessible by every CPU via DMA over PCIe. However, different cores experience different access timings since computer architectures nowadays have non-uniform memory accesses (NUMA). As such, both CPU and the main memory are split into several NUMA nodes; memory accesses and device accesses via PCIe within the same NUMA node are faster than across nodes as the latter are forced to use the slower QuickPath interconnect (QPI) link.

X-Lane operates its *dedicated RX ring buffers*, one on the NIC and one in the main memory (X-Lane queues in Fig. 2), for packets received on the lane to prevent jitter from the regular system packets' head-of-line blocking. The TX ring buffer remains unaffected as there is no risk of head-of-line blocking when the NIC transmits packets. In addition, X-Lane selects its dedicated core such that it runs on the NUMA node that the NIC's PCIe lanes are connected to, thus avoiding the QPI link when performing a DMA to the NIC to send or receive packets.

Packet notification. While the NIC constantly polls its local TX ring buffer, populated by cores, and thus does not need any extra step to send packets, the NIC driver running on a core must be informed by the NIC that a packet is waiting to be processed in an RX ring buffer. The driver can be notified by: (1) receiving an IRQ sent by the NIC for each received packet, which is fast but inefficient for bursty traffic that creates a lot of IRQ masks, or (2) regularly polling the NIC's RX ring buffer (as with DPDK [21]), that fetches packets in batches but incurs a latency penalty for older packets (at the front of the queue) and for low polling frequencies.

X-Lane uses the IRQ-based approach to optimize delivery timing. X-Lane's core is not subject to bursty IRQs as the bandwidth is carefully managed and smoothed by the X-Lane controller (cf. § 2.2). As shown in Fig. 2, a NIC receiving a packet sends an IRQ to X-Lane's core, set with a fitting IRQ mask, using receive flow steering [47] (step 1). In response, X-Lane's core timestamps the packet, doing it as early as possible to minimize pre-stamping jitter, and copies the packet via DMA from X-Lane's queue in the NIC to X-Lane's queue in the main memory to prepare it for inspection (step 2). X-Lane then shares the packet timestamp with the application via the X-R bridge and only delivers the unpacked payload once it has been inspected (step 3.a), also via the X-R bridge. X-Lane does not change how packets are handled on the regular system, e.g., with NAPI, DPDK (step 3.b).

4.3.4 Endhost Implementation Discussion

Additional work *in* the kernel would further improve the readiness of the implementation. For instance, X-Lane is currently limited by the granularity of some kernel boot parameters that affect all cores (e.g., disabling the NMI watchdog) and would benefit from per-core feature selection to better isolate its core. Further, most of these features are statically set at boot time, or even compile time. A dynamic configuration would help X-Lane's adaptation at runtime, reducing its endhost footprint when X-Lane is unused. Ideally, we would be able to fully isolate cores at runtime to greatly improving X-Lane's efficiency both in terms of endhost resource utilization and implementation effort.

X-Lane currently uses one core but can scale to multiple without introducing delays as long as they are in the same

NUMA node. The implementation currently focuses on Intel Xeon architecture, but AMD's EPYC has fewer NUMA nodes yet more cores, different memory management, and PCIe 4 that could improve X-Lane's performance.

4.4 Jitter in Endhost Specialized Hardware

As an alternative to endhost commodity HW, we propose an implementation of X-Lane on recent intelligent network devices (smartNICs) that completely avoid kernel-induced jitter since they are not managed by it.

Our implementation supports Netronome's smartNICs with NFP-4000 network flow processors. The NFP-4000 natively supports programs in microC, a dialect of C, and P4 [15] via a P4-to-microC transpiler. We chose microC to implement X-Lane's services on the NFP-4000-powered smartNIC as it is more expressive than P4 despite recent developments on the latter, e.g., microC can directly access packet processing, flow processing cores, internal and external memory units.

Following the NFP-4000's architecture [8], X-Lane components are running on a flow processing island that has 12 flow processors and its own memory to buffer packets. The number of flow processors used for X-Lane can be scaled on demand to match the traffic. Unlike the commodity HW implementation, here X-Lane has direct access to the packet processing pipeline and the ingress/egress buffers closest to the physical interface which greatly reduces the jitter associated to sending/receiving packets on endhosts (cf. § 4.3.3).

5 Example Services Exploiting X-Lane

We propose two services (cf. § 2.4), a failure detector (FD) service and a state machine replication (SMR) service, that exploit X-Lane to accelerate asynchronous protocols. These services are available for applications as part of the X-KM.

5.1 Failure Detector X-FD

We leverage a periodic multicast protocol (cf. § 2.1) that resides at the core of X-Lane to propose a heartbeat-based FD, X-FD, with a heartbeat period T . Unlike \mathcal{HB} [11] that outputs a vector of message counters to the application, X-FD tracks the state of remote processes in an alive table stored in the X-R bridge that can be read by any application.

X-FD operates in three successive steps. First, a user space application increments a timer value in the R-X bridge at least once per period T . Due to the jitter-prone nature of the application, the value update period must be much smaller than T (e.g., $T/3$ in § 6.4). Second, X-FD reads the corresponding value once per T from the R-X bridge and uses it for the heartbeat message, which is sent through X-Lane every period. Finally, when the destination endhost receives the packet at the queue dedicated to X-Lane on the NIC, X-FD optimistically timestamps the packet (cf. § 4.3.3) and, while the

packet’s payload is being analyzed, the alive table is updated with sender IP, port and last alive message timestamp.

5.2 State Machine Replication X-Raft

We offer a second service by adapting Raft [45], a popular SMR protocol [35, 36], to X-Lane in the form of the X-Raft service — a faster version of Raft using the periodic multicast protocol (and Raft’s acks).

We adapted the well known etcd Raft [4] without any structural modifications to the algorithm or to its different phases (e.g., leader election, log replication/recovery, membership).

X-Raft uses the R-X bridge to enable an application to interact with the SMR (e.g., to propose a value) and uses the X-R bridge to notify the application. Leader election and consensus rounds are performed in X-Lane without interacting with the application.

X-Raft uses X-FD to detect process failure and initiate leader reelection if needed. Throughput-oriented log replication packets are sent via a lower-priority sub-lane with a very small period while commit statements are piggybacked on X-FD’s low-jitter periodic messages. In addition, X-Raft batches parallel consensus instances in one packet akin to other consensus protocols [57]. Timeouts are greatly reduced thanks to X-Lane’s low latency.

The log hosted by the leader is a buffer for uncommitted inputs; an input i is removed from the log when all replicas commit to a state that includes i . X-Raft uses a ring buffer for the log that is big enough to store the logs long enough for all replicas to commit a state or fail. The commit state pointer on the ring buffer is updated when replicas commit a new state.

6 Evaluation

In this section we assess the performance of X-Lane by first evaluating the latency and jitter of the underlying switching HW (§ 6.1), followed by extensive evaluation of X-Lane’s communication timings (§ 6.2) and their variability (§ 6.3). We then evaluate the X-Lane-enabled services by measuring latency and accuracy of the FD service (§ 6.4), and latency and throughput of the SMR service both in isolation and once integrated in the Redis key-value store (§ 6.5).

Tab. 1 presents an overview of the implementation efforts behind each endhost component of X-Lane.

6.1 Hardware Setup

We ran our evaluation in a production data center of SAP SE hosting Arista 7280CR-48 [3] switches and 17 servers with Intel Xeon E5-2680 v4 at 2.40GHz (26 cores, 52 threads), 1 TB RAM, Mellanox ConnectX-4 4x10 GbE [7] and Intel XL710 4x10 GbE [6] as commodity NICs, and Netronome Agilio CX 2x10 GbE [8] smartNICs.

Table 1: Number of lines of code for each X-KM component.

Core component	#LoC	Service (cf. § 5)	#LoC
Controller client	476	X-FD	223
NIC bridge	515	X-Raft	843
SmartNIC bridge	163		

Switches’ timing impact. We evaluated the impact of switches on latency and jitter by running multiple benchmarks with varying numbers of switches between endhosts. We observed a stable latency overhead per switch of 3 μ s for unicast and 6 μ s for multicast with no measurable jitter beyond this difference, as expected [23]. We also evaluated the accumulated impact of switches in common data center topologies [5], by running benchmarks up to a 4-hop topology; it only impacted latency, not on jitter. For this reason, we evaluated X-Lane and its services on a 1-hop topology. This topology simulates in-rack computing that represents the majority of communication in optimized systems [5].

Note that the Arista 7280CR-48 switches we used are much slower than, for instance, switches from the Arista 7150 series with processing times of 350 ns according to their data sheet [2]. *Theoretically*, such switches could thus reduce the latency of our setup by at least 2.6 μ s, without affecting jitter.

6.2 Timing Observations

Most related works focus on reducing overall latency and maximizing network utilization, this work emphasizes jitter as another, crucial, dimension for many applications and in particular coordination tasks. Hence, we compare latency and jitter of three variants of X-Lane to each other, against QJump [24], and DPDK [21]. DPDK was used at a lower level by, and thus frames the performances of, many related works on low latency (e.g., Homa [44], Fastpass [48]), high performance OSs (e.g., IX [14], ZygOS [50]), and high performance SMRs (e.g., HovercRaft [33]) (cf. § 7).

Setup. We compare five configurations — DPDK, QJump, and three variants of X-Lane. The two main variants are specific to the used HW, and the third serves as a baseline:

X-Lane_{SNIC}: X-Lane on intelligent network devices;

X-Lane_{COM}: X-Lane on commodity HW;

X-Lane₀: X-Lane_{COM} with modifications made to CPU scheduling (cf. § 4.3.1) and interrupts (cf. § 4.3.2) disabled.

We report DPDK’s values using default settings as its maximum jitter did not vary measurably when varying its settings, only the number of packets with such high jitter.

We measured latency and jitter of the periodic unicast protocol on all configurations. We report latency as the time between a process sending a packet and the receiving process timestamping said packet. Sender and receiver processes

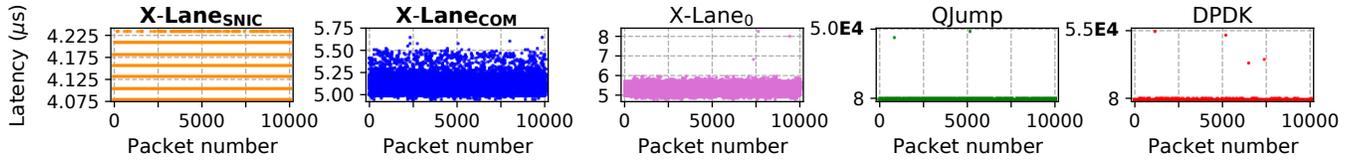

Figure 4: Overview of 10,000 packet latency (in μs) on the three X-Lane variants, QJump and DPDK. Note y-axes greatly vary.

Table 2: Summary of X-Lane’s timings showing 0th, 50th, 99th, 100th latency λ percentiles (in μs), maximum jitter δ_{max} (in ns) from λ_{min} , and a metric based on probability bound (i.i.d. assumption) for $10 \times \lambda_{99\text{th}}$ violation over next 100,000 packets. Replacing our Arista 7280CR-48 by an Arista 7150 could in theory reduce all latencies by 2.6 μs (cf. § 6.1).

Approach	λ_{min}	$\lambda_{50\text{th}}$	$\lambda_{99\text{th}}$	λ_{max}	δ_{max}	$P_{10-\lambda, 99\text{th}}^{100,000}$
X-Lane _{SNIC}	4.082	4.133	4.234	4.234	152	0.104
X-Lane _{COM}	4.938	5.130	5.446	5.649	655	0.301
X-Lane ₀	4.789	5.351	5.823	8.247	3.2E3	0.823
QJump	4.270	7.702	5.1E2	4.8E4	4.8E7	1.000
DPDK	4.103	8.904	4.0E2	5.4E4	5.4E7	1.000

are co-located on the same server to avoid cross-server clock skew; packets are still sent though the network. Processes sent packets with a 1 s period for QJump and DPDK due to high jitter, and a 10 ms period for X-Lane.

Dataset. The runs resulted in 181,440,000 packets for each approach, sampled over 21 days in a production data center of SAP SE. X-Lane variants ran with substantial cross-traffic and varying endhost utilization (up to an average CPU usage of 90%) while DPDK and QJump ran on an idle network of idle endhosts, setting the bar much higher for X-Lane. All possible point-to-point connections between servers were evaluated.

Latency and jitter results. Overall the results reveal: (1) holistic approaches (X-Lane_{SNIC}, X-Lane_{COM}) perform better than network-focused ones (X-Lane₀, QJump) and endhost-focused ones (DPDK), (2) offloading X-Lane to smartNICs (X-Lane_{SNIC}) further improves timings compared to the already efficient commodity HW approach (X-Lane_{COM}).

Tab. 2 overviews the timing measurements while Fig. 5 complements the table by exhibiting the main percentiles of the packet jitter distribution of each configuration. Even when running on commodity HW, X-Lane_{COM} shows great performance benefits compared to QJump and DPDK, e.g., $1.501 \times$ and $1.735 \times$ lower median latency, and $72,758 \times$ and $81,816 \times$ lower maximum jitter, respectively. Unsurprisingly, the results indicate that offloading X-Lane to an intelligent network device achieves the best results across the board. Compared to X-Lane_{COM}, X-Lane_{SNIC} achieves $1.241 \times$ lower median latency and $4.377 \times$ lower maximum jitter. As jitter is the most

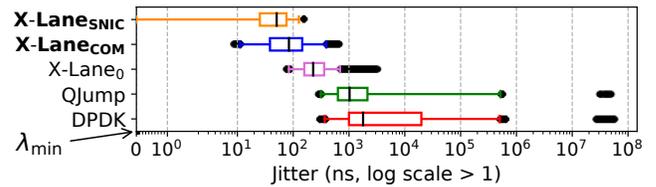

Figure 5: Distribution of X-Lane’s packet jitter δ (in ns, log scale for data > 1). A jitter of 0 corresponds to the packet(s) with minimum latency λ_{min} within a dataset. Boxes are 25th/75th percentiles, black bars are medians, whiskers are 1st/99th percentiles, further data points are grayed out.

important factor for coordination tasks in distributed systems, X-Lane shows its drastic reduction of maximum jitter makes it a prime candidate for such tasks (cf. § 6.4, § 6.5). The difference in timings between X-Lane₀ and X-Lane_{COM} shows the importance of tuning on endhost commodity HW (cf. § 4.3) to reduce maximum jitter, i.e., tail latencies.

Fig. 4 further shows the individual latency of 10,000 packets among the highest outliers. Some packets for QJump and DPDK, i.e., the “outliers” in Fig. 5, dramatically increase the jitter implying all the bad side-effects for coordination.

6.3 Latency Bound Tightness

We study the variability of the results obtained after 21 days of sampling in § 6.2 to determine the tightness of X-Lane’s bounds. We first focus on packets whose latencies are beyond the 99th percentile, then propose an extrapolation using a simple probability-based metric.

Beyond the 99th percentile. Fig. 6 depicts percentiles characteristic of tail latency based on the sampled dataset. DPDK, which has the highest λ_{avg} , makes one jump at the 99.98th percentile. At the 99.997th percentile, we see once again that as more of QJump’s “outliers” are taken into account, there is a sharp increase in tail latency. All X-Lane variants exhibit a stable behavior with X-Lane_{SNIC} being the most stable followed by X-Lane_{COM} and X-Lane₀. Another indication that X-Lane fully bounds the latency is the relative jitter defined as $(\lambda_{\text{max}} - \lambda_{\text{min}}) / \lambda_{\text{avg}}$. While the relative jitter is ≈ 0.02 for X-Lane_{SNIC}, ≈ 0.13 for X-Lane_{COM}, and ≈ 0.36 for X-Lane₀, the values for DPDK and QJump are orders of magnitude higher: $\approx 1,807$ and $\approx 1,113$, respectively.

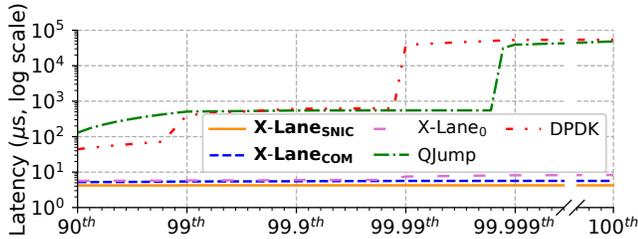

Figure 6: Tail latencies at different percentiles (different numbers of “nines”) observed over 21 days.

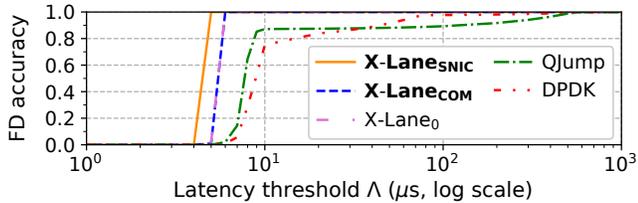

Figure 7: Accuracy of X-FD achieved when varying the latency threshold Λ . An alive process is incorrectly suspected of having failed if its heartbeat latency is greater than Λ .

Probability-based metric. We consider as a metric the probability of having among the next N packets *at least one* with latency exceeding λ , $\lambda > \lambda_{\text{avg}}$. We cannot get that probability’s true value, so we use instead an upper bound P_λ^N under a simplifying assumption that the law of large numbers applies; i.e., packet latencies are independent and identically distributed, and we have performed enough experiments for sample mean λ_{avg} and variance σ^2 to be close to their true values. We derive the probability bound P_λ^1 for a single violation from the following tail-bound: $P_\lambda^1 \leq \sigma^2 / (\lambda - \lambda_{\text{avg}})^2$. By using an independence assumption we further get $P_\lambda^N \leq 1 - (1 - P_\lambda^1)^N$. P_λ^N is a rough bound used only as a metric: the smaller its value is for an approach, the less that approach is prone to outliers.

Tab. 2 shows the probability to violate an SLO of $10 \times \lambda_{99\text{th}}$ over 100,000 packets. The results support a greater reliability of X-Lane’s measured latency over that of QJump and DPDK.

6.4 Failure Detector X-FD

We implemented the X-FD service (cf. § 5.1) atop all five configurations described in § 6.2 to compare the accuracy and completeness they provide in practice. We ran X-FD with 17 servers and a heartbeat period T of 1 ms whose value is incremented in an application every $T/3$. We varied the latency threshold Λ after which a process p is suspected of failure by others if no message was received from p in Λ .

Fig. 7 shows the rate of correct detection (i.e., accuracy) of the FDs with various threshold Λ (i.e., timeliness of completeness). We omitted T in the computation of the threshold. In practice, X-FD implemented on X-Lane reached perfect accuracy with practical thresholds well below 8 μs , and even below 5 μs for X-Lane_{SNIC}. QJump reaches $\approx 90\%$ accuracy within

10 μs but struggles for *a few milliseconds* for the remaining 10% needed for perfect accuracy. DPDK takes longer.

These results mean for instance that X-Lane can detect leader failures (e.g., in Raft [45]) orders of magnitude faster than its “low-latency” counterparts. Re-elections can promptly start hence greatly improving liveness.

6.5 State Machine Replication X-Raft

We implemented X-Raft (cf. § 5.2) using X-Lane_{COM} and evaluated it against etcd Raft [4] by measuring the latency and throughput of write requests (i.e., operations) in groups of 3 to 9 processes, one per server. The configuration was evaluated by having an application send write requests to the group. Latencies were measured as the time between the user space sender emits a request and the time it is available for all user space applications in the group. Accesses to the log, hosted in a RAM disk, were thus not included in the latencies. The sender emits once 10 M write requests whose size follows a truncated normal distribution: min = 1 B, max = 10 MB and observed mean = 25.6 B, standard deviation = 10 B.

Fig. 8 shows X-Raft performs much better than etcd both in terms of average latency, 15.7 μs for X-Raft, 26 ms for etcd, and average throughput, 96 MB/s for X-Raft, 1.1 MB/s for etcd. We note that, compared to a unicast protocol, X-Raft experiences 3 μs of added delay due to the switch processing multicast (cf. § 6.1). Unlike etcd, X-Raft batches requests before sending them and relies on multicast that scales well with regard to group size. etcd’s bandwidth requirement however is linearly proportional to group size.

Treating write requests as operations, with 25.6 B mean request size, X-Raft achieves 3.7 M ops/s mean throughput. As a comparison, HovercRaft [33] achieves 1 M ops/s with 24 B requests but uses programmable switches, and NOPaxos [40] achieves 250 k ops/s (unknown size) but centralizes traffic.

Redis integration. To evaluate the genericity of X-Lane, we replaced the default inconsistent replication protocol of the Redis key-value store [9] with X-Raft. The result, a strongly consistent replicated key-value store, only took 26 lines of code of integration. Fig. 8 shows latency and write throughput for Redis and Redis+X-Raft with 3-9 servers. X-Raft reduces latency 18 \times on average and increases throughput 1.5 \times .

7 Related Work

Distributed coordination and failure detection. Over the years, several authors have explored improvements of coordination for distributed systems but only considering individual components or specific problems. Seminal works like mostly-ordered multicast [49] and unreliable ordered multicast [40] are multicast approaches where the ordering is done at the switches. Both approaches greatly improve the

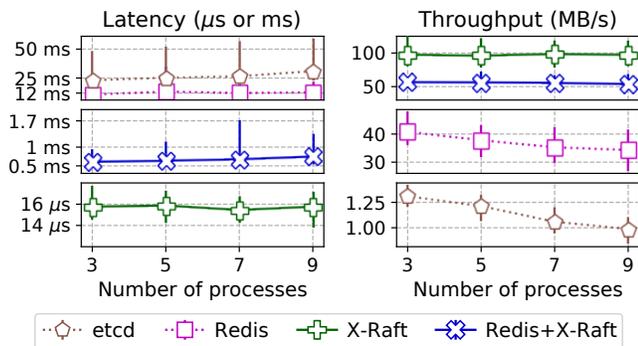

Figure 8: Write latency and throughput of X-Raft, etcd Raft, and Redis stand-alone vs with X-Raft. Mean values are plotted with min-max vertical bars.

Paxos [37] consensus protocol thanks to in-network ordering. R2P2 [34]-based HovercRaft [33], NetPaxos [17], and Consensus in a Box [29] similarly leverage switches for consensus protocols; like the Albatross [38] membership service, they do not give guarantees under an overloaded network. Their main goal is to speed up resolution of individual services via specific switch instrumentation, without considering other instances of the same protocol, other such protocols, or the network as a whole. Additionally, these approaches do not include controlled interaction to the endhosts' user space required for many jitter-bounded applications (e.g., FDs).

Silo [32] shows feasibility of guarantees without constraining network elements; the guarantees provided are however not strong enough for applications like FDs in terms of jitter and packet loss. Falcon [39] focuses on what the network needs to provide to implement a perfect (reliable) FD, rather than how it can do so, and resorts to program-controlled crashes when the FD falsely suspects processes of being crashed due to missed timeouts, contradicting reliability.

Low latency. In recent years there were numerous proposals for achieving low latency network communication. The introduced approaches typically bound latency at the 99th percentile. The reason for the 99th percentile is that it is hard to deal with the sources of jitter in a complex system (cf. §4.3). Tails of the tail [41], a seminal work in this area, identifies major jitter sources on endhosts, but does not consider the network, and focuses on 99th and 99.9th percentile latency, not 100th. Another path leading work is QJump [24] which proposes to achieve bounded latency on commodity hardware, but focuses on queues' priorities for low latency delivery and does not consider sources of jitter on endhosts (cf. §4.3).

The DPDK framework is known for its fast and efficient poll mode drivers and fast packet processing capabilities. It has a wide range of driver implementations for various NICs. The DPDK developers have restructured and implemented a majority of the network device driver code and structure.

DPDK operates by polling the network device from the user space application, which allows the programmer to harvest network packets bypassing the kernel network stack completely. As mentioned in §6.2 many works build on DPDK, e.g., Homa [44], Fastpass [48], IX [14], ZygOS [50]. These approaches try to optimize utilization and 99th percentile latency. Thus, they could be applied for the regular system but as shown in §6.3 are insufficient for X-Lane.

Time synchronization. DTP [53], Huygens [22] and Sundial [42] are time synchronization schemes for data centers with precision below 100 ns. However, time synchronization alone does not enable interactions with bounded latency.

Endhost synchrony. Efforts on achieving real-time (RT) guarantees for commodity OSs like Linux are related to X-Lane. RTLinux [51] is a real-time OS microkernel running the entire Linux OS as a fully preemptive process. RTLinux treats every process as having RT requirements, while X-Lane can treat a process in fair scheduled manner, or with even stronger RT guarantees; traditional RT schedulers, e.g. EDF [43], can actually not guarantee that a specific task is performed by a given deadline, as they can not predict the system environment and are influenced by system service executions.

8 Conclusions

X-Lane implements unprecedented low latency and jitter for coordination interaction crucial to the liveness of many applications in data centers. As this is not needed for all types of distributed interaction, X-Lane confines these bounds to an express lane, which is carefully isolated from the regular existing environment for best-effort traffic both in the network and at the endhosts. X-Lane's original design uses commodity SW and HW, and smartNICs when available.

X-Lane opens up many avenues for future research, e.g., which parts of an application best benefit from X-Lane, how to design and optimize coordination protocols accordingly. We are exploring extensions and refinements of our work such as expanding the endhost implementation (cf. §4.3), adding services (e.g., clock synchronization), and enhancing X-Lane's safety towards practical synchronous services.

Understanding Precision Time Protocol in Today’s Wi-Fi Networks: A Measurement Study

Paizhuo Chen Zhice Yang

School of Information Science and Technology, ShanghaiTech University

Abstract

Emerging mobile applications involving distributed control and sensing call for accurate time synchronization over wireless links. This paper systematically studies the performance of Precision Time Protocol (PTP) in today’s Wi-Fi networks. We investigate both software and hardware PTP implementations. Our study uncovers the root causes of software PTP synchronization errors. We show that with fine-tuned system configurations and an online calibration procedure, software PTP can achieve reasonable accuracy with off-the-shelf Wi-Fi devices. Hardware PTP requires a PTP hardware timestamping clock not contained in Wi-Fi NICs. We propose a method to make use of the hardware TSF counter to emulate the PTP clock. Rigorous tests traversing various conditions show that both software and hardware PTP implementations can achieve a 1- μ s level of accuracy in today’s Wi-Fi networks.

1 Introduction

Emerging mobile devices are rich in sensing, actuation, and computational capabilities. A shared time basis is essential for coordinating multiple of these devices and fusing the data they collect to enable innovative applications [23, 44]. For example, if the cameras of multiple co-located smartphones are synchronized, the videos they record can be used for 3D view synthesis, which can shift the production of volumetric [20] and free viewpoint [12] videos from fixed and professional studios to flexible and amateur scenarios; If drones and robots are synchronized, a fleet of them can cooperate, *e.g.*, to deliver a large object exceeding their individual capacities.

There are many ways to wirelessly synchronize (sync) mobile devices. Some are laboratory prototypes [31, 41] while some are already used in commercial products, *e.g.*, GPS [38], cellular [46]. They differ in targeting accuracy and application scenarios. For general networked devices, a convenient solution is through network protocols. In this paper, we focus on synchronization in Wi-Fi networks, as Wi-Fi is prevalent and will continue to play a critical role in future edge networks.

There are several synchronization choices in Wi-Fi networks. IEEE 802.11 itself defines the Time Synchronization Function (TSF) [3], which syncs clients to the connected AP

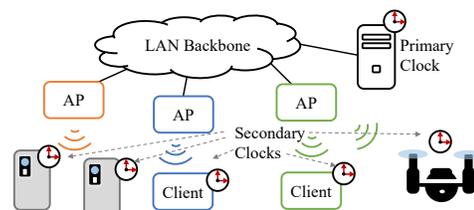

Figure 1: Scenarios of Wi-Fi Synchronization. APs are synchronized by the backbone. System clocks of Wi-Fi clients (*e.g.*, smartphones and drones) across different APs are synchronized to the primary clock. (In the context of this paper, we use Primary/Secondary clocks to replace the Master/Slave clocks used in the conventional synchronization terminology)

by resetting clients’ time to the time broadcasted in the AP’s beacons. However, TSF is only effective within a single AP’s coverage, whereas the mobile clients may span a larger geometrical area. For example, the logistics robots might operate across multiple APs to transport items. To achieve synchronization on such a scale (Figure 1), the industry’s standard practice is to use the Precision Time Protocol (PTP).

PTP is originally designed for LANs (IEEE 1588) [1] and can achieve nanosecond accuracy through timestamping the network packets. Attempts to extend PTP to wireless LAN or Wi-Fi can be traced back to the early Wi-Fi era [29]. The major difference from the wired situation is that the wireless channel introduces uncertainties in PTP timestamps [22]. This problem can be well addressed by hardware-assisted timestamping, *i.e.*, hardware PTP. The representative hardware PTP design is the latest IEEE 802.11 feature - Fine Timing Measurement (FTM) [3]. An alternative way is software PTP, which timestamps packets in the host software and hence is subject to various uncertainties caused by packet loss, channel contention, and host scheduling [22, 33]. Existing studies suggest ways to eliminate the uncertainties, *e.g.*, taking timestamps in the interrupt service routine (ISR) [33].

However, when we tried to apply the above implementations and insights to practical use, we encountered multiple friction and glitches, and finally failed. We intended to use

PTP to improve the synchronization of mobile cameras [20] for better 3D video synthesis. Our cameras are built on the Jetson Kit [14], a typical commercial off-the-shelf (COTS) development platform. For hardware PTP, while FTM seems perfect, we found that commercial FTM WNICs are mainly for positioning purposes [27] and the synchronization interface is proprietary and not publicly available. We then implemented software PTP based on existing work, but its performance is not as good as described. We found most of the related work was conducted around a decade ago, and thus many findings are no longer sufficient to explain and improve the PTP performance on current mobile CPUs and Wi-Fi NICs. To fulfill our application goal, we were forced to revisit PTP under the context of today's Wi-Fi networks and devices. We sought to uncover the factors affecting the PTP performance and ways to contain them.

A working PTP system mainly consists of two parts. The upper part, *i.e.*, the PTP daemon, such as `linuxptp` [15] and `gptp` [8], implements the PTP protocol state machine and clock tuning algorithms. The lower part timestamps PTP packets, and is finished in a way to minimize any timing uncertainties. The lower part, to our knowledge, only has proprietary implementations [11]. We develop two versions of the PTP lower part. The software PTP implementation timestamps packets in the WNIC driver. The hardware PTP implementation uses the TSF counter to timestamp packets in the WNIC hardware. They are both based on hacking and modifications on an open source WNIC driver and work seamlessly with existing PTP daemons. Their source code is available at [18]. Based on those, we conduct measurements to understand PTP performance in mobile platforms and practical Wi-Fi situations. Our key findings are:

- The major causes of software PTP's unstable performance are the power saving and performance optimization mechanisms employed in modern mobile systems. We reveal that WNIC's interrupt mitigation and CPU's idle power management are the dominating factors.
- With proper configurations, software PTP is reasonably accurate (sub- μ s bias) and stable (1- μ s jitter). A limitation of software PTP is the asymmetry interrupt responsiveness of host platforms. We propose a convenient online calibration method to address it.
- Hardware PTP can be supported by COTS WNICs by making full use of TSF counter. Although TSF counter is periodically affected by Wi-Fi TSF synchronization, our analysis suggests that it is still sufficiently accurate when the beacon frequency is as high as the default value.
- Hardware PTP is accurate, stable (sub- μ s bias error and sub- μ s jitter), and independent of software configurations. Similar to the wired PTP situation, calibration of the hardware timestamper is needed to achieve high accuracy when using different models of WNIC.

Our measurements traverse various workloads and conditions, covering both normal and extreme use scenarios. Our

analysis provides a sound and up-to-date understanding of Wi-Fi PTP performance. The implementation incorporating our findings renders an accurate and scalable synchronization solution for general mobile systems. It allows us to continue investigating 3D video synthesis from videos captured by multiple mobile cameras.

2 Background

2.1 Clocks in Computer

A clock is a tool that measures the elapse of time, and normally consists of an oscillator and a counter. The oscillator periodically generates ticks at a fixed rate of R Hz. The counter is triggered on each tick and counts the number of ticks from the time it is powered on, says T_0 . Let n denote the value of the counter, and n/R measures the elapsed time since T_0 .

In practice, T_0 is arbitrary. It is more convenient to count the elapsed time T_{off} from a chosen reference time T_{ref} . T_{off} can be measured by other clocks. At time t_i , the counter of the clock is n_i , and the "time" of the clock is defined by

$$T_i = T_{\text{off}} + \frac{n_i}{R}. \quad (1)$$

T_i measures the elapsed time since T_{ref} . In particular, when T_{ref} is a known absolute time, *e.g.*, the start of 1 January 1970, we say T_i measures the absolute time. Equation (1) maps the value of the clock counter to the time of the clock through two parameters, $\{T_{\text{off}}, R\}$. This tuple uniquely determines the time of a clock.

Modern computers contain multiple clocks that belong to different hardware modules. This paper is related to three clocks: SYSTEM clock from the host computer, TSF clock from the WNIC, and PTP clock from the Ethernet NIC. Each clock has a counter, an oscillator, and the corresponding tuple $\{T_{\text{off}}, R\}$. System clock represents the clock that the software can refer to. In our experiments, TSC clock [10] in x86 PCs and CCNT clock [6] in ARM platforms are used as the source of system clock. We use T_i^{SYS} to denote the time of the system clock, *i.e.*, system time. When describing multiple hosts, we use an intermediate superscript to differentiate, *e.g.*, $T_i^{\text{P}_{\text{SYS}}}$ and $T_i^{\text{S}_{\text{SYS}}}$ denote the system time of clock P and clock S respectively.

TSF is defined in the IEEE 802.11 standard as a mandatory feature. Every WNIC maintains a 64-bit TSF counter with a 1 MHz tick rate. TSF counter can be accessed by software through reading TSF registers. We use n_i^{TSF} to denote the counter value, and T_i^{TSF} to denote the mapped TSF time. Similarly, T_i^{PTP} denotes the time of the hardware clock of the Ethernet NIC supporting PTP protocol.

2.2 PTP Basics

PTP is defined in the IEEE 1588 standard [1] to achieve time synchronization for networked computers on the LAN scale. PTP works by timestamping PTP packets. The protocol syncing the secondary clock (S) to the primary clock (P) is explained in Figure 2. The SYNC packet is sent out

from the host of the primary clock, and timestamped by the primary clock as T_1^P . The SYNC packet is received by the host of the secondary clock, and timestamped by the secondary clock as T_2^S . In the reverse direction, the DELAY REQUEST packet triggers two timestamps T_3^S and T_4^P . FOLLOW UP and DELAY REPLY packets are used to convey T_1^P and T_4^P to the host of the secondary clock for calculating the clock offset. If the clock drift is ignored in the period of measurement, the four timestamps have the following relation: $T_1^P - T_2^S = \Delta - T_{\text{delay}}^{P \rightarrow S}$; $T_4^P - T_3^S = \Delta + T_{\text{delay}}^{S \rightarrow P}$, where T_{delay} denotes the network latency between the two hosts. In a single hop network connection like Wi-Fi, this value is stable and symmetric¹, *i.e.*, $T_{\text{delay}}^{P \rightarrow S} = T_{\text{delay}}^{S \rightarrow P}$, the offset from the primary clock can be calculated by

$$\Delta = \frac{(T_1^P - T_2^S) + (T_4^P - T_3^S)}{2}. \quad (2)$$

According to this offset value, the secondary clock can be adjusted, *e.g.*, by tuning $\{T_{\text{off}}^S, R^S\}$, to reduce any future Δ .

In practice, the synchronization accuracy of PTP depends on how precisely the four timestamps are associated with the packet transmission (Tx) and reception (Rx) events. Usually, there are errors δ between the time the timestamps are taken and the time the Tx/Rx events happen. Therefore, the actual relation of timestamps is:

$$T_1^P - T_2^S = \Delta - T_{\text{delay}}^{P \rightarrow S} + \delta_{\text{Tx}}^P - \delta_{\text{Rx}}^S \quad (3)$$

$$T_4^P - T_3^S = \Delta + T_{\text{delay}}^{S \rightarrow P} + \delta_{\text{Rx}}^P - \delta_{\text{Tx}}^S, \quad (4)$$

where $\delta_{\text{Rx/Tx}}^{P/S}$ denote the errors of Tx/Rx timestamps of the Primary/Secondary clock receptively. Equation (2) becomes:

$$\frac{(T_1^P - T_2^S) + (T_4^P - T_3^S)}{2} = \Delta - \frac{(\delta_{\text{Tx}}^P - \delta_{\text{Tx}}^S) + (\delta_{\text{Rx}}^P - \delta_{\text{Rx}}^S)}{2}. \quad (5)$$

As $\delta_{\text{Rx/Tx}}^{P/S}$ is unknown, the offset calculation by (2) contains errors and affects the synchronization accuracy.

In Ethernet hardware PTP implementations, timestamps are taken by the NIC hardware, and thus $\delta_{\text{Rx/Tx}}^{P/S}$ are relative stable and can be compensated. $|\Delta|$ calculated by (2) can be limited to sub-*ns*. Software PTP timestamps packets in software routines. The uncertainties of software stack bring about variances in $\delta_{\text{Rx/Tx}}^{P/S}$ and result in synchronization errors at the *ms*-level. In LAN situations, as hardware PTP has been widely supported by Ethernet NICs, software PTP is usually used for testing or a temporary choice when there is no compatible PTP NICs.

3 Measurement Methodology

3.1 Testbed

Hardware. The PCs are all Lenovo ThinkCentre M920t-D224 with identical hardware (Intel i5-8500 CPU, 4 GiB RAM). The motherboard has three PCIe slots. The high throughput x16 slot is directly connected to the CPU, which

¹ Assuming identical PHY rate or the transmission time is compensated.

is normally used by PCIe GPU. The remaining $\times 1$ and $\times 4$ peripheral slots are connected to the CPU through a PCIe switch in the Intel chipset. As the peripheral PCIe slots and the GPU slot have different access latency profiles [32], the WNICs in our experiments are all plugged into the $\times 1$ peripheral slot. In fact, PCIe latency is closely related to PTP performance, but it normally does not affect the accuracy, see discussions in §4.2.1 and §5.2.1.

We use the Jetson Xavier NX development kit [14] (6 ARMv8.2 cores @ 1.4GHz, 8 GiB RAM, by default, 4 cores are disabled) to evaluate the performance of mobile platforms. The Jetson board by Nvidia has a powerful GPU, which is irrelevant to synchronization, but this board is popular for prototyping video-based edge applications, hence we adopt it for the study. The board has two PCIe slots. One is used for WNIC and the other for Ethernet NIC through an M.2. to PCIe adapter [4].

We use Atheros AR9388, an ath9k-compatible WNIC, for the measurement. ath9k is a mature open source WNIC driver that we can modify and work on. In addition to WNICs, the PCs and mobile platforms are equipped with Intel I210 Ethernet NICs, which support hardware PTP and are mainly used for measuring the accuracy of Wi-Fi synchronization (see §3.3 and Figure 3).

We mainly use the above hardware platforms to present the measurement results, but our findings and conclusions are verified with several similar platforms: Hikey 970 development board [9] (8 ARM cores), ODYSSEY board [16] (Intel Celeron J4105 CPU), and ThinkCentre (Intel i5-6500 CPU).

Software. The operating system running on PCs is Debian GNU/Linux 9.8 (stretch) with kernel 4.19.37. The Jetson board uses Debian with kernel 4.9.6 maintained by the community. NONE of them are the real-time (rt) version. We use hostapd to set up Wi-Fi Access Points on PCs. linuxptp [15] is a user space daemon that implements the PTP protocol, and sends and receives PTP packets through the network socket. It is also responsible for synchronizing two clocks in a local system through the PTP kernel interface [17], *i.e.*, sync the system clock to the hardware PTP clock or vice versa. We do not modify linuxptp nor the PTP kernel interface. Instead, our implementation patches the ath9k driver to allow COTS Wi-Fi NICs to work properly with the existing PTP software stack.

3.2 Measurement Settings

When applying PTP to sync Wi-Fi connected devices belonging to different APs, Wi-Fi APs might play different roles. When they are in the transparent clock mode [1], Wi-Fi clients are directly synchronized to the primary clock, which is hosted, for example, by a computer connected to the backbone Ethernet. APs only help to forward PTP packets from/to the primary clock. However, they need to compensate for the forwarding delay, which is hard to achieve in COTS APs. To avoid such complexities, we adopt the boundary clock

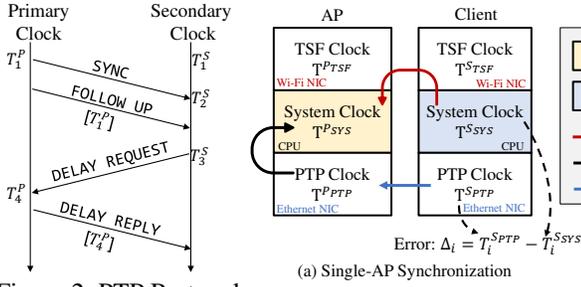

Figure 2: PTP Protocol.

mode [1], where the synchronization chain is divided into multiple domains. Wi-Fi clients are first synchronized to their primary clocks hosted by their APs. The APs are then synchronized to a primary clock connected to the LAN backbone. In this way, all of the clients, whether within the same AP or not, are synchronized.

As the LAN PTP is mature, we assume the APs are correctly synchronized. The boundary clock mode allows us to focus on the single-hop wireless synchronization within one AP. The following measurements are firstly conducted in the Single-AP situation to study the core impacting factors, and then in the Cross-AP situation to show the feasibility.

3.2.1 Single-AP Situation

The measurement settings are shown in Figure 3 (a). A PC is used as the Wi-Fi AP. It also hosts the primary clock. The associated Wi-Fi clients are either PCs or Jetson boards. The synchronization frequency (each round of procedures in Figure 2 counts as one time) is 4 times per second. For experiments other than long-term tests, synchronization data is collected for 10 mins, *i.e.*, about 2400 offset samples (the first half is dropped to wait for synchronization algorithms to converge [39]). Experiments are conducted in a typical lab environment, using the IEEE 802.11a protocol (5 GHz, single antenna) in a relatively clean channel. To evaluate the performance, we traverse the following factors:

Network and System Factors are the network protocol and system-specific factors that the end systems can control and affect.

- **CPU load.** We study the impact of computational resources of the host system by varying the CPU usage to 0%, 50%, and 100%. `stress-ng` is used to generate CPU workload at the secondary host (client) by continually performing floating point calculation. We keep the CPU load of the primary host (the AP) unchanged, as asymmetrical conditions are more likely to introduce synchronization errors. CPU turbo boost is disabled, and WNIC driver is bound to a fixed core to avoid the interference on the measurement.

- **Network traffic.** A socket program is developed to generate UDP traffic between the AP and clients. (a) The intensity of the traffic is characterized by the packet rate, *i.e.*, packet per second (PPS). The fine-grained traffic pattern is randomized by varying the inter-packet space. (b) The size of the packet is the number of bytes in the UDP payload. (c) We use `iwconfig` to fix the PHY rate from 6 Mbps to 54 Mbps.

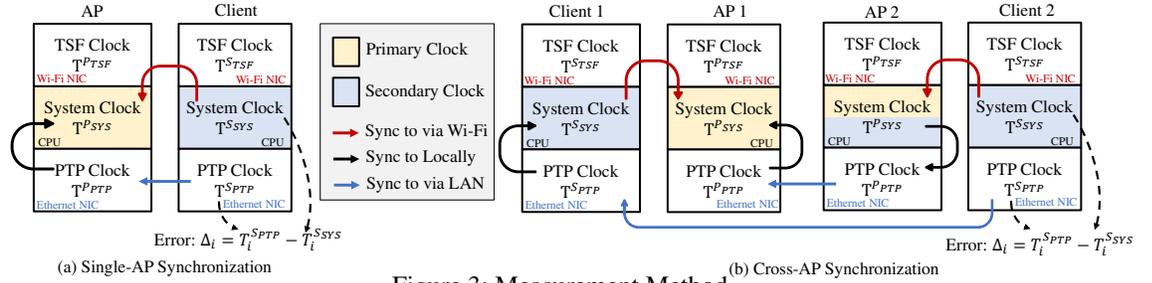

Figure 3: Measurement Method.

Note that different combinations of PPS, packet size, and PHY rate result in different amounts of *channel idle time* and *throughput*, which, according to our evaluation, have no obvious impact on the results, hence we do not list them as independent factors. Further, the network traffic is bidirectional, but we find the impact of the uplink traffic (from client to AP) is less obvious, thus only the downlink cases are presented in the paper, *i.e.*, both CPU and network load are applied to the Wi-Fi clients.

Wireless-specific Factors. Wireless networks differ dramatically from wired networks in channel properties. We consider mobility, signal strength, and neighboring interference. These factors are out of the control of the end systems and have obvious impacts on general wireless transmissions. The mobility is introduced by moving and rotating the client. The received signal strength is controlled by placing the client to different locations. The interference is generated by a signal jammer, which is another pair of PCs sending random packets with Wi-Fi carrier sense turned off.

3.2.2 Cross-AP Situation

Based on the Single-AP setup, we measure Cross-AP synchronization by syncing APs via the LAN PTP. Figure 3 (b) is the measurement setup. Client 1 and Client 2 are synchronized by first syncing Client 1/2 to AP 1/2 and then syncing AP 2 to AP 1. The two APs are directly connected by Ethernet. A scalable way to sync more APs multiple hops away is using PTP switches. Note that the system clock of AP 2 is a boundary clock serving as the primary clock for its clients, and it is also a secondary clock from the point of view of AP 1 that AP 2 is synchronized to. We denote the synchronization chain with arrows: Client 1 $\xrightarrow{\text{sync}}$ AP 1 $\xleftarrow{\text{sync}}$ AP 2 $\xleftarrow{\text{sync}}$ Client 2. In cross-AP measurements, the CPU and network load are only applied to Client 1. APs and Client 2 are load free.

3.3 Performance Metrics

In the Single-AP situation in Figure 3 (a), T^{SSYS} is synchronized to T^{PSYS} via Wi-Fi. To measure its accuracy, we use LAN PTP as the reference. The AP and client hosts are connected by an Ethernet link. The PTP clock of the client's Ethernet NIC is synchronized to AP's system clock through hardware LAN PTP. Note that the difference between T^{SPTP} and T^{PSYS} is at the ns-level, thus we use $\Delta_t = T_i^{SPTP} - T_i^{SSYS}$ to measure the synchronization error. The mean and standard

deviation (std) of Δ_i , indicating bias and stability (jitter) respectively, characterize the synchronization performance. In the Cross-AP situation, we care about how clients belonging to different APs are synchronized, and thus use the Ethernet link to connect the two clients for comparing the difference of their system clocks through the LAN PTP. The method is similar to the Single-AP situation and shown in Figure 3 (b).

4 Software PTP

This section first describes our implementation of software PTP (§4.1). We analyze its performance from a system perspective (§4.2.1). Based on that, we propose system tuning techniques to improve the performance (§4.2.2) and a calibration procedure for using with diverse host platforms (§4.2.3). We conclude the trade-offs and limitations in §4.3.

4.1 Implementation - Software PTP

The PTP mechanism does not discriminate between Wi-Fi and Ethernet, but software PTP implementations do require NIC driver support to achieve reasonable accuracy. A user space program can take timestamps on its network socket but this just leads to a trivial NTP implementation, which has accuracy at the level of tens of *ms* [37]. According to equation (3)(4), software timestamps should be taken as close as possible to the Rx/Tx events to avoid software uncertainties. Therefore, Ethernet software PTP implementations normally take timestamps through the assistance of the NIC driver. However, we have not noticed any WNIC drivers provide such support, so we implement one for ath9k.

As WNICs use interrupts to inform the operating system about the Rx/Tx events, the system clock of the host is used to timestamp the PTP Tx/Rx events in the WNIC's interrupt service routine (ISR). The timestamps are first filled into a PTP-reserved field of packets' socket buffer, and then conveyed to and used by the kernel PTP subsystem and userspace PTP applications, *e.g.*, `linuxPTP`.

4.2 Findings and Analysis - Software PTP

Through measuring our software PTP implementation, the preliminary finding is that its synchronization is neither accurate nor stable. For example, when syncing two PCs under 48 Mbps PHY, 64 Byte size, 6000 PPS background traffic, the mean error is -1134 μs with std 992.5 μs . Results of using Jetson as the client are even worse, the mean error is -1892 μs with std 2947 μs . The performance is not consistent with the existing studies having similar implementations but with older platforms [33]. Our newer platforms perform much worse. To uncover the reasons, we look into the cause of the inaccuracy.

4.2.1 Root Cause of Inaccuracy

PTP accuracy is determined by T_{delay} and $\delta_{\text{Rx/Tx}}^{P/S}$ in equation (3)(4). For transmissions between Wi-Fi clients and AP, $T_{\text{delay}}^{P \rightarrow S} = T_{\text{delay}}^{S \rightarrow P}$, so the inaccuracy is caused by $\delta_{\text{Rx/Tx}}^{P/S}$. To characterize $\delta_{\text{Rx/Tx}}^{P/S}$, we measure its value of our platforms.

As shown in Figure 4, the measurement is aided by the TSF counter. When a packet is received, a WNIC takes several actions. First, it records the value of its TSF counter as $n_{\text{Rx}}^{\text{TSF}}$ at the time when the last bit of the packet is decoded. Second, the WNIC generates an interrupt to notify the operating system and also provides a brief description of the received packet, which contains $n_{\text{Rx}}^{\text{TSF}}$. Third, in the ISR of the WNIC driver, the operating system handles the Rx interrupt and takes software timestamp T^{SYS} . Once the software timestamp is taken, we read and record the TSF counter as $\hat{n}_{\text{Rx}}^{\text{TSF}}$. Since the I/O latency of reading TSF counter is relatively stable and small, $\hat{n}_{\text{Rx}}^{\text{TSF}} - n_{\text{Rx}}^{\text{TSF}}$ is just the number of 1 MHz ticks that $\delta_{\text{Rx}} + \frac{T_+^{\text{TSF}} - T^{\text{TSF}}}{2}$ takes². δ_{Rx} can then be obtained. As when a packet is transmitted, the WNIC also reports the Tx status through an interrupt, the process of measuring δ_{Tx} is similar. Moreover, as δ_{Tx} is close to δ_{Rx} and their trend is identical, we use $\delta_{\text{Rx/Tx}}$ to describe them interchangeably.

The results of $\delta_{\text{Rx/Tx}}$ of software timestamps are shown in Table 1, from which we identify two system optimization mechanisms, Interrupt Mitigation/Throttling and CPU Power Management, which increase $\delta_{\text{Rx/Tx}}$ and cause large jitters, corrupting the synchronization performance.

Interrupt Mitigation. Interrupt mitigation is a mechanism to reduce CPU overhead by aggregating NIC interrupts [13]. When multiple NIC events occur in a period, only one interrupt is generated to notify the host system. The trade-off is, interrupts of most packets are delayed and the host system is less timely in response to network events. Interestingly, while this feature is well-known in Ethernet NICs, to our knowledge, it is rarely mentioned and evaluated under the COTS Wi-Fi context. Actually, we have not noticed any WNIC driver implements and provides the configuration interface, before our software PTP implementation.

When PPS is low (row 1 of Table 1), the mean and peak of $\delta_{\text{Rx/Tx}}$ are about 500 to 700 μs , indicating most packets need to wait for at least 500 μs for an aggregated interrupt. This is because, by default, the WNIC needs to wait for 500 μs to see if there is a consecutive packet following. When PPS increases, the inter packet space is less than 500 μs . The 500 μs threshold would lead to an unbounded waiting time, so the WNIC sets another threshold to limit the maximum waiting time, which is around 2000 μs (see peaks of row 3 of Table 1).

In cases with large asymmetric PPS, interrupt mitigation affects $\delta_{\text{Tx}}^P - \delta_{\text{Tx}}^S$ and $\delta_{\text{Rx}}^P - \delta_{\text{Rx}}^S$ in (5) by more than 2000 μs , causing the sync error at a similar level. Interrupt mitigation can be disabled by hacking the WNIC (see §4.3). After doing so, the distribution of $\delta_{\text{Rx/Tx}}$ becomes much sharper (see the peak and mean difference of row 4,5,6 of Table 1), but when the CPU load is light, its mean is still as large as 176 μs (row 4 of Table 1). The reason is the following factor.

² $T_+^{\text{SYS}} - T^{\text{SYS}}$ is the PCIe WNIC read latency. For our PC's $\times 1$ slot, it is about 1.7 μs . For Jetson's $\times 4$ slot, it is about 1.4 μs .

CPU C-state	Network		CPU Load

Table 1: Error of Software Timestamp. Mean error and peak (mode) of the error distribution in unit of μs . The width of the color bars in each table cell illustrates the relative size of the underlying values. The bar of mean (blue)/peak (green) logarithmically grows from right to left/from left to right. Rx IMT is short for Rx Interrupt Mitigation.

CPU Idle Power Management. Modern CPUs leverage several mechanisms to dynamically conserve power [5]. When the CPU is idle, it might choose to turn off different numbers of hardware components, represented by different CPU idle states or C-states [43], e.g., from C0 to C8 in Intel i5 8500. CPU in deeper C-state consumes less power, but takes more time to wake up to the active state C0, e.g., to handle interrupts. As a result, power management mechanisms tend to let CPUs stay in lighter C-states when there likely are more intensive tasks or more frequent interrupts. This explains why $\delta_{Rx/Tx}$ decreases when CPU load and PPS increase (row 4,5,6 of Table 1). Different CPU and PPS loads lead to 150 μs difference in $\delta_{Rx/Tx}$, causing 150 μs mean error in synchronization. CPUs can be forced to stay in C0 state via its `sysfs`, in which it takes the least latency to respond to interrupts.

4.2.2 Software PTP with Proper System Configurations

Guided by the above analysis, we improve our software PTP implementation by disabling interrupt mitigation and forcing CPUs in C0 state. When the hardware of AP and client hosts is identical, the synchronization error in most cases is within 1 μs , with std less than 1 μs (A,C,E column of Table 2). However, it becomes less accurate when the hosts hardware is heterogeneous (the right subtable of Table 2). The reasons are rooted in the following factors.

In column AA, CC, and EE of Table 2, there is a constant bias of 4.x μs . This bias can be explained by comparing row 7-9 with row 10-12 of Table 1. Compared with Jetson, PC's software timestamps are delayed by 4.x μs , causing 4.x μs residues in $\delta_{Tx}^P - \delta_{Tx}^S$ and $\delta_{Rx}^P - \delta_{Rx}^S$ in (5), which leads to the bias error. What causes the difference between $\delta_{Rx/Tx}^P$ and $\delta_{Rx/Tx}^S$? Is ARM handling WLAN interrupts more timely than x86? These questions are out of our scope, but we have the following experience. Note that as both PC and Jetson are in C0 state in row 7-12 of Table 1, $\delta_{Rx/Tx}$ does not contain too much latency to wake up the CPU. Hence, $\delta_{Rx/Tx}$ mainly consists of two parts. One is attributed to the *WNIC interrupt latency*.

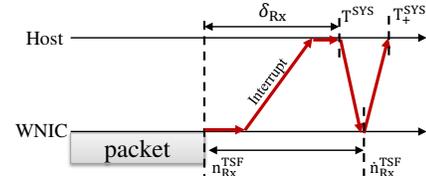

Figure 4: Using TSF Counter to Measure the Error of Software Timestamp.

There is an undocumented but stable delay between the end of Rx/Txing a packet and the issuing of the interrupt. This part is slightly different for the Rx and Tx chain, and different WNIC models. The remaining part (5 to 10 μs) characterizes the *responsiveness of the host system* in handling PCIe interrupts. Through extensive tests, we find this part varies with different host hardware, kernel versions, PCIe slots, and even CPU loads. Asymmetric interrupt responsiveness is common in host systems, which affects the PTP accuracy at the level of (less than) 10 μs .

4.2.3 Software PTP with Calibration

We discuss the calibration of the two types of bias errors.

Asymmetric Host Interrupt Responsiveness. Our insight is from the measurement method of Table 1. We note that the interrupt responsiveness is relatively stable when CPUs are in C0 and interrupt mitigation is off. Under such configurations, both the AP and client hosts can measure $\delta_{Rx/Tx}$ online when there is WLAN traffic, thus it is practically convenient. When using identical WNIC models, the *WNIC interrupt latencies* cancel out in (5), hence the secondary clock can subtract $\delta_{Tx}^P - \delta_{Tx}^S$ and $\delta_{Rx}^P - \delta_{Rx}^S$ from (5) to compensate for the bias of the host interrupt responsiveness.

Specifically, we measure all rows from 7 to 12 of Table 1. As the values are very close, only a subset is also enough. Note that the distribution of $\delta_{Rx/Tx}$ is single side and positive. The peak or mode of the measured $\delta_{Rx/Tx}$ is chosen as the specific value of $\delta_{Rx/Tx}$ for calibration (the mean value is affected by the long tail). We use the average of the peak values in Table 1 to compensate for the bias in Table 2. The compensated results are shown in Table 3. The mean error is less than 1 μs , which is comparable to the case using identical hardware (left subtable of Table 2). The std is $\times 3$ to $\times 5$ larger. The reason is the Jetson (ARM) platform is not as stable as the PC platform in handling interrupts. Jetson's $\delta_{Rx/Tx}$ contains a longer tail, which also can be observed from Table 1. i.e., PC's mean and peak is closer than Jetson's.

To investigate the long-term stability, we log the synchronization error (after calibration) for 14 hours for the same hardware settings as Table 3. A script is used to generate random CPU and network load to the client during the measurement to emulate practical scenarios. The overall mean error is 0.17 μs with std around 1.8 μs , indicating stable and accurate synchronization between the two hosts. Due to space limitations, we omit the measurement results of cross-AP and wireless-specific factors for software PTP. As the findings and conclusions are identical to the hardware PTP, the reader can

Network			PC (Client) $\xrightarrow{\text{sync to}}$ PC (AP)

refer to §5.2.2 and §5.2.3.

The above calibration procedure is based on measuring $\delta_{\text{Tx/Rx}}$, which is the time between the WNIC taking TSF timestamp ($n_{\text{Tx/Rx}}^{\text{TSF}}$) and the host system taking software timestamp (T^{SYS}). When we treat $\delta_{\text{Tx/Rx}}$ as the error of software timestamp, there is an implicit assumption that the TSF timestamp $n_{\text{Tx/Rx}}^{\text{TSF}}$ and the packet event have a known and fixed association, e.g., it is taken at the end of the packet, which, however, is not be true for different models of WNICs. Some models take TSF timestamps shortly after the end of the receiving, while others might take at the middle. We term this model-dependent factor as *TSF offset*. The *TSF offset* combined with the *WNIC interrupt latency* contributes about 10 μs to latencies in Table 1. While the *TSF offset* is unknown, it is fixed for the same model, hence it also automatically cancels out in equation (5) when using WNICs of the same model. However, when using different WNIC models, it needs offline calibration. We will revisit this issue later in §5.2.1.

WNIC Interrupt Latency is another hardware-related bias source. We note that the *TSF offset* only affects the above calibration, but *WNIC Interrupt Latency* is intrinsic in software PTP. When interrupt mitigation is disabled, the interrupt should be issued once the Tx/Rx event is finished, but in practice, there is a model-dependent delay, which can be observed when using different WNIC models on identical host platforms. Due to the coupling with the *TSF offset*, its value cannot be measured with the method in Figure 4. As a model-dependent factor, it needs offline calibration similar to *TSF offset*.

4.3 Discussion - Software PTP

Software PTP timestamps packets in ISR, which is a standard software routine in the network stack. Under certain configurations, software PTP can achieve inspiring results. The accuracy is μs -level and the std is within 2 μs , which is accurate enough for many time-sensitive applications. Next, we discuss the trade-offs and limitations.

Power Efficiency. Interrupt mitigation and CPU idle states are critical for the software PTP performance. However, completely disabling them is a concern for most mobile devices, as they are limited in battery life. A general workaround is duty cycling. Since PTP does not need to frequently exchange packets, PTP packets can be pre-scheduled at given time slots, during which the mobile host switches to the “active” mode (with C0 and IMT off) for precisely timestamping PTP packets. Additionally, there are other specific alternatives. For example for retaining idle states, the AP can choose to pre-heat the client by sending a dummy packet before every PTP packet. The client will be wakened up by the pre-heat packet. For reducing the number of interrupts while keeping responsive to PTP packets, PTP traffic can be assigned to the Rx priority queue (see the following paragraph). Moreover, since the PTP measurement is periodical, it has a negative impact on the IEEE 802.11 power-saving (PS) mode. We will discuss this issue later with hardware PTP in §5.3.

Hardware Compatibility. While software PTP is mainly finished in software routines, it depends on disabling interrupt mitigation to improve the PTP performance, which is not a typical configurable parameter in COTS WNICs. We achieve this in two ways. The first is to completely disable this feature through specific registers, which might lead to too many interrupts overwhelming the host system. Another way is to prioritize PTP packets. By default, Tx interrupt mitigation is disabled by the driver. The WNIC we tested implements two hardware Rx queues with different priorities. Packets with high IEEE 802.11 QoS priority are handled by the high-priority Rx queue, and their interrupts are delivered instantly without the mitigation delay. The above two approaches are all hardware-dependent features. While we have not confirmed the compatibility of other WNICs except for the ath9k series, we think such features are functionally reasonable and are likely supported by other modern WNICs.

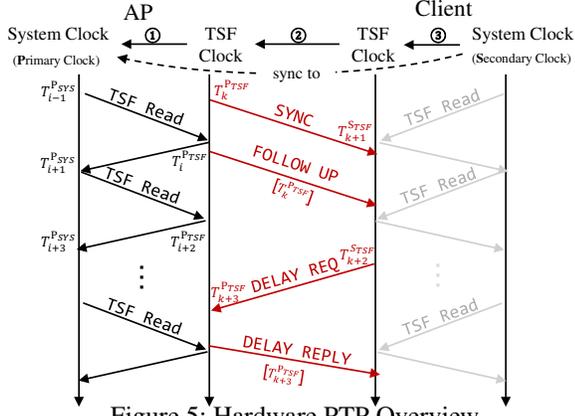

Figure 5: Hardware PTP Overview

5 Hardware PTP

This section first describes our implementation of hardware PTP for Wi-Fi devices (§5.1). Then we analyze its performance by considering the host system and hardware factors (§5.2.1). As a wireless synchronization approach, the impact of mobility and wireless channel conditions are considered in §5.2.2. Additionally, §5.2.3 demonstrates the feasibility of cross-AP synchronization. We summarize the benefit and limitations of hardware PTP in §5.3.

5.1 Implementation - Hardware PTP

Hardware PTP needs hardware counters to timestamp network packets, but how can the WNICs support a hardware feature that they are not originally designed for?

Our key insight is to treat the TSF clock as the hardware timestamping clock. The feasibility is based on two features. First, WNIC uses the TSF counter to timestamp network packets, for the purpose of protocol debugging, packet sniffing, *etc.* Second, the TSF counter can be accessed by the host operating system, through reading the TSF counter registers. The above features are the necessary conditions for a PTP hardware clock. By using the TSF counter, hardware PTP can be realized in Wi-Fi NICs in the same way as the Ethernet NICs. This subsection highlights the major procedures (①-③) shown in Figure 5:

① Generate $T^{P_{TSF}}$ and $T^{S_{TSF}}$. According to equation (1), we maintain a TSF clock for each WNIC based on its TSF counter. The time of the clock is denoted as T^{TSF} , which is determined by TSF counter and the clock parameters $\{T_{off}^{TSF}, R^{TSF}\}$.

② Sync $T^{P_{TSF}}$ to $T^{P_{SYS}}$. The host of the primary clock, *i.e.*, the AP, synchronizes its TSF clock to its system clock. The method is to read each clock and tune TSF clock's parameters $\{T_{off}^{P_{TSF}}, R^{P_{TSF}}\}$ to minimize the difference between $T^{P_{SYS}}$ and $T^{P_{TSF}}$. In practice, the latency and jitter of obtaining timestamps must be taken into consideration. We adopt a sandwich-like reading sequence to access $T^{P_{SYS}}$ and $T^{P_{TSF}}$ multiple times, and only the one with the smallest read latency ($T_{i+1}^{P_{SYS}} - T_{i-1}^{P_{SYS}}$), say k , are used to estimate their clock offset, *i.e.*, $\Delta = T_k^{P_{TSF}} - \left(\frac{T_{k-1}^{P_{SYS}} + T_{k+1}^{P_{SYS}}}{2}\right)$.

③ Sync $T^{S_{TSF}}$ to $T^{P_{TSF}}$. The host of secondary clock synchronizes its TSF clock to $T^{S_{TSF}}$ according to PTP protocol in Figure 2. Note that the WNIC hardware automatically timestamps packets with TSF counter. The value of the counter is transformed to TSF time according to ①. After each round of measurement, the time offset of two TSF clocks is estimated by $((T_1^{P_{TSF}} - T_2^{S_{TSF}}) + (T_4^{P_{TSF}} - T_3^{S_{TSF}}))/2$, according to which the host of $T^{S_{TSF}}$ tunes its TSF clock's parameters $\{T_{off}^{S_{TSF}}, R^{S_{TSF}}\}$ to minimize the offset between $T^{S_{TSF}}$ and $T^{P_{TSF}}$. Since $T^{P_{TSF}}$ has been synchronized to the primary clock $T^{P_{SYS}}$ in ①, $T^{S_{TSF}}$ is thus synchronized to $T^{P_{SYS}}$.

④ Sync $T^{S_{SYS}}$ to $T^{S_{TSF}}$. The host of secondary clock synchronizes $T^{S_{SYS}}$ to $T^{S_{TSF}}$ by tuning parameters $\{T_{off}^{S_{SYS}}, R^{S_{SYS}}\}$ like step ①. As $T^{S_{TSF}}$ has been synchronized to $T^{P_{SYS}}$ in step ②, the system clocks of two hosts, *i.e.*, $T^{P_{SYS}}$ and $T^{S_{SYS}}$, are then synchronized.

The above procedures mimic the implementation of hardware PTP of Ethernet NICs. However, unlike the Ethernet case, the TSF counter is not a free-running counter in Wi-Fi NICs. We analyze the impact of this difference in the following subsection.

5.2 Findings and Analysis - Hardware PTP

The measurement experiments are identical to the software PTP situation. The results are shown in Table 4. In all the cases, the mean error is less than $1 \mu s$ with std less than $1 \mu s$. Compared with software PTP, no obvious difference is observed when using different host platforms. This is because the timestamps are taken by the WNIC hardware, and involve no operations of the host system. A similar long-term measurement is conducted using Jetson as the client. The overall mean error is $-0.16 \mu s$ with std around $0.5 \mu s$. The sync std/jitter is smaller than the software PTP.

5.2.1 Potential Cause of Inaccuracy

While the accuracy is close to the resolution of the TSF counter (1 MHz), we investigate the following factors to provide a sound understanding on why and under what conditions the hardware PTP implementation works well.

Symmetry of PCIe Single-way Latency. In step ① and ③ in §5.1 and Figure 5. The TSF clock is obtained by accessing the TSF counter. This procedure relies on a PCIe read action to the WNIC registers, *i.e.*, memory-mapped I/O (MMIO) read. To account for the read latency, the read action is sandwiched by two timestamps of the system clock and the average of the two system timestamps is used to approximate the actual time of accessing the TSF counter. In fact, the read action contains a read request and a read reply, *i.e.*, a round trip. As a consequence, the estimation method assumes that the latencies of the read request and reply are equal, *i.e.*, the PCIe single-way latency should be symmetrical.

We are not able to quantitatively validate the symmetry due to the lack of a PCIe analyzer. However, in general, it should approximately hold, as the same problem exists in Ethernet

Table 5: Hardware PTP with Free-running TSF Counter (μs). Notations are same as Table 2. ROLE is the Wi-Fi mode of host (either Client or Access Point). The TSF counter of client mode is not free-running and used for comparison. BI is short for the Beacon Interval in unit of Time Unit (TU, 1024 μs in IEEE 802.11). The default BI is 100 TU, *i.e.*, 102.4 ms.

NICs (according to results in Table 4, the impact of this factor is not obvious in our WNICs). During the test, we also notice that the read latency slightly varies with the platform load, this is again related to the power management mechanisms, but it does not break the symmetry.

We note that the read latency of different hosts or PCIe slots is usually different (recall footnote 2 in §4.2.1), but the difference does not affect hardware PTP. This is because PCIe read actions only happen locally on the host system to relate the system clock to the hardware NIC clock. Whether $(T_{k-1}^{P_{\text{SYS}}} + T_{k+1}^{P_{\text{SYS}}})/2$ can accurately estimate $T_k^{P_{\text{TSF}}}$ or not only depends on the symmetry of single-way latencies, rather than the total read latency $T_{k+1}^{P_{\text{SYS}}} - T_{k-1}^{P_{\text{SYS}}}$.

Impact of TSF Synchronization. Note that in PTP, the timestamping clock should be a free-running clock. This is only true for the Wi-Fi AP. The TSF counters of the Wi-Fi clients are automatically set to the value of the AP’s TSF counter contained in the beacon packet broadcast by the AP every 102.4 ms. As many Wi-Fi timing functions, such as power save wake up, transmission scheduling, *etc.*, rely on TSF, therefore disabling the TSF synchronization would lead to a mess in the Wi-Fi network. Therefore, we design a new experiment to compare the performance of hardware PTP using/not using free-running TSF counters.

We use two PCs as APs and set their system clocks as the PTP primary clock and secondary clock respectively. The two APs work in the same channel, which allows them to overhear the broadcast packets from each other. The unicast addresses of PTP packets are modified to the broadcast address, so that two APs can exchange PTP packets to allow hardware PTP to operate in the same way as before. Since they are all in the AP mode, their WNICs’ TSF counters are free-running. The synchronization results are shown in Table 5.

Comparing row 3 of Table 5 and row 1 of Table 4, there is no obvious performance increase or reduction when using a free-running TSF counter. However, when the beacon interval is increased, *i.e.*, the TSF synchronization frequency is reduced. The case using the free-running counter stays the same (row 2 of Table 5), while the normal configuration becomes more unstable (row 1 of Table 5). This is because the TSF counter of the Wi-Fi AP is free-running, but the TSF counter of the Wi-Fi client is periodically set to beacons. Due to the frequency drift between the two TSF counters, the value of the client’s counter jumps once it is reset by the beacons. The longer the client’s TSF counter does not sync to the beacon, the larger the jumps are. Therefore, lower sync frequency results in larger jitters in the client’s PTP clock $T^{S_{\text{TSF}}}$, and hence the sync results.

Comparing row 1 of Table 5 (BI=1000) and row 1 of Table 4 (BI=100), when the frequency of beacons is as high as the default (BI=100), the impact of TSF synchronization is limited due to two reasons. First, by default, the TSF counter is actually so frequently updated, that the jump values of the TSF counter are very small. For our WNICs, the clock drift is 20 ppm, meaning that the counter at most drifts 2 μs in each 100 TU. Second, the jumps of the TSF counter do not affect the TSF clock at the same level. This is because when an offset of TSF clocks is observed by the PTP protocol (② of §5.1), $T^{S_{\text{TSF}}}$ is adjusted by the rate part, *i.e.*, parameter R in equation (1), and several control filters are used to smooth the impact of noise and outliers. Due to the above reasons, when the client’s TSF counter is frequently updated to the AP’s, it can be viewed as a “free-running” counter, which has exactly the same rate as the AP’s TSF counter but with more jitters.

Impact of TSF Offset. Hardware PTP uses the TSF counter to timestamp packets, hence $\delta_{\text{Rx/Tx}}$ in (5) is free of the impact of the host system but is affected by the WNIC *TSF offset*. When WNICs have different *TSF offsets*, $\delta_{\text{Rx/Tx}}$ in equation (5) will not cancel out, which results in bias error. In another experiment not presented here, we replaced the client’s WNIC with another model of Atheros NIC, then a constant positive 1 μs mean error occurred in all the cases. This implies $\delta_{\text{Rx/Tx}}$ does exist and differs across models. Other indirect evidence is from the driver source code. There are registers with magic numbers for compensating TSF timestamps, which directly affect the mean errors in Table 4. Similar to the software PTP, one can use WNICs of the same model to avoid *TSF offset* (the host platforms may differ), otherwise, an

Table 6: Cross-AP Hardware PTP Results (μ s). Notations are same as Table 2.

Factors	Acronyms	Meaning
Network & CPU Load	load	Network and CPU load are applied to (load) or not applied to (load) the client. When applying the load, we use the same configuration as cell 6-EE of Table 1, i.e., 48 Mbps, 64 Byte, 5000 PPS, 100% CPU.
Mobility	static* walk rotate	The mobility is introduced through holding the client to walk or rotating it, while keeping the AP static. The moving speed introduced by walking and rotating is around 1 m/s and 2 m/s.
Signal Strength	-30 dBm -55 dBm* -75 dBm	The received signal strength is adjusted by placing the client in different locations. The value is measured and reported by the WNIC hardware on the per packet basis.
Interference	none* 100 PPS 250 PPS	Two hosts are configured to transmit Wi-Fi packets (64 Byte @ 6 Mbps) with carrier sense disabled. Their transmissions not only occupy the channel but can also interfere with on-going PTP transmissions.
	default	Default configurations for comparison are denoted with *

Table 7: Measurement Acronyms.

offline calibration procedure is needed to measure and correct *TSF offset*. A typical solution (like the hardware offset in PTP Ethernet NICs) is to measure those model-dependent values with a reference clock, then the driver maintainer corrects them in the source code.

5.2.2 Wireless-Specific Impacting Factors

As a wireless synchronization approach, PTP over Wi-Fi may also be affected by wireless-specific factors. We study their impact by performing PTP under different mobility, signal strength, and interference levels. The error distributions are shown in Figure 6. In most cases, no obvious difference is observed from the default case, meaning that these factors do not affect PTP synchronization. This is because both hardware and software PTP depend on the accuracy of the timestamps of the PTP packets, but these wireless factors can not affect successfully-decoded packets³. Also, note that the neighboring interference significantly decreases the accuracy. This is because, due to the strong interference, PTP packets are jammed, postponed, and (mostly) dropped. As a result, the PTP algorithm does not have enough timestamps for clock adjustment, which significantly increases sync intervals and causes large jitters.

5.2.3 Cross-AP Synchronization

We conduct measurements of cross-AP synchronization (see Figure 3 (b)). Results are shown in Table 6. Compared with the Single-AP situation in Table 4, the mean error is similar. This is because when APs are synchronized boundary clocks,

³Depending on the implementation, TSF timestamps might be related to the PHY-layer frame synchronization, which is affected by channel conditions. However, the error should be within one cyclic prefix, i.e., 0.8 μ s in 802.11a.

Network		PC (Client 1) → PC (AP 1) ↗ Jetson (Client 2) → PC (AP 2) ↘						
		CPU Load						
Rate	Size	PPS	0%		50%		100%

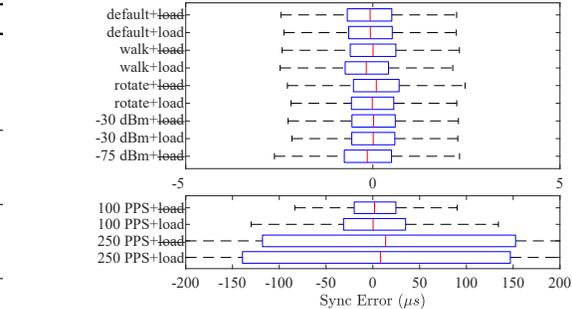

Figure 6: Sync Error Distribution v.s. Wireless Impacting Factors. The central mark indicates the median, and the left and right edges of the box indicate the 25th and 75th percentiles, respectively. Refer to Table 7 for the explanation of acronyms. There is no network load at -75 dBm case, as the SNR is not enough to decode 48 Mbps PHY rate packets.

clients synced to one AP are also synced to other APs and clients. The synchronization performance among clients is determined by the wired link and the Wi-Fi link. The former is guaranteed by Ethernet PTP (ns-level), while the latter has been studied in our previous measurements (μ s-level). However, jitters of the Cross-AP are more intense than that of the Single-AP. This is because Table 6 compares the clocks of client1 and client2 rather than clocks of client and AP. When two secondary clocks (hosted by client1 and client2) are synchronized to the same primary clock (hosted by AP1), their errors are independent random variables. The variance of their difference is the sum of their individual variances. This is a known limitation of the PTP boundary clock mode, whose error is accumulated along the sync chain [7].

5.3 Discussion - Hardware PTP

We discuss the potential improvement and power efficiency of hardware PTP, and then we compare it with software PTP.

Further Improvement. Hardware PTP syncs two hosts with high resolution system clocks (sub ns-level) via low-resolution (1 μ s) TSF clocks. In principle, the synchronization resolution is related to the stability, rather than the resolution of TSF clocks. A finer resolution might be achieved by sending a burst of PTP measurement packets with a fixed inter-packet interval. It might be possible to infer or interpolate sub- μ s timestamps by analyzing the rounding/stepping patterns of TSF timestamps.

Power Efficiency. Hardware PTP does not need to timely activate the host system for software timestamping, since

HOST	WNIC	Software PTP	Hardware PTP
same	same	✓	✓
diff.	same	int. calib.	✓
same	diff.	hw calib.	hw calib.
diff.	diff.	int.+hw calib.	hw calib.
timestamp packets		ISR	hw support
read TSF counter		no need	hw support
power efficiency		similar	

Table 8: Software and Hardware PTP Requirements

the timestamps have been taken by the WNIC hardware and stored in the meta info associated with the packets. However, PTP traffic has a negative impact on the IEEE 802.11 PS mode, where the WNIC of the client is aggressively turned down into a low power mode when there is no traffic. The AP buffers packets for the PS client and sends notifications through the beacons. The client WNIC wakes up at every beacon to check if there are packets for it, if there are, the WNIC will heuristically stay active for a certain period. As a result, the PTP traffic stimulates the WNIC periodically, making the PS mode deficient. We measure the impact with a power meter. When there is no traffic, the PS mode can save 0.37 W. When the PTP (4 PPS) is enabled, the PS can only save 0.15 W. Considering the overall standby power of the Jetson board is only 2 to 3 W, the trade-off between synchronization accuracy and power efficiency must be carefully considered when applying PTP to low-power applications.

On the other hand, when the PS is enabled, PTP packets will be delayed for 30 to 100 ms, but the delay does not affect the synchronization performance. This is because the timestamp of a buffered packet is taken when it is sent off to the air and when it is correctly received by the client.

Hardware v.s. Software PTP. From Table 2 and 4, both hardware and software PTP implementations can achieve μ s-level accuracy with COTS Wi-Fi devices, which we believe is sufficient for most time sensitive mobile applications. Besides, they inherit the benefit of PTP and can extend the synchronization range across multiple APs. To make the choice between them, we summarize their requirements in Table 8. When using different hosts for the primary and secondary clocks, software PTP needs to calibrate the interrupt responsiveness (int.calib. see §4.2.3). When using different WNICs, they both need offline calibration to correct hardware offsets (hw calib. see §4.2.3 and §5.2.1). We note that to support hardware PTP, the WNIC should be able to timestamp packets with its TSF counter and also provide the counter reading interface (see §5.1). While TSF is a mandatory feature of IEEE 802.11, these features are not, hence they might not be available on COTS WNICs. In short, if there are supported WNICs, hardware PTP is a convenient and accurate choice for Wi-Fi synchronization. Otherwise, software PTP is a more general and flexible choice with different levels of accuracy requiring different levels of calibration.

6 Other Wi-Fi Synchronization Protocols

This section compares PTP with TSF and FTM.

TSF synchronization is automatically finished by the WNIC hardware. The AP broadcasts the value of its TSF counter in beacon frames, according to which its client WNICs reset their TSF counters. Since TSF is originally designed for timing functions of Wi-Fi protocol, the TSF counter by default is not related to the host system clock. Therefore, we measure the difference between the TSF counters of the AP and the client to estimate the synchronization error. Their TSF counters are read and sandwiched by synchronized Ethernet PTP clocks like Figure 5. The time offset between the client and AP counter is calculated and shown in Table 9.

Similar to the hardware PTP implementation, errors of TSF synchronization are independent of the host system and the system load. There is a bias error of -4μ s and the jitter is larger. The bias error is attributed to different TSF offsets of the Tx and Rx chain, *i.e.*, $\delta_{Tx} \neq \delta_{Rx}$. Bias is a common error source of single-way synchronization methods. The jitter is caused by the TSF counter jumps caused by the frequency drift. Additionally, TSF cannot be directly used to sync clocks in the cross-AP situation. We note that while the above problems are not fundamental, for example, the bias error can be calibrated, a complete solution would probably just lead to our hardware PTP implementation, which makes use of the two-way PTP measurement to factor the offset off and leverages existing PTP interface to sync clocks in a scalable manner.

FTM/TM is the latest feature of the IEEE 802.11 standard. They use dedicated WNIC hardware for timestamping. FTM and TM differ in resolution. TM is at the level of 10 ns, while FTM is ps-level. FTM's high time resolution is designed for measuring the time-of-flight (ToF) of radio waves for ranging. Another goal of TM/FTM (IEEE 802.11as Clause 12 [2]) is to extend the LAN PTP synchronization to Wi-Fi devices, targeting the same problem as our PTP implementations.

Although some COTS WNICs support FTM for localization [27], they rarely expose the synchronization interface. After extensive tries, the only feasible way we found (by referring to the PTP daemon `gptp` [8] managed by Intel) to enable synchronization of FTM WNICs is: 1. using Intel FTM WNICs (Intel 8260 AC) with 2. proprietary Windows driver [11] 3. in the Wi-Fi direct mode (Ad-Hoc mode). We also note that even though it does work, the running protocol is TM rather than FTM (they differ in time resolution), which is observed through packet sniffing.

Given the above hardware and software, we are still not able to measure the accuracy of TM/FTM as Windows 10 does not natively support hardware PTP and Windows Server does not support the WNIC driver, thus the ground truth cannot be obtained. However, the std of the sync error can be measured and is shown in Table 10. The std is around 0.4μ s, which is close to our hardware PTP based on the TSF counter, but

Network			PC (Client) $\xrightarrow{\text{sync to}}$ PC (AP)					
			CPU Load					
Rate	Size	PPS	0%		50%		100%	
/	/	0	-3.78	1.09	-3.62	0.96	-3.67	1.13

			AA	BB	CC	DD	EE	FF

Table 9: TSF Synchronization Results. Values are in unit of μs . Notations are same as Table 2.

Network	CPU Load			std
	0%	50%	100%	
0%	0.39	0.44	0.41	
50%	0.36	0.36	0.34	
100%	0.37	0.38	0.39	

Table 10: TM Results. Values are std of estimated synchronization error in unit of μs . CPU load and network load (represented by channel occupancy) are generated by CPUSTRES and PSPING from Sysinternals [19]

this value is actually very large compared with its 10 ns-level timestamp resolution. The reason is unknown but it is probably caused by the incomplete implementation or being intentionally disabled/hidden by the Intel firmware.

We believe FTM and TM provide an ideal solution for Wi-Fi synchronization, but it seems its primary goal is positioning and the synchronization feature is publicly unavailable right now. This is probably because FTM is only an optional feature of IEEE 802.11, or simply because of market reasons.

7 Related Work

Due to the importance of synchronized time in distributed systems [30], network synchronization protocols have been extensively discussed [42]. In a small network scale like LANs, the network delay between nodes is stable under prioritized switching [47] and the packets can be accurately timestamped by NIC hardware. These facts guarantee the performance of LAN PTP, and in practice it achieves nanosecond accuracy with commercial Ethernet NICs [25]. It is natural to extend PTP to wireless LANs due to the synchronization demand of mobile systems [44]. Corresponding practices started a decade ago and a comprehensive survey is given by [34]. We next review software and hardware PTP separately.

For hardware PTP, existing work focuses on improving timestamp accuracy and precision. The challenge is that wireless channels bring uncertainties to the received RF signals, making it hard to determine the accurate start of the packet. Modern OFDM-based and wideband PHYs allow the accuracy to reach several ps. However, most research work is based on laboratory prototypes [22, 24, 28] and commercial FTM WNICs are mainly for ranging and positioning purposes [27]. As a result, the performance of hardware PTP with COTS Wi-Fi devices remain unknown. Our work makes hardware PTP available on COTS devices and then characterizes its performance.

Our hardware PTP implementation is based on the TSF counter, so it is related to TSF-based synchronization ap-

proaches. RF-WiFi [45] makes use of TSF interrupts to notify the host systems so that they can take synced actions. Mahmood *et al.* study the IEEE 802.11 Timing Advertisement feature [36], which uses beacon frames to convey AP’s system clock to clients. However similar to TSF, it is single-way and thus has a bias. We have not encountered any works which make use a TSF counter as a hardware PTP clock.

For software PTP, the majority of existing work was conducted ten years ago with IEEE 802.11b Atheros WNICs. As a result, most insights no longer sufficient to light the current situation due to the rapid evolution of mobile systems. For example, the PCI DMA latency [33] becomes a minor issue since newer WNICs use PCIe [40]. The TSC clock is stable and independent of the core frequency [35] due to the adoption of invariant TSC in modern processors [21]. The impact of the CPU and network load is studied by existing work [26, 33], but our measurement reveals that they are not major factors.

Existing discussions on CPU idle power management focus on server platforms [43]. Our work reveals its impact on mobile platforms and on synchronization performance. Further, we have not noticed any discussion on interrupt mitigation under the context of Wi-Fi networks. As far we know, Atheros 802.11b WNICs does not have this feature, and hence past work based on old WNICs is able to achieve stable software PTP performance even without realizing this factor.

8 Conclusion

Accurate time synchronization is a key enabler for many distributed control and sensing applications. In this work, we study the performance of PTP protocol in Wi-Fi networks through systemic implementation and rigorous evaluation. The in-depth discussion and open-source implementation render a useful reference for designing and adopting PTP in Wi-Fi networks.

Abstract

The satellite-ground integrated network is highly heterogeneous with diversified applications. It requires congestion control (CC) to achieve consistent high performances in both long-latency satellite networks and large-bandwidth terrestrial networks and cope with different application requirements. However, existing schemes can hardly achieve these goals, for they cannot balance the objectives of CC (i.e., throughput, delay) adaptively and are not objective-configurable. To address these limitations, we propose and implement a novel adaptive CC scheme named AUTO, based on Multi-Objective Reinforcement Learning (MORL). It is *environment-adaptive* by training a MORL agent and a preference adaptation model. The first can generate optimal policies for all possible preferences (i.e., the relative importance of objectives). The latter automatically selects an appropriate preference for each environment, by taking a state sequence as input to recognize the environment. Meanwhile, AUTO can satisfy diversified application requirements by letting applications determine the input preference at will. Evaluations on emulated networks and the real Internet show that AUTO consistently outperforms the state-of-the-art in representative network environments and is more robust to stochastic packet loss and rapid network changes. Moreover, AUTO can achieve fairness against different CC schemes.

1 Introduction

To achieve global coverage and meet the excessive custom demand for data access, the satellite-ground integrated network has attracted intensive research interest [1]. It is highly heterogeneous where a node can send data to different peers through both satellite networks located at different orbits, and ground networks including the Internet and cellular networks [2]. To achieve consistent high user experiences in all these environments with widely varying packet loss rates, round-trip time (RTT) and available bandwidth, *adaptive Congestion Control (CC)* is one of the key technologies [3]. Basically,

(a) Inter-datacenter network

(b) Satellite network

Figure 1: Sending rates of two CC schemes that adopts two different preferences. A fixed preference can only achieve high performance in specific types of environments.

it determines sending rates, convergence speeds, and the reactivity to network fluctuations of underlining flows. It has two competing objectives, i.e., optimizing link utilization (high throughput) while avoiding congestion (low queuing delay) [4].

The two objectives have to be balanced adaptively in different environments [5], since a fixed preference (i.e., the relative importance of the objectives) can only achieve high performance in specific types of environments. To illustrate this phenomenon, we conduct an experiment by first training two Reinforcement Learning (RL) based CC schemes using the same training ground with two different preferences. We evaluated their performances in the emulated inter-datacenter network and the satellite network WINDs [6] based on Pantheon [7]. The former is high-speed and has a short buffer while the latter has a long latency. As shown in Figure 1, putting higher weight on “throughput” achieves good performance in the satellite network but meanwhile suffers from severe packet loss in the ground network. The main reason is that a saturated buffer only has little punishment on the final reward and the trained model cannot detect the congestion. In contrast, putting higher weight on “delay” suffers from slow convergence in the satellite network because it is too sensitive to delay variation.

Meanwhile, a CC schemes for the integrated network

*Feilong Tang is the corresponding author of this paper.

will serve diversified applications at the same time. Delay-sensitive applications such as online meetings require higher weight to be put on “delay”, while throughput-sensitive applications such as file synchronization require higher weight to be put on “throughput”. To cope with all these requirements, the CC scheme should be able to let applications determine the preference at will.

Lots of CC schemes have been proposed in recent years, which can be classified into *heuristic-based* or *learning-based* schemes. Unfortunately, they cannot achieve the consistent high performance in all environments nor cope with diversified application requirements [7]. We analyze the reasons in what follows.

Heuristic-based methods hard-wire actions with predefined events or signals (e.g., packet loss, delay variation) based on the analysis of network characteristics. However, the analysis is not suitable for all kinds of network environments [8]. For example, *loss-based* methods such as TCP Cubic [9] take packet loss as the sign of congestion and is not suitable for unreliable lossy scenarios, while the *delay-based methods* such as Copa [4] don’t work well in the short buffer scenarios for the delay fluctuates in a very small range [10]. Meanwhile, the hard-wire mapping fundamentally limits the objective configurability.

Existing learning-based methods can only achieve high performance in specific network environments [5, 8]. One of the main reasons is that they convert the objectives into a single reward function (RL) [5, 11–15] or utility function (online learning) [16–18] by introducing fixed empirical preferences and determine actions accordingly. Although training a series of models with different preferences to cope with different environments may alleviate this problem, the lack of an environment recognition method makes them unable to switch models adaptively.

Based on above analyses, we in this paper propose an *Adaptive congestion control method based on mULTI-Objective reinforcement learning*, abbreviated as AUTO. It first divides time into consecutive monitoring intervals and formulates the CC as an extended version of the multi-objective Markov decision process. It then trains a *MORL agent* and a *preference adaptation model*, based on which it adjusts the sending rate at the end of each interval. Compared with existing approaches, it has following characteristics.

Firstly, AUTO is *environment-adaptive*. It automatically balances the two objectives in different environments where the preference adaptation model can adaptively select an environment-adaptive preference for users, by taking a state sequence as input to recognize the network environment. Meanwhile, the policy agent can generate optimal policies for all possible network states and preferences. Combining the two components, AUTO achieves the consistent high performance in different environments.

Secondly, AUTO is *objective-configurable*. Since the MORL agent only needs to be trained once and can deal

with any input preferences, AUTO can cope with diversified application requirements.

Moreover, AUTO is *competitive-configurable*. The input preference determines the AUTO’s delay-sensitivity and further influence its competitiveness against other flows. Therefore, AUTO can achieve fairness against different competing CC schemes and allows users to explicit adjust the priority of different flows, by adjusting the preference.

Main contributions are summarized as follows.

1. We propose an efficient and practical *Multi-Objective Reinforcement Learning (MORL) framework*. It trains a single MORL agent that can recover optimal policies for all possible preferences.
2. We propose a novel *environment-adaptive preference selection method*. We first propose a policy similarity model, based on which we find the best preference for each training environment by comparing with the expert policy. Then we train a preference adaptation model to automatically select preferences.
3. We propose and implement AUTO based on the above framework and method. It is easy to deploy for it requires sender-only modification. It consistently outperforms than the state-of-the-art in representative scenarios and is more robust to network changes and packet loss. Moreover, it can achieve fairness against other CC methods.
4. We develop an emulation-based training suite Pantheon-Gym for MORL-based CC. It eases the training by providing standard OpenAI Gym interfaces for researchers.

2 Related Work

We classify related work on learning-based CC methods into the following three categories.

RL-based methods train a policy model with the goal of maximizing a reward function. QTCP [13] adopted the Q-Learning framework and formulate the reward function as the proportional fairness [19] of throughput and delay. RL-TCP [12] adopted a SARSA [20] based RL framework and added the packet loss rate in the reward function. Their actions specify how to change the congestion window in response to variations in the network environments and they are trained on simulators NS2 [21] and NS3 [22] respectively. Aurora [5] formulate the reward function as the weight sum of throughput and delay. Meanwhile, it implements a simulation-based gym environment. To train the agent on real network environments, authors in [14] adopt the same reward function and designed Park, which is an open platform for learning-augmented computer systems. Considering the delayed action phenomenon, an asynchronous RL framework called MVFST-RL was proposed in [11]. To combine reinforcement learning and traditional CC schemes, TCP-RL [15] took different traditional CC schemes as the action space and trained the model through emulations built by the Linux tool. To solve the CC problem

for multi-path TCP, authors in [23] proposed SmartCC, which calculates the reward according to throughput, latency, and delay jitter. Authors in [24] proposed DRL-CC, which adopts the goodput as rewards. To solve the centralized congestion control problem, Iroko [25] formulate the reward function as a function of the bandwidth utilization and the latency of all links. Its action is to regulate the sending rates of all nodes. However, the trained policy model can only be applied to the fixed network topology and is intractable for large networks.

Online learning-based methods try to fine-tune the sending rate and decide the adjustment direction according to a utility function and they also split the time into consecutive monitoring intervals. PCC-Allegro [16] formulates the utility function as a function of the sending rate and the loss rate, while Vivace [17] puts delay into consideration on this basis. PCC Proteus [18] defines two kinds of utility functions. It can behave as a primary protocol for primary flows or an effective “scavenger” that only utilizes the residue bandwidth of primary flows. Compared with the RL-based methods, online learning-based methods cannot learn the prevailing network regularities and have been shown to have poorer performance than RL-based methods [5].

Inverse RL-based methods seek to avoid the empirical preference setting by finding a reward function from the expert demonstrations. Indigo [7] trained a model to adjust the sending rate every 10 ms by directly imitating expert behaviors. This kind of method is not objective-configurable and cannot cope with different application requirements. Meanwhile, both the RL-based and inverse RL-based methods cannot achieve fairness against other flows [5], since their competitiveness is not configurable and strongly related to the training environments.

To cope with the heterogeneity of the integrated network, we in this paper propose a new kind of learning-based method, i.e., *MORL-based method*. It addresses the limitations of existing methods and is environment-adaptive, objective-configurable, and competitive-configurable. Thus, it can achieve consistent high user experience for flows passing through different environments and with different performance requirements.

3 Multi-objective Reinforcement Learning based Congestion Control

In this section, we propose practical methods for training the MORL agent that can generate optimal policies for all possible preferences.

3.1 Congestion Control Formulation

In order to apply the MORL framework, we first formulate the congestion control as a *Multi-Objective Markov Decision Process (MOMDP) with delayed actions*. Formally, it can be described by a tuple $(\mathcal{S}, \mathcal{A}, \mathcal{P}, \mathcal{R}, \Omega, \gamma, f_\Omega)$, where

- $\mathcal{S} \subseteq \mathbb{R}^n$ is the continuous state space;
- \mathcal{A} is the discrete action set;
- \mathcal{P} is the Markovian transition model;
- $\mathcal{R} : \mathcal{S} \times \mathcal{A} \rightarrow \mathbb{R}^2$ is the set of two reward functions and corresponds to the two objectives for CC;
- $\Omega \subseteq \mathbb{R}^2$ is the preference space;
- $\gamma \in [0, 1)$ is the discount factor;
- f_Ω is the set of preference functions that convert the reward vector into one scalar according to the chosen preference $\omega \in \Omega$.

In this work, preference $\omega \in \Omega$ is a vector of two values, i.e., $\omega = [\omega_t, \omega_d]$ is the weight on throughput and delay respectively. Meanwhile, we consider functions in f_Ω are linear functions, i.e.,

$$f_\omega(\mathcal{R}(s, a)) = \omega^T \mathcal{R}(s, a), \forall s \in \mathcal{S}, \forall a \in \mathcal{A} \quad (1)$$

In the MOMDP, a policy π is associated to an expected return for a given preference $\omega \in \Omega$, which is denoted as

$$J_\omega^\pi = \mathbb{E}_{s_t \sim \mathcal{P}, a_t \sim \pi} \left[\sum_{t=0}^T \gamma \cdot f_\omega(\mathcal{R}(s_t, a_t)) \right] \quad (2)$$

where $s_t \sim \mathcal{P}$ means state s_t is sample from \mathcal{P} and $a_t \sim \pi$ means action a_t is selected according to policy π .

The goal for solving MOMDP is to find the set of Pareto-optimal policies for all possible preferences, which is depicted as

$$\Pi^* = \{\pi | \exists \omega \in \Omega, \nexists \pi' : J_\omega^{\pi'} > J_\omega^\pi\}. \quad (3)$$

MOMDP with delayed actions is an extension of the MOMDP, which means that actions won't take effect immediately and therefore the state s_{t+1} is not only influenced by action a_t and state s_t , but also influenced by the previous actions and states. It is caused by two reasons. Firstly, the apply of the action is delayed due to the policy lookup time [11]. Since the environment is running asynchronously, it would keep transmitting data based on the old action a_{t-1} during the policy looking up. Secondly, the state observation is delayed since the states are updated based on packet ACKs. After action a_t is applied, it takes about $0.5 \cdot \text{rtt}_t$ for receiver to receive the packets sent based on a_t . It takes another $0.5 \cdot \text{rtt}_t$ to response the ACKs. Thus, the observed network state is influenced by the action made rtt_t before.

In what follows, we describe the formulation of state space, reward functions, the action set and the Monitoring Interval (MI) in detail.

State space considering delayed actions (\mathcal{S}). To accurately identify the network congestion without explicit network information, we select the following features to model network states. To further improve the robustness and generalization of the trained model, we try to use relative values instead of absolute values such as latency and sending rate.

- **Latency Ratio** r_{lat}^t [19]. Latency ratio is the ratio of the current MI's mean latency to minimum observed mean latency, which is one of the most important features to detect congestion.
- **Sending Ratio** r_{send}^t [5]. Sending ratio is the ratio of the number of sent packets to the number of acknowledged packets. It helps agents adjust the sending rate.
- **Packet Loss Rate** r_{loss}^t . The r_{send}^t is influenced by the inflight ACKs. To prevent the agent from overestimating the congestion level, we add r_{loss}^t in the state.
- **Latency Gradient** g_{lat}^t [17]. Latency gradient is the derivative of latency with respect to time. The agent can infer that the sending rate is greater than the capacity if $g_{lat}^t > 0$.
- **Action** a_t . Considering that the state is influenced by the previous actions (the delayed action phenomenon), the action history should be put in the state to fasten convergence [11].

The delayed action phenomenon makes the reinforcement learning more challenging, since it is hard for agents to catch the real transition for the MOMDP. Therefore, we let each state be a history of the network statistics so that the agent can capture the influence of previous action on future states. We use h to represent the history length and the state $s_t \in \mathcal{S}$ can be formulated as

$$s_t = \{r_{lat}^{t-i}, r_{send}^{t-i}, r_{loss}^{t-i}, g_{lat}^{t-i}, a_{t-i} \mid i \in [0, h]\}. \quad (4)$$

Multi-Objective Reward Functions (\mathcal{R}). The goal of the CC is to achieve both high throughput and low queuing delay. Correspondingly, we adopt the average throughput, denoted as throughput_t , and the negative mean RTT as reward functions, i.e.,

$$\mathcal{R}(s_t, a_t) = [\text{throughput}_t, -\text{rtt}_t]. \quad (5)$$

RTT-adaptive monitoring interval. In AUTO, the state and the rewards are calculated at the end of each MI. A short MI is not enough for capturing the real transition in long-RTT scenarios, while setting the MI too long reducing the real-time responsiveness to the network dynamics in short-RTT scenarios. To cope with the heterogeneous network environment and considering that each action takes about $0.5 \cdot \text{rtt}_{t-1}$ to take effects, we adopt the RTT-adaptive MI and set the length of each MI to

$$|\text{MI}_t| = \min\{0.5 \cdot \text{rtt}_{t-1}, 1.5 \cdot \text{rtt}_r^{\min}\} \quad (6)$$

where rtt_r^{\min} is the observed minimum RTT. It guarantees that the MI is longer enough and meanwhile let CC be able to quick react to congestion.

Action set (\mathcal{A}). In our proposed CC scheme, each action corresponds to an adjustment on the sending rate. To adapt to heterogeneous environments with variant bandwidth, we seek

to adjust the sending rate proportionally and adopt an action set containing seven discrete values:

$$\mathcal{A} = \{\div 2, \div 1.3, \div 1.1, \times 1, \times 1.1, \times 1.3, \times 2\} \quad (7)$$

where “ $\div x$ ” means “dividing the sending rate by x ”, and “ $\times x$ ” means “multiplying the sending rate by x ”.

Since the reward function is the combination of throughput and delay, the agent will observe the equivalently bad rewards when the sending rate raises to 50x or 100x bandwidth and the buffer queue is saturated. In the training stage, bonding the sending rate to reasonable limits will produce the same transitions and meanwhile decrease CPU overheads caused by packet generation and sending. Thus, we set the sending rate in MI_t , denoted as sr_{t+1} , to

$$sr_{t+1} = \min(\text{apply}(sr_t, a_t), 500\text{Mbps}) \quad (8)$$

where $\text{apply}(sr_t, a_t)$ is a function that applies action a_t on sending rate sr_t .

3.2 Parallel MORL Training Framework

The goal of the MORL agent is to achieve consistent high performance in diverse environments under different preferences. Since the optimal policy in these scenarios varies, the MORL agent has to be trained in a series of environments with different network characteristics and input preferences. It results in the *catastrophic forgetting problem* [26] and *extended training time*, where catastrophic forgetting means that the knowledge for previously learned environment is abruptly destroyed by the training in the new environment.

To cope with these issues, we utilize an efficient parallel MORL training framework as shown in Figure 2. Basically, it is an extended version of the Asynchronous Advantage Actor-Critic framework [27] and has three key points. Firstly, it is *asynchronous*, which means multiple agents are used to train actors in parallel and updates the global parameters periodically. To deal with the catastrophic forgetting problem, we train the agent in different environments simultaneously, by letting each agent interacts with a specific type of environment (e.g., long latency, low bandwidth, high throughput weight). Secondly, it is based on the actor-critic paradigm [28]. In the training phase, the actor updates the policy parameters in the direction suggested by the critic while the critic updates the value function parameters. Thirdly, it uses the *advantage* function instead of the raw value of an action [29], which helps us better compare the actions for a given state and makes the training process more stable.

The adopted framework greatly improves learning efficiency. On the one hand, it fastens the interaction through parallel training. On the other hand, it improves the sample efficiency by adopting the off-policy RL approach, which reuses any past episodes through the experience replay mechanism. Furthermore, it improves the exploration efficiency since the

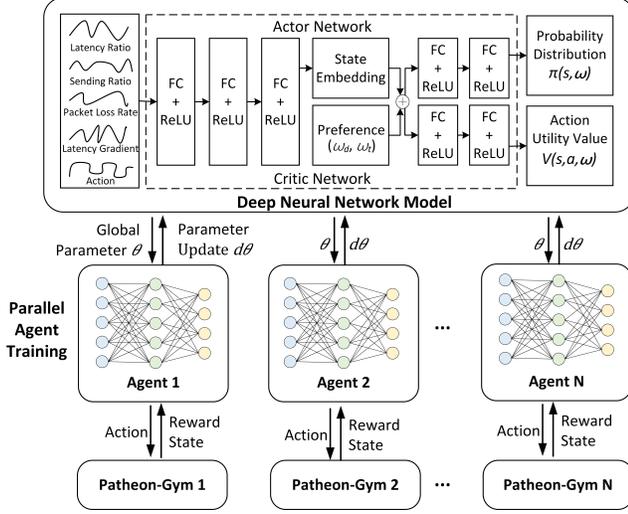

Figure 2: MORL Training Framework.

adopted off-policy brings better explorations for sample collection, by following a behavior policy that is different from the target policy.

Deep Neural Network Model. As shown in Figure 2, we use two deep neural networks with state s and preference ω as input and $2|\mathcal{A}|$ Q-values as output. The first is the actor network, which outputs the probability distribution over the action space. The second is the critic network, which outputs the utility value of the action. The parameters in two networks are denoted as θ_π and θ_v , respectively.

The two networks share three fully connected layers, each of which uses a rectified linear activation unit (ReLU) for feature extraction from raw inputs. The extracted features are then concatenated with the preference value and fed into different fully connected layers for output.

3.3 Agent Training Strategies

To train the MORL agent with multiple reward functions, we update the neural network model according to a generalized version of bellman equation [30]

$$\mathbf{Q}^\pi(s, a, \omega) = \mathbb{E}_{s' \sim P} \left[\mathcal{R}(s, a) + \gamma \mathbb{E}_{a' \sim \pi} [\mathbf{Q}^\pi(s', a', \omega)] \right] \quad (9)$$

where \mathbf{Q} is the Multi-Objective Q-value (MOQ-value) function. Its key idea is to use the vectorized value function to perform envelope updates. It allows our method to quickly align one preference with optimal rewards and trajectories that may have been explored under other preference. Thus, it can learn a single parametric representation for optimal policies over the whole preference space.

Based on the above equation, we can calculate the target for a given transition (s, a, s', \mathbf{r}) at step k by

$$\mathbf{y} = \mathbb{E}[\mathbf{r} + \gamma \arg_{\omega'} \max[\omega'^T \mathbf{Q}(s', a, \omega'; \theta_k)]] \quad (10)$$

where s and s' are the previous state and the current state, a is the adopted action, \mathbf{r} is the reward vector, ω' is sampled according to a fixed distribution, θ_k is the network parameters at step k and $\mathbf{Q}(\cdot; \theta)$ is the MOQ-value function parameterized by θ . Then, we can use the mean square error (MSE) between the prediction returned by the neural networks and the target,

$$L^A(\theta) = \mathbb{E}_{s, a, \omega} \left[\|\mathbf{y} - \mathbf{Q}(s, a, \omega; \theta)\|_2^2 \right] \quad (11)$$

3.3.1 Homotopy optimization

Unfortunately, directly optimizing L^A is challenging in practice since it is non-smooth considering that the optimal frontier contains a large number of discrete solutions. To solve this problem, we adopt homotopy optimization [31] similar to [30]. To be specific, we construct an auxiliary loss function L^B that directly optimize the scalarized Q value as,

$$L^B(\theta) = \mathbb{E}_{s, a, \omega} [\|\omega^T \mathbf{y} - \omega^T \mathbf{Q}(s, a, \omega; \theta)\|]. \quad (12)$$

Thus, the overall loss function is formulated as

$$L(\theta) = (1 - \lambda) \cdot L^A(\theta) + \lambda \cdot L^B(\theta) \quad (13)$$

where λ slowly increases from 0 to 1 in the training process and shifts the loss function from L^A to L^B .

Finally, we can calculate the stochastic gradient of network parameters by

$$d\theta_\pi = \frac{1}{N_\omega N_\tau} \sum_{i, j} T_{ij} \quad (14)$$

$$d\theta_v = (1 - \lambda) \cdot \nabla_{\theta_v} L^A(\theta_v) + \lambda \cdot \nabla_{\theta_v} L^B(\theta_v) \quad (15)$$

where N_ω and N_τ are the minibatch sizes for sampling transitions and preferences respectively and

$$T_{ij} = [\omega_i^T (\mathbf{V}_{ij} - \mathbf{V}(s_j, \omega_i; \theta_v))] \nabla_{\theta_\pi} \log \pi(a_j | s_j, \omega_i; \theta_\pi).$$

Here, $\mathbf{V}(s_j, \omega_i; \theta_v)$ is the baseline for calculating the advantage [29] and \mathbf{V}_{ij} is the estimated optimal value, which can be calculated by

$$\mathbf{V}_{ij} = \begin{cases} \mathbf{r}_j & \text{if done} \\ \mathbf{r}_j + \gamma \arg_{\omega' \in W} \max \omega_i^T \mathbf{V}(s_{j+1}, \omega'; \theta) & \text{o.w.} \end{cases} \quad (16)$$

3.3.2 Early termination trick

For training efficiency, the *needle-in-the-haystack problem* [14] has to be solved, which is described as follows. In the exploration stage of the training, the agent performs random walks and may be trapped in congestion states, i.e., when the sending rate is above the available network bandwidth and the buffer is saturated, the agent can only observe equivalently bad rewards (which is the combination of throughput and latency). It provides meaningless gradients and results in extremely inefficient training.

To solve this problem and stabilize the training process, we propose a simple but useful method called *early termination trick*. The basic idea is to increase the training step length according to the episode index. In this work, we adopt a linear function to calculate the termination index of each training step, which is depicted as

$$f_{et}(i) = \delta_a + (i \bmod \delta_b) \quad (17)$$

where δ_a is the initiate step length and δ_b is the step growth speed.

Algorithm 1: Agent Training Algorithm

Input: Minibatch sizes N_τ and N_ω ; network parameters θ_π and θ_v ; λ for homotopy optimization; δ_a and δ_b in the early termination trick.

Output: Trained parameters θ_π and θ_v .

- 1 Initialize replay buffer $\mathcal{D}_\tau = \{\}$.
 - 2 Set $\mathcal{D}_\omega = U\{\omega_r + \omega_d = 1 | \omega_r \in (0, 1), \omega_d \in (0, 1)\}$.
 - 3 **for** $episode = 1, \dots, M$ **do**
 - 4 Synchronize parameters $\theta'_v = \theta_v$ and $\theta'_\pi = \theta_\pi$.
 - 5 Sample a preference $\omega \sim \mathcal{D}_\omega$.
 - 6 **for** $t = 0, \dots, N - 1$ **do**
 - 7 **if** $t \geq f_{et}(episode)$ **then**
 - 8 **break**
 - 9 Calculate state s_t according to Eq. (4).
 - 10 Sample an action $a_t \sim \pi(a_t | s_t, \omega; \theta'_\pi)$.
 - 11 Get $(\mathbf{r}_t, s_{t+1}, done)$ from the environment.
 - 12 Set $\mathcal{D}_\tau = \mathcal{D}_\tau \cup (s_t, a_t, \mathbf{r}_t, s_{t+1})$.
 - 13 **if** $|\mathcal{D}_\tau| \geq N_\tau$ **then**
 - 14 Sample $(s_j, a_j, \mathbf{r}_j, s_{j+1}) \sim \mathcal{D}_\tau$.
 - 15 Sample $W = \{\omega_1, \omega_2, \dots, \omega_{N_\omega}\} \sim \mathcal{D}_\omega$.
 - 16 Calculate $d\theta_\pi$ and $d\theta_v$ using Eq. (14)(15)
 - 17 Perform asynchronous update of θ_v using $d\theta_v$ and of θ_π using $d\theta_\pi$.
 - 18 **return** θ_π and θ_v ...
-

3.3.3 Training algorithm

Combine the above components, we get the agent training algorithm as shown in Algorithm 1, which works as follows. We first initialize the replay buffer as an empty set (line 1) and adopt a uniform distribution for preference sampling (line 2). At the beginning of each episode, the agent synchronizes the network parameters with the global parameters (line 4). Next, it interacts with the environment to collect the trajectory for the replay buffer (lines 5-12). Considering the needly-in-the-haystack problem, the step length is calculated based on the early termination trick (lines 7-8). Then the stochastic gradient of the parameters for the actor network ($d\theta_\pi$) and for the critic network ($d\theta_v$) are calculated according to the sampled transitions and the homotopy update trick (lines 13-

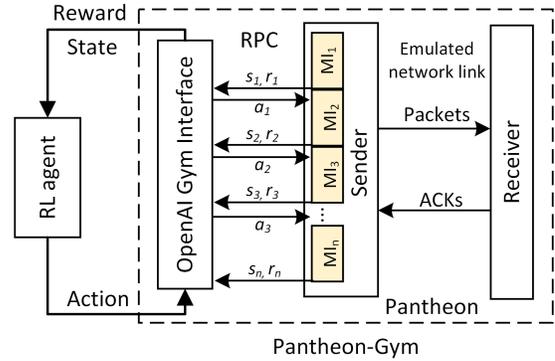

Figure 3: Pantheon-Gym architecture.

16). Finally, the global parameters are updated asynchronously based on $d\theta_\pi$ and $d\theta_v$ (line 17).

Essentially, Algorithm 1 is to iteratively apply the Bellman optimality operator \mathcal{T} on \mathbf{Q} . Since \mathcal{T} is a contraction mapping on the complete pseudo-metric space, Algorithm 1 will finally terminate with a MOQ-value function \mathbf{Q} that is equivalent to the preferred optimal value function \mathbf{Q}^* based on the Multi-Objective Banach Fixed-Point Theorem [30].

3.4 Pantheon-Gym: MORL Training Suite For CC

To train the models and to facilitate further research, we present Pantheon-Gym, which is an asynchronous MORL suite for CC based on the OpenAI Gym interface [32] and Pantheon [7] as shown in Figure 3. It supports MORL by returning a reward vector rather than a single scalar. Meanwhile, it interacts with the MORL agent with the standard OpenAI Gym interface, letting researchers design their own agent in an easy way.

Besides the features adopted in our state space, it also supports various kinds of features including 1) sending rate; 2) receiving rate; 3) 95th percentile latency; 4) the exponentially-weighted moving average (EWMA) of the queuing delay; 5) the EWMA of the sending rate; 6) the EWMA of the receiving rate. Users can conveniently customize their own reward functions and state space.

Compared with Aurora [5] which proposes a training suite based on a simulated network environment, Pantheon-Gym provides more realistic training data by adopting an emulated network environment. To promote bandwidth utilization and training efficiency, Pantheon-Gym trains models in an asynchronous fashion similar to MVFST-RL [11]. The agents, Gym interface and the emulated network work in different processes and communicate with each other through remote procedure calls. Therefore, the environment steps are not blocked by the policy lookup and the forward-pass in the training stage.

4 Environment-Adaptive Preference Selection Method

In this section, we propose a novel environment-adaptive preference selection method by training the preference adaptation model with the help of the expert policy. When the preference is not determined by the upper-level application, it automatically selects a suitable preference by taking the state sequences as input to recognize the network environment.

4.1 Expert Policy

In the training stage, since we know the link capacity, we can construct an expert policy π^* that adjusts the sending rate to the link capacity as quickly as possible. More specifically, assuming c is the link capacity, then the action produced by the expert policy at each MI is depicted as

$$\pi^* : a_t = \arg_{a \in \mathcal{A}} \min(|\text{apply}(sr_t, a) - c| + c * \mathbb{1}_{\text{apply}(sr_t, a) > c}) \quad (18)$$

where $\mathbb{1}_{\text{apply}(sr_t, a) > c}$ is a binary function that outputs 1 if $\text{apply}(sr_t, a)$ is larger than the link capacity c . It guarantees that actions that do not cause excessive sending rate will be prioritized.

4.2 Policy Similarity Model

We next propose a policy similarity model based on the cumulative reward distributions [33], which is used to quantify the similarity between the expert policy and the policy for a given preference ω . Based on it, we find the best preference for each training environment. Compared with ordinary methods that only use the expectations to estimate the policy, such a method achieves higher accuracy.

The cumulative reward for policy π is defined as

$$\hat{\mathcal{R}}^\pi = \sum_{t=0}^T \gamma^t \mathcal{R}(s_t, a_t). \quad (19)$$

Due to the transition probability, $\hat{\mathcal{R}}^\pi$ is a random variable in \mathbb{R}^2 . For a given policy π , we further define its Markov chain as $\mathcal{M}(\pi) = \{\mathcal{S}, \mathcal{A}, \mathcal{P}, \mathcal{R}, \pi\}$. Then the cumulative distribution of $\hat{\mathcal{R}}^\pi$ can be formulated as,

$$P^\pi(\boldsymbol{\epsilon} | s, a) = \Pr(\hat{\mathcal{R}}^\pi \leq \boldsymbol{\epsilon} | s, a, \mathcal{M}(\pi)) \quad (20)$$

By assuming this distribution follows a multi-variable Gaussian distribution $G(\boldsymbol{\epsilon}; \theta)$ parameterized by θ , and adopting a Monte Carlo sampling technique to collect dataset \mathcal{D} , we can get the distribution parameters by,

$$\Theta^* = \arg_{\Theta} \max \mathbb{E}_{\mathcal{D}}(G(\boldsymbol{\epsilon}; \Theta)) \quad (21)$$

We then use the Kullback-Leibler divergence [34] between the expert and the policy generate by different preference as the similarity measurement, which is formulated by

$$D_{\text{KL}}(G^* \| G_\omega) = \int_{-\infty}^{\infty} G(\boldsymbol{\epsilon}; \Theta^*) \log \left(\frac{G(\boldsymbol{\epsilon}; \Theta^*)}{G(\boldsymbol{\epsilon}; \Theta_\omega)} \right) d\boldsymbol{\epsilon} \quad (22)$$

where $G^* = G(\boldsymbol{\epsilon}; \Theta^*)$ and $G_\omega = G(\boldsymbol{\epsilon}; \Theta_\omega)$ are the Gaussian distributions for the expert policy and the policy generated by preference ω . A larger D_{KL} means that the similarity between the two policies is lower.

4.3 Preference Adaptation Model

Based on the policy similarity model, we first find the most suitable preference ω for each training environment, under which the reward distribution is most similar to that of the expert policy (i.e., $D_{\text{KL}}(G^* \| G_\omega)$ is minimized). Then, by running a set of experiments using an indicator preference $\tilde{\omega}$, we can collect the training dataset $\mathcal{D}_p = \{(\mathcal{S}_0, \omega_0^*), (\mathcal{S}_1, \omega_1^*), \dots, (\mathcal{S}_n, \omega_n^*)\}$, where \mathcal{S}_i is a state trajectory, and ω_i^* is the most suitable preference for \mathcal{S}_i .

Build upon this dataset, the policy adaptation problem can be formulate as a classification problem where each candidate preference can be seen as a class. To solve this problem, we train a *preference adaptation model* named *AdaM* using supervised learning. *AdaM* is a three-layer neural network. The first two layers of it are Long Short-Term Memory (LSTM [35]) layers that can efficiently handle the sequence data while the last layer is a fully connected layer.

We adopt the cross entropy loss [36] to train *AdaM*, which is formulated as

$$\mathcal{L} = - \sum_{i=0}^N \omega_i \log(\omega_i^*) \quad (23)$$

where ω_i^* is the ground truth for training sample i , while ω_i is the prediction. We omit the details of the training procedure since it is a classical supervised learning.

Algorithm 2: Preference Adaptation Algorithm

Input: Trained model *AdaM* and π ; indicator preference $\tilde{\omega}$; sample count SC .

Output: Optimal ω for the current environment.

- 1 Initialize sequence buffer $\mathcal{S} = \{\}$.
 - 2 Observe the current state s according to Eq. (4).
 - 3 Get instruction policy $\pi_{\tilde{\omega}}$
 - 4 **for** k from 1 to SC **do**
 - 5 Sample an action $a_t \sim \pi_{\tilde{\omega}}(s)$.
 - 6 Observe a new state s' .
 - 7 Set $\mathcal{S} = \mathcal{S} \cup s'$.
 - 8 Set $s = s'$.
 - 9 **return** $\omega = \text{AdaM}(\mathcal{S})$.
-

Once we train the *AdaM*, we can use Algorithm 2 to infer the most suitable preference. It first initializes the state sequence buffer and observes the initial state (lines 1-2). Then, it collects a state sequence by interacting with the environment using the policy generated by the indicator preference $\tilde{\omega}$ (lines 3-8). Finally, we infer the best preference using the trained adaptation model *AdaM* (line 9).

5 Implementation and Evaluations

5.1 System Settings

Model Training and AUTO Implementation. We adopted the same training parameters as Aurora [5] to train the MORL agent as shown in Table 1. All parameters are sampled uniformly except the queue size, for which the log is sampled uniformly. The history length is set to 10. To train the preference adaptation model, we set the sample count SC to 10 and set the indicator preference $\tilde{\omega}$ to $[0.3, 0.7]$, i.e., the weights of throughput and delay are 0.3 and 0.7 respectively.

Table 1: Training Parameters

Bandwidth	Latency	Queue size	Loss rate
100-500 pps	50-500 ms	2-2981 packets	0-5%

We train models with 16 workers in parallel with different sampled preferences. It takes around 7 days on a server with Intel Xeon Gold 6148 CPU and 128G memory to converge. The whole model takes about 0.5 milliseconds on our server. Using the two trained models, we implemented a user-space prototype on top of Pytorch [37] and the UDT framework [38]. It only requires modifications on the sender side and it works smoothly when any other CC scheme on the receiver-side sends per-packet ACK.

Evaluation environments. We evaluate performances in both emulated environments and the real Internet through following tools.

- Pantheon [7]. The Pantheon is a community evaluation platform. It supports performance evaluations on the Internet and meanwhile can generate *calibrated network emulators* that capture the diverse performance of real Internet paths. It only supports point-to-point topology and can run one scheme at once.
- CoCo-Beholder [39]. The CoCo-Beholder is an emulator based on Pantheon. It emulates multiple flows with different CC schemes on a dumbbell topology.

Compared CC algorithms. We compare AUTO with state-of-the-art methods that have been proven to achieve high performance in the heterogeneous network, including heuristic-based CC algorithms FillP [40], Copa [4], BBR [41] and LEDBAT [42], online learning based method PCC-Allegro [16] and Vivace [17], inverse RL based method Indigo [7], RL-based method Aurora [5], and statistic-based method TaoVA [43]. We further adopt classic TCP variants including TCP Cubic [9] and TCP Vegas [44] as baselines.

5.2 Achieve Consistent High Performance in Different Environments

We first show AUTO achieves consistent high performance in different network environments by evaluating its perfor-

mance in three real-world, representative, and very different environments and a hybrid network environment.

5.2.1 Satellite network

The first representative environment is the satellite network, where links typically have longer RTT. We evaluate the performance on Pantheon parameterized with the real-world measurements of the WINDs satellite system [6], replicating an experiment from the PCC-Allegro paper [16]. The link has 800 ms RTT, 42 Mbps capacity, 0.74% stochastic loss rate, and a queue size of 1500. Part of the comparison algorithms have been shown to achieve high performance in this environment, including PCC-Allegro [16], Vivace [17] and Copa [4].

Figure 4(a) shows as expected, AUTO achieves different trade-off results between delay and throughput by inputting different preferences. Therefore, AUTO can cope with different application requirements. In contrast, other methods only obtain a single trade-off result.

For each comparison algorithm, there is always a preference under which AUTO achieves a better performance. Compared with methods that work well in satellite network environments, AUTO (0.8, 0.2)¹ achieves similar throughput but 14% shorter delay compared to PCC-Allegro, and 30.0% higher throughput and 20.6% shorter delay than Vivace, while AUTO (0.5, 0.5) achieves 6.9% higher throughput and 12.2% shorter delay than Copa. Compared with Indigo, the throughput and the delay of AUTO (0.2, 0.8) are 19.9% higher and 5.0% shorter respectively. Compared with BBR, AUTO (0.2, 0.8) achieves 153.5% higher throughput and 5.7% shorter delay. Compared with schemes that achieve short delay, the throughput of AUTO (0.05, 0.95) is about 1.1 times of FillP, 3.1 times of Aurora, 4.0 times of TaoVA, 15.3 times of TCP Cubic, 29.2 times of TCP Vegas, and 86 times of LEDBAT.

In this environment, (0.5, 0.5) is selected as the default preference by the preference adaptation model. Its corresponding packet loss rate is shown in the blue bar in Figure 5, which is 79.0% and 85.9% lower than Copa and PCC-Allegro that achieve comparable throughput. With much higher throughput, the packet loss rate of AUTO (0.3, 0.7) is also lower than FillP, BBR, Vivace, and Aurora.

5.2.2 Cellular network

The second representative environment is the cellular network, where the links have time-varying speeds and are usually modeled as Poisson Point Processes (PPP). We emulate this environment on Pantheon parameterized with the real-world measurements of the path from Amazon Web Services (AWS) in Brazil to the Colombia cellular network, replicating an experiment from Pantheon [7]. The link has 260 ms RTT, 3.04 Mbps capacity, 0.6% stochastic loss rate, and a queue size of 426.

With different preferences, AUTO outperforms other meth-

¹We use AUTO (ω_t, ω_d) to represent AUTO with preference set to $[\omega_t, \omega_d]$.

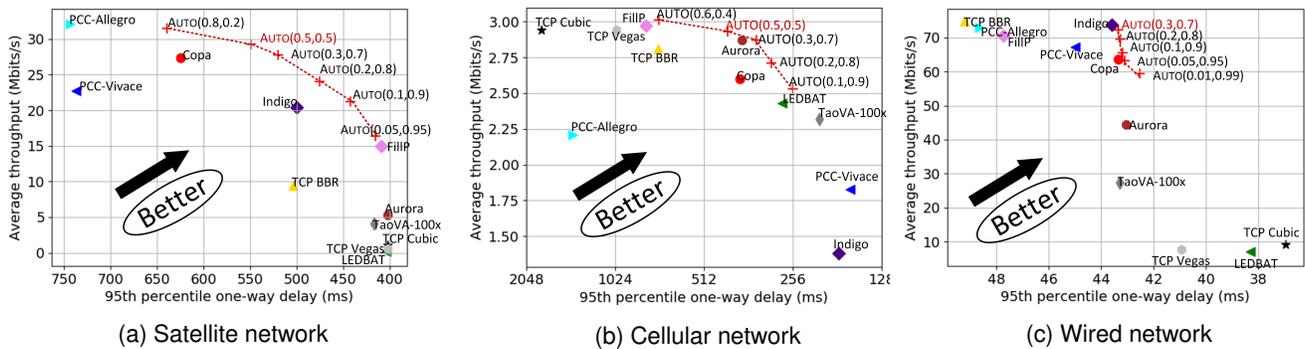

Figure 4: Throughput v.s. 95th percentile one-way delay in three representative environments. AUTO achieves consistent high performance and can cope with different application requirements by achieving a series the Pareto dominate results.

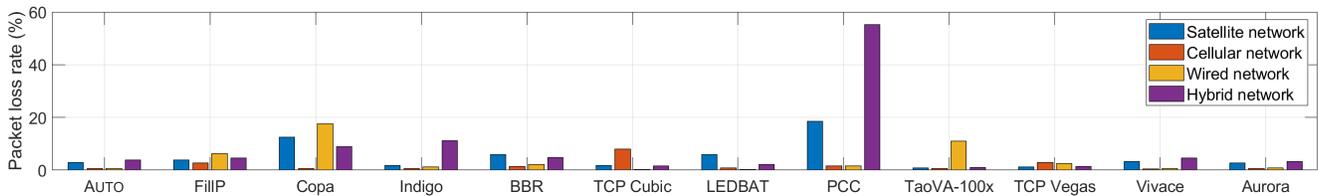

Figure 5: Packet loss rate in the satellite, cellular, wired, and hybrid network environments

ods in different aspects as shown in Figure 4(b). By setting the preference to (0.6, 0.4), AUTO achieves the highest throughput. Compared with other methods that prefer high throughput, it achieves 61.1%, 28.2% and 9.7% shorter delay than TCP Cubic, TCP Vegas and FillIP respectively. By putting more weight on delay, AUTO achieves shorter delay at the expense of lower throughput. Statistically, AUTO (0.3, 0.7) achieves 5.7% higher throughput and 16.3% shorter delay than Copa. With almost the same throughput, it achieves 10.2% lower latency compared with Aurora. AUTO (0.1, 0.9) achieves 4.1% higher throughput and 8.3% shorter delay than LEDBAT. For other methods that achieve low link utilization in this environment, AUTO (0.1, 0.9) achieves 9.1%, 14.5%, 38.3% and 83.3% higher throughput than TaoVA, PCC-Allegro, Vivace and Indigo respectively.

The default preference in this environment is (0.5, 0.5). Under this preference, the packet loss rate of AUTO is 0.64% and is lower than all other methods except Vivace, which achieves 0.56% packet loss rate but very low link utilization.

5.2.3 Wired network

The third representative environment is the wired network, where the links have higher bandwidth and shorter buffer. We evaluate the performance in this environment on the real Internet by utilizing two servers located at Shanghai and Hong Kong respectively. The link between the two server has about 36.2 ms RTT and 80 Mbps capacity.

Although the link bandwidth in the evaluate environment is far beyond the training range [1.12 Mbps, 5.6 Mbps], AUTO

still achieves a set of Pareto dominant results as shown in Figure 4(c). This is because the adopted state space achieves a good generalization of the model. By setting the preference as FillIP, Copa, PCC-Allegro, Vivace and Indigo and meanwhile achieves shorter delay. Due to the stochastic packet loss, TCP Cubic, TCP Vegas and LEDBAT have poor performance in this test. Due to the slow convergence, the throughput of Aurora is 38.5% lower than AUTO (0.3, 0.7).

In this test, the queuing delay fluctuate in a small range because of the small queue size. If setting the throughput weight too large (≥ 0.4), AUTO will neglect the small queuing delay, which will result in high packet loss rate. Therefore, we set the throughput weight no higher than 0.3. In contrast, the delay-based method Copa cannot detect congestion correctly and therefore has large packet loss rate as shown in Figure 5.

Similar to the previous results, the default preference setting (0.3, 0.7) achieves lower packet loss rate than other CC algorithms that achieve the similar throughput. Quantitatively, the packet loss rate of AUTO (0.3, 0.7) is 88.9% lower than FillIP, 96.0% lower than Copa, 42.1% lower than Indigo, 57.3% lower than PCC-Allegro and is 2.7% lower than Vivace.

5.2.4 Hybrid network

To show AUTO can cope with the heterogeneous satellite-ground integrated network, we next evaluate the performance on an emulated hybrid network path using Pantheon. The hybrid path contains a satellite link with 800 ms RTT and 42 Mbps bandwidth, and a terrestrial link with 40 ms RTT and

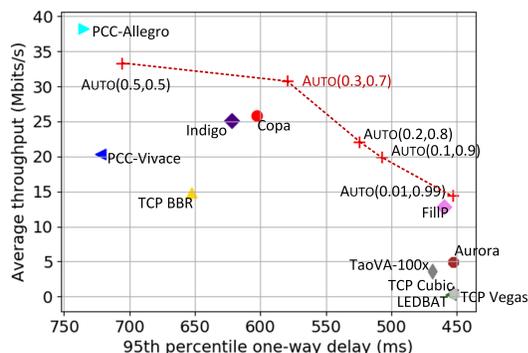

Figure 6: Throughput v.s. 95th percentile one-way delay in the hybrid network environment.

60 Mbps bandwidth.

For congestion control, the hybrid path can be abstracted as a single special link. Its delay and packet loss rate are the total delay and the overall packet loss rate of the path respectively, while its bandwidth is the bandwidth of the bottleneck link on the path. Since the bandwidth-delay ratios of hybrid paths are covered by representative environments, AUTO can well cope with it. As shown in Figure 6, AUTO achieves both high throughput and low latency. With similar latency, AUTO(0.01, 0.99) achieves 14.36 Mbps throughput, corresponding to a gain of 52.2 \times , 30.9 \times , 18.9 \times , 2.9 \times , 1.9 \times , and 12.5% over LEDBAT, TCP Vegas, TCP Cubic, TaoVA, Aurora, and FillP respectively. With similar throughput, it also improves the delay by 30.7% compared with BBR. AUTO(0.1, 0.9) achieves similar delay with Vivace but its delay (507.2 ms) is 29.8% shorter. Compared with Copa, AUTO(0.3, 0.7) improves the throughput and delay by 18.6% and 3.9% respectively. Meanwhile, it achieves 22.5% higher throughput and 6.9% lower delay compared with Indigo.

From the perspective of packet loss rate, the default preference setting (0.3, 0.7) performs better than all other methods that achieve a link utilization rate higher than 15%. As shown in Figure 5, it still achieves 15.0%, 16.9%, 18.9%, 57.0%, 65.5% lower packet loss rate than FillP, Vivace, BBR, Copa, and Indigo respectively. Although PCC-Allegro achieves the highest throughput in this scenario, it fails to detect congestion since the chosen preference is not suitable for this scenario. It suffers from 55.11% packet loss rate, which is 13.3 \times higher than AUTO(0.3, 0.7).

5.2.5 Summary

Existing CC methods cannot adapt to diversified environments. For example, BBR and FillP suffer from low throughput or long delay in the satellite, cellular, and the hybrid network environments. Due to the fixed monitoring interval and lack of consideration on delayed action phenomenon, Indigo can only achieve high performance in the wired network environment. Due to the empirical preference settings, PCC

suffers from unacceptably high packet loss in the satellite environment, Vivace suffers from low throughput in both satellite and cellular network environments, while Aurora has poor performance in the satellite and the wired network environments.

In contrast, AUTO adapts to different network environments by automatically adjusting the preference. Although we adopt a relatively small training range, the trained policy model achieve high performance since there is no absolute value in the state space. Its performance can be further improved by adding more training environments. Further, by finding the Pareto-optimal frontier, AUTO can cope with different application requirements.

5.3 Adapt to Rapid Network Changes

We next show AUTO achieves high reactivity and adapts to the rapid network changes by emulating a link with dynamic available bandwidth, which changes every 5 seconds with a uniform distribution ranging from 2 Mbps to 10 Mbps. The link delay and loss rate are set to 50 ms and 1% respectively.

Figure 7(a) shows that AUTO achieves highest average throughput. Quantitatively, it reaches 5.95 Mbps and 92.3% link utilization, corresponding to a gain of 2.6%, 5.1%, 7.0%, 11.8%, 16.9%, 37.4%, 45.5%, 75%, 1.58 \times , 2.79 \times , 3.92 \times over FillP, Vivace, BBR, Copa, TaoVA, Indigo, PCC-Allegro, Aurora, LEDBAT, TCP Vegas and Cubic, respectively. To further demonstrate AUTO's reactivity, we show AUTO achieves shorter delay comparing to other algorithms that achieve comparable throughput in the blue bar. More specifically, compared with FillP, Vivace and BBR, the delay of AUTO is 25.4%, 96.6%, and 74.7% shorter.

Figures 7(b)-(m) illustrate the behavior of different CC methods across time. As shown in Figure 7(b), AUTO's sending rate fluctuates around the available bandwidth since it adjusts the sending rate mainly according to delay variation. It tries to increase the sending rate when the latency ratio is small and to decrease otherwise. FillP and BBR also achieve good performance but have longer converge time when the bandwidth suddenly increases. Although Vivace achieves high throughput, it cannot cope with the bandwidth decrease and result in extremely long delay and high packet loss rate. Due to the slow convergence, Aurora has low reactivity and suffers from poor bandwidth utilization. Other algorithms such as Copa, Indigo, Cubic, Vegas, and LEDBAT cannot cope with the variant bandwidth or misestimate the network status due to the stochastic packet loss rate. Their and suffer from low throughput.

5.4 Resilient to Stochastic Packet Loss

Then, we show that AUTO is resilient to stochastic packet loss, which is challenging for CC algorithms since the stochastic packet loss caused by poor link quality could let CC algorithms mistakenly think that congestion occurred and further

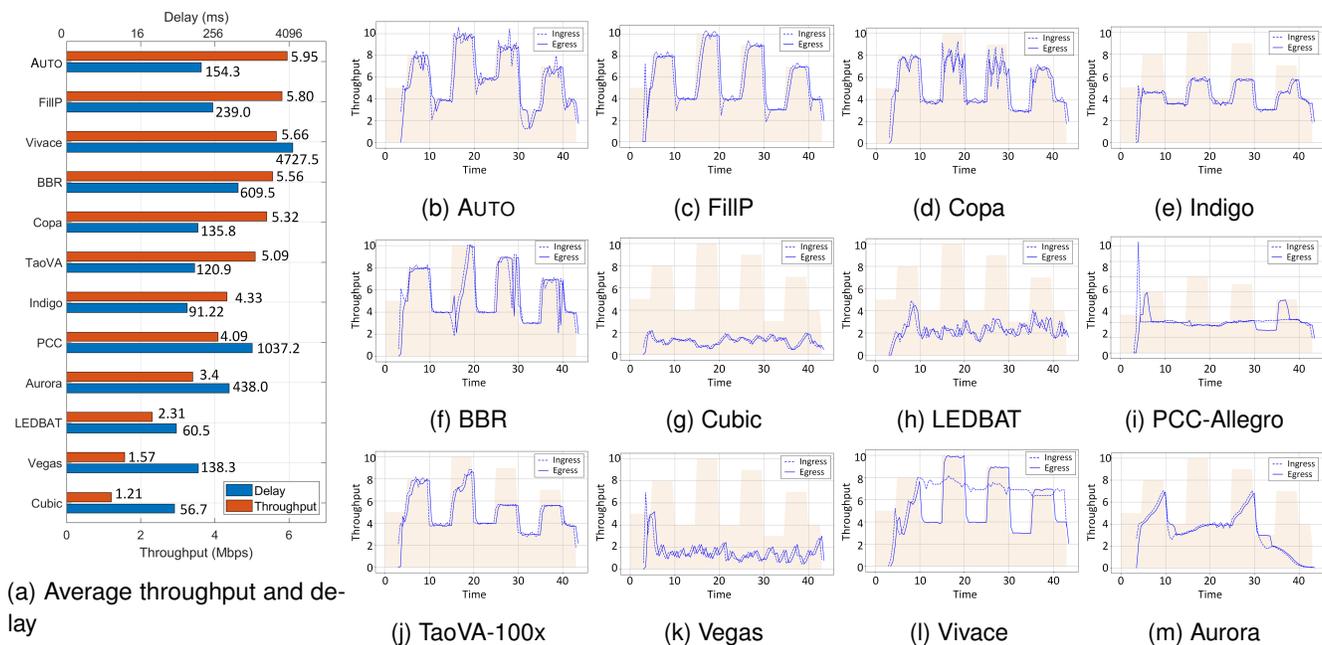

Figure 7: Performance evaluations in the rapidly changing network scenario.

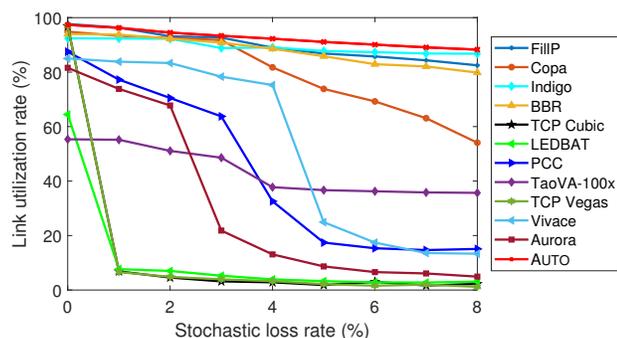

Figure 8: Link utilization v.s. stochastic loss rate.

decrease the sending rate. We test AUTO against other algorithms under an emulated link with a rate of 12 Mbps bandwidth and an RTT of 200 ms. To further test the robustness of the trained policy model, we let the stochastic loss rate of the link range from 0% to 8%, which is beyond our training range [0%, 5%].

As shown in Figure 8, AUTO achieves consistent high link utilization under all stochastic loss rates. Even when the stochastic loss rate is set to 8%, which is outside the training range, AUTO achieves 88.25% link utilization, which is 6.9% higher than the second-highest method FillP. The main reason is that AUTO judges whether congestion occurs by jointly considering the latency ratio, the latency gradient, the sending ratio, and the loss rate. Since the stochastic loss rate only influences the last two features, AUTO still can detect congestion accurately. With a similar reason, Indigo also achieves high

link utilization. In contrast, the link utilization of Aurora falls sharply when the stochastic loss rate larger than 2% due to the fixed preference. BBR adjusts the sending rate according to the estimated bandwidth and minimum latency, thus, it is less affected by the stochastic loss rate. Since packet loss is not considered in the packet arrival model, the performance of Copa degrades when the stochastic loss rate is larger than 3%. TaoVA fails to consider lots of real network parameters such as stochastic loss rate and link buffer size and its link utilization ranges from 35% to 55%. For PCC-Allegro and Vivace that adopt the fixed weight on the packet loss rate in the utility function, their performance is poor when the stochastic packet loss rate is large since the calculated utilities are always low. As for TCP Cubic, TCP Vegas and LEDBAT, they are designed for reliable network environments and are sensitive to packet loss. They achieve relatively high link utilization when there is no stochastic packet drop on the link, and their link utilization drops to about 3% when the stochastic loss rate increases to 8%.

5.5 Fairness Against Different CC Schemes

Last, we show that AUTO is competitive-configurable and can achieve fairness against different CC schemes with different competitiveness, which solves the pain point of existing offline learning-based CC methods [5]. We first set up two flows on a dumbbell topology using CoCo-Beholder [39] with one flow using AUTO and competing with another flow using other CC schemes. The bottleneck link has 100 ms RTT, 20 Mbps capacity, and a queue size of 200. After 30 seconds running, we evaluate the Jain's Fairness Index (JFI) of the

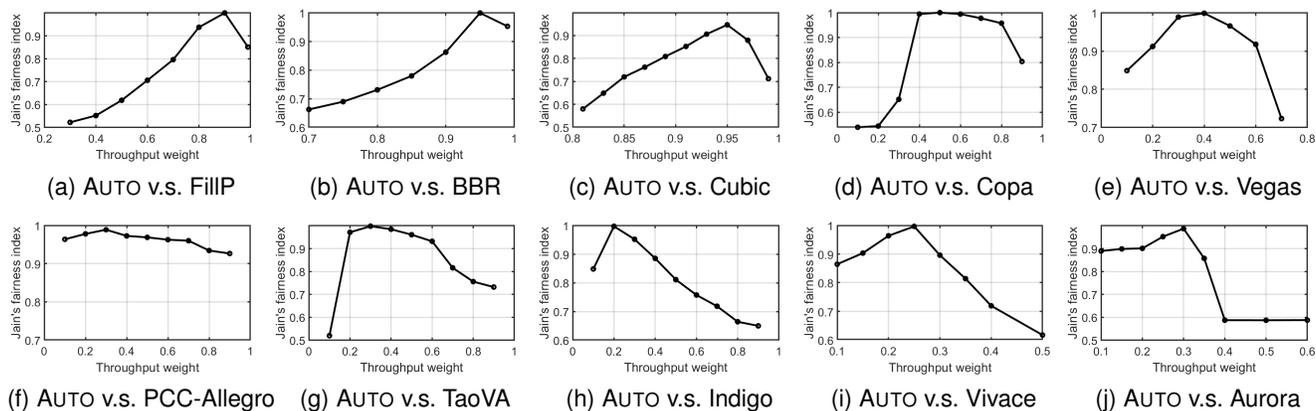

Figure 9: JFI between AUTO and other CC schemes v.s. the throughput weight (ω_t). The delay weight is set to $1 - \omega_t$.

two flows, which is calculated by \bar{x}^2/\bar{x}^2 and $\mathbf{x} = [x_{\text{AUTO}}, x_C]$ is the throughput of AUTO and the competing scheme respectively. The JFI ranges from 0.5 (worst case, the throughput of one flow is 0) to 1 (best case, the two flows have the same throughput).

As shown in Figure 9, the JFI first increases with the throughput weight and then decreases. This is because the competitiveness of AUTO increases along with the throughput weight so that the JFI increases before AUTO achieves the same competitiveness as the competing flow and decreases after. More specifically, with a small throughput weight, AUTO is extremely delay-sensitive and tends to decrease the sending rate when the competing flow causes the increase of the queuing delay. On the contrary, if higher weight is put on throughput, AUTO will be more competitive and decrease the sending rate only if the latency ratio is large.

Therefore, AUTO can always find a suitable preference such that the two flows achieve comparable throughput on the shared link. When competing with CC schemes with high competitiveness, AUTO achieves the fairness by increasing the throughput weight. For example, FillP, BBR and TCP Cubic have high competitiveness for the first two adjust the sending rate based on the estimated bandwidth and the last reduces the congestion window size only when there is packet loss. As shown in Figures 9(a)-(c), by setting preference to (0.9, 0.1), (0.95, 0.05) and (0.95, 0.05), AUTO achieves the fairness against FillP, BBR and TCP Cubic respectively. In contrast, by putting higher weight on delay, AUTO can play well with delay-sensitive CC algorithms. Among the selected CC schemes, Indigo, Vivace and Aurora are more delay-sensitive due to their selected features or the rate adjusting mechanism. As shown in Figure 9(h)-(j), AUTO achieves the fairness against these three algorithms by setting the preference to (0.2, 0.8), (0.25, 0.75), and (0.3, 0.7) respectively.

Meanwhile, the competitive-configurable characteristic also supports users to explicitly set the priority for different flows. For example, users can adjust the throughput weight

of flows that require high bandwidth (e.g., file downloading) to larger than that of delay-sensitive flows (e.g., online meeting). By doing so, the performance of delay-sensitive can be guaranteed while other flows only use the residue bandwidth.

6 Conclusion

We proposed AUTO, an adaptive CC algorithm based on multi-objective reinforcement learning for the heterogeneous satellite-ground integrated network. It doesn't target at finding the optimal result for a single preference, but instead aims for finding *optimal policies for all possible preferences*. Thus, AUTO can cope with heterogeneous network environments and diversified application requirements using a single agent, by taking different preferences as input. To adjust the preference adaptively in different environments, we next proposed an environment-adaptive preference selection method by training a preference adaptation model. To train the agent on emulated environments and to facilitate further research, we developed a training suite Pantheon-Gym for MORL-based CC. Evaluation results show that AUTO achieves consistent high performance in representative network environments, adapts to rapid network changes, is resilient to stochastic packet loss, and can achieve fairness against different CC schemes.

Abstract

In this work, we ask: what would it take for, say, a campus network operator to tell the network, using natural language, to “*Inspect traffic for the dorm*”? How could the network instantly and correctly translate the request into low-level configuration commands and deploy them in the network to accomplish the job it was “asked” to do? We answer these questions by presenting the design and implementation of LUMI, a new system that (i) allows operators to express intents in natural language, (ii) uses machine learning and operator feedback to ensure that the translated intents conform with the operator’s goals, and (iii) compiles and deploys them correctly in the network. As part of LUMI, we rely on an abstraction layer between natural language intents and network configuration commands referred to as *Nile* (Network Intent Language). We evaluate LUMI using synthetic and real campus network policies and show that LUMI extracts entities with high precision and compiles intents in a few milliseconds. We also report on a user study where 88.5% of participants state they would rather use LUMI exclusively or in conjunction with configuration commands.

1 Introduction

Deploying policies in modern enterprise networks poses significant challenges for today’s network operators. Since policies typically describe high-level goals or business intents, the operators must perform the complex and error-prone job of breaking each policy down into low-level tasks and deploying them in the physical or virtual devices of interest across the entire network. Recently, *intent-based networking (IBN)* has been proposed to solve this problem by allowing operators to specify high-level policies that express how the network should behave (e.g., defining goals for quality of service, security, and performance) without having to worry about how the network is programmed to achieve the desired goals [17]. Ideally, IBN should enable an operator to simply tell the network to, for example, “*Inspect traffic for the dorm*”, with the network instantly and correctly breaking down such an intent into configurations and deploying them in the network.

In its current form, IBN has not yet delivered on its promise of fast, automated, and reliable policy deployment. One of the main reasons for this shortcoming is that, while network policies are generally documented in natural language, we cannot currently use them as input to intent-based management systems. Despite growing interest from some of the largest tech companies [7, 47, 62] and service providers [32, 38, 52], only a few research efforts [4, 13] have exploited the use of natural language to interact with the network, but they lack support for IBN or other crucial features (e.g., operator confirmation and feedback). However, expressing intents directly in natural language has numerous benefits when it comes to network policy deployment. For one, it avoids the many pitfalls of traditional policy deployment approaches, such as being forced to learn new network programming languages and vendor-specific Command-Line Interfaces (CLI), or introducing human errors while manually breaking down policies into configuration commands. At the same time, its appeal also derives from the fact that it allows operators to express the same intent using different phrasings. However, the flexibility makes it challenging to generate configurations, which must capture operator intent in an unambiguous and accurate manner.

In this paper, we contribute to the ongoing IBN efforts by describing the design and implementation of LUMI, a new system that enables an operator “to talk to the network”, focusing on campus networks as a use case. That is, LUMI takes as input an operator’s intent expressed in natural language, correctly translates these natural language utterances into configuration commands, and deploys the latter in the network to carry out the operator’s intent. We designed LUMI in a modular fashion, with the different modules performing, in order: information extraction, intent assembly, intent confirmation, and intent compilation and deployment. Our modular design allows for easy plug-and-play, where existing modules can be replaced with alternative solutions, or new modules can be included. As a result, LUMI’s architecture is extensible and evolvable and can easily accommodate further improvements or enhancements.

In addressing the various challenges above, we make the following contributions:

Information extraction and confirmation. We build on existing machine learning algorithms for *Named Entity Recognition (NER)* [30] to extract and label entities from the operator’s natural language utterances. In particular, we implement NER using a chatbot-like interface with multi-platform support (§3) and augment the existing algorithm so that LUMI can learn from operator-provided feedback (§5).

Intent assembly and compilation. We introduce the *Network Intent Language (Nile)*, use it as an abstraction layer between natural language intents and network configuration commands for LUMI, and illustrate its ability to account for features critical to network management such as rate-limiting or usage quotas (§4). We also show how LUMI enables compilations of *Nile* intents to existing network programming languages (§6), such as *Merlin* [57].

Evaluation. We evaluate (§8) LUMI’s accuracy in information extraction, investigate LUMI’s ability to learn from operator-provided feedback and measure both the compilation and deployment times in a standard campus topology [5]. Using our own datasets consisting of synthesized intents as well as real-world intents derived from network policies published by 50 different campus networks in the US, we show that LUMI can extract entities with high precision, learn from the feedback provided by the operator, and compile and deploy intents in less than a second.

User study. In addition to an in-depth evaluation of LUMI, we also report our main findings of a small-scale user study, with 26 subjects (§9). The study was performed to get feedback from subjects on the perceived value of using natural language for network management with LUMI and soliciting user feedback during the intent confirmation stage.

Prototype. We implemented our prototype of LUMI using a combination of tools and libraries (*e.g.*, Google Dialogflow [28], *Scikit-learn* library [49]). The full implementation as well as all datasets used in our evaluation are available on the project’s website [39].

Together, the results of our evaluation and user study show that LUMI is a promising step towards realizing the vision of IBN of achieving fast, automated, and reliable policy deployment. By allowing operators to express intents in natural language, LUMI makes it possible for operators to simply talk to their network and tell it what to do, thus simplifying the jobs of network operators (*i.e.*, deploying policies) and also saving them time. While promising, developing LUMI into a full-fledged production-ready system poses new and interesting challenges on the interface of networking and NLP, which we detail in §10.

2 Lumi in a Nutshell

Figure 1 illustrates the high-level goal of LUMI with the intent example “*Hey, Lumi! Inspect traffic for the dorm*” and shows the breakdown of the workflow by which LUMI accomplishes

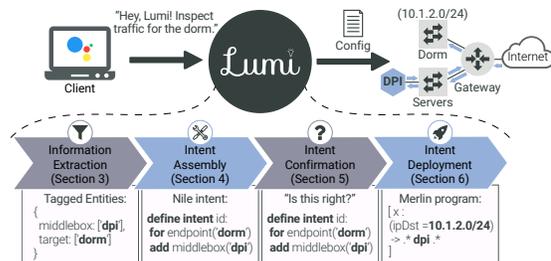

Figure 1: The four modules of LUMI.

the stated objective. Below, we provide a brief overview of the four key components that define this workflow (*i.e.*, the LUMI pipeline) and refer to the subsequent sections for a more in-depth description and design choices of each of these modules.

First, for the Information Extraction module (described in Section 3), we rely on machine learning to extract and label entities from the operator utterances and implement them using a chatbot-like conversational interface. The extracted entities form the input of the Intent Assembly module (described in Section 4), where they are used to compose a *Nile* network intent. *Nile* closely resembles natural language, acts as an abstraction layer, and reduces the need for operators to learn new policy languages for different types of networks. Then, as part of the Intent Confirmation module (described in Section 5), the output of the Intent Assembly module (*i.e.*, a syntactically-correct *Nile* intent) is presented to the network operator, and their feedback is solicited. If the feedback is negative, the system and the operator iterate until confirmation, with the system continuously learning from the operator’s feedback to improve the accuracy of information labeling over time. Finally, once the system receives confirmation from the operator, the confirmed *Nile* intent is forwarded to the Intent Deployment module. Described in Section 6, this module’s main task is to compile *Nile* intents into network configuration commands expressed in *Merlin* and deploy them in the network. In Section 6, we also explain why we picked *Merlin* as a target language over other alternatives.

3 Information Extraction

The main building blocks for LUMI’s Information Extraction module are a chatbot interface as the entry point into our system and the use of Named Entity Recognition (NER) [30] to extract and label entities from the operators’ natural language intents. Given the popularity of personal assistants, such as Google Assistant, Amazon’s Alexa or Apple’s Siri, our goal in providing a natural language interface for LUMI goes beyond facilitating the lives of traditional network operators and seeks to also empower users with little-to-no knowledge of how to control their networks (*e.g.*, home users).

Even in the case of the traditional user base of network operators, providing a natural language interface to interact with the system benefits teams composed of operators with

different levels of expertise or experience. This type of interface is particularly relevant in campus or enterprise networks with small groups and in developing countries where network teams are often understaffed and lack technical expertise. In short, while deploying a policy as simple as redirecting specific traffic for inspection can be a daunting task for an inexperienced operator, nothing is intimidating about expressing that same policy in natural language and letting the system worry about its deployment, possibly across multiple devices in the network.

Solving the NER problem typically involves applying machine learning (for extracting named entities in unstructured text) in conjunction with using a probabilistic graphical model (for labeling the identified entities with their types). Even though, in theory, NER is largely believed to be a solved problem [43], in practice, to ensure that NER achieves its purpose with acceptable accuracy, some challenges remain, including careful “entity engineering” (*i.e.*, selecting entities appropriate for the problem at hand) and a general lack of tagged or labeled training data.

Below, we first discuss the entity engineering problem and propose a practical solution in the form of a hierarchically-structured set of entities. Next, we describe in more detail the different steps that the NER process performs to extract named entities from a natural language intent such as “*Inspect traffic for the dorm*” and label them with their types. Finally, to deal with the problem caused by a lack of labeled training data, we describe our approach that improves upon commonly-used NER implementations by incorporating user feedback to enable LUMI to learn over time.

Table 1: Hierarchical set of entities defined in LumI.

Type	Entity Class
Common	@middlebox, @location, @group, @traffic, @protocol, @service, @qos_constraint, @qos_metric, @qos_unit, @qos_value, @date, @datetime, @hour
Composite	@origin, @destination, @target @start, @end
Immutable	@operation, @entity

3.1 Entity Selection

To ensure that NER performs well in practice, a critical aspect of specifying the underlying model is entity engineering; that is, defining which and how many entities to label in domain application-specific but otherwise unstructured text. On the one hand, since our goal with LUMI is to allow operators to change network configurations and manipulate the network’s traffic, the set of selected entities will affect which operations are supported by LUMI. As discussed in more detail in Section 4, LUMI-supported actions are dictated almost entirely by what intent constructions *Nile* supports. At the same time,

we would like to consider a generic enough set of entities to enable users to express their intents freely, independent of *Nile*. Moreover, the selected set of entities should also allow for easy expansion (*e.g.*, through user feedback; see Section 3.4 below) while ensuring that newly added entities neither introduce ambiguities nor result in unforeseen entries that might break the training model.

On the other hand, the selected set of entities directly influences the trained model’s accuracy, especially if the entities have been chosen poorly. Therefore, it is crucial to pick a set of entities that is at the same time rich enough to solve the task at hand and concise enough to avoid ambiguities that might hamper the learning process. For instance, one common source of uncertainty in network intents is highlighted with the two examples “*Block traffic from YouTube*” and “*Block traffic from the dorms*”. Here, the word ‘from’ appears in both intents but is used for two different purposes. While in the first example, it specifies a service, in the second example, it defines a location. If we choose to tag both entities (*i.e.*, “YouTube” and “dorms”) with the same entity type (*e.g.*, “location”) to avoid ambiguities, we lose information on what is being tagged (*i.e.*, service vs. location). However, if we simply use different entities for both cases (*e.g.*, “service” and “location”), we generate an ambiguity (*e.g.*, very similar phrasings produce entirely different results) that causes the accuracy of the NER model to decrease as similar example intents are encountered (*e.g.*, “*Block traffic from Twitter*”).

With these design requirements in mind, we defined the set of LUMI entities hierarchically and organized them into three different categories: common, composite, and immutable entities (see Table 1). Here, common entities form the bottom of the hierarchy, comprise raw textual values, and largely determine what LUMI can understand. For instance, the textual values in the common entity class @middlebox are network functions such as firewalls, packet inspection, and traffic shaping. The hierarchy’s intermediate level consists of composite entities. The entities in this class do not have any inherent nouns, verbs, or even synonyms associated with them; they only establish a relationship between common entities through the aggregation of prepositions. For instance, the composite entity class @origin consists of composite values such as “from @location” and “from @service”. Composite entities help avoid the ambiguity problem mentioned earlier. Finally, immutable entities make up the top of the hierarchy and form the core of LUMI. In particular, while the entity class @operation expresses the operations that *Nile* supports, the entity class @entity consists of a list of LUMI-supported common entities.

3.2 Entity Encoding: Bi-LSTMs

Figure 2 shows the overall NER architecture that we use in LUMI and illustrates the critical intuition behind NER; that is, finding named entities in unstructured text (*e.g.*, “*Inspect traffic for the dorm*” in Step 1 in Figure 2) and labeling them

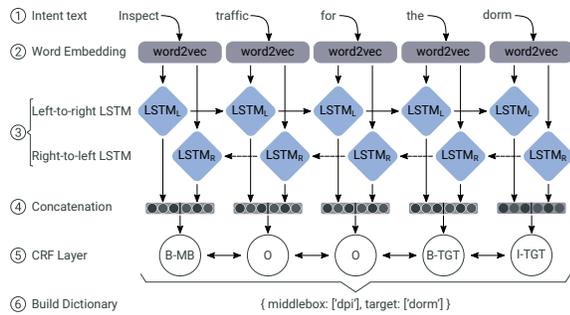

Figure 2: The NER architecture with Bi-LSTM (see Section 3.2) and CRF (see Section 3.3). The entity tags are abbreviated as MB for middlebox and TGT for target.

with their types (e.g., Step 6 in Figure 2). With respect to the machine learning part of the NER problem, standard approaches leverage Recurrent Neural Networks (RNN) [34]; i.e., a family of neural networks that processes arrays of data sequentially, where the output of one element is carried over as input to the next element in the sequence. However, RNNs typically require numerical inputs and not words. Therefore, when applied in the context of our text processing problem, each word of an intent that the operator expresses in natural language has to be first encoded into a numerical vector before an RNN can process it. Rather than using one-hot encoding [30], a simple encoding scheme that represents each encoded word as a vector of 0's and 1's, we rely in Step 2 (see Figure 2) on a more powerful approach that uses one-hot encoded vectors of words as input to a word embedding algorithm known as *word2vec* [44]. The *word2vec* algorithm uses a pre-trained mini-neural network that learns the vocabulary of a given language (English, in our case) and outputs a vector of decimal numbers for each word. As a neural network, *word2vec* can provide similar vector representations for synonyms, so that words with similar meanings (e.g., 'dormitories' and 'housing') have similar embedded vectors, which in turn allows an RNN to process them similarly.

Before processing the output of *word2vec*, we need to specify the type of RNN model in our architecture. The Long Short-Term Memory (LSTM) model has been a popular choice for text processing [25] as it can capture and carry over dependencies between words in a phrase or intent (e.g., to identify multi-word expressions). It also creates a context-full representation of each processed word as an encoded array of numerical values. However, to further enhance each word's context, in our LUMI design of the information extraction stage, we rely in Step 3 on an enhanced version of LSTM, the so-called Bi-LSTM model [16, 36]. The Bi-LSTM approach yields the best results for the English language in a majority of evaluated cases [63]. In a Bi-LSTM, a phrase is evaluated by two LSTMs simultaneously, from left-to-right and from right-to-left, and the outputs of the two LSTMs are then concatenated to produce a single output layer at a given position, as shown in Step 4.

3.3 Entity Labeling: CRFs

The labeling part of the NER problem consists of using the context-full encoded vectors of words to represent the "observed" variables for a type of probabilistic graphical models known as Conditional Random Fields (CRFs) [33], as shown in Step 5. CRFs are a widely-used technique for labeling data, especially sequential data arising in natural language processing. Their aim is to determine the conditional distribution $P(Y|X)$, where $X = \{x_1, x_2, \dots, x_n\}$ represents a sequence of observations (i.e., encoded vectors of words in a sentence) and $Y = \{y_1, y_2, \dots, y_m\}$ represents the "hidden" or unknown variable (i.e., NER tags or labels) that needs to be inferred given the observations. CRFs admit efficient algorithms for learning the conditional distributions from some corpus of training data (i.e., model training), computing the probability of a given label sequence Y given observations X (i.e., decoding), and determining the most likely label sequence Y given X (i.e., inference).

The technical aspects of the specific CRF model we use in this work are described in detail in LUMI's website [39] and show the flexibility afforded by CRF models to account for domain-specific aspects of labeling sequential data (e.g., accounting for the likelihood of one entity label being succeeded by another). However, irrespective of the specific CRF model used, the method outputs as the most likely tag for a given word the one with the highest probability among all tags. Specifically, at the end of Step 5, the result of the NER algorithm is provided in the form of named entities with IOB tagging [30]. In IOB tagging, each named entity tag is marked with an indicator that specifies if the word is the beginning (B) of an entity type or inside (I) of an entity type. If a word does not match any entity, then the algorithm outputs an (O) indicator (for "outside"). Note that by using IOB tagging, it is possible to distinguish if two side-by-side words represent a single entity or two completely different entities. For instance, without IOB-tagging, it would be impossible to tag an operation like "rate limiting" as one single named entity. Finally, we parse the IOB-tagged words resulting from the NER model, build a dictionary with the identified entities, and output it in Step 6 as the final result of LUMI's Information Extraction module.

3.4 NER and Learning

The described NER process is an instance of a supervised learning algorithm. It uses a corpus of training data in the form of input-output examples where input is an intent (i.e., phrase with named entities defined in LUMI and other words or non-entities), and an output is the list of named entities with IOB tagging (i.e., correct entity tags or labels). The primary training step consists of both adapting the weights of the Bi-LSTM model to extract the desired X vector and re-calculating the conditional distribution $P(X|Y)$ to infer the correct NER tags Y and may have to be repeated until convergence (i.e., Steps 3-5).

Note that retraining can be done each time the existing corpus of training data is augmented with new key-value pairs or with existing entities used in a novel context (*i.e.*, requiring a new tag). A basic mechanism for obtaining such new key-value pairs or for benefiting from the use of existing entities in a novel context is to engage users of LUMI and entice their feedback in real-time, especially if this feedback is negative and points to missing or incorrect pieces of information in the existing training data. By enticing and incorporating such user-provided feedback as part of the Intent Confirmation stage (see Section 5 for more details), LUMI’s design leverages readily available user expertise as a critical resource for constantly augmenting and updating its existing training data set with new and correctly-labeled training examples that are otherwise difficult to generate or obtain. After each new set of key-value pairs is obtained through user feedback, LUMI immediately augments the training corpus and retrains the NER model from scratch.

In light of the hierarchical structure of our LUMI-specific entities set, with user-provided feedback, we aim to discover and learn any newly-encountered common entities. Moreover, as the data set of common entities is augmented with new training instances, the accuracy of identifying composite entities also improves. With respect to the immutable entities, since the entity class *@operation* dictates what operations LUMI supports and understands, these operations cannot be learned from user-provided feedback. However, given the limited set of LUMI-supported operations, a relatively small training dataset should suffice to cover most natural language utterances that express these operations. As for the entity class *@entity*, being composed of a list of LUMI-supported common entities, it ensures that user-provided feedback can be correctly labeled.

4 Intent Assembly

Using a chatbot interface with NER capabilities as the front end of LUMI solves only part of the network intent refinement and deployment problem. For example, if a network operator asks a chatbot “Please add a firewall for the backend.”, the extraction result could be the following entities: *{middleboxes: ‘firewall’}*, *{target: ‘backend’}*. Clearly, these two key-value pairs do not translate immediately to network configuration commands. Assembling the extracted entities into a structured and well-defined intent that can be interpreted and checked for correctness by the operator before being deployed in the network calls for introducing an abstraction layer between natural language intents and network configuration demands.

To achieve its intended purpose as part of LUMI, this abstraction layer has to satisfy three key requirements. First, the operations supported by the abstraction layer’s grammar have to specify what entities to extract from natural language intents. Instead of trying to parse and piece together every possible network configuration from user utterances, we require that a predefined set of operations supported by the abstrac-

tion layer’s grammar guide the information extraction process. As a result, when processing the input text corresponding to a network intent expressed by the operator in natural language, we only have to look for entities that have a matching operation in the abstraction layer’s grammar, as those are the only ones that the system can translate into network configurations and subsequently act upon.

A second requirement for this abstraction layer is to allow for easy confirmation of the extracted intents by the operators by having a high level of legibility. We note that requiring confirmation does not burden the operators in the same manner that requiring them to express their network intents directly in the abstraction layer’s language would. For instance, it is well-known that a person who can understand a written sentence cannot necessarily create it from scratch (*i.e.*, lacking knowledge of the necessary grammar).

Finally, the abstraction layer is also required to allow different network back-ends as targets given that a wide range of candidate network programming languages [6, 11, 21, 31, 46, 54, 57] exist, and none of them seem to have been favored more by operators or industry yet. Using an abstraction layer on top of any existing languages allows us to decouple LUMI from the underlying technology, so we can easily change it if a better option arises in the future.

4.1 Nile: Network Intent Language

To satisfy the above requirements, in our design of the Intent Assembly module (*i.e.*, stage two of the LUMI pipeline), we rely on the Network Intent Language (*Nile*) to serve as our abstraction layer language. In a previous work [29], we proposed an initial version of *Nile* that provided minimal operation support for intent definition and focused primarily on service-chaining capabilities. Here, we extend this original version to cover crucial features for network management in real-world environments (e.g., usage quotas and rate-limiting). Closely resembling natural language, the extended version of *Nile* has a high level of legibility, reduces the need for operators to learn new policy languages for different types of networks, and supports different configuration commands in heterogeneous network environments. Operationally, we designed this module to ingest as input the output of the information extraction module (*i.e.*, entities extracted from the operator’s utterances), assemble this unstructured extracted information into syntactically-correct *Nile* intents, and then output them.

Table 2: Overview of *Nile*-supported operations.

Operation	Function	Required	Policy Type
from/to	endpoint	Yes	All
for	group/endpoint/service/traffic	Yes	All
allow/block	traffic/service/protocol	No	ACL
set/unset	quota/bandwidth	No	QoS
add/remove	middlebox	No	Service Chaining
start/end	hour/date/datetime	No	Temporal

Table 2 shows the main operations supported by our extended version of *Nile*, and the full grammar of *Nile* is made available in LUMI’s website [39]. Some of the operations have opposites (e.g., allow/block) to undo previously deployed intents and enable capturing incremental behaviors stated by the operators. Some operations in a *Nile* intent are mandatory, such as **from/to** or **for**. More specifically, an operator cannot write an intent in *Nile* without stating a clear target (using **for**) or an origin and a destination (using **from/to**) when the direction of the specified traffic flow matters.

To enforce the correct syntax of the assembled intent, we leverage the *Nile* grammar to guarantee that the intent contains the required information for correct deployment. If the grammar enforcement fails due to the lack of information, the system prompts the operator via the chatbot interface to provide the missing information. Assume, for example, that the operator’s original intent stated “Please add a firewall.”, without providing the target of the intent. Since specifying a target is required according to the *Nile* grammar, the module will not attempt to construct a *Nile* program but will instead interact with the operator to obtain the missing information.

4.2 *Nile* Intents: An Example

With *Nile*, we can express complex intents intuitively. For example, an input like “Add firewall and intrusion detection from the gateway to the backend for client B with at least 100mbps of bandwidth, and allow HTTPS only” is translated to the *Nile* intent shown in Listing 1. The **group** function is used as a high-level abstraction for clients, groups of IP addresses, VLANs, or any other aggregating capacity in low-level network configurations. Note that the IDs provided by the operator must be resolved during the compilation process, as they represent information specific to each network. This feature of the language enhances its flexibility for designing intents and serving as an abstraction layer. The example illustrates how *Nile* provides a high-level abstraction for structured intents and suggests that the grammar for *Nile* is expressive enough to represent many real-world network intents.

```
define intent qosIntent:
  from endpoint('gateway')
  to endpoint('database')
  for group('B')
  add middlebox('firewall'), middlebox('ids')
  set bandwidth('min', '100', 'mbps')
  allow traffic('https')
```

Listing 1: *Nile* intent example.

5 Intent Confirmation (Feedback)

The major challenge with using natural language to operate networks (e.g., as part of IBN) is that the method is inherently ambiguous. There are many different forms in which an operator can express the same intent in different network environments in natural language. Despite recent advances, natural language processing is prone to producing false positives or false negatives, resulting in incorrect entity tagging,

leading to deploying incorrect network configuration commands. However, to be of practical use, network configurations are required to be unquestionably unambiguous and correct-by-construction.

One approach to address this challenge is to create an extensive dataset with training phrases and entities. However, it is unrealistic to expect that such a dataset will cover every possible English language (or any other language for that matter) example of phrase construction with domain-specific entities. Operators are free to use terms or expressions that the system has never encountered in the past. However, without proper safeguards, any such new phrase will likely result in misconfigurations of the network. An alternative approach to implementing a reliable intent deployment process is through “learning from the operator.” Here, the basic idea is to leverage the operators’ existing knowledge by requesting their feedback on the information extracted from natural language intents. Then, in the case of negative feedback, it is critical to engage with the operators to identify missing or incorrect pieces, include this such acquired new knowledge as additional phrases or entities in the original training dataset, and retrain the original learning model.

Our solution to deal with the ambiguity inherent in using natural language to express network intents follows the learning approach and leverages the chatbot interface implemented as part of our first module. In particular, in designing the intent confirmation module for realizing stage three of the four-stage LUMI pipeline, we require the output of the intent assembly module (i.e., syntactically-correct *Nile* intents) to be confirmed by the operator. When presented with assembled intents that result in false positives or negatives, the operator is asked to provide feedback that we subsequently use to augment the original training dataset with new labeled data; that is, LUMI is capable of learning new constructs over time, gradually reducing the chances of making mistakes. While this interaction may slow down initial intent deployments until LUMI adapts to the operator’s usage domain, it is essential to guarantee reliable intent refinement and deployment.

Extracting pertinent information from user feedback also requires identifying specific entities in the user text, similarly to extracting entities from an input network intent. To this end, LUMI uses the same NER model for both tasks, relying primarily on the immutable *@entity* for extracting which entity class is being augmented and what value is being added. Relying on the same NER model also requires us to train the model to identify and extract entities in the received user feedback. However, since we limit LUMI’s interactions with the user to answering simple questions, processing user feedback does not require a large set of training samples.

To reduce an operator’s need for technical knowledge during this intent confirmation stage, we opted for supporting feedback interactions that induce the operator to provide the information that LUMI needs (i.e., offering suggestions and asking complementary questions). Also, to provide operators

with more flexibility and not insist that they have to use specific keywords, this module compares the entities and values provided by the operators with synonyms already in the training dataset. Figure 3 illustrates a case where, due to a lack of training, LUMI misses an entity in the input text, and the confirmation mechanism lets operators easily catch this mistake and provide the necessary feedback for LUMI to learn. Also, note that our design of this module is conservative in the sense that operator feedback is requested for each assembled intent, irrespective of the level of confidence that LUMI has concerning its accuracy.

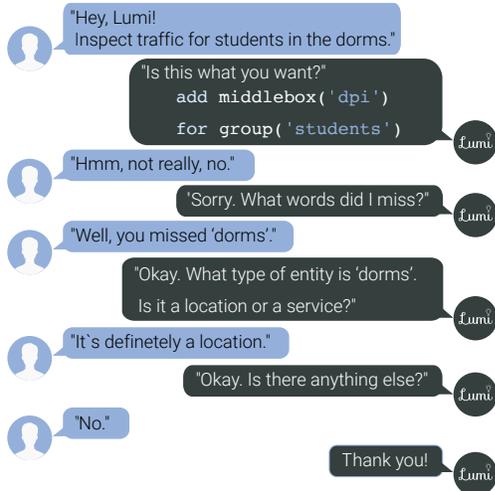

Figure 3: LUMI’s feedback mechanism in action.

6 Intent Deployment

The fourth and last stage of LUMI compiles the operator-confirmed *Nile* intents into code that can be deployed on the appropriate network devices and executes the original network intent expressed by the operator in natural language. Fortunately, the abstraction layer provided by *Nile* enables compilations to a number of different existing network configurations, including other policy abstractions languages such as *Merlin* [57], *OpenConfig* [48], *Janus* [2], *PGA* [51], and *Kinetic* [31].

For our design of LUMI’s Intent Deployment module, we chose to compile structured *Nile* intents into *Merlin* programs. We picked *Merlin* over other alternative frameworks because of its good fit with *Nile*, the network features it supports, its performance, and the availability of source code. Also, given that none of the existing network programming languages natively supports all features proposed in *Nile*, we opted for the one that had the largest intersection of supported operations. In the process, we mapped each *Nile* feature to a corresponding *Merlin* feature.

Resolving logical handles. Logical handles in *Nile* intents are decoupled from low-level IP addresses, VLAN IDs and IP prefixes, which LUMI now resolves (e.g., `dorm` → `10.1.2.0/24`) using information provided during the bootstrap process. ACLs rules are resolved similarly. Once LUMI

produces *Merlin* programs with resolved identifiers (i.e., VLAN IDs, IPs and prefixes), compilation to corresponding OpenFlow rules is handled by *Merlin*.

Temporal constraints and QoS. As *Merlin* does not support temporal policies, LUMI stores every confirmed *Nile* intent so that it can install or remove device configurations according to times and dates defined by the operator. We achieve quota restrictions (not natively supported by *Merlin*) by relaying all traffic marked with a quota requirement to a traffic-shaping middlebox, taking advantage of *Merlin*’s support for middlebox chaining. Other QoS policies, such as rate-limiting, are already supported in *Merlin*.

Middlebox chaining. LUMI focuses on middlebox chaining, i.e., correctly relaying traffic specified in the intents through a specified middlebox. Since the actual configuration of each middlebox is currently done outside of LUMI, LUMI can handle chaining policies associated with *any* middlebox type, virtual or physical, compilation for which is straightforward since *Merlin* natively supports middlebox chaining.

7 Implementation

We implemented LUMI’s prototype using different tools and libraries for each module of the LUMI-pipeline. For the chatbot interface and NER, we used Google Dialogflow [28] because of its conversational interface and multi-platform integration. However, these stages can be easily implemented with other open-source NLP frameworks (e.g., SpaCy [26] and Stanford CoreNLP [41]) or machine learning toolkits such as Scikit-learn [49] and Keras [18]. We exported the Dialogflow implementation of LUMI as JSON files and uploaded them to GitHub [39], so other researchers can build on our work and reproduce our results.

We implemented the WebHook service that Dialogflow calls with the extracted entities in Python. This service builds the *Nile* intents and interacts with the chatbot interface if necessary. We implemented the compilation of *Nile* programs into *Merlin* programs and the deployment of the resulting *Merlin* program as a separate Python RestAPI service that the previous WebHook service calls after the operator confirms that the intent is correct. We developed this module as a separate service so that it can be deployed on a local server with access to the network controller. All the other modules can be deployed on a cloud server. The full implementation of LUMI, comprising over 5,451 lines of Python code and 1,079 lines of JavaScript and HTML, a working demo, and all datasets used in the course of this work are publicly available [39].

8 Evaluation

In this section, we first evaluate the accuracy of our Information Extraction module to show that LUMI extracts entities with high precision and learns from operator-provided feedback. We then show that LUMI can quickly compile *Nile* intents into *Merlin* programs and deploy them. To assess the accuracy of the Information Extraction module, we use the standard metrics Precision, Recall, and F1-score. For the

evaluation of the Intent Deployment stage, we measure the compilation time for translating *Nile* intents into Merlin statements and their deployment time.

8.1 Information Extraction

Evaluating systems like LUMI is challenging because of (i) a general lack of publicly available datasets that are suitable for this problem space (several operators we contacted in industry and academia gave proprietary reasons for not sharing such data), and (ii) difficulties in generating synthetic datasets that reflect the inherent ambiguities of real-world Natural Language Intents (NLIs).

To deal with this problem, we created two hand-annotated datasets for information extraction. The dataset *alpha* is “semi-realistic” in the sense that it is hand-crafted, consisting of 150 examples of network intents that we generated by emulating an actual operator giving commands to LUMI. In contrast, the *campi* dataset consists of real-world intents we obtained by crawling the websites of 50 US universities, manually parsing the publicly available documents that contained policies for operating their campus networks, and finally extracting one-phrase intents from the encountered public policies. From those 50 universities, we were able to extract a total of 50 different network intents. While some universities did not yield any intents, most universities published network policies related to usage quotas, rate-limiting, and ACL, and we were able to express all of them as *Nile* intents. We manually tagged the entities in each of these 200 intents to train and validate our information extraction model.

We used both datasets, separately and combined, to evaluate our NER model, with a 75%-25% training-testing random split. The small size of each dataset precludes us from performing conventional cross-validation. Table 3 shows the results for the *alpha* dataset, for the *campi* dataset, and for a combination of the two and illustrates the high accuracy of LUMI’s information extraction module. Given the way we created the training examples for the *alpha* dataset, the excellent performance in terms of Precision, Recall, and F1-score is reassuring but not surprising. In creating the intent examples, we paid special attention to extracting all the entities defined in LUMI (see Section 3.1) and also creating multiple intents for each entity class.

Table 3: Information extraction evaluation using the *alpha* and *campi* dataset.

Dataset	# of Entries	Precision	Recall	F1
<i>alpha</i>	150	0.996	0.987	0.991
<i>campi</i>	50	1	0.979	0.989
<i>alpha + campi</i>	200	0.992	0.969	0.980

At the same time, despite the largely unstructured nature and smaller number of intent examples in the *campi* dataset, the results for that dataset confirm the above observation.

Even though the example intents in this case were not designed with the NER model in mind, LUMI’s performance remains excellent and is essentially insensitive to the differences in how the intent examples were generated. We attribute this success of LUMI at the information extraction stage to both continued advances in using machine learning for natural language processing and the fact that the complete set of LUMI-defined entities is relatively small and at the same time sufficiently expressive.

8.2 Intent Confirmation and Feedback

To evaluate the impact of operator-provided feedback on LUMI’s ability to learn, we first trained our NER model using 75% of the combined *alpha* and *campi* datasets (*i.e.*, a total of 150 training examples) and then used the remaining 25% of examples (*i.e.*, a total of 50 test entries) as new intents that we presented LUMI in random order. We fed each of the 50 test intents into the NER model for information extraction and evaluated the Precision and Recall on a case-by-case basis. If a new intent generated False Positives or False Negatives, we inserted the intent into NER’s existing training dataset, alongside the pre-tagged entities, mimicking the operator’s feedback given during the Intent Confirmation stage.

The results for this experiment (Precision, Recall and F1-score) are shown in Figures 4a and 4b. Since each point in the plots represents the Precision/Recall for one specific test sample rather than for the global model, the depicted values fluctuate as test samples are checked one after another. As can be seen, while Precision quickly reaches and then stays at 1.0, the Recall metric dips each time the model encounters an entity or construct it has not yet seen (*i.e.*, resulting in a False Negative). However, as more of these examples become part of NER’s training data through the feedback mechanism (and because of re-training of the model after each new example is added), these dips become less frequent. Out of the 50 test intents, only eight resulted in a dip in Recall; that is, were used as feedback. Note, however, that the cases where the model does not identify an entity are precisely the situations where feedback is most informative and enables the model to learn for the benefit of the users.

To assess how often a user has to rely on the feedback mechanism, we repeated our experiment 30 times, each time with a different 75-25 training-testing split. The resulting mean values for Precision and Recall are shown in Figures 4c and 4d, with corresponding 95% confidence intervals. As expected, over the 30 repetitions, both Precision and Recall remain close to 0.99, with very small fluctuations. And just as in the previous experiment, whenever there is a significant variation in Precision or Recall (*i.e.*, large confidence intervals), we added that particular intent example to NER’s latest training dataset and retrained the model. We attribute the fact that about 20% of the test examples were used as feedback to the small size of our training dataset, but argue that having only this many feedbacks is a positive outcome.

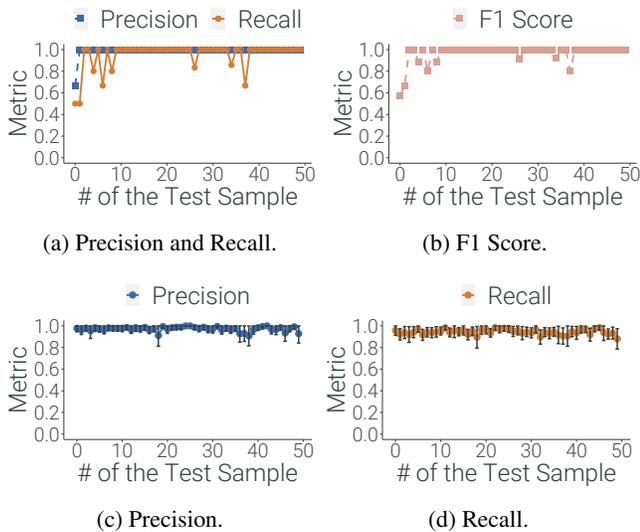

Figure 4: Feedback impact on information extraction.

8.3 Intent Deployment

To evaluate the deployment capabilities of LUMI, we compile and deploy five categories of *Nile* intents, with an increasing level of complexity: middlebox chaining, ACL, QoS, temporal, and intents with mixed operations. The last category of intents mixes *Nile* operations with distinct goals, which we use to evaluate the deployment of more complex intents. We generated a dataset with 30 intents per category, totaling 150 different intents, and measured the mean compilation and deployment time of each category. We ran this experiment on a generic campus network, with approximately 180 network elements. We relied on the Mininet [35] emulator to perform the experiments. The results are given in Table 4. While deployment time necessarily depends on the network environment, in our setting, we consistently measured sub-second combined compilation and deployment times.

Table 4: Compilation and deployment time for five categories of *Nile* intents.

Intent Type	Compilation Time (ms)	Deployment Time (ms)
Middlebox chaining	4.402	110
ACL	3.115	112
QoS	3.113	136
Temporal	4.504	111
Mixed	4.621	1030

9 User Study

To evaluate LUMI’s ability to work in a real-world environment rather than with curated datasets of intents, we designed and carried out a small-scale user study. Specifically, we wanted to assess three critical aspects of our system: (i) How well does the information extraction process work with actual humans describing their intents in different forms and phrasings? (ii) How often is it necessary for operators to provide feedback for LUMI while using the system? and (iii) Com-

pared to existing alternative methods, what is the perceived value of a system like LUMI that leverages natural language for real-time network management?

In this section, we describe the experiments we conducted, the participants’ profiles, and the obtained results. We set up the user study as an online experiment that users could access and participate in anonymously. To select participants for the user study from different technical backgrounds and still keep their anonymity, we distributed a link to the online user study in mailing lists of both networking research groups and campus network operators. According to the guidelines of our affiliated institution, due to the fully anonymous nature of the experiment, no IRB approval was required to conduct this study, so this work does not raise any ethical issues.

9.1 Methodology

Participating users were asked to fill out a pre-questionnaire (e.g., level of expertise, degree of familiarity with policy deployment, and use of chatbot-like interfaces) and then take on the role of a campus network operator by performing five specific network management tasks using LUMI. Based on the information these users provided in their pre-questionnaire, we had participants from three different continents: the Americas (88.5%), Europe (7.7%), and Asia (3.8%).

Each of the tasks required the user to enforce a specific type of network policy: (i) reroute traffic from the internet to an inspection middlebox; (ii) limit the bandwidth of guest users using torrent applications; (iii) establish a data usage quota for students in the university dorms; (iv) block a specific website for students in the labs, and (v) add a daily temporal bandwidth throttle to the server racks from 4pm to 7pm. Every interaction users had with LUMI was logged to a database for post-analysis.

After finishing the tasks, users were asked to complete a post-questionnaire (e.g., number of completed tasks, the perceived value of LUMI, and comments on its usability). The complete set of management tasks presented to the users and all the results are available on the LUMI’s website. Out of the 30 participants, four did not complete the online questionnaires and were excluded from the study, leaving a total of 26 subjects. Figure 5 shows a breakdown of the user profiles by type of job, level of experience with network management, and familiarity with chatbot-like interfaces.

Figure 5: Subjects profiles.

9.2 Information Extraction and Feedback

To assess the accuracy of our Information Extraction module, we use the number of tasks each participant concluded. For

completing any given task, a specific set of labeled entities was required to build the correct *Nile* intent. Hence, each user’s number of completed tasks reflects how accurately LUMI identified the entities in the input texts. The results in the left part of Figure 6 show that most users completed either 5/5 or 4/5 tasks. Some examples of successful intents for each task can be found on LUMI’s website [39]. An analysis of the users’ interactions with the system revealed that LUMI had trouble understanding temporal behavior (e.g., “from 4pm to 7pm”), likely due to a lack of such training examples. This issue prevented some users from completing all five tasks. One user could not complete any task, reportedly because of an outage in the cloud provider infrastructure used to host LUMI.

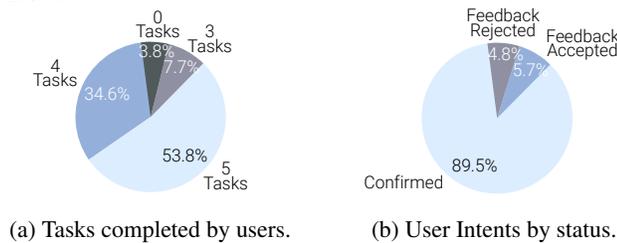

Figure 6: LUMI information extraction and feedback.

To evaluate the value of LUMI’s feedback mechanism as part of the Intent Confirmation module, we considered all intents that the 26 users generated and checked how many were confirmed and how many were rejected. If an intent was rejected, the user could provide feedback to correct it, thus improving LUMI. Such a corrected intent could then once again be accepted or rejected by the user. The right-hand side of Figure 6 gives the breakdown of the intents and shows that, most of the time, LUMI correctly interpreted the users’ intents; in the few times feedback was needed, LUMI was able to correct and learn more often than not. This result is encouraging given the somewhat limited amount of data with which LUMI was trained.

On further analysis of the interactions that users had with LUMI, we observed that the feedback mechanism worked as expected in cases where the participants used a different or unusual phrasing of their intents. For instance, one user expressed the intent for task 3 in an unstructured manner, as “*student quota dorms 10GB week*”, in which LUMI was not able to recognize the word “*dorms*” as a *@location* entity. However, the user then provided feedback that was successful in correcting the original *Nile* intent.

One concrete example where the feedback was unsuccessful happened in task 3, with a user that typed the intent “*Lumi, limit students to 10GB maximum download per week in dorms*”. LUMI was only trained to recognize phrases of the form “10GB per week”, and the additional text in between resulted in LUMI being unable to recognize the user’s phrase. When asked what information LUMI had missed, the user provided feedback indicating that “10gb/wk” was an entity class and “Gb per week” was the value, instead of labeling

“Gb per week” as a *@qos_unit* entity. We note that LUMI is an initial prototype, and such cases can be avoided in the future by improving the clarity of suggestions LUMI makes to the user, and by including sanity checks on user inputs.

9.3 Users Reactions and Usability

In the post-questionnaire, we asked the users to comment on LUMI’s usability and overall merit by answering three questions: (i) How easy was it to use LUMI to configure the network? (ii) Compared to traditional policy configuration, how much better or worse was using LUMI instead? and (iii) Would they rather use LUMI to enforce policies or conventional network configuration commands. Figures 7, 8 and 9 summarize the users’ responses, broken down by expertise in network management. The results show that the participants’ overall reaction to LUMI was very positive, with most of them stating that they would either use LUMI exclusively or, depending on the tasks, in conjunction with configuration commands. Note that the expert users who identified themselves as campus network operators all had a positive reaction to LUMI. Overall, among all different levels of expertise, 88.5% of participants stated they would rather use LUMI exclusively or in conjunction with configuration commands.

We also asked participants to provide insights they had that could help us improve the implementation and design of LUMI. One important feedback we received was the lack of support for querying the network state. For example, one participant stated:

“*Many network management tasks are about monitoring something or figuring out what’s happening, not just installing a new policy...*”

While LUMI was not designed with this goal in mind, we do not foresee any major NLP challenge to incorporate such features into it, as the entity set could be extended to cover this use case. Acquiring the state information from the network requires further investigation, but LUMI’s modular design makes it simpler to plug in a new module or an existing one [13] to query the network devices. This would enable LUMI to “understand” changes made through other tools, as LUMI will likely co-exist with different management applications in real deployments. Overall, the feedback received from participants was positive and highlighted the promise and value of LUMI.

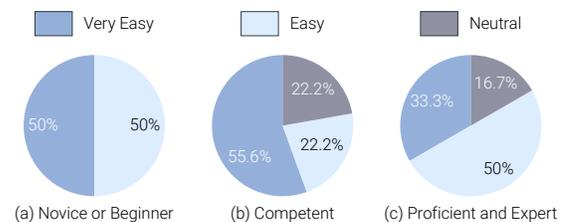

Figure 7: User reaction to LUMI’s usability, by expertise on network management.

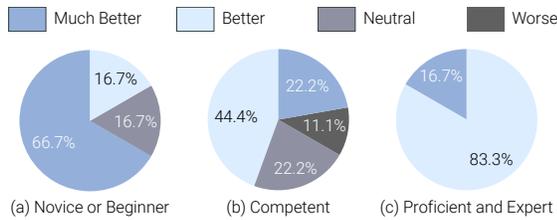

Figure 8: User reaction to LUMI's when compared to traditional network configuration, by expertise on network management.

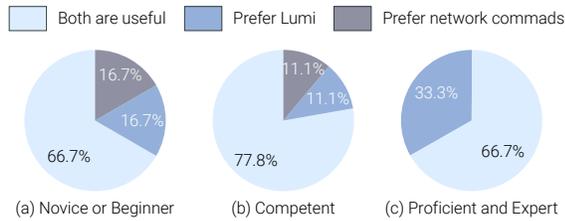

Figure 9: User reaction to LUMI's when compared to traditional network configuration, by expertise on networking.

10 Ongoing Work and Open Problems

While we consider LUMI to be a promising and necessary step towards fully realizing IBN, several challenges remain and are part of our ongoing work.

10.1 Ambiguities in natural language policies

NLP policies have the potential for ambiguities. In exploring this issue further, we extracted pairs of intents from our *campi* dataset and generated 213 pairs in all. Furthermore, we adapted existing NLP efforts on contradiction detection in general text [24, 37, 40, 42, 53, 55, 60] by developing a Random Forest Classifier trained to classify pairs of network intents based on contradiction indicators (features) found between the two input intents. The classifier flagged 9 cases with potential contradictions.

Manual inspection of all 213 intent pairs indicated that most of these cases were benign. They typically corresponded to cases where universities expressed policies that depended on a user's total traffic usage over different time periods (e.g., a 10 GB weekly limit vs a 5 GB daily limit). In these cases, the two policies could be applied in any order with no negative consequences. One interesting case, however, was a campus that expressed two different policies at different locations on their website. The first policy indicated H323 video conferencing was allowed by the University firewall, while the second indicated MSN audio and video communications were not allowed. This is a case where the relative precedence between the two policies impacts their joint effect.

Part of our ongoing work is to combine LUMI with formal methods to help detect ambiguities that are potentially of concern. Specifically, translating NLP policies into LUMI intents enables the use of automated methods that can check

whether the impact of applying two policies is sensitive to their relative ordering, but also provides opportunities to use methods for detecting policy conflicts [2, 51].

10.2 Deploying Lumi in a production network

The initial design of LUMI was aimed at solving management problems that arise in a Campus network environment. We have been engaged in discussions with operators of our campus network regarding validating LUMI in production. Below, we discuss some of the issues raised by the operators and outline challenges and potential solutions.

Co-existing with current technologies. Most campus networks consist of legacy network equipment from multiple vendors with vendor-specific configuration interfaces. Getting LUMI "production-ready" requires developing a *Nile* compiler that can accommodate this diversity in legacy devices. Since the *Nile* abstraction offers isolation from the system's interface and minimizes the need for changes in the early stages of the LUMI pipeline, it is well-suited for Open-Config [48], a vendor-neutral model for network management that is supported by an increasing number of devices.

Extending LUMI for other use-cases. While we have focused on Campus networks, deploying LUMI in other environments may require extending its feature set. For example, unlike the Campus networks we have access to, multi-tenant data-center networks may use VXLANs or NVGRE as solutions to scalably share network infrastructure between tenants. However, LUMI is easily extended to support such features, and we illustrate the four generic steps required for such extension with the VXLAN example. In a first step, one must decide the abstraction level in which LUMI should handle natural language text. Consistent with LUMI's design philosophy, for VXLAN support, a high-level intent could be "*Block incoming traffic for tenant A*", where "*tenant A*" refers to a specific VXLAN Network Identifier (VNI). Next, LUMI's training dataset has to be augmented appropriately, the *Nile* language must be extended with new keywords (e.g., a `tenant('A')` operator for the VXLAN example), and the *Nile* compiler has to be instrumented to handle the new set of configurations. In the case of VXLAN, similarly to VLANs, tenants names must be mapped to VNIs. Lastly, since OpenFlow switches support VXLANs, all that is needed is to extend *Merlin* to allow matching traffic based on VNI for each tenant.

Creating sandbox environments. Migrating LUMI to production requires that operators have trust in LUMI. Based on our discussions with operators, a mirrored sandbox environment [3] could be a good starting point.

10.3 How to verify if Lumi is correct?

We discuss potential sources of errors in each stage of the LUMI pipeline and possible solution approaches.

Translating human language to *Nile* intents. Information extraction from natural language is inherently prone to errors. LUMI alleviates this problem by asking operators for

feedback and using their responses to check if the extracted information was correct. Over the longer term, we plan to leverage ongoing ML research efforts that focus on making ML models more robust and secure so they can be deployed in security- and safety-critical settings such as production network environments [9, 27].

Compiling *Nile* intents. Recent works on formal network verification [1, 10, 50] provide sub-second verification of waypointing, reachability, and isolation properties and are well suited for verifying configurations generated by LUMI-compiled intents. LUMI supports time-constrained intent deployment as well as QoS features. Despite recent work on verifying such properties (e.g., [31, 58]), more advances may be needed in the area, including the possible adaption of existing verification techniques to a LUMI-specific setting.

Post-deployment behavior monitoring. Ultimately, we envision the LUMI pipeline shown in Figure 1 to include a monitoring module for verifying that the deployed configurations respect the intents produced by the refinement process and achieve the objective(s) that the operator expressed (in natural language) in the first place. By monitoring both the traffic and configurations of specific devices affected by a deployed intent, such a module would allow operators to query at any time if the deployed intent produced the desired network behavior [22], thereby improving the operators' trust in relying on LUMI. However, deciding which traffic, devices, and properties to monitor will require instrumenting networks with an unprecedented level of control that is currently only possible by leveraging the latest programmable data plane technologies [8, 23]. At the same time, the development of such a module can be viewed as a first step towards realizing the vision of self-driving networks [12, 19, 45].

11 Related Work

Natural language in networking. Very few prior works use natural language to interact with the network. In [13], the authors present *Net2Text*, a system that allows network operators to query network-wide forwarding behaviors using natural language, but it does not allow operators to configure the network. Alsudais *et al.* [4] proposes using natural language to deploy network intents. It uses the Stanford CoreNLP Parts-of-Speech (POS) Tagger [61] to parse and structure the input text but does not cover NLP aspects relevant to LUMI such as intent confirmation for user feedback and learning over time.

Network programming languages. Recent works on IBN feature several intent languages, frameworks, and compilers to efficiently deploy intents in network devices and middleboxes [2, 6, 21, 31, 51, 54, 57, 59]. At the same time, Cocoon [54] introduces a framework to guarantee the correctness of SDN programs that resembles our approach, but it uses first-order logic. With LUMI, we examine the use of machine learning to convert natural language intents into lower-level configurations without the need for using a specific programming language.

Natural language processing. Information extraction has been addressed with different methods and techniques, including (i) only CRF models [20]; (ii) character-level embeddings instead of whole words [34], and (iii) rule-based approaches [15]. Yet, recent studies [63] show the benefits of the approach considered as part of LUMI. To our knowledge, the problem of using natural language for management tasks has not received much attention in the networking domain.

IBN. INSpIRE [56] focuses on intents related to security middleboxes and uses a refinement process to determine which middleboxes should compose a service chain to fulfill an intent. Cheminod *et al.* [14] propose an automatic process for refining, deploying, and enforcing ACL policies that use set notation for policy specification. PGA [51] applies a graph-based abstraction to compose high-level policies and deploy them in SDN networks. Janus [2] extends PGA to support policies with QoS requirements, mobility, and temporal dynamics. However, these proposals differ from LUMI as they are not concerned with using natural language or obtaining feedback from the network operator.

12 Conclusions

In this paper, we propose LUMI, a novel end-to-end intent refinement and deployment system that allows operators to express their intents in natural language and then check and confirm the intents before deploying them in the network. By demonstrating that LUMI can successfully deal with a wide range of network policies, this paper represents a promising step towards realizing the vision of intent-based networking with natural language. Still, much work remains. For example, while our design choices for LUMI's different modules resulted in a working prototype, other features might be necessary for a production-ready version of the system. However, LUMI's modular design can readily accommodate such improvements. Also, since LUMI in its current form is mainly intended for use in campus networks, supporting other environments (e.g., home or enterprise networks) will most likely require that the set of *Nile* operations and functions (and in turn the set of LUMI entities) be judiciously extended.

Acknowledgments

We thank our shepherd Costin Raiciu and the anonymous reviewers for their valuable feedback. We thank Jennifer Rexford, Hyojoon Kim, Shir Landau-Feibish, and Ross Teixeira for their feedback on earlier drafts of this paper. We also thank the anonymous participants of our user study for their contributions and insights. Abstract

As a common choice for fault tolerance in today’s storage systems, erasure coding is still hampered by the induced substantial traffic in repair. A variety of erasure codes and repair algorithms are designed in recent years to relieve the repair traffic, yet we unveil via careful analysis that they are still plagued by several limitations, which restrict or even negate the performance gains. We present RepairBoost, a scheduling framework that can assist existing linear erasure codes and repair algorithms to boost the full-node repair performance. RepairBoost builds on three design primitives: (i) repair abstraction, which employs a directed acyclic graph to characterize a single-chunk repair process; (ii) repair traffic balancing, which balances the upload and download repair traffic simultaneously; and (iii) transmission scheduling, which carefully dispatches the requested chunks to saturate the most unoccupied bandwidth. Extensive experiments on Amazon EC2 show that RepairBoost can accelerate the repair by 35.0-97.1% for various erasure codes and repair algorithms.

1 Introduction

Today’s storage systems are often composed of a large number of *storage nodes* (called “nodes” for brevity) to accommodate the explosively increasing data volume, making failures arise unexpectedly yet prevalently. To protect data reliability even in the presence of failures, many storage systems resort to *replication* [14] and *erasure coding* [47], both of which rely on pre-storing additional redundancy to repair the lost data. As opposed to replication that simply stores identical replicas, erasure coding can assuredly attain the same fault tolerance degree with much less storage consumption [59], and hence is much more preferable in commodity storage systems [4–6, 41, 43]. In principle, erasure coding consists of two lightweight computational operations, namely *encoding* (i.e., generating redundant chunks based on the original data chunks) and *decoding* (i.e., repairing the original data chunks based on the

surviving chunks), so as to realize the efficient transformation between the original data and redundancy.

Although being storage-efficient, erasure coding is prone to substantial *repair traffic* (i.e., the amount of data transmitted over the network for repair), as it often needs to retrieve multiple surviving chunks to repair a single chunk. To relieve the I/O amplification problem in repair, existing studies mainly resort to the following approaches: (i) constructing new theoretical erasure codes with provably reduced repair traffic (e.g., Locally Repairable Codes [21, 28, 52], Rotated-RS codes [27], and regenerating codes [13, 44, 49, 58]); (ii) designing efficient repair algorithms to parallelize the repair process [22, 32, 40, 56]; and (iii) utilizing machine-learning-based prediction techniques [16, 34, 42] to proactively restore the data with the repair algorithms before failure occurrence [38, 54] (see §2.2 for details).

Our observation is that most existing erasure codes and repair algorithms mainly focus on the single-chunk repair, yet the full-node failure (i.e., all the chunks in a node are permanently lost) must simultaneously manipulate the repair of multiple chunks. Thus, *there exists a gap between the deployment of existing repair approaches and the requirement of full-node repair*. Such a gap leads to several practical limitations: (i) they do not specifically leverage the full-duplex transmission to saturate the available bandwidth; (ii) they fail to carefully schedule the transmission of chunks to fully utilize the bandwidth at all times; (iii) they neglect the elastic cooperation of different repair algorithms to meet diverse reliability guarantees [25] and access popularities [9, 23]; and (iv) they have dedicated repair strategies with the pre-specified data routing among nodes, thereby increasing the implementation complexity (see §2.3 for details). Therefore, how to seamlessly deploy existing repair approaches to efficiently tackle the full-node repair remains a challenging yet crucial issue in erasure-coded storage.

We bridge this gap by designing RepairBoost, a scheduling framework that can assist a variety of erasure codes and repair algorithms to speed up a full-node repair. The main idea behind RepairBoost is to formulate a single-chunk re-

*Corresponding author: Zhirong Shen (shenzr@xmu.edu.cn).

pair through a *repair directed acyclic graph* (RDAG), which characterizes the data routing over the network and the dependencies among the requested chunks for repair. RepairBoost then decomposes an RDAG into multiple *repair tasks*, each of which performs data uploads and downloads to facilitate the repair. RepairBoost balances the repair traffic and bandwidth utilization in the full-node repair through the following two steps: (i) it carefully dispatches the repair tasks of multiple RDAGs to the corresponding nodes for balancing the overall upload and download repair traffic; and (ii) it coordinates the execution orders of repair tasks to saturate the utilization of the available upload and download bandwidth. To summarize, our main contributions include:

- **[Design]** We propose RepairBoost to assist existing erasure codes and repair algorithms for speeding up the full-node repair. RepairBoost formulates a single-chunk repair through an RDAG. It then balances the upload and download repair traffic via carefully assigning the repair tasks of RDAGs to the nodes. RepairBoost also formulates the maximum flow problem [57] to schedule the data transmission for saturating the unoccupied bandwidths (§3.1-§3.3).
- **[Generality]** We also show that RepairBoost can be extended to tackle multiple node failures and boost the repair in heterogeneous environments (§3.4).
- **[Implementation]** We implement a prototype of RepairBoost with C++, which can be an independent middleware deployed atop existing storage systems for repair scheduling. We also demonstrate the portability of RepairBoost by integrating it into Hadoop HDFS 3.1.4 with limited modifications to the codebase (with around 270 LoC added) (§4).
- **[Evaluation]** We evaluate the performance of RepairBoost on Amazon EC2 [8], showing that it can support a variety of erasure codes and repair algorithms and increase the repair throughput by 35.0-97.1% (§5).

The source code of our RepairBoost prototype can be reached via <https://github.com/shenzr/repairboost-code>.

2 Background

We start with the basics of erasure coding (§2.1) and elaborate on existing attempts for repair acceleration in erasure-coded storage (§2.2). We also summarize the limitations that remain to be addressed (§2.3).

2.1 Basics

Erasur coding introduces slight computational operations to reduce the storage overhead for reliability assurance [59]. It operates on data in units of *chunks*, which are a collection of data with the size of several megabytes (e.g., 64 MB in Hadoop HDFS [6] and 256 MB in Facebook’s data-warehouse cluster [48]). Formally, erasure coding can be con-

figured via two integer parameters, namely k and m , which tune the storage efficiency and fault tolerance assurance. A (k, m) erasure code encodes every k equal-sized data chunks $\{D_1, D_2, \dots, D_k\}$ at a time to generate additional m redundant chunks (called *parity chunks*) $\{P_{k+1}, P_{k+2}, \dots, P_{k+m}\}$. In this paper, we mainly consider the *linear erasure codes*, where each parity chunk can be expressed as a *linear combination* of the k data chunks via the Galois Field arithmetic [46], given by $P_{k+j} = \sum_{i=1}^k \alpha_{i,j} D_i$, where $\alpha_{i,j}$ ($1 \leq i \leq k$ and $1 \leq j \leq m$) is the encoding coefficient used by the data chunk D_i to calculate the parity chunk P_{k+j} . Such $k+m$ data and parity chunks that are encoded together collectively constitute a *stripe* (or a coding group [33, 62]), ensuring that *any* k out of $k+m$ chunks of the same stripe *always* suffice to restore (decode) the original k data chunks (a.k.a. *Maximum Distance Separable* (MDS) property in coding theory). In other words, the (k, m) erasure code can tolerate *any* m chunk failures for every stripe.

In practice, data chunks in storage systems are often organized into multiple stripes, which are *independently* manipulated by erasure coding. Hence, by distributing the $k+m$ chunks of each stripe across $k+m$ distinct nodes (i.e., one chunk per node), we can always guarantee data reliability in the face of no more than *any* m node failures. In this paper, we equally treat the data and parity chunks in repair, and just refer to them as “chunks.”

A variety of erasure codes have been proposed for decades, where Reed-Solomon (RS) codes [51] are the most popular code construction used in production storage (e.g., Ceph [4], Hadoop HDFS [6], QFS [43], Facebook f4 [41], and Yahoo Cloud Object Store [5]), since they support any parameters of k and m . For simplicity, we denote the RS code configured by the parameters k and m as $RS(k, m)$ and use it as our case study throughout the paper. For example, Figure 1(a) depicts a stripe of $RS(4, 2)$. We also show that our work is applicable to other linear erasure codes (§5.3).

2.2 Repair

Repair in erasure-coded storage is often classified into (i) *full-node repair*, which restores all lost chunks in a failed node (e.g., caused by a disk failure), and (ii) *degraded reads* to the temporarily unavailable chunks (e.g., caused by system upgrades and network disconnections) or the chunks that have not yet been repaired in the full-node repair. In this paper, we mainly focus on the *single full-node repair*, which is recognized as one of the top causes of service downtime [35]. Our work can also tackle multiple node failures (§3.4).

The full-node repair has to manipulate the repair across multiple stripes. Although being storage-efficient, erasure coding is prone to a high repair penalty. For example, $RS(k, m)$ needs to retrieve k surviving chunks of the same stripe to recover a lost chunk, thereby amplifying the storage and network I/Os in repair by k times. Specifically, suppose that a chunk C^* fails and $\{C_1, C_2, \dots, C_k\}$ is the set of k chunks

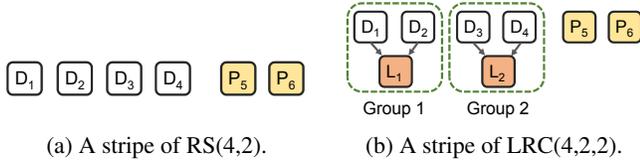

Figure 1: Examples of RS codes and LRCs.

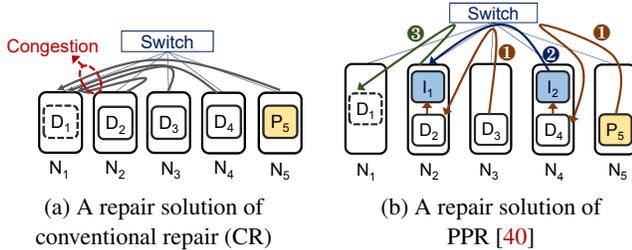

Figure 2: Repair solutions for RS(4,2). D_1 indicates the repaired chunk. N_1 is the destination node.

within the same stripe of C^* . We can repair C^* using a linear combination of the k chunks as:

$$C^* = \sum_{i=1}^k \beta_i C_i, \quad (1)$$

where β_i is the decoding coefficient used by C_i for repairing C^* . In this paper, we refer to the node storing the repaired chunk as the *destination node*.

In view of the high repair penalty, existing studies design solutions that mitigate the repair penalty as follows.

Repair-efficient erasure codes: They relieve the repair traffic with theoretical guarantees through the construction of erasure codes, where *Locally Repairable Codes* (LRCs) [21, 52] and regenerating codes [13, 44, 48, 49, 58] are two representatives. LRCs are configured via three parameters, namely k , l , and m . $LRC(k, l, m)$ extends $RS(k, m)$ by organizing the k data chunks of a stripe into l groups (assuming that k is divisible by l) and maintaining an additional *local parity chunk* for each group. This design allows a single data chunk to be repairable by retrieving merely $\frac{k}{l}$ surviving chunks within the same group¹. Figure 1(b) shows a stripe of $LRC(4, 2, 2)$, where L_i is the local parity chunk of the i -th group ($1 \leq i \leq 2$).

On the other hand, regenerating codes reduce the repair traffic by (i) requiring surviving nodes to send the linear combination of the locally stored data [13] and (ii) contacting more surviving nodes to assist the repair [49]. Recently proposed regenerating codes (e.g., Butterfly codes [44] and Clay codes [58]) further eliminate the needs of computations in the surviving nodes, which can simply retrieve the required sub-chunks directly from surviving nodes for repair.

Repair algorithms: While erasure codes specify *which chunks* should be retrieved for repair, repair algorithms mainly focus on *how* to quickly retrieve the surviving chunks over

the network for existing erasure codes. They accelerate the repair by exploiting the unoccupied bandwidth without reducing the repair traffic. Each repair algorithm specifies a *repair solution* for a lost chunk, including the data routing and execution orders among the surviving nodes. Figure 2(a) shows the repair solution of D_1 under the *conventional repair* (CR) for $RS(4, 2)$, where it transmits four surviving chunks $\{D_2, D_3, D_4, P_5\}$ at the same time to the destination node N_1 . Suppose that a chunk can be transmitted over a network link in a *timeslot*. The conventional repair takes four timeslots for N_1 to download the four chunks, because of the congestion of the download link of N_1 . PPR [40] relieves the network congestion by decomposing a single-chunk repair into multiple sub-stages and executing them in parallel, so as to fully utilize the available bandwidth. Figure 2(b) depicts a single-chunk repair solution under PPR for $RS(4, 2)$, which accomplishes the repair in three timeslots: (i) in the first timeslot (1), we transmit D_3 to N_2 and add them together (as in Equation (1)) to generate an intermediate chunk I_1 , while at the same time sending P_5 to N_4 to generate another intermediate chunk I_2 ; (ii) in the second timeslot (2), we transmit I_2 to N_1 and add I_2 with I_1 to restore the lost chunk D_1 (as in Equation (1)); and (iii) in the third timeslot (3), we deliver D_1 to the destination node. Thus, PPR exploits the available bandwidth across multiple nodes at each timeslot to mitigate the network congestion in a single-chunk repair. ECPipe [32] further reduces the repair time to almost one timeslot by decomposing the repair of a lost chunk into the pipelined repair operations of multiple smaller sub-chunks.

Proactive repair with erasure coding: Both repair-efficient erasure codes and repair algorithms are *reactive*, implying that they launch the repair operation only *after* failures truly occur. *Proactive* repair [38, 54] further reduces the window of data vulnerability by using *machine-learning-based failure prediction models* (e.g., Bayes classifier [16], support vector machines [42], and random forest [34]), such that it can detect in advance the nodes impending to fail and *proactively* repair the data in such nodes *before* the failure occurrence. Proactive repair can be realized by the data migration and the decoding of chunks based on erasure coding [54], where we mainly focus on the latter in this paper.

2.3 Limitations

By examining existing attempts to accelerate the repair of erasure-coded storage, we identify the following limitations that, if not properly addressed, will limit the performance gains when they are directly employed for the full-node repair.

Limitation 1 (L1): Failing to utilize the full duplex transmission. Most existing studies overlook the *full duplex transmission* [12, 36] in repair, which enables a node to send (upload) and receive (download) data simultaneously and independently; as a result, they cannot properly balance the upload and download repair traffic in the full-node repair. Figure 3 shows two examples of repair under CR (where N_i is the i -th

¹LRC(k, l, m) also needs k chunks to repair a global parity chunk (e.g., P_5 and P_6 in Figure 1(b)).

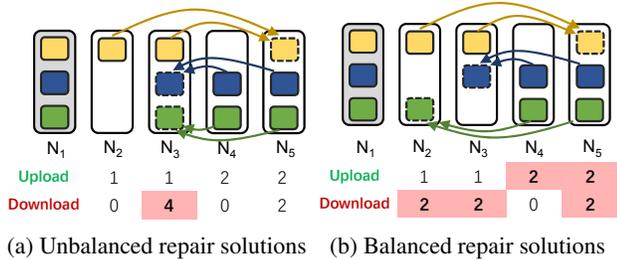

Figure 3: L1 (Failing to utilize the full duplex transmission). The repair time is determined by the most loaded node (with the red color in the background).

node), where the first example needs to download four chunks (at N_3) to accomplish the repair, while the latter only uploads and downloads at most two chunks for repair. This example indicates that balancing the upload and download repair traffic in the full duplex transmission has the potential to reduce the overall repair time, which is determined by the node with the most upload or download repair traffic.

Specifically, the repair-efficient codes [13, 21, 44, 48, 49, 58] reduce a single chunk’s repair traffic without concerning traffic balancing. Some repair algorithms (e.g., ECPipe [32] and PPR [40]) mainly focus on accelerating a single chunk’s repair, while paying limited attention to balance the upload and download repair traffic in the full-node repair. Although ClusterSR [55] balances the inter-cluster upload and download repair traffic, it still does not balance the upload and download bandwidths in general storage systems.

Limitation 2 (L2): Failing to fully utilize the bandwidth at each timeslot. While existing repair algorithms can relieve the download bottleneck within a single-chunk repair (e.g., PPR [40] and ECPipe [32]), they simply combine the repair solutions of multiple chunks to cope with the full-node repair. This may unintentionally lead to the link congestion again and make the bandwidth under-utilized in the full-node repair.

Figure 4 shows how transmission scheduling affects the repair. In Figure 4(a), after the transmissions of C_2 and C_4 in the first timeslot, the transmissions of C_3 (from the node N_5 to N_3) and C_7 (from N_2 to N_3) compete for the bandwidth of the download link of N_3 . Figure 4(a) gives priority to C_3 in the second timeslot. Since C_6 can only be transmitted after receiving C_7 , Figure 4(a) finally needs four timeslots. As a comparison, Figure 4(b) sends C_7 at the second timeslot, allowing the transmission of C_6 and C_3 to be performed in parallel without bandwidth competition. Hence, Figure 4(b) only uses three timeslots. This example indicates that the repair solutions in the full-node repair should be carefully scheduled.

Limitation 3 (L3): Inflexibility. Many repair algorithms [22, 32, 40, 55, 56] treat every chunk equally and repair all the lost chunks using the same repair algorithm. This repair fashion is simple yet inflexible, as it cannot elastically combine different repair algorithms, and make them cooperate for diverse reliability requirements [25] and skewed access popu-

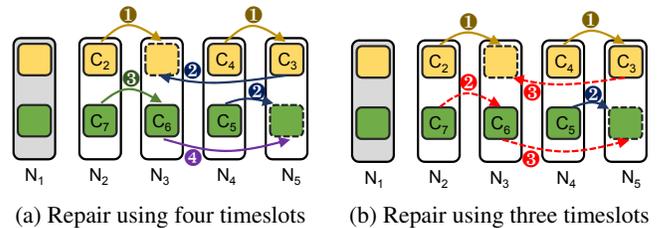

Figure 4: L2 (Failing to fully utilize the bandwidth at each timeslot). The transmission scheduling affects the bandwidth utilization.

larity in real-world storage systems [9, 23]. For example, we can combine ECPipe [32] and CR, such that we use ECPipe to repair the chunks that require higher reliability guarantee, while employing CR to restore the remaining ones, so as to regulate the repair traffic and foreground traffic.

Limitation 4 (L4): Lack of a general framework for the full-node repair. Existing distributed storage systems deploy different specific repair algorithms for a single-chunk repair. For example, many commodity storage systems (e.g., Hadoop HDFS [7] and Windows Azure Storage [21]) still rely on CR in a single-chunk repair due to its simplicity, while PPR [40] and CAR [56] can be used in hierarchical storage systems to reduce inter-rack repair traffic. It is desirable to have a *general* framework that simultaneously supports different types of repair algorithms for different deployment scenarios.

3 RepairBoost Design

We present RepairBoost, a scheduling framework that can assist a variety of erasure codes and repair algorithms to boost the full-node repair performance.

Assumptions: RepairBoost is designed based on the following assumptions. First, RepairBoost mainly focuses on a single full-node repair, which is reported as the most predominant failure event in practice (e.g., 98% of the total failure events [50]). Nevertheless, RepairBoost can be extended to tackle a multi-node failure (i.e., more than one node in a stripe fails) (§3.4). Second, to simplify our discussion, we elaborate RepairBoost using RS codes in homogeneous environments (i.e., with identical link bandwidth), yet we also show that RepairBoost works for other erasure codes (§5.3) and can be deployed in heterogeneous environments (i.e., with different link bandwidth) (§3.4).

Overview: RepairBoost uses the following techniques to address the limitations aforementioned (§2.3). It first abstracts a single-chunk repair solution via a general *repair directed acyclic graph (RDAG)* (§3.1). By supporting the scheduling of multiple RDAGs, RepairBoost can achieve both *flexibility* (i.e., allowing the collaboration of different repair algorithms; L3 addressed) and *generality* (i.e., being workable for various erasure codes and repair algorithms; L4 addressed).

RepairBoost then decomposes multiple RDAGs into vertices that have dedicated repair tasks. It then carefully assigns

the repair tasks to the nodes, so as to balance the overall upload and download repair traffic across the surviving nodes (§3.2; L1 addressed).

RepairBoost finally constructs a directed network based on the surviving nodes and the corresponding repair tasks. It then determines the chunks to be transmitted by solving a maximum flow problem [57], so as to fully saturate the unoccupied upload and download bandwidth at each timeslot (§3.3; L2 addressed).

3.1 Repair Abstraction

RDAG construction: We first formalize a single-chunk repair solution through a *directed acyclic graph* (DAG), which is called the *Repair DAG* (RDAG). For $RS(k, m)$, the RDAG of a lost chunk can be initialized over $k + 1$ vertices, where the k vertices $\{v_1, v_2, \dots, v_k\}$ represent the k nodes that store the requested surviving chunks for repair, while v_{k+1} denotes the destination node. Also, we employ directed edges among vertices to represent the data routing directions specified in repair algorithms.

We construct the edges based on the following rules. Given two vertices v_i and v_j ($1 \leq i \neq j \leq k + 1$), we use a directed edge $e_{i,j}$ to indicate that v_i is designated to send a surviving chunk to v_j . Hence, if $e_{i,j}$ exists, we say that v_i is a *child* of v_j , and conversely v_j is the *parent* of v_i . For v_j (where $j \neq k + 1$), it has to collect all the requested surviving chunks from its children, add them together with the local data it stores using the decoding coefficient (see Equation (1)), and send the result to its parent. Therefore, in this RDAG, v_j can send a chunk for repair once all the chunks required from its children are received. As the full-node repair has to recover multiple chunks, a node may have multiple parents and children across different RDAGs.

Repair process guided by RDAG: The repair starts from the *leaf vertices* (i.e., those that do not have any child) and ends at v_{k+1} : for each edge $e_{i,j}$ ($1 \leq i \neq j \leq k + 1$), if v_i has sent the requested chunk to v_j for repair, we remove $e_{i,j}$ from the RDAG; further, for each leaf vertex v_i , if there is no edge connecting to it (indicating that v_i has already transmitted all the requested chunks to its parents), we remove v_i from the RDAG as well. Hence, as the repair proceeds, the number of vertices in the RDAG will gradually decrease and the lost chunk is successfully repaired once the vertex v_{k+1} becomes a leaf vertex eventually.

Example: We take the RDAG of PPR in Figure 5 as an example, where $k = 4$. Suppose that the four requested surviving chunks in $\{v_1, v_2, \dots, v_4\}$ are denoted by $\{C_1, C_2, \dots, C_4\}$, respectively. In the first stage, v_1 sends a chunk $\beta_1 C_1$ to its parent v_2 (where β_1 is the decoding coefficient of C_1 ; see Equation (1)), while at the same time v_3 sends another chunk $\beta_3 C_3$ to its parent v_4 . We also update the RDAG by removing $e_{1,2}$, $e_{3,4}$, v_1 , and v_3 . In the second stage, the leaf vertex v_2 combines $\beta_1 C_1$ with its stored chunk C_2 and sends the result $\beta_1 C_1 + \beta_2 C_2$ to its parent v_4 . In the third stage, after collect-

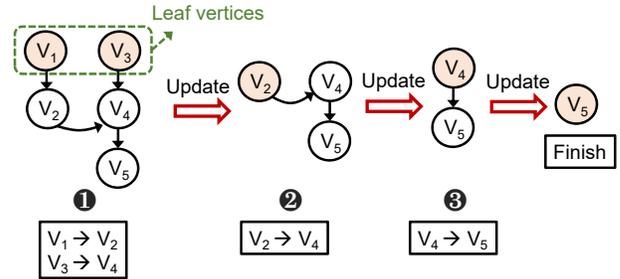

Figure 5: Example of an RDAG of PPR [40] when $k = 4$. The vertex with pink color indicates the leaf vertex. We repeatedly update an RDAG as the repair proceeds.

ing two chunks from its children, v_4 combines $\beta_1 C_1 + \beta_2 C_2$, $\beta_3 C_3$, and its locally stored chunk C_4 to restore the lost chunk $C^* = \sum_{i=1}^4 \beta_i C_i$, and finally sends C^* to v_5 . The repair of C^* completes when v_5 becomes a leaf vertex.

Advantages of an RDAG: The RDAG design has the following advantages. First, an RDAG is a general formalization of a single-chunk repair solution. That is, we can construct an RDAG for any given repair algorithm once we identify the surviving chunks needed for repair and the data routing strategy performed among them. Thus, RepairBoost is applicable to a variety of erasure codes (e.g., RS codes, LRCs, and regenerating codes) and single-stripe repair algorithms (e.g., CR, PPR, and ECPipe). This design also resolves the tensions of deploying specific repair algorithms (i.e., being general) and facilitates their co-existence (i.e., being flexible).

Second, an RDAG describes how data is transmitted over the network and also the dependency (or relationship) among the k surviving chunks involved in the repair. Given an RDAG, we can readily identify that the leaf vertices with different parents in an RDAG can be potentially transmitted in parallel to occupy the available bandwidth without network congestion (e.g., v_1 and v_3 in Figure 5). We leverage this property in the transmission scheduling (§3.3).

Third, an RDAG also indicates the repair tasks of each vertex. For example, we can learn that v_4 in Figure 5 needs to download two chunks and upload one chunk in the repair. We explore the traffic balancing through the assignment of repair tasks (§3.2).

Discussion: OpenEC [29] proposes an ECDAG to characterize the encoding and decoding processes. Both an RDAG and an ECDAG are fundamentally different in the following aspects: (i) *physical meanings of edges*: the edges in an ECDAG represent the encoding and decoding operations, while the edges in an RDAG specify the routing and dependencies in repair; (ii) *graph structures*: an ECDAG introduces *virtual vertices* to denote the intermediate chunks generated, while an RDAG is built over the chunk repaired and the surviving chunks for repair; and (iii) *graph maintenance*: an ECDAG keeps the graph unchanged throughout the encoding and decoding processes, while an RDAG is iteratively updated with the repair progress.

16:   $d_{N^*} = d_{N^*} + d_{\bar{v}}$ 
17:  return  $N^*$ 
18: end function
```

3.2 Repair Traffic Balancing

After constructing the RDAGs for the lost chunks in a failed node, RepairBoost then assigns the repair tasks by mapping the vertices to the nodes, such that (i) the fault tolerance degree (i.e., the tolerable number of failed nodes) offered by erasure coding must be preserved after repair, and (ii) the upload and download repair traffic across the whole system should be as balanced as possible.

Retaining fault tolerance degree: Given an RDAG of a lost chunk, we assign the k vertices $\{v_1, v_2, \dots, v_k\}$ to the k nodes that store the surviving chunks of the same stripe. We also map v_{k+1} to the node that does not store any chunk of the same stripe before the repair. By doing so, RepairBoost ensures that the $k + m$ chunks of the same stripe still reside in $k + m$ different nodes after repair, thereby retaining the node-level fault tolerance offered by erasure coding (§2.1).

Balancing repair traffic: Given an RDAG, we represent the repair task of a vertex v_i by a tuple (u_{v_i}, d_{v_i}) (where $1 \leq i \leq k + 1$), which indicates the numbers of chunks being uploaded and downloaded by v_i in this RDAG, respectively.

We classify the vertices of an RDAG into three categories: (i) the leaf vertex v_i , which only sends (uploads) surviving chunks for repair (i.e., $u_{v_i} > 0$ and $d_{v_i} = 0$); (ii) the *root vertex*, which only receives (downloads) data for repair (i.e., $u_{v_i} = 0$ and $d_{v_i} > 0$); and (iii) the intermediate vertex, which receives (downloads) multiple chunks from its children and sends (uploads) one intermediate chunk to its parent (i.e., $u_{v_i} = 1$ and $d_{v_i} > 0$). For example, in Figure 5, v_1 is a leaf vertex, v_2 is an intermediate vertex, and v_5 is the root vertex.

After collecting the three kinds of vertices from multiple RDAGs, our main idea is to give priority to map the intermediate and root vertices to the nodes, with the primary objective

of balancing the download repair traffic at first. We then carefully assign the leaf vertices to further balance the upload repair traffic. Algorithm 1 shows the pseudo-code of the mapping algorithm for the intermediate vertices.

Algorithm details: Let \mathcal{T} be the set of the intermediate vertices that have not been assigned yet. Let \mathcal{M} be the mapping established. RepairBoost first initializes \mathcal{M} as an empty set and sorts the intermediate vertices in \mathcal{T} by the number of chunks required to be downloaded in descending order (Lines 2-3 in Algorithm 1). It then pinpoints the vertex \bar{v} that needs to download the most chunks for repair among the vertices of \mathcal{T} (Line 5). RepairBoost finds the set of nodes (denoted by \mathcal{N}) that store the surviving chunks requested in the RDAG of \bar{v} but have not been assigned the repair task of this RDAG (Line 6). It then searches the node for \bar{v} by calling the MAP function (Line 7).

In the MAP function, RepairBoost selects the node N^* that has the least download traffic among the ones in \mathcal{N} (Line 13), where d_{N_i} denotes the number of downloaded chunks of the node N_i . It then maps \bar{v} to N^* . RepairBoost later excludes \bar{v} from the set of \mathcal{T} (Line 14), and increases the numbers of the uploaded and downloaded chunks (denoted by u_{N^*} and d_{N^*}) of N^* by the task of \bar{v} (Lines 15-16). The mapping indicates that N^* will serve as \bar{v} in the corresponding RDAG by uploading and downloading the requested surviving chunks specified to \bar{v} . RepairBoost repeats the above steps until all the intermediate vertices have been assigned to the corresponding nodes (Lines 4-9).

We analyze the computational complexity of Algorithm 1. Suppose that the number of nodes participating in repair is n and $|\mathcal{T}|$ is the number of intermediate vertices in \mathcal{T} . We note that: (i) the sorting of the intermediate vertices (Line 3) incurs a computational complexity of $O(|\mathcal{T}| \cdot \log(|\mathcal{T}|))$, and (ii) the mapping of an intermediate vertex (Lines 5-8) incurs a computational complexity of $O(n \cdot \log n)$, which will be executed for $|\mathcal{T}|$ times (Line 4). Thus, the overall computational complexity of Algorithm 1 is $O(|\mathcal{T}| \cdot \log(|\mathcal{T}|) + |\mathcal{T}| \cdot n \cdot \log n)$.

RepairBoost then maps the root and leaf vertices to the corresponding nodes in the similar way, except the following differences: (i) when mapping the root vertex of an RDAG, RepairBoost selects the node with the lightest download repair traffic among the ones, which does not store any chunk within the same stripe of the repaired chunk; (ii) when mapping the leaf vertices of an RDAG, RepairBoost chooses the nodes with the lightest upload repair traffic among the ones, which not only store the surviving chunks within the same stripe of the repaired chunk, but also have not been mapped with any vertex of this RDAG.

Example: Figure 6 shows an example of mapping an RDAG to the nodes. Given an RDAG, we decompose it into vertices with the tuples (u_{v_i}, d_{v_i}) ($1 \leq i \leq k + 1$ and $k = 4$ in this example), which specify the numbers of uploaded and downloaded chunks for repair (Step 1). For example, v_2 needs to upload and download one chunk. To map the intermedi-

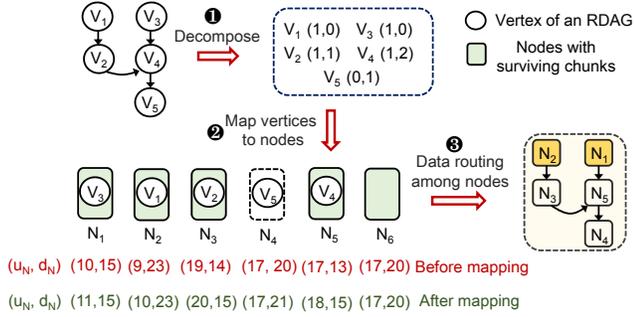

Figure 6: Example of mapping vertices of an RDAG to nodes. We select an RDAG of PPR to repair a chunk of RS(4, 2). N_2 and N_1 are the leaf vertices of this RDAG after mapping. The numbers in red (resp. green) denotes the upload and download traffics afforded by a node before (resp. after) the mapping.

ate vertices (i.e., v_2 and v_4), we first consider v_4 as it needs to download the most chunks. Since N_5 needs to download the fewest chunks (i.e., 13) among $\{N_1, N_2, N_3, N_5, N_6\}$ that store the surviving chunks, we map v_4 to N_5 , and update the numbers of uploaded and downloaded chunks afforded by N_5 afterwards (Step 2). After all the five vertices of an RDAG have been assigned, we can learn the data routings among nodes $\{N_1, N_2, \dots, N_5\}$ to repair the chunk (Step 3).

3.3 Transmission Scheduling

After establishing the mapping from the RDAGs to the nodes for balancing the overall upload and download repair traffic (§3.2), it does not necessarily achieve the lower-bound of the repair time, as the bandwidth may not be utilized at each timeslot during the repair (L2 in §2.3).

To further saturate the bandwidth utilization, RepairBoost formulates the transmission scheduling as a *maximum flow problem* [57]. Specifically, suppose that there are n nodes participating in the full-node repair. We can construct a network based on the RDAGs of the lost chunks. This network is built over $2n + 2$ vertices (Figure 7), with a source s , a sink t , n sender vertices $\{S_1, S_2, \dots, S_n\}$ representing the n nodes that can potentially send data for repair, and another n receiver vertices $\{R_1, R_2, \dots, R_n\}$ representing the n nodes that may receive data at the same time. We then establish the connections as follows: for any two vertices S_i and R_j ($1 \leq i \neq j \leq n$), we establish the connection between S_i and R_j once S_i can send a chunk to R_j according to the RDAGs. Each connection between S_i and R_j is assigned with the capacity of one, implying that we can send one surviving chunk at a time from S_i and R_j . Thus, our objective is to find a maximum flow over the network whose capacity denotes the most chunks that can be transmitted simultaneously at this timeslot, so as to saturate the available upload and download bandwidth.

After establishing the maximum flow, we dispatch the chunks according to the selected edges of the maximum flow. If S_i has many chunks to be sent, we prefer to send a chunk, such that sending this chunk can make a parent of S_i become a leaf vertex in an RDAG in the next timeslot (§3.1). Our

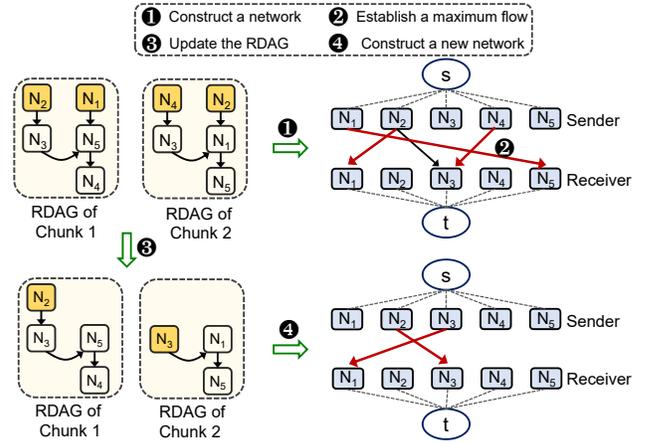

Figure 7: Example of transmission scheduling (where $k = 4$ and $n = 5$). The red arrows means the maximum flows established.

objective is to establish the maximum flow, while at the same time helping increase the number of edges of the network in the next scheduling. This can potentially increase the capacity of the maximum flow in the next transmission.

Once the chunks associated with the edges of the maximum flow have all been transmitted, we accordingly delete the corresponding edges in the RDAGs and update the network based on the residual RDAGs. We repeat the scheduling until all the lost chunks of the failed node have been repaired.

Example: Figure 7 shows an example to repair two chunks among five surviving nodes (i.e., $n = 5$). There are three nodes (i.e., N_1, N_2 , and N_4) that can send chunks for repair (marked in yellow color) in the RDAGs at the very beginning. We construct the network (Step 1) based on the two RDAGs and find the maximum flow (Step 2). The maximum flow indicates that we can send the chunks as follows for transmitting the most chunks simultaneously: $N_1 \rightarrow N_5$ (in the RDAG of the chunk 1), $N_2 \rightarrow N_1$ (in the RDAG of the chunk 2), and $N_4 \rightarrow N_3$ (in the RDAG of the chunk 2). We then update the RDAGs by removing the edges associated with the transmitted chunks and marking the leaf vertex at this time (Step 3). We repeat the construction of the network and the finding of the maximum flow for the residual RDAGs (Step 4).

Complexity analysis: Suppose that there are n nodes and e edges in a network. We can use Dinic’s algorithm [24] to find the maximum flow, whose computational complexity is $O(n^2e)$.

3.4 Extensions

Multi-node repair: We offer two options when using RepairBoost to cope with multi-node repair. The first approach is to simply repair each failed node individually until all the failed nodes are repaired successfully. The second approach is to give priority to repairing the stripes that comprise more failed chunks or popularly accessed chunks, so as to meet the requirements on system reliability and access performance.

Heterogeneous environments: RepairBoost can also be adapted to heterogeneous environments. When given the available link bandwidth, RepairBoost can deduce the time to upload and download a chunk at first. It can amend the repair traffic balancing (§3.2) by mapping the vertices to the nodes based on the times for uploading and downloading a chunk (rather than the numbers of uploaded and downloaded chunks in the design for homogeneous environment). This can ensure that the upload and download times are almost the same across the nodes.

RepairBoost then adopts the following ways in the polling mode for transmission scheduling: (i) it pinpoints the node (denoted by N') that spends the least time in uploading and downloading data for repair; (ii) it sorts the set of links \mathcal{L} connected to N' based on the available bandwidth; and (iii) it picks the link from \mathcal{L} that owns the largest upload or download bandwidth for data transmission. RepairBoost repeats the above steps until all the requested chunks are transmitted.

Adaptation to network conditions: RepairBoost can also adapt to network conditions (e.g., random network congestion). Specifically, RepairBoost can break an entire full-node repair process into several subprocesses, each of which repairs a number of single chunks. RepairBoost can then monitor the completion times of nodes in each subprocess to infer the network status, and proactively adjust the repair solutions of next subprocesses. For the node that takes the longest (resp. shortest) time in a subprocess, we can speculatively lessen (resp. increase) the upload and download repair traffic it affords in the next subprocess to balance the repair time across the surviving nodes.

4 Implementation

We implement a prototype of RepairBoost in C++ with around 3,200 lines of codes (LoC), which can serve as an independent middleware running atop existing storage systems to instruct the repair operations on behalf of them. We realize the encoding and decoding functionalities based on the coding library Jerasure v2.0 [2]. We maintain an in-memory key-value store in each node and transmit data through the interfaces of Redis [3].

System architecture: Figure 8 presents the architecture of RepairBoost, which comprises a *coordinator* sitting on the metadata server and multiple *agents* running on the nodes (with one agent per node). The coordinator manages the metadata of stripes (e.g., the mapping from chunks to stripes, and the nodes that the $k + m$ chunks of every stripe reside), while the agents are standby to wait for the repair commands and perform the repair operations cooperatively.

Operating flow: Once a node failure event is reported to the metadata server, the coordinator first pinpoints the IDs of the lost chunks as well as the identities of the associated stripes. It then establishes the *repair solution* of each lost chunk,

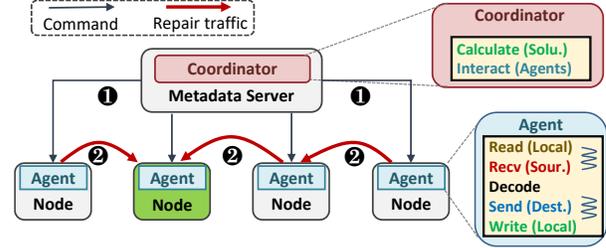

Figure 8: System architecture of RepairBoost. For simplicity, we only illustrate the repair of a single stripe. The node with green color denotes the destination node of this stripe.

including the k surviving chunks selected to participate in the repair, the data routing among the nodes, and the destination node to store the repaired chunk. The repair solutions are sealed into *repair commands* whose format is pre-determined and understood by the agents, which will then be sent to the agents that involve in the repair operations (Step 1).

Upon receiving the repair commands, the agents first extract the repair solutions. They then work cooperatively by (i) reading the requested surviving chunks locally stored, (ii) sending them to the appointed relay nodes, and (iii) decoding (repairing) the lost chunks and storing them locally (Step 2). To accelerate the repair operations, RepairBoost partitions a chunk into many smaller *packets* and uses the multi-threading technique to pipeline the disk I/O, network transmission, and computation in unit of packets.

Integration with Hadoop HDFS: We also integrate RepairBoost into Hadoop HDFS 3.1.4 [6] by adding around 270 LoC². We deploy the coordinator in the NameNode and run agents in the DataNodes. Specifically, when the NameNode is aware of the node failure through periodical heartbeats issued by the DataNodes, the coordinator intercepts the repair commands and calculates the repair solutions via extracting the metadata information (about the addressing of stripes and chunks) from the NameNode³. We then trigger RepairBoost to repair the lost data on behalf of HDFS. To facilitate the integration, RepairBoost also adds a `RepairBoostReconstructor` class in the `erasurecode` package of the DataNode, which collects the repaired chunks from its agent and writes them to the underlying storage of HDFS.

5 Performance Evaluation

We carry out extensive testbed experiments to evaluate the performance of RepairBoost. We summarize our major findings as follows: (i) RepairBoost can improve the repair throughput by 35.0-97.1% (§5.2-§5.4); (ii) RepairBoost can assist the

²Although Hadoop HDFS 3.1.4 employs Intel ISA-L [1] for erasure coding realizations, we can still employ Jerasure Library to repair the lost data with the same Cauchy matrix [2]. We have confirmed the decoding correctness in our evaluation.

³RepairBoost accesses the metadata of the Namenode via executing the command `"hdfs fsck / -files -blocks -locations"`.

repair for a variety of erasure codes and repair algorithms (§5.3); (iii) RepairBoost is more advantageous in the environment with lower network bandwidth (§5.2); (iv) RepairBoost retains its effectiveness when being used in heterogeneous environments and multi-failure repair (§5.4).

5.1 Setup

Testbed and preparations: We evaluate the performance of RepairBoost on Amazon EC2 [8] to unveil its performance in a real-world cloud scenario. We set up 17 virtual machine instances with the type of `m5.large` in the US East (North Virginia) region. Each instance runs Ubuntu 16.04.7 LTS, and is equipped with two vCPUs with 2.5 GHz Intel Xeon Platinum, 8 GB RAM, and 40 GB of EBS storage. The network bandwidth between any two instances is around 1 Gb/s (measured by `iperf`) and the disk bandwidth is around 130 MB/s. Among the 17 instances, we run the RepairBoost coordinator on one instance and deploy the RepairBoost agents on the remaining 16 instances.

Before triggering the repair, we first warm up the system by writing sufficient data encoded by the selected erasure coding scheme. We then erase the data of one instance to mimic a node failure and launch RepairBoost for data repair. We measure the latency, from the time when the failure event is reported to the time when all the lost data is repaired and persisted. We mainly focus on the *repair throughput*, defined as the size of data repaired per time unit. A higher repair throughput indicates a shorter window of vulnerability and hence stronger data reliability.

Erasure codes and repair algorithms: We demonstrate the flexibility, generality, and effectiveness of RepairBoost via deploying RepairBoost atop the following representative erasure codes and repair algorithms. We mainly consider three representative erasure codes: (i) the conventional RS codes [51] that are popularly used in today’s storage systems; (ii) LRCs [21, 52] that trade additional storage overhead for reducing the repair traffic, and (iii) Butterfly code [44], a systematic *minimum storage regenerating* (MSR) code with the minimum repair traffic for a single-node repair.

We also focus on three typical repair algorithms: (i) the conventional repair that transmits k chunks directly to the destination node for repair; (ii) PPR [40], which decomposes a single-chunk repair into sub-stages and exploits the execution parallelism of the sub-stages; and (iii) ECPipe [32], which partitions a chunk into equal-sized slices and pipelines their transmission across the surviving nodes for repair.

Selection of baseline: To select an appropriate baseline approach for comparison, we consider two candidates: a *random selection* (RAN) approach and an LRU-based selection approach. Specifically, the random selection randomly chooses k nodes for data retrieval from the $k + m - 1$ nodes that store the surviving chunks of the corresponding stripe, and also a destination node for data repair from the remaining nodes (§3.2). In the LRU-based selection, we track the timestamp of

Code	CR		ECPipe		PPR	
	RAN	LRU	RAN	LRU	RAN	LRU
RS(6,3)	1.64	1.65	1.25	1.44	1.30	1.43
RS(10,4)	1.67	1.82	1.14	1.41	1.25	2.01
LRC(6,2,2)	1.67	1.68	1.34	1.32	1.46	1.37
LRC(8,2,2)	1.63	1.65	1.25	1.26	1.33	1.43
RC(4,2,5)	1.71	1.74	1.29	1.31	1.37	1.32
RC(5,3,6)	1.70	1.73	1.25	1.30	1.33	1.35

Table 1: Comparison of the random selection and LRU-based selection in terms of their load balancing degrees.

each node when it was last selected for repair, and choose the k nodes for data retrieval from the $k + m - 1$ corresponding nodes and a destination one for data repair with the smallest timestamps. When the nodes to be selected have the same timestamp, the LRU-based selection always chooses the one with the smallest node ID.

We evaluate the *load balancing degrees* of the two approaches as $\frac{L_{max}}{L_{balanced}}$, where L_{max} represents the maximum upload and download repair traffic of a node across the system, while $L_{balanced}$ denotes the upload (or download) repair traffic that is balanced on a node. We can determine $L_{balanced}$ by dividing the amount of repair traffic by the number of surviving nodes.

We consider two representative configurations for each erasure code: RS(6,3) (also used in QFS [43] and Hadoop HDFS [6]), RS(10,4) (used in Facebook f4 [41]), LRC(6,2,2) (also deployed in Windows Azure Storage [21]), LRC(8,2,2) [28], RC(4,2,5)⁴ [44] and RC(5,3,6) (a high-rate MSR code that requires $d = k + 1$ [53]). We randomly distribute the chunks of a stripe across 16 nodes and repeat the test for five runs.

Table 1 gives the load balancing degrees of both the random selection and the LRU-based selection. We see that the random selection generates more balanced repair traffic in most cases. The reason is that the LRU-based selection prioritizes the nodes that have the smallest timestamps and IDs, and the repair traffic becomes progressively imbalanced when more chunks are repaired. Thus, we choose the random selection as the baseline for comparison.

Default configurations: Unless otherwise specified, we select the following default configurations throughout the evaluation. We set the chunk size to 64 MB (the default value in Hadoop HDFS) and the packet size to 1 MB. We mainly consider the following erasure codes: RS(6, 3) [6, 43], LRC(6, 2, 2) [21], and Butterfly(4, 2) [44]. We repair 100 chunks in each test and repeat it for five runs.

5.2 Experiments on Sensitivity

We first study the effectiveness of the parameters configured in RepairBoost on the actual repair performance.

⁴We use $RC(k, m, d)$ to represent the regenerating code that encodes k data chunks into $k + m$ coded chunks, where a data chunk can be repaired by retrieving data from any $d \geq k$ surviving coded chunks [13].

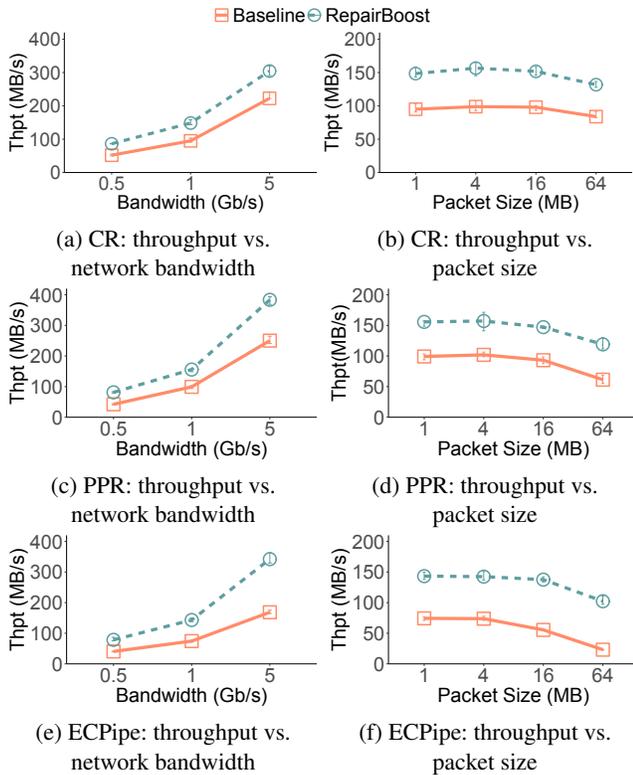

Figure 9: Experiment 1 (Impact of network bandwidth and packet size).

Experiment 1 (Impact of network bandwidth and packet size): We first assess the impact of network bandwidth on the repair throughput when coupling RepairBoost with existing repair algorithms. We vary the network bandwidth from 0.5 Gb/s (i.e., the network bandwidth dominates the repair) to 5 Gb/s (i.e., the disk bandwidth dominates the repair), and evaluate the repair throughput in different repair scenarios.

Figures 9(a), 9(c), and 9(e) show that the repair throughput generally increases with the available network bandwidth, as more data can be transmitted per time unit. Overall, RepairBoost can improve the repair throughput by 72.3% on average for different repair algorithms when compared to the baseline. In addition, we identify that RepairBoost is more advantageous in the network-bandwidth-dominated scenario, as RepairBoost balances the repair traffic and arranges the data transmission for maximizing the utilization of network bandwidth in repair. Specifically, the improvement of RepairBoost on the repair throughput increases from 53.0% (when the network bandwidth is 5 Gb/s) to 96.4% (when the network bandwidth is 0.5 Gb/s). It is worth noting that RepairBoost mainly considers the application scenario where the data transfers across the network dominate the repair performance, which conforms to the assumptions made by many previous studies [19, 40, 56, 58]. Even in the scenario with high-performance network systems (e.g., InfiniBand [45]) for fast memories (e.g., Intel Optane DIMM [61]), RepairBoost can still maintain its performance gain, since the network

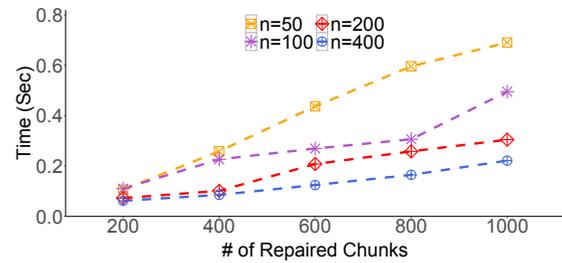

Figure 10: Experiment 2 (Computation time).

bandwidth is likely to be more stringent than the aggregated memory bandwidth (e.g., 44.8 Gb/s of the network bandwidth in RDMA versus 84.8 Gb/s of the write bandwidth in six Optane DIMMs [26]).

As RepairBoost employs multi-threading to pipeline the disk I/O and data transmission in repair, we also study the impact of packet size on the repair performance, where the packet size is changed from 1 MB (i.e., 64 packets per chunk) to 64 MB (i.e., one packet per chunk).

Figures 9(b), 9(d), and 9(f) indicate that the repair throughput decreases when the packet size increases, since the available disk and network bandwidth can be more extensively utilized in repair when a chunk comprises more packets. The multi-threading feature has no effect when the packet size reaches 64 MB (i.e., the chunk size), thereby leading to the lowest repair throughput. Overall, RepairBoost improves the repair throughput by 97.1% compared to the baseline under different packet sizes.

Experiment 2 (Computation time): We allocate one instance on Amazon EC2 with the same configurations as described in §5.1. We measure the computation time needed by RepairBoost to generate the repair solutions under different numbers of nodes (denoted by n) and repaired chunks.

Figure 10 shows the results. We make three observations. First, when the number of nodes is fixed, the computation time of RepairBoost gradually increases with the number of chunks being repaired, as RepairBoost has to process more RDAGs in the repair traffic balancing and transmission scheduling. Second, when the number of repaired chunks is fixed, the computation time drops when more nodes can participate in the repair, as RepairBoost can dispatch more chunks at a time. Third, the computation time needed by RepairBoost is always less than 0.9 seconds, thereby demonstrating that it is qualified to be deployed in the online repair scenario.

As the coordinator is only in charge of solving for the repair solutions and interacting with agents (§4), this experiment can evaluate the scalability of RepairBoost to some extent. When RepairBoost is deployed in a large-scale system (e.g., with thousands of nodes), we offer two options to further reduce the computation time. First, we can break a full-node repair into several subprocesses and iteratively repair a small number of chunks for each subprocess. Second, we can compute the repair solutions in advance and perform the repair based on the pre-computed results when a failure happens.

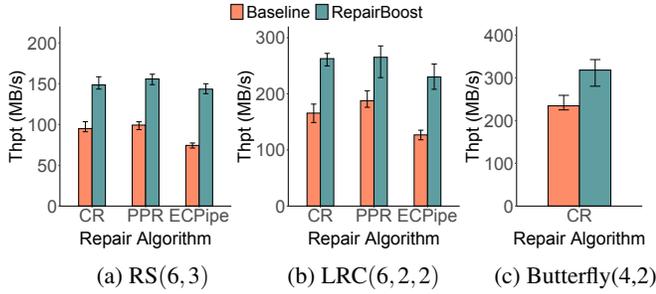

Figure 11: Experiment 3 (Generality).

5.3 Experiments on RepairBoost Property

We also analyze the properties of RepairBoost, in terms of generality and technique breakdown.

Experiment 3 (Generality): We validate the generality of RepairBoost using a variety of representative erasure codes. Given an erasure code, we measure the repair throughput when RepairBoost is coupled with different repair algorithms. Note that we only consider CR for Butterfly(4,2) as it repairs a chunk with multiple sub-chunks coming from different surviving chunks.

Figure 11 shows that all the repair algorithms assisted by RepairBoost can boost the repair for different erasure codes, thereby demonstrating the generality of RepairBoost. Overall, RepairBoost can improve the repair throughput by 60.4% on average for different erasure codes when compared to the baseline. RS(6,3) has the lowest repair throughput (Figure 11(a)), as most of the time it needs to retrieve the most chunks for repair. While LRC(6,2,2) comprises the same number of data chunks (i.e., k) as RS(6,3) within a stripe, it achieves a higher repair throughput (Figure 11(b)), as it only retrieves three chunks to accomplish most of a single-chunk repair. Butterfly(4,2) reaches the highest repair throughput (Figure 11(c)), as it needs to fetch only half of the remaining data (i.e., $\frac{k+1}{2}$ surviving chunks on average per failed chunk).

We also identify that ECPipe reaches the lowest repair throughput for both RS(6,3) and LRC(6,2,2). The root cause is that an RDAG under ECPipe only has one chunk to be transmitted at a time, hence limiting the repair parallelism.

Experiment 4 (Breakdown analysis): We decompose RepairBoost to demonstrate the effectiveness of each designed technique. For simplicity of presentation, we abbreviate the techniques of RepairBoost as follows: (i) *repair traffic balancing* (RTB), which balances the upload and download repair traffic (§3.2) without performing transmission scheduling, and (ii) *transmission scheduling* (TS), which simply schedules data transmission (§3.3) without considering repair traffic balancing.

Figure 12 shows the repair throughput of the baseline, RTB, TS, and RepairBoost. We make two observations. First, the effectiveness of RTB and TS varies across different repair algorithms. For example, TS outperforms RTB for PPR and ECPipe, but reaches a lower repair throughput for CR. Sec-

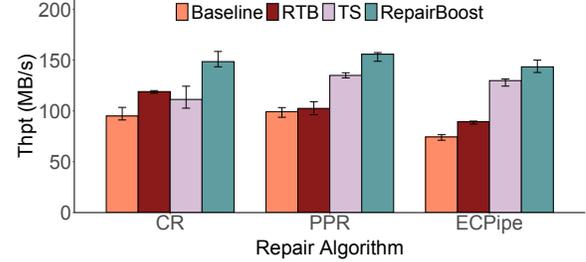

Figure 12: Experiment 4 (Breakdown analysis).

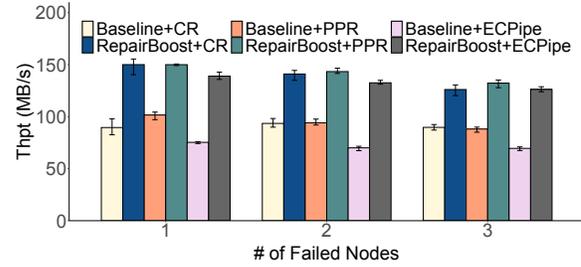

Figure 13: Experiment 5 (Performance on multi-node repair).

ond, RepairBoost always reaches the highest repair throughput, indicating that the two techniques in RepairBoost are complementary without comprising the effectiveness of each other. Specifically, RepairBoost achieves 45.7% and 19.8% higher repair throughput than RTB and TS, respectively.

5.4 Experiments on Practicality

We further assess the practicality of RepairBoost by measuring its performance when tackling multi-failure repair and the single-node failure in heterogeneous environments.

Experiment 5 (Performance on multi-node repair): We extend RepairBoost and study its performance when repairing multiple failed nodes. We erase the data stored in a number of nodes to mimic multiple node failures. We then schedule the RDAGs of the lost chunks for repair. As RS(6,3) can tolerate at most three node failures, this experiment measures the repair throughput when the number of failed nodes increases from one to three.

Figure 13 indicates that RepairBoost also speeds up the repair for multiple failures. Specifically, RepairBoost can improve the repair throughput by 39.5% (when tackling a single node failure) and by 35.7% (when tackling triple node failures). The repair throughput gained by RepairBoost drops slightly when more nodes fail, as fewer surviving nodes can be selected for RepairBoost to balance repair traffic and schedule transmission.

Experiment 6 (Performance with bandwidth heterogeneity): We finally assess the performance of RepairBoost in the presence of bandwidth heterogeneity. We organize the 16 instances with agents into four clusters, where each cluster comprises four instances and the intra-cluster bandwidth is 1 Gb/s. We then use the Linux bandwidth control tool `tc` to throttle the inter-cluster bandwidth for producing the bandwidth diver-

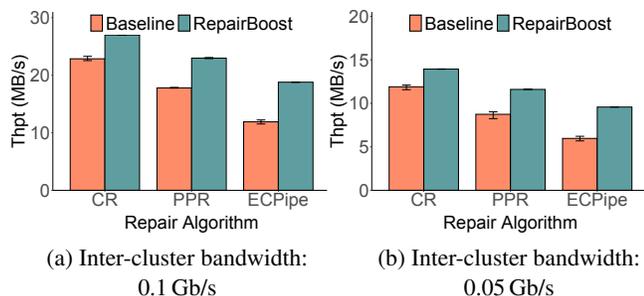

Figure 14: Experiment 6 (Performance with bandwidth heterogeneity).

sity phenomenon in data centers [10, 15]. Specifically, we vary the inter-cluster bandwidth from 0.05 Gb/s to 0.1 Gb/s, such that the over-subscription ratio (i.e., calculated by dividing the intra-cluster bandwidth by the inter-cluster bandwidth) ranges from 10 to 20, as shown in prior studies [10, 15, 55].

Figure 14 shows that RepairBoost retains its effectiveness on accelerating the full-node repair in heterogeneous environments, especially when the inter-cluster bandwidth is more scarce. Specifically, the improvement of repair throughput gained by RepairBoost is 35.0% when the inter-cluster bandwidth is 0.1 Gb/s (Figure 14(a)), and increases to 36.8% when the inter-cluster bandwidth reduces to 0.05 Gb/s (Figure 14(b)).

6 Related Work

We review existing studies to accelerate full-node repair from the following aspects: repair-efficient codes, repair algorithms, and proactive repair with erasure coding.

Repair-efficient codes: LRCs [21, 52] and Rotated-RS codes [27] reduce the repair traffic via loosening the storage efficiency requirement (i.e., increasing a handful of storage overhead). Regenerating codes [13] alleviate the repair traffic by requiring the surviving nodes to send a linear combination of the locally stored data or requiring more surviving nodes to participate in the repair (e.g., product-matrix MSR codes [49]). Butterfly code [44] and Clay code [58] can directly send the locally stored data for repair. Hitchhiker [48] makes the chunks across stripes dependent in the code construction for reducing the repair traffic. Different from the concrete constructions of erasure codes, RepairBoost is a scheduling approach that can assist the full-node repair for a variety of erasure codes.

Repair algorithms: Degraded-first scheduling [31] proposes to launch the degraded read tasks with a higher priority to leverage the unused network bandwidth. PUSH [22] pipelines the transmission of the requested chunks to alleviate the network congestion in repair. PPR [40] partitions an entire repair solution into small sub-stages and executes them in parallel. ECPipe [32] further partitions a chunk into smaller slices and pipelines the transmission of the slices, such that the complexity of the repair time approaches to $O(1)$ in homogeneous

environment. In view of the bandwidth diversity in hierarchical data centers, CAR [56] and ClusterSR [55] reduce and balance the inter-cluster repair traffic, which is considered more scarce than intra-cluster repair traffic. ECWide [18] addresses the repair of wide stripes with ultra-low redundancy in hierarchical data centers. Most of these studies pay special attention to the single-chunk repair, while RepairBoost can help different repair algorithms accelerate the full-node repair.

Proactive repair with erasure coding: Existing mature machine-learning-based failure prediction often take input the SMART attributes [11, 17, 30, 38, 64] combined with additional system events [60] and performance metrics [37], and exhibit high prediction accuracy (e.g., at least 95% [11, 30, 39, 64]) with low false alarm rate (also called false positive rate, e.g., up to 2.5% [38], 0.2-0.4% [63]). FastPR [54] couples migration and erasure-coding-based repair to accelerate the proactive repair. Hu et al. [20] suggest proactively launching degraded reads to bypassing the hotspots, so as to reduce the tail latency in read operations. As an orthogonal study, RepairBoost is also applicable to the proactive repair that employs erasure coding for data recovery.

7 Conclusion

Erasure coding is a storage-efficient means to assure data reliability, yet it is prone to magnify the repair traffic. We present RepairBoost, a scheduling framework that boosts the full-node repair for various erasure codes and repair algorithms. RepairBoost employs a graph abstraction, called an RDAG, to characterize the single-chunk repair solution. It then carefully assigns the repair tasks of the RDAGs to the nodes for balancing the upload and download repair traffic. RepairBoost further schedules the transmission of chunks to saturate the unoccupied bandwidths. Extensive experiments on Amazon EC2 demonstrate the generality, flexibility, and effectiveness of RepairBoost.

KVIMR: Key-Value Store Aware Data Management Middleware for Interlaced Magnetic Recording Based Hard Disk Drive

Yuhong Liang, Tsun-Yu Yang, and Ming-Chang Yang
The Chinese University of Hong Kong

Abstract

Log-Structured Merge-Tree (LSM-tree) based key-value (KV) store provides write-intensive applications with high throughput on Hard Disk Drive (HDD). Recently, the emerging Interlaced Magnetic Recording (IMR) technology makes the IMR based HDD become another desirable option to construct a cost-effective KV store because of its high areal density. Nevertheless, we observe that deploying LSM-tree based KV store on IMR based HDD may suffer noticeable degradation on throughput of incoming reads/writes. Thus, this paper presents KVIMR, a data management for constructing a cost-effective yet high-throughput LSM-tree based KV store on IMR based HDD. KVIMR is architected as a *middleware*, interposed between LSM-tree based KV store and IMR based HDD, to embrace the compatibility for mainstream LSM-tree based KV store implementations with limited modifications. Technically, KVIMR adopts a novel *Compaction-aware Track Allocation* scheme, which leverages the special properties behind the compaction process to remedy the throughput degradation. KVIMR further utilizes a novel *Merged RMW* approach to improve the efficiency of persisting a multi-track-sized file of KV store into IMR tracks with the ensured crash consistency. Our evaluations on several well-known LSM-tree based KV store implementations reveal that KVIMR not only improves the overall throughput by up to $1.55\times$ under write-intensive workloads but even achieves $2.17\times$ higher throughput under high space usage of HDD, as compared with the state-of-the-art track allocation scheme for IMR.

1 Introduction

Persistent key-value (KV) stores have gained popularity in diverse data-intensive applications, ranging from electronic commerce [15], internet services [43], to cloud environments [13, 33], because of its high efficiency in insertions, point and range queries, and deletions. Among various implementations of KV store, Log-Structured Merge-Tree (LSM-tree) [38] based KV stores (e.g., BigTable [13], Cassandra [34], LevelDB [21], HBase [26], HyperLevelDB [17] and

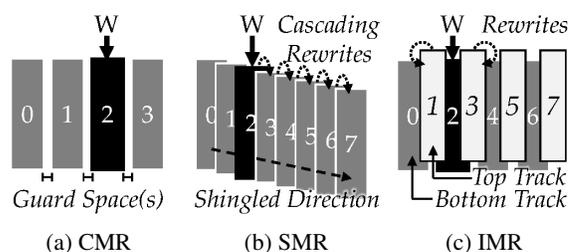

Figure 1: Track Layouts of CMR, SMR, and IMR.

RocksDB [18]) demonstrate its strength in delivering high write throughput on the mechanical hard-disk drive (HDD). The reason is that the LSM-tree takes advantage of the sequential access strength of HDD [38] by first batching the inserted KV pairs in memory and then persisting the batched data from memory into HDD sequentially.

With the explosive growth of data, how to construct a *cost-effective* KV store has become another vital challenge. However, the most common type of HDD, i.e., the *Conventional Magnetic Recording (CMR)* based HDD, has reached its bottleneck in providing higher areal density [11] to lower its *cost-per-GB* because of the super-paramagnetic effect [37]. Among various novel technologies that can break such areal density limitation [12, 16, 28, 30–32, 35, 40, 44, 46, 55], *Shingled Magnetic Recording (SMR)* technology [10, 47] is an eligible alternative of CMR for offering higher areal density gain with limited manufacturing changes [49, 51]. Different from the CMR track layout in which a small *guard space* is introduced to every two physically-adjacent tracks (as shown in Figure 1a), every SMR track is partly overlapped by its subsequent one(s), making that SMR tracks are placed closer to each other (as shown in Figure 1b). However, with this “shingled” track layout, data updates to a single SMR track may incur the time-consuming *track rewrites* over a great amount of subsequent tracks along the shingled direction, so as to avoid losing any valid data [10, 51]. Although lots efforts have been made to tackle the track rewrite issue for SMR based HDD at different layers [10, 27, 39, 41, 42, 51–53], *the applicability of SMR based HDD is still limited because of its long write tail-latency* [51].

More recently, the emerging *Interlaced Magnetic Recording* (IMR) technology [28] has been validated for being effective in delivering *even-higher* areal density with *reduced* track rewrite issue than the SMR [22], making the IMR become a more desirable successor to the CMR. In general, the areal density gain of IMR is mainly attributed to the linear density increasing of tracks with different laser currents [22, 23]. As shown in Figure 1c, IMR embraces a new “interlaced” track layout to organize tracks into *top tracks* and *bottom tracks*, with each bottom track overlapped partially by two adjacent top tracks. With this interlaced track layout, any top tracks can be freely updated *without* incurring any track rewrites; whilst updates to a bottom track would only introduce *at most two* track rewrites on its two adjacent top tracks. Moreover, to conduct track rewrites with ensured crash consistency, the *read-modify-write* (RMW) approach [25] is presented.

Inspired by the *ever-high* areal density and the *reduced* track rewrite issue of IMR technology, this paper for the first time, seeks for the possibility in constructing a *cost-effective yet high-throughput* LSM-tree based KV store on IMR based HDD. Nevertheless, we observe that deploying LSM-tree based KV stores on IMR based HDD may still suffer noticeable degradation on throughput of incoming reads/writes. The reason is that the RMW process of IMR based HDD may amplify the background I/Os introduced by the compaction process of LSM-tree based KV store, and such amplified background I/Os may thereby degrade the efficiency of the compaction process and further slow down the throughput of incoming reads/writes [9, 39, 53]. Moreover, none of the existing designs for managing IMR tracks is able to well remedy such throughput degradation, because the special software behavior, hid behind compaction process of the LSM-tree based KV store, is out of their design considerations.

With the goal of alleviating the noticeable throughput degradation caused by the IMR technology, this paper presents KVIMR, a data management middleware for constructing a *cost-effective yet high-throughput* LSM-tree based KV store on IMR based HDD. In particular, KVIMR is architected as a *middleware*, sitting between LSM-tree based KV store and IMR based HDD, in order to facilitate 1) the support for various existing implementations of LSM-tree based KV store with limited modifications and 2) the direct and efficient management on IMR based HDD.

To make KVIMR be aware of the software behaviour of LSM-tree based KV store with limited overhead, the most key semantic information (i.e., the “level” information) regarding the data of LSM-tree is passed to KVIMR along with data writes. Given the “level” information as a clue, KVIMR introduces a novel *Compaction-aware Track Allocation* scheme to allocate tracks for data of LSM-tree KV store according to the “level” information. This scheme effectively remedies the throughput degradation and improves the compaction efficiency by 1) minimizing the time-consuming RMWs when persisting data files (i.e., *SSTables*) of LSM-tree based KV

store and 2) efficiently accessing the data files of LSM-tree based KV store during the compaction process. To further improve the compaction efficiency when the time-consuming RMWs are inevitable, KVIMR employs a novel *Merged RMW* approach to efficiently persist a multi-track-sized data file of LSM-tree based KV store into IMR tracks. Its key idea is to re-order the multiple “track-by-track” RMWs into a single “merged” RMW while still nicely ensure the crash consistency. With this approach, KVIMR significantly reduces the number of required `sync`-like functions, which have adverse effects on I/O performance of HDD [2, 24, 45], and avoids redundant track rewrites caused by the track-by-track RMW approach.

KVIMR is developed in C++ and provides a POSIX complaint interface for the existing LSM-tree KV store implementations to interact with IMR based HDD. Specifically, we modify three well-known LSM-tree KV stores, i.e., RocksDB [18], LevelDB [21], and HyperLevelDB [17], by replacing the native file operations with a similar set of file operations provided by KVIMR to access the data files in an emulated IMR based HDD. Our evaluations on these three LSM-tree based KV store implementations reveal that KVIMR not only improves the overall throughput by up to $1.55\times$ under write-intensive workloads but even achieves $2.17\times$ higher throughput under high space usage of HDD, as compared with the state-of-the-art track allocation scheme for IMR.

The rest of this paper is organized as follows: Section 2 presents the background and motivation regarding this work. Section 3 introduces the design of KVIMR. Then, Section 4 provides the implementation details and demonstrates the evaluation results. Finally, Section 5 presents relevant studies and Section 6 concludes this work.

2 Background and Motivation

2.1 LSM-Tree based KV Store

Because of the strength in delivering high write throughput on the mechanical HDD, Log-Structured Merge-Tree (LSM-tree) [38] inspires many well-known key-value (KV) stores, such as RocksDB [18], LevelDB [21], and HyperLevelDB [17]. In general, these LSM-tree based KV stores embrace a similar design concept, borrowed from LSM-tree, on managing KV pairs in the HDD, and support a similar set of KV operations such as `put`, `get` and `delete` operations.

The `put` operation is for inserting KV pairs into the KV store. To deliver high throughput of `put` operations on HDD, LSM-tree based KV store first batches all the inserted KV pairs in an in-memory sorted skiplist namely *Memtable*. When the Memtable exceeds its size limit (e.g., 64 MB in RocksDB [18]), LSM-tree based KV store creates a new Memtable to keep accommodating new KV pairs, while the old Memtable is converted to an immutable in-memory sorted skiplist namely *Immutable Memtable*. In the background, an important thread takes over the Immutable Memtable

and persists it into HDD as an in-disk sorted string table (SSTable). In addition, all the SSTables in the disk are organized into multiples levels (i.e., $L_0 \sim L_n$), similar to the multiple in-disk components of the LSM-tree [38], and the size limit of each level increases exponentially by a factor (e.g., 10 in both LevelDB [21] and RocksDB [18]) from L_1 to larger level(s). Moreover, the SSTable converted from the Immutable Memtable is usually placed at L_0 first; then, once the total size of SSTables of any level L_i exceeds its size limit, the background thread keeps performing the *compaction process* in a cascading way to compact the KV pairs from smaller levels to larger levels, until all levels are within their size limits. Specifically, the compaction process 1) picks one SSTable in L_i , 2) merges it with all SSTables with overlapped key ranges in L_{i+1} , 3) creates new SSTable(s) into L_{i+1} , and finally 4) deletes all stale SSTables from the KV store sooner or later.

Besides of the `put` operation, LSM-tree based KV store also supports the `get` operation to read out the value associated with the given key. Specifically, to find out the latest version of value, LSM-tree based KV store searches the requested key-value pair(s) from Memtable, Immutable Memtable, and SSTables from smaller levels to larger levels in order. Moreover, LSM-tree based KV store also supports the `delete` operation to remove specific KV pair(s) from the KV store.

2.2 Interlaced Magnetic Recording

Interlaced Magnetic Recording (IMR) [28] is a new disk technology that adopts the “interlaced” track layout to increase the areal density by shortening the distance between adjacent tracks. As shown in Figure 1c, tracks of IMR based HDD are organized into *top tracks* and *bottom tracks*, and each bottom track (e.g., Track #2) is overlapped partially by two adjacent top tracks (e.g., Tracks #1 and #3). However, with this interlaced track layout, *writing data into any bottom track will destroy the (valid) data stored in the two adjacent top tracks*. Thus, in order to protect the (valid) data of top tracks against data loss on writing data into bottom tracks, the *read-modify-write (RMW)* approach [25] is introduced; specifically, it ensures the crash consistency by quarantining that the following sequence of “read-modify-write” can be enforced: 1) “Read”: Backing up the valid data of the two adjacent top tracks in a *backup region*; 2) “Modify”: Writing the updated data properly to the bottom track; and 3) “Write”: Re-writing the backed-up valid data back to the adjacent top tracks.

Since the RMW is time-consuming [48], most existing studies for IMR based HDD focus on how to minimize the probability of incurring the RMWs. Specifically, some propose to reduce RMWs via *track allocation* (i.e., how IMR tracks are allocated to accommodate the written data). For example, Gao *et al.* present a *three phase track allocation* to allocate tracks based on three phases of disk space usage [19, 20]: In the first phase, data are placed into *bottom tracks only* until all the bottom tracks are full of data (i.e., 0% ~ 50% space usage); in

the second phase, data are placed into *every other top tracks* until half of the top tracks are used (i.e., 50% ~ 75% space usage); and in the third phase, data are placed into *the rest of top tracks* (i.e., 75% ~ 100% space usage). As a result, the first phase would not incur any RMW(s), while the second phase (resp. to the third phase) ensures at most one (resp. to two) top track(s) will be re-written on writing data into any bottom track. Based on the three phase track allocation, Wu *et al.* further propose a *zigzag track allocation* to reverse the track allocation order in the second phase, making every other top tracks be allocated from inner tracks to outer tracks, for better preserving data locality [48, 50].

Another series of studies tries to minimize the probability of incurring the RMWs by considering the *update frequencies of data*. Notably, in the literature, the *frequently-updated data* (resp. to *less-frequently-updated data*) are also referred to as the *hot data* (resp. to *cold data*). For example, Wu *et al.* propose a *top buffer* design to exploit a few top tracks as “write buffer” to place the hot data, and a *block swap* method to exchange the hot data in bottom tracks with the cold data in top tracks, so as to reduce the RMWs caused by updating hot data in bottom tracks [48, 50]. More recently, Hajkazemi *et al.* propose three new track-level techniques, namely *track flipping*, *selective track caching*, and *dynamic track*, to reduce the amount of writes to bottom tracks by moving hot data to top tracks and cold data to bottom ones in different ways [25]. However, please note that, although time-consuming RMWs can be indeed reduced by considering the update frequencies of data, *not all sorts of applications can be benefited from this series of studies*. For example, the data of LSM-tree based KV stores (i.e., SSTable), which is our target application, are written once but *never updated* before being deleted.

2.3 Motivation: Degradation on Throughput and Compaction Efficiency

In order to investigate how serious the performance of LSM-tree based KV store would be degraded by the time-consuming RMW process of IMR technology, we deploy the widely used RocksDB on an 100 GB, emulated IMR based HDD. In particular, in order to reasonably allocate IMR tracks for accommodating SSTables, we implement the classical *sequential allocation* scheme [41] (denoted as *Seq*), and the state-of-the-art, IMR based *three-phase allocation* scheme [19, 20, 50] (denoted as *3Phase*). Moreover, to fairly compare and demonstrate that how the performance of IMR based *three-phase allocation* is affected by the RMW process, we also deploy RocksDB on an 100 GB CMR based HDD and adopts *three-phase allocation* scheme to allocate CMR tracks for accommodating SSTables (denoted as *CMR*). More details about the implementations can be found in Section 4.1.

Figure 2a shows the performance of randomly loading/inserting 75 millions of 1 KB KV pairs, generated by YCSB [14], into RocksDB, where the x-axis denotes different

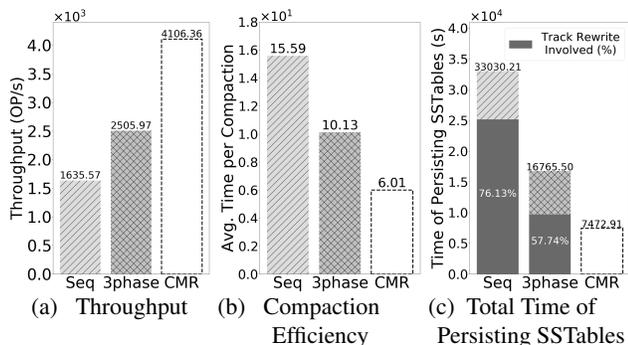

Figure 2: Performance of Loading 75 Millions of KV Pairs into RocksDB under Different Track Allocation Schemes.

schemes of track allocation and the y-axis shows the throughput (i.e., the number of I/Os per second). It can be observed that, although the IMR based 3phase indeed effectively achieves $1.53 \times$ higher throughput than the classical Seq, there still exists a large room for improvement since the IMR based 3phase also suffers 38.97% degradation on throughput as compared to that of CMR. Since it is known that the write throughput of a LSM based KV store could be significantly affected by the compaction process [9, 39, 53], Figure 2b further shows the *compaction efficiency*, which is regarded as the average time required by a compaction process, achieved by different track allocation schemes. It can be observed that, as compared with CMR, Seq and 3phase require $2.59 \times$ and $1.68 \times$ longer time to complete a compaction process on average, and result in the observed degradation on throughput.

Furthermore, based on our investigation, the observed compaction efficiency degradation of Seq and 3phase can be mainly attributed to the time-consuming RMW process of IMR technology. The reason is that the compaction process involves persisting SSTables into HDD, and the time-consuming RMW process could be thereby frequently triggered during the compaction process. Thus, to explicitly demonstrate how the compaction efficiency is affected by the RMW process, Figure 2c shows the total time of persisting SSTables (during the compaction processes) required by different track allocation schemes and indicates the portion of time spent on rewriting top tracks during the RMW process. It can be observed that, when compared with CMR, the total time of persisting SSTables required by Seq and 3phase is noticeably lengthen by around $4.42 \times$ and $2.24 \times$ respectively. The reason is that Seq and 3phase entail 25145.76 and 9681.21 seconds on rewriting top tracks during the RMW process, which account for 76.13% and 57.74% of their respective total time of persisting SSTables. Motivated by such observed degradation on throughput and compaction efficiency, a novel middleware KVIMR is proposed in Section 3 to deliver high throughput on IMR based HDD with limited changes to the well-known LSM-tree based KV store implementations.

3 KVIMR

3.1 System Architecture

As shown in Figure 3, KVIMR is architected as a *middleware* between LSM-tree based KV store and IMR based HDD, so as to facilitate 1) the support for various LSM-tree based KV store implementations with limited modifications and 2) the direct and efficient management on IMR based HDD.

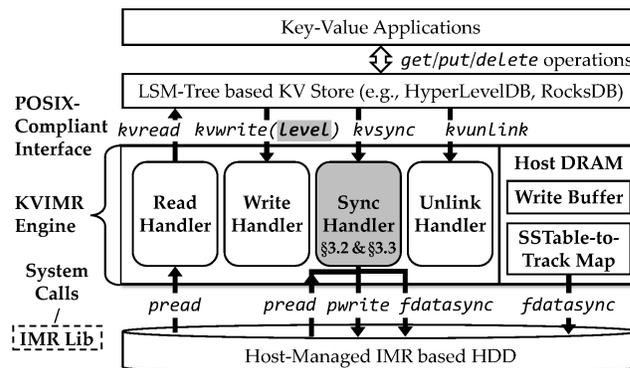

Figure 3: The System Architecture of KVIMR.

To realize this objective, KVIMR provides a POSIX compliant interface [5] so that the upper LSM-tree based KV store can easily access its SSTables through a similar set of common file operations (i.e., kvread/kvwrite/kvsync/kvunlink operations) on IMR based HDD with very limited modifications. Besides, to make the KVIMR be aware of the special *compaction behaviour* behind the LSM-tree based KV store, we promote to pass the “level” information of SSTables along with the kvwrite file operation on writing SSTables. Notably, since the *level* information is one of key design principles of the LSM-tree, it can be widely found in the mainstream LSM-tree based KV store implementations, such as RocksDB [18], LevelDB [21] and HyperLevelDB [17]. Thus, we argue that *the attempt to pass down the level information will not limit the applicability but instead increase the generality and compatibility of KVIMR*. It is also worth noting that, based on our experience in integrating KVIMR with the three aforementioned LSM-tree based KV store implementations, the modifications of replacing POSIX interface (with file operations provided by KVIMR) and passing level information to KVIMR are just about 100 lines of codes for each KV store implementation.

On the other hand, in our implementation, by employing the existing pread/pwrite/fdatasync system calls with the O_DIRECT flag, KVIMR directly manages the data of files (e.g., SSTables) and performs the RMW approach [25] on tracks of the emulated IMR based HDD (please see Section 4.1 for details). Please note that recent researches have demonstrated that the host-managed HDD model and the libzbc interface [4] can simplify and facilitate the direct management on SMR based HDD [52, 53]. We envision such host-managed HDD model and library (referred to as

IMRLib in Figure 3) will also be available for IMR based HDD with the provision of fundamental functions (such as reading/writing/syncing data and exposing track information), so that a unified application programming interface (API) can be offered for the development of KVIMR. We leave the IMRLib extension to KVIMR in the future.

If we take a closer look at Figure 3, the core KVIMR engine maintains an *SSTable-to-Track Map* and allocates a *Write Buffer* in the DRAM space of the host system, and incorporates four *Handlers* to take over the *kvread/kvwrite/kvsync/kvunlink* file operations from the upper LSM-tree based KV store respectively. Their main functionalities and interactions are summarized as follows:

- **SSTable-to-Track Map (or S2TMap)** maintains the one-to-many relationship between an SSTable and multiple IMR tracks allocated for it, because the SSTable size in the mainstream LSM-tree based KV store implementations is usually larger than the IMR track size (which is 2 MB [25, 50]). We implement S2TMap as `map<sstable id, track list>` and only allocate an IMR track for a single SSTable file for simplicity. Notably, since S2TMap is the key metadata of KVIMR, how to maintain and promise the crash consistency of S2TMap will be discussed in detail in Section 3.4.

- **Write Handler** is responsible for temporarily buffering the written SSTable in the *Write Buffer* (in the DRAM space) whenever the background thread (i.e., compaction process) of KV store invokes *kvwrite* operations to pass down the SSTable data into middleware, so that the entire SSTable can be later persisted into the IMR based HDD by the *Sync Handler* in one shot. Notably, at runtime, the *Write Buffer* of KVIMR only holds a few SSTables at any given time, since each compaction process/thread only creates one SSTable at a time and will persist it into the storage by the *Sync Handler*. That is, once an SSTable is persisted, KVIMR immediately releases the corresponding DRAM space to keep low demand of *Write Buffer*.

- **Sync Handler** is in charge of persisting the buffered SSTable into IMR tracks (based on different track allocation schemes) whenever the background thread (i.e., compaction process) of KV store needs to ensure the SSTable data are persisted in HDD by invoking *kvsync* operation. In addition, during the process of SSTable persisting, the *Sync Handler* also performs the RMW approach to rewrite tracks (if needed) to ensure the crash consistency of written data, and builds the relationship between the specified SSTable and the allocated tracks in S2TMap to facilitate the subsequent accesses to persisted SSTables. Moreover, at runtime, to efficiently determine whether the RMW approach is needed, KVIMR also maintains a bitmap in the DRAM space to keep track of the allocation status of tracks. However, this bitmap does not have to be persisted in HDD since it can be easily rebuilt by scanning S2TMap.

- **Read Handler** fetches the requested part of an SSTable from the corresponding track(s) of the IMR based HDD by

looking up the S2TMap whenever the KV store needs to read the content of SSTable by invoking *kvread* operation (e.g., upon performing the compaction process or servicing *get* operations).

- **Unlink Handler** is to remove an SSTable from HDD and label the corresponding track(s) as *free tracks* (i.e., tracks containing *no* valid data) by resetting the corresponding entries in S2TMap whenever the background thread (i.e., compaction process) of KV store invokes *kvunlink* operation to delete an SSTable from HDD.

Among these four handlers, the *Sync Handler* plays the most critical role to affect the throughput of incoming reads/writes, since how SSTables are persisted into tracks of IMR based HDD may largely affect the number of incurred time-consuming RMWs and the efficiency of the background compaction process. Thus, in the following sections, *we shall mainly focus on the design of the Sync Handler*.

3.2 Compaction-aware Track Allocation

Given the *level* information of SSTables as a clue, this section explores how to leverage the special behavior behind compaction process to properly allocate the *two-tier* IMR tracks for accommodating the *multi-level* SSTables. Specifically, Section 3.2.1 first introduces two special properties, namely *compaction frequency* and *compaction locality*, extracted from the compaction process. Then, based on the observed properties and the *level* information of SSTables, Section 3.2.2 introduces a novel *Compaction-aware Track Allocation* scheme to alleviate the throughput degradation by 1) minimizing the time-consuming RMWs and 2) efficiently accessing the SSTables during the compaction process.

3.2.1 Special Properties of Compaction Process

Compaction Frequency. In an LSM-tree based KV store, SSTables of different levels usually have different frequencies of being compacted (i.e., *compaction frequency*) by the compaction process. The reason is twofold: First, as introduced in Section 2.1, the compaction process usually takes place in a cascading way, from smaller levels to larger levels; second, the size limits of different levels increase exponentially along with the levels. As a result, the SSTables of *smaller* levels are more likely to be compacted frequently than that of *larger* levels [29, 54]. In other words, *the lifespan of SSTables of larger levels tends to be longer than that of smaller levels*.

Compaction Locality. Based on our investigation, there exists a very special access locality, namely *compaction locality*, among *different rounds* of compaction process in LSM-tree based KV store. Specifically, as introduced in Section 2.1, a single round of compaction process merges the victim SSTable and the existing SSTables with overlapped key ranges into new SSTables with *close* key ranges. Moreover, since these newly generated SSTables are composed of KV pairs of

close key ranges, they (or part of them) are more likely to be involved (specifically, `read` and `unlink`) in the latter round(s) of compaction process as compared to other SSTables with far key ranges. That is, there exists a special access tendency that the SSTables generated by a round of compaction process are likely to be involved in the latter round(s) of compaction process, and we refer it as *compaction locality*.

3.2.2 Design of Compaction-aware Track Allocation

Based on the two observed special properties, this section presents the design of the *Compaction-aware Track Allocation* scheme, which comprises two major steps, namely *Step 1) Level based Bi-Tiering* and *Step 2) Relaxed-Sequential Track Allocation*, in allocating tracks for an SSTable.

Step 1) Level based Bi-Tiering The first step determines which tier of tracks (i.e., either top tier of tracks or bottom tier of tracks) should be used to accommodate an SSTable based on its level information.

Based on the property of *compaction frequency*, the lifespan of SSTables of larger levels tends to be longer than that of smaller levels. Such property inspires us that, if bottom tracks can be allocated to accommodate SSTables with larger levels (rather than smaller levels), the bottom tracks will be occupied by SSTables with longer lifespan and will not be frequently re-allocated by other SSTables with shorter lifespan. That is, the key idea of the first step is to *allocate bottom tracks to accommodate SSTables of larger levels, so that the probability of incurring the RMWs on allocating bottom tracks could be thereby minimized*.

As shown in Figure 4, in our implementation, we propose to allocate the bottom tracks only for SSTables of the “current largest” level (e.g., L_5), while allocate the top tracks for SSTables of the non-largest levels (e.g., $L_0 \sim L_4$). This is because, given that the total capacity of bottom tracks and top tracks in IMR based HDD are roughly the same [19, 20] while the size limits among levels in LSM-tree based KV store increase exponentially by a factor (which is usually larger than 2 [17, 18, 21, 36]), the bottom tracks would be fully allocated by SSTables of the largest level when the LSM-tree grows.

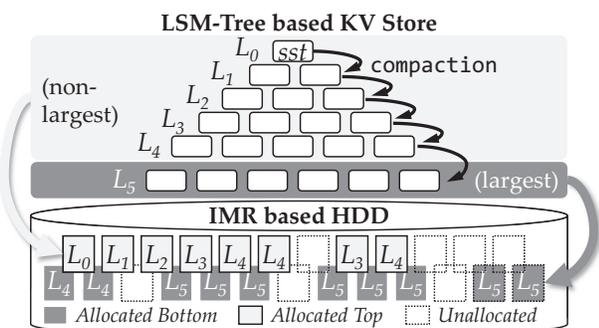

Figure 4: The Level based Bi-Tiering (Step 1).

Moreover, as astute readers may have noticed, when the LSM-tree keeps growing, the size limit of the largest level

may become larger than the total capacity constituted by all bottom tracks; as a result, accommodating all the SSTables of the largest level in bottom tracks may become impossible. However, we argue that *this situation will not contradict the design concept of the first step*. The reason is that, although we have no choice to accommodate some SSTables of the largest level in top tracks, all the bottom tracks can still be allocated only by SSTables of the largest level, so that the probability of incurring the RMWs on allocating bottom tracks can be still effectively minimized.

Step 2) Relaxed-Sequential Track Allocation The second step further determines which tracks in the specific tier (that is decided by the *Level based Bi-Tiering* (i.e., Step 1)) should be allocated to accommodating an SSTable.

The design principle of the second step is inspired by the following two observations. First, according to the property of *compaction locality*, the SSTables generated by a round of compaction process are likely to be involved in the latter round(s) of compaction process. Second, since IMR based HDD adopts the similar rotational disk mechanisms of CMR based HDD, accessing data sequentially is also much efficient than accessing it randomly in IMR based HDD. Thus, we argue that *it may be beneficial to accommodate the SSTables generated by a round of compaction process into tracks “as sequential as possible”*. The reason is that the SSTables generated by a round of compaction process can be sequentially written into tracks with *high sequential write performance*, and also be sequentially compacted by the latter round(s) of compaction process with *high sequential read performance*.

However, in order to comply with the proposed *Level based Bi-Tiering* (i.e., Step 1) and avoid any data migrations or RMWs, a *Relaxed-Sequential Track Allocation* is instead adopted to *relax* the degree of sequentiality on track allocation from two aspects: First, since all the SSTables generated in a round of compaction process must belong to *same* level, the proposed *Level based Bi-Tiering* would suggest accommodating all of these SSTables in the *same* tier of tracks (i.e., either bottom tracks or top tracks). Thus, instead of allocating the tracks in the *strictly-sequential* order (i.e., one bottom track followed by the adjacent top track), we propose to allocate bottom tracks and top tracks *separately* to accommodate SSTables in the *relaxed-sequential* order (i.e., one bottom track followed by the adjacent bottom track, or one top track followed by the adjacent top track). Second, when allocating tracks in the relaxed-sequential order, we propose to further *relax* the degree of sequentiality by “skipping” the track(s) which are currently allocated by other SSTables or may incur the time-consuming RMWs if possible. However, if none of the unallocated/free bottom tracks can be allocated without incurring RMWs, we propose to allocate the nearest unallocated bottom track to best preserve the degree of sequentiality.

3.3 Merged Read-Modify-Write

To further improve the compaction efficiency when the time-consuming RMWs are inevitable, this section explores how to improve the efficiency of persisting the buffered SSTable from the *Write Buffer* into the allocated tracks. Specifically, Section 3.3.1 first introduces the process of persisting the buffered SSTable when the *Naïve RMW* approach [25] is employed. Then, Section 3.3.2 reveals the potential inefficiency of the *Naïve RMW* approach and introduces a novel *Merged RMW* approach which re-orders multiple RMWs into a “merged RMW” with the improved persisting efficiency and the ensured crash consistency.

3.3.1 SSTable Persisting with Naïve RMW

Algorithm 1 shows the process of *SSTable Persisting with Naïve RMW*, which persists the buffered SSTable (denoted as SST) from the *Write Buffer* into the allocated track(s) (denoted as *TrackList*) when the *Naïve RMW* approach [25] is employed. Notably, the notations $SST[i]$ and $TrackList[i]$ denote that the i^{th} track-size content of the SST should be persisted into the i^{th} allocated track in *TrackList*.

First of all, the content of the buffered SSTable are persisted into the allocated tracks on a *track-by-track* basis (i.e., *at the granularity of a track* [25]) (Lines 1~14). Specifically, if track rewrite(s) are incurred when writing $SST[i]$ into $TrackList[i]$, the *Naïve RMW* is performed as follows (Lines 4~12): First, it performs back-up (Lines 5~6), followed by invoking a *sync*-like function to ensure the valid data of the adjacent top track(s) are safely persisted into *BackupRegion* (Line 7); Second, it writes the content of $SST[i]$ into the $TrackList[i]$ (Line 8), followed by invoking a *sync*-like function to ensure $SST[i]$ is safely persisted into the IMR based HDD (Line 9); Thirdly, it performs move-back (Lines 10~11), followed by invoking a *sync*-like function to ensure the backed-up valid data are safely persisted into adjacent top tracks (Line 12). Otherwise, if track rewrite(s) are not incurred when writing $SST[i]$ into $TrackList[i]$, $SST[i]$ are directly written into the $TrackList[i]$ (Lines 13~14). Finally, a *sync*-like function is invoked to ensure that the entire SST is safely persisted into the IMR based HDD (Line 15).

Please be noted, in general, the *sync*-like function (e.g., *sync* [2, 7], *fdatasync* [3], *flush* [4]) is used to ensure that the data previously written by the *write*-like function(s) can be safely persisted into the storage device such as HDD. That is, the *sync*-like functions invoked during the naïve RMWs (i.e., Lines 7, 9 and 12) are actually served as critical *write barriers* to ensure that the correct sequence of “read-modify-write”, as described in [25], can be enforced. This also explains why for most of cases, there is no need to invoke a *sync*-like function after writing the $SST[i]$ into $TrackList[i]$ which does not incur any track rewrite(s) (i.e., Lines 13~14). However, if there exist un-synced track(s) which are adjacent to the to-be-written $TrackList[i]$, a *sync*-like function may

Algorithm 1: SSTable Persisting with Naïve RMW

```
Input: SST: the content of an SSTable to be persisted.
Input: TrackList: the list of the allocated tracks for SST.
1 for  $i \leftarrow 0$  to TrackList.size do
2   if any adjacent tracks of TrackList[ $i$ ] is un-synced then
3     sync; // ensure valid data are persisted
4   if writing to TrackList[ $i$ ] incurs top track rewrite(s) then
5     /* -- Naïve RMW Begin -- */
6     read the valid data from adjacent top track(s);
7     write the valid data into BackupRegion;
8     sync; // ensure valid data are persisted
9     write SST[ $i$ ] to TrackList[ $i$ ];
10    sync; // ensure SST[ $i$ ] is persisted
11    read the valid data from BackupRegion;
12    write back the valid data into adjacent top track(s);
13    sync; // ensure valid data are persisted
14    /* -- Naïve RMW End -- */
15  else
16    write SST[ $i$ ] to TrackList[ $i$ ];
17 sync; // ensure the entire SST is persisted
```

be invoked to ensure the valid data of un-synced tracks are persisted into HDD by a correct sequence (Lines 2~3).

3.3.2 SSTable Persisting with Merged RMW

Although the process of *SSTable Persisting with Naïve RMW* (i.e., Algorithm 1) looks simple and elegant, nevertheless, based on our investigation, there exist two sources of inefficiency hid behind it when the size of an SSTable is (much) larger than the size of an IMR track. First, although the *sync*-like functions ensure the *Naïve RMW* approach against unexpected crashes, they also bring severe performance degradation to the whole process. The rationale behind this is that the *sync*-like functions have adverse effects on I/O performance of HDD [2, 24, 45]. Second, since *Naïve RMW* approach must be performed on a *track-by-track* basis, the valid data of some top tracks are actually backed up and written back redundantly, resulting in the doubled read, write and *sync* workloads.

Thus, in order to further improve the efficiency of persisting the buffered SSTable from the *Write Buffer* into the allocated track(s) when the RMWs are incurred, this section introduces a novel *Merged RMW* approach. Its key idea is to *re-order* multiple *track-by-track* naïve RMWs into a single “merged RMW”, so as to significantly reduce the number of required *sync*-like functions and avoid redundant track rewrites while still ensure the crash consistency.

Algorithm 2 depicts the process of *SSTable Persisting with Merged RMW*, which persists the buffered SSTable (denoted as SST) from the *Write Buffer* into the allocated track(s) (denoted as *TrackList*) by employing the newly proposed *Merged RMW* approach. First of all, different from the process shown in Algorithm 1, this process firstly performs the

Algorithm 2: SSTable Persisting with Merged RMW

```
Input: SST: the content of an SSTable to be persisted.  
Input: TrackList: the list of the allocated tracks for SST.  
// The parts of SST incurring track rewrites  
1 if persisting SST incurs track rewrites then  
    /* -- Merged RMW Begin -- */  
2     for  $i \leftarrow 0$  to TrackList.size do  
3         if writing to TrackList[i] incurs track rewrites then  
4             read the valid data from adjacent top track(s);  
5             write the valid data to BackupRegion;  
6         sync; // ensure valid data are persisted  
7     for  $i \leftarrow 0$  to TrackList.size do  
8         if writing to TrackList[i] incurs track rewrites then  
9             write SST[i] to TrackList[i];  
10        sync; // ensure SST[i] is persisted  
11    for  $i \leftarrow 0$  to TrackList.size do  
12        if writing to TrackList[i] incurs track rewrites then  
13            read the valid data from BackupRegion;  
14            write back the valid data into adjacent top  
            track(s);  
15        sync; // ensure valid data are persisted  
    /* -- Merged RMW End -- */  
// The rest parts of SST w/o track rewrites  
16 for  $i \leftarrow 0$  to TrackList.size do  
17     if SST[i] is un-written && TrackList[i] is a bottom then  
18         write SST[i] to TrackList[i];  
19 sync; // ensure data to bottom are persisted  
20 for  $i \leftarrow 0$  to TrackList.size do  
21     if SST[i] is un-written && TrackList[i] is a top then  
22         write SST[i] to TrackList[i];  
23 sync; // ensure the entire SST is persisted
```

Merged RMW approach to handle all the allocated bottom track(s) that would incur top track rewrite(s) on a batch basis as follows (Lines 1~15): First, it backs up the valid data of all the involved adjacent top track(s) into the *BackupRegion* in a batch (Lines 2~5) before invoking the *first* sync-like function to ensure all of these valid data are safely persisted into the IMR based HDD (Line 6); Second, it writes the content of SST into all the involved bottom tracks in a batch (Lines 7~9) before invoking the *second* sync-like function to ensure these written parts of SST are safely persisted into the IMR based HDD (Line 10); Thirdly, it moves back all the backed-up valid data from the *BackupRegion* into the involved adjacent top track(s) in a batch (Lines 11~14) before invoking the *third* sync-like function to ensure these backed-up valid data are safely persisted into the IMR based HDD (Line 15).

Next, this process persists the remaining parts of SST, which would not incur top track rewrite(s), into the corresponding tracks (Lines 16~23) as follows: First, this process gives the highest priority to write the un-written parts

of SST into their corresponding bottom tracks in a batch (Lines 16~18). This is because, if the un-written parts of SST are written into top tracks first, the subsequent writes to adjacent bottom tracks may instead incur extra track rewrites over those “just-written” top tracks. Then, a sync-like function should be invoked (Line 19) to ensure the data writes to bottom tracks (if any) are persisted into HDD. Finally, this process writes the un-written parts of SST into their corresponding top tracks in a batch, followed by invoking a sync-like function to ensure the entire SST are safely persisted into HDD (Lines 20~23).

Compared with the SSTable persisting process with *Naïve RMW* approach (i.e, Algorithm 1), the SSTable persisting process with the *Merged RMW* approach not only significantly minimizes the number of required sync-like functions (specifically, at least 1 and at most 5), but also avoids the redundant backup and write-back of top tracks (since the involved top tracks are only backed up and written back once). Moreover, the *Merged RMW* approach nicely ensures the crash consistency for the SSTable by backing up the parts of SSTable residing in top tracks into the *BackupRegion*, before writing any data into bottom tracks that would incur top track rewrites. However, it is worth noting that the *Merged RMW* approach requires a larger *BackupRegion* than the *Naïve RMW* approach, in order to back up the valid data of all the involved adjacent top track(s) in a batch. Specifically, the size of the *BackupRegion* required by the *Merged RMW* approach is just twice as the size of an SSTable, which should be a negligible storage overhead compared with the total capacity of HDD.

Notably, as astute readers may have noticed, an alternative approach, which organizes all tracks into “regions” of a fixed number of consecutive tracks, is also able to reduce the numbers of track rewrites and sync-like functions as does KVIMR. That is, this approach may always write a whole SSTable into a fixed-sized region by writing all the bottom tracks then all the top tracks in the region. Although such approach looks simple and effective indeed, however, we argue that it might inevitably waste the disk space (since the actual sizes of SSTables are not fixed and could be smaller than the fixed SSTable size limit in the mainstream LSM-tree based KV store implementations). Thus, KVIMR adopts a more flexible *Compaction-aware Track Allocation* and *Merged RMW* to avoid such space waste issue while reduce the numbers of track rewrites and sync-like functions.

3.4 Crash Consistency

Since the proposed KVIMR does not introduce significant changes to the core design of LSM-tree based KV stores, the crash consistency mechanisms of different LSM-tree based KV stores still remain and work nicely in the same way.

KVIMR further ensures the crash consistency regarding its key metadata (i.e., SSTable-to-Track Map (S2TMap)) as follows: First, to avoid incurring the time-consuming RMW

processes over IMR tracks, we propose to persist the track-level S2TMap into a few reserved top tracks of IMR based HDD or other persistent storage device, which can be freely updated, in the system. Second, to better manage the persisting overhead, we propose to persist S2TMap whenever the LSM-tree based KV store persists their key metadata (e.g., the *manifest* file) after each successful compaction process. This ensures that the metadata of KVIMR can always be consistent with that of the LSM-tree based KV store, so that both LSM-tree based KV store and KVIMR can be recovered to a consistent state successfully after unexpected system crashes.

4 Evaluation

4.1 Evaluation Setup

In this section, we evaluate the effectiveness of the proposed KVIMR middleware. Since there is no available real products of IMR based HDDs to date, we follow the emulation approach suggested in [39] to emulate an 100 GB IMR based HDD with a real CMR based HDD (model no. ST500DM002 [1]) so that the evaluated results can accurately reflect actual performance of the disk internal activities. Particularly, we split the LBA range into 2 MB tracks as suggested in [25, 50], organize the tracks by the interlaced track layout of IMR, and read/write to tracks with IMR-like restrictions [28]. In addition, we architect the KVIMR as a middleware as introduced in Section 3.1 and develop KVIMR in the user-space using C++, and employ the existing `pread/pwrite/fdatasync` system calls with the `O_DIRECT` flag to directly manage SSTables and perform the RMW approach over tracks of the emulated IMR based HDD. Moreover, the following schemes are implemented and integrated with the KVIMR middleware for evaluation purposes:

- **Seq** allocates all tracks in a sequential order (i.e., one track followed by the subsequent one(s)) but skips tracks that have been allocated by other SSTables; and it adopts the *Naïve RMW* approach [25] to perform track rewrites.
- **3Phase** allocates the unused tracks in the following order: bottom tracks, every other top tracks, and the rest of top tracks [19, 20]; and it adopts the *Naïve RMW* approach [25] to perform track rewrites.
- **KVIMR-N** denotes the proposed *Compaction Aware Track Allocation* scheme (presented in Section 3.2) with the *Naïve RMW* approach [25].
- **KVIMR-M** denotes the proposed *Compaction Aware Track Allocation* scheme (presented in Section 3.2) with the proposed *Merged RMW* approach (presented in Section 3.3).

On the other hand, we modify three well-known implementations of LSM-tree based KV store, i.e., RocksDB [18], LevelDB [21], and HyperLevelDB [17], so that they can access its SSTables through a set of POSIX complaint file operations provided by the KVIMR middleware as presented in Section 3.1. The metadata (e.g., *manifest*, *WAL*) of these

LSM-tree based KV store implementations are currently kept in an SSD alongside (like GearDB’s implementation [53]). However, since the size of metadata is relatively small, these metadata can also be managed in a few IMR tracks with little performance impact. Notably, because of limited page length, we mainly demonstrate the evaluation results collected from RocksDB. In addition, we adopt the default settings [18] (e.g., the SSTable size is 64 MB, the size limit of level 1 is 256 MB, `kLO_SlowdownWritesTrigger` and `kLO_StopWritesTrigger` are 20 and 36 respectively) to configure RocksDB, but further set the `compaction_readahead_size` to 2 MB (as suggested in [6]) and `bloom_bits` to 10 (as suggested in [6]) to have better performance on HDD. Moreover, we revise the benchmark tool `db_bench` released with RocksDB, LevelDB, and HyperLevelDB, so as to evaluate the performance of different schemes under various workloads generated by YCSB [14]. All the experiments are conducted on a workstation PC, which is equipped with two Intel(R) Xeon(R) E5-1630 v4 @ 3.70 GHz processors and 16 GB DDR4 DIMM memory, where the operating system is 64-bit Ubuntu 14.04.1 LTS with Linux kernel version 3.13.0.

4.2 Evaluation Results

4.2.1 Overall Load Performance

This section investigates the overall performance under different schemes by randomly loading/inserting 75 millions of 1 KB KV pairs into RocksDB. Figure 5 shows the overall performance results, where the x-axis of each sub-figure denotes different schemes and the y-axis of each sub-figure shows the results from different performance metrics. For ease of the comparison, the throughput of adopting three-phase allocation scheme to allocate CMR tracks for accommodating SSTables (denoted as CMR as in Section 2.3) is also plotted in Figure 5 as a horizontal dashed line. From Figure 5a, we can firstly observe that both KVIMR-N and KVIMR-M achieve significant throughput improvements when compared with Seq and 3Phase. Specifically, KVIMR-N achieves $1.44\times$ and $2.21\times$ higher throughput than that of Seq and 3Phase. Moreover, it can be also observed that KVIMR-M further improves the throughput by 7.0% as compared to KVIMR-N, because of the improved compaction efficiency contributed by the proposed Merged RMW approach. More encouragingly, KVIMR-M achieves a comparable throughput as compared to CMR with only about 5.5% degradation.

To better demonstrate the compaction efficiency of different schemes, Figures 5b and 5c respectively demonstrate the number of compactions and the sum of execution time of compactions (or *cumulative compaction time* [18]) during the loading process. It can be clearly observed from Figure 5b that all the schemes share similar number of compactions. This is because all the schemes are implemented as middleware (similar to the proposed KVIMR), and the design regarding how RocksDB performs compaction processes

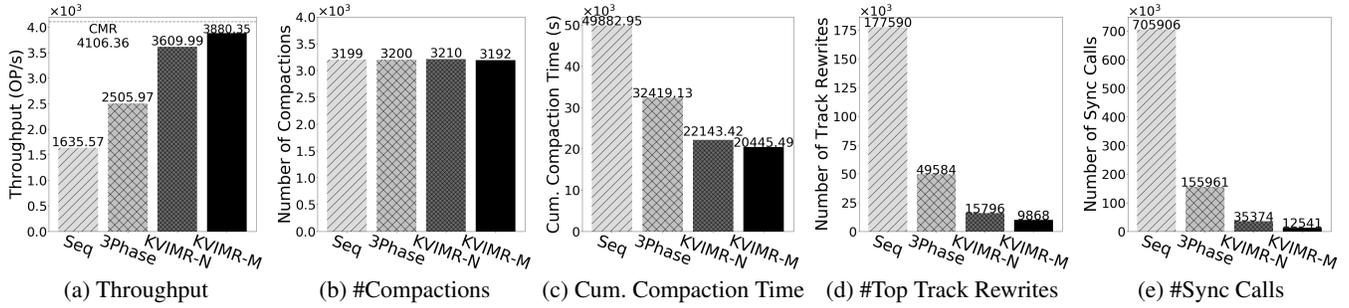

Figure 5: Overall Performance Results of Loading 75 Millions of KV Pairs into RocksDB.

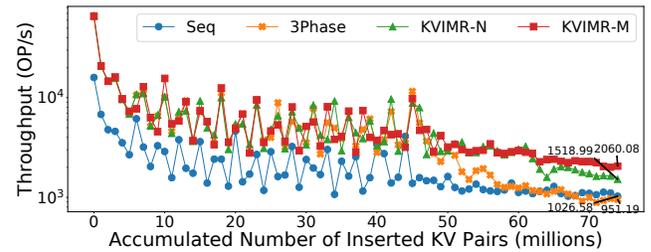

is not changed. However, from Figure 5c, we can observe that, KVIMR-N and KVIMR-M effectively reduce the cumulative compaction time required to complete a similar numbers of compactions, and thereby greatly improve the compaction efficiency (i.e., the average time required to perform a compaction process). Specifically, KVIMR-N largely reduces the cumulative compaction time by 55.61% and 31.69% as compared to Seq and 3Phase. Moreover, KVIMR-M further reduces the cumulative compaction execution time by 7.67% as compared to KVIMR-N.

Based on our investigation, the improvement on the overall throughput and the reduction on the cumulative compaction time (achieved by KVIMR-N and KVIMR-M) can be mainly attributed to the prevention of time-consuming RMW processes, which may incur additional track rewrites and sync calls to slow down the efficiency of persisting SSTables. Figures 5d and 5e reveal the numbers of (top) track rewrites and the numbers of sync calls incurred by different schemes during the loading process. It can be firstly observed that, KVIMR-N and KVIMR-M significantly reduce the numbers of top track rewrites and sync calls as compared to Seq and 3Phase. Specifically, KVIMR-N decreases the number of top track rewrites by 91.11% and 68.14% and diminishes the number of sync calls by 94.99% and 77.32% as compared to Seq and 3Phase, respectively. The main reason behind such reductions is that, KVIMR-N leverages the *compaction frequency* to allocate the IMR tracks for accommodating SSTables, so as to minimize the occurrence of time-consuming RMW processes. It is also worthy to see that, compared to KVIMR-N, KVIMR-M further reduces the numbers of top track rewrites and sync calls by 37.53% and 64.55%. The is because KVIMR-M adopts the proposed Merged RMW to cleverly circumvent the redundant top track rewrites and bound the number of sync calls, when the time-consuming RMWs cannot be fully avoided by the proposed Compaction-aware Track Allocation.

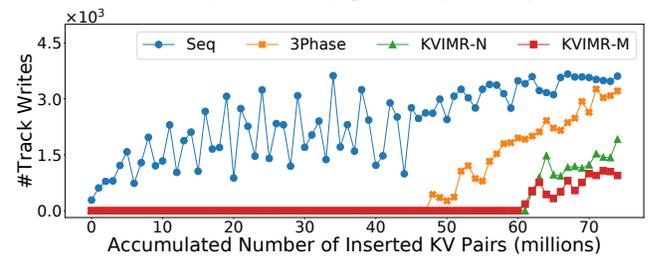

4.2.2 Load Performance Changes

Besides the overall performance results presented in Figure 5, it is also valuable to investigate how the throughput and other performance metrics actually change along the whole loading process. Figures 6a, 6b and 6c respectively show the throughput, the number of incurred track rewrites, and the number of invoked sync calls for loading every 1 million of KV pairs,

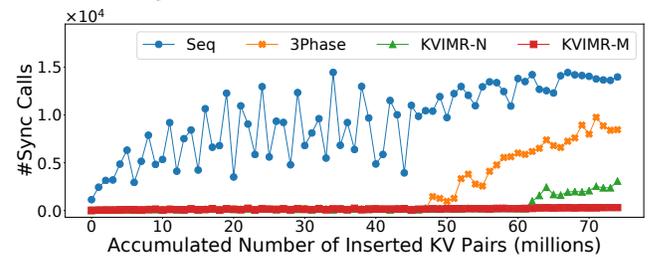

where the x-axis of each sub-figure denotes the accumulated number of inserted/loaded KV pairs.

(a) Changes in Throughput during Loading.

(b) Changes in the Number of Incurred Track Rewrites.

(c) Changes in the Number of Invoked Sync Calls.

Figure 6: Performance Changes during Loading.

First of all, from Figure 6a, we can observe that, compared with Seq and 3Phase, KVIMR-N and KVIMR-M lead to the much higher throughputs, almost for every 1 million of inserted KV pairs along the whole loading process. The main reason behind this is that, as revealed by Figures 6b and 6c, KVIMR-N and KVIMR-M incur much less number of top track rewrites and sync calls during the whole loading process. Interestingly, after inserting about 60 millions of KV pairs, KVIMR-M starts to achieve the highest throughput than the rest of schemes. For example, KVIMR-M achieves 26.27% higher throughput than that of KVIMR-N for the last 1 million of in-

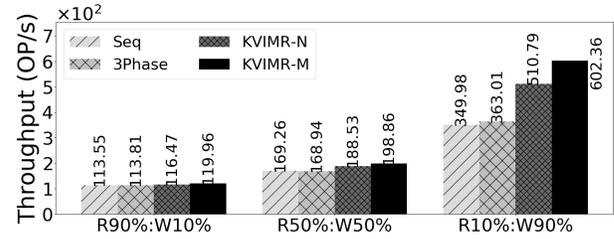

serted KV pairs. The reason is that, when the RMW processes are inevitable during the late loading process, the proposed Merged RMW approach can cleverly avoid redundant top track rewrites and bound the number of sync calls, resulting in the improved efficiency of persisting SSTables.

By contrast, *Seq* achieves the lowest throughput almost during the whole loading process, and *3Phase* starts to encounter noticeable throughput degradation after inserting about 50 millions of KV pairs and suffers very low throughput as *Seq* at the very end of the loading process. In particular, as observed from Figure 6a, *KVIMR-M* achieves $2.01\times$ and $2.17\times$ higher throughput than that of *Seq* and *3Phase* respectively for the last 1 million of inserted KV pairs. Such serious throughput degradations of *Seq* and *3Phase* can be attributed to their track allocation designs. Particularly, *Seq* writes the SSTable data in a strictly-sequential order (i.e., one track followed by the subsequent one(s)), resulting in that the time-consuming RMW processes are mostly incurred whenever writing to any bottom track(s). On the other hand, *3Phase* only utilizes bottom tracks to accommodate the SSTable data and fully avoids RMW processes during the first phase (i.e., before inserting 50 millions of KV pairs). However, when *3Phase* starts to allocate top tracks to accommodate SSTables afterwards, it may incur more and more RMW processes as the space usage of HDD increases due to the lack of consideration regarding compaction frequency.

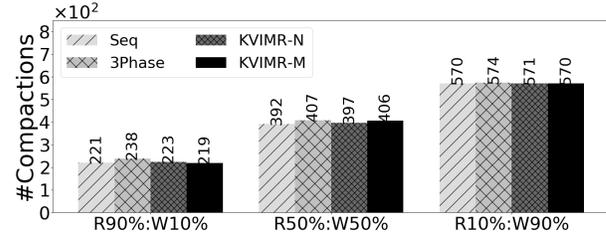

4.2.3 Throughput under Different Workloads

To further investigate the throughput under read-write mixed workloads, we randomly insert and retrieve 7.5 millions of KV pairs after loading the 75 millions of KV pairs into RocksDB. In particular, three workloads of different read/write (R/W) ratios (i.e., R90%:W10%, R50%:W50%, and R10%:W90%) generated by YCSB [14], which follow the Zipfian distribution, are used to represent different *write intensities*. Figure 7a shows the throughputs of different schemes, where the x-axis denotes different R/W ratios and the y-axis shows the throughput. It can be firstly observed that the throughputs of all the evaluated schemes increase as the write intensity (or write ratio) increases. This is because, randomly reading a large amount of KV pairs from LSM-tree based KV store might seriously slow down the overall throughput due to the poor random access performance of HDD.

More importantly, as revealed by Figure 7a, *KVIMR-N* and *KVIMR-M* are more effective in improving the throughput as the write intensity keeps increasing, as compared to *Seq* and *3Phase*. Specifically, *KVIMR-N* and *KVIMR-M* lead to at least 2.28%, 10.22% and 28.93% throughput improvements (than that of *Seq* and *3Phase*) under workloads of R90%:W10%, R50%:W50% and R10%:W90% respectively. This is because, as shown in Figure 7b, for all the evaluated schemes, the number of incurred compactions increases as the write intensity increases. Such increasing number of compactions implies that more SSTables need to be persisted into HDD, leaving a

(a) Throughput under Workloads of Various R/W Ratios.

(b) #Compactions under Workloads of Various R/W Ratios.

Figure 7: Throughput under Workloads of Various R/W Ratios

larger room for *KVIMR-N* and *KVIMR-M* to reduce the number of track rewrites and sync calls for higher throughput gains (under workloads of higher write intensities).

4.2.4 Throughput under Different Sizes of SSTable

To understand how the impact of SSTable size on the throughput, we randomly loading/inserting 75 millions of 1 KB KV pairs into RocksDB under different sizes of SSTable. Specifically, as suggested in the [8], since HDD typically demonstrates better performance under larger sizes of SSTable, this section mainly evaluates the throughput of different schemes when SSTable size ranges from 64MB to 512MB.

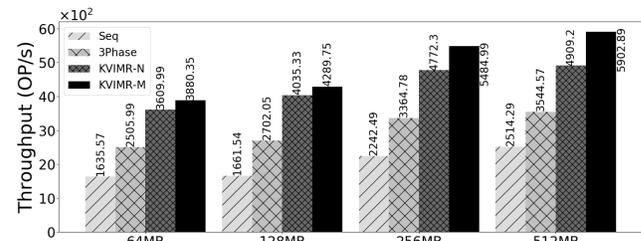

Figure 8: Throughput under Different Sizes of SSTable.

Figure 8 shows the overall load performance results, where the x-axis denotes different SSTable sizes and the y-axis denotes the throughput. It can be firstly observed that all the schemes achieve higher throughput with larger SSTable sizes. Besides, *KVIMR* still effectively and stably achieves better throughput than that of *Seq* and *3Phase* as the SSTable size increases. More interestingly, as compared to *KVIMR-N*, *KVIMR-M* tends to be more effective in improving the throughput when the SSTable size increases. Specifically, the performance gaps between *KVIMR-N* and *KVIMR-M* are 7.0%, 5.9%, 13.0%, 16.8% with SSTables sizes of 64 MB, 128 MB, 256 MB and 512 MB respectively. The key reason of such increasing performance gap is that the Merged RMW adopted

by KVIMR-M has potential to circumvent more redundant top track rewrites and reduce more number of sync calls with larger SSTable sizes.

4.2.5 Support for Other LSM-tree based KV Stores

To demonstrate the great compatibility of KVIMR, we further conduct the load throughput evaluation (i.e., loading 75 millions of 1 KB KV pairs generated by YCSB [14]) on other two well-known LSM-tree based KV stores: LevelDB [21], and HyperLevelDB [17]. Notably, to present the performance results on the same basis, we apply the same configurations adopted by RocksDB to both LevelDB and HyperLevelDB for achieving better HDD performance. That is, we set the SSTable size to 64 MB, set the size limit of level 1 to 256 MB and set *kLO_SlowdownWritesTrigger* and *kLO_StopWritesTrigger* to 20 and 36 respectively. Moreover, since LevelDB and HyperLevelDB lack the design of *compaction_readahead_size*, we instead set the *block_size* to 2 MB to have better performance on HDD as suggested by [6].

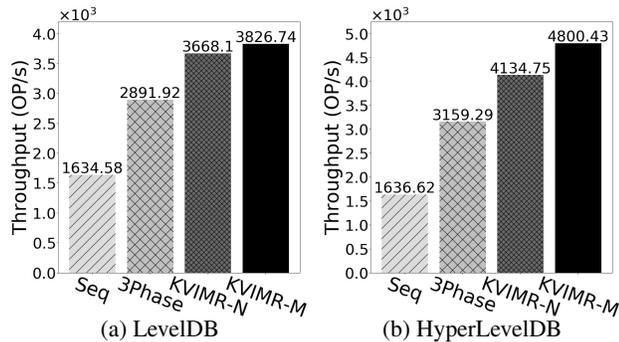

Figure 9: Throughput of Loading 75 Millions of KV Pairs into Other Well-Known LSM-tree based KV Stores.

Figures 9a and 9b show the overall throughput achieved by LevelDB and HyperLevelDB respectively upon loading 75 millions of 1 KB KV pairs. It can be clearly observed that the trends of overall throughputs achieved by the evaluated schemes under LevelDB and HyperLevelDB are quite similar to what we can observe under RocksDB (see Figure 5a). That is, KVIMR-N and KVIMR-M still effectively achieve better throughputs than that of Seq and 3Phase by at least 55.43% and 21.16% under LevelDB respectively (and by at least 60.41% and 23.59% under HyperLevelDB respectively).

5 Related Work

There exist some mentionable studies proposed to address the track rewrite issue of Shingled Magnetic Recording (SMR) based HDD by introducing the following techniques to the existing LSM-tree based KV store implementations. For example, SMRDB [39] proposes to enlarge the SSTable size to the band/zone size of SMR based HDD to avoid track rewrites, arranges SSTables into only two levels with the key ranges of SSTables overlapped within the same level, and presents a new cost-considered compaction design. Another study called

SEALDB [52] proposes to group the SSTables involved in a compaction into a set, and then sequentially writes a set of SSTables into a variable-sized *dynamic band* to mitigate the track rewrite issue. A more recent study namely GearDB [53] proposes to sequentially write the SSTables of the same level into the same *SMR band/zone*, and further introduces a *Gear Compaction* to avoid garbage collection in SMR based HDD.

The aforementioned designs indeed take effect at mitigating the track rewrite issue of SMR; however, they could be *ineffective* when blindly applied to IMR based HDD since SMR and IMR technologies adopt naturally-different track layouts. Specifically, all these designs must write the SSTables into SMR tracks in a “strictly-sequential” order (i.e., one track followed by the subsequent one(s)). As revealed by our evaluation, sequentially writing SSTables into IMR tracks may incur serious throughput degradation, since writing to any bottom track may cause the time-consuming RMW(s) to rewrite its adjacent top track(s) in the IMR based HDD. On the other hand, all these designs are developed by revamping the existing LSM-tree based KV store (i.e., LevelDB [21]). That is, they are all tightly-coupled with one specific implementation of the LSM-tree based KV store, making them costly to be upgraded with the software updates of KV store and integrated with other representative implementations of the LSM-tree based KV store, such as the widely deployed RocksDB [18].

6 Conclusion

This paper presents KVIMR, a data management middleware, to construct a cost-effective yet high-throughput LSM-tree based KV store on IMR based HDD. KVIMR delivers great compatibility for mainstream LSM-tree based KV store implementations without introducing significant modifications by being architected as a middleware sitting between LSM-tree based KV store and IMR based HDD. Technically, KVIMR remedies the throughput degradation resulted from IMR through the proposing of two novel designs: a *Compaction Aware Track Allocation* scheme to minimize the time-consuming RMWs and efficiently access the SSTables during the compaction process, and a *Merged RMW* approach to improve the efficiency of persisting an SSTable into IMR based HDD when the time-consuming RMWs are inevitable. Our evaluations on three well-known LSM-tree based KV store implementations (i.e., RocksDB, LevelDB, and HyperLevelDB) reveal that KVIMR not only improves the overall throughput by up to $1.55\times$ under write-intensive workloads but even achieves $2.17\times$ higher throughput under high space usage of HDD, as compared with the state-of-the-art three-phase track allocation scheme for IMR.

Abstract

Modern key-value (KV) stores adopt the LSM-tree as the core data structure for managing KV pairs, but suffer from high write and read amplifications. Existing LSM-tree optimizations often make design trade-offs and are unable to simultaneously achieve high performance in writes, reads, and scans. To resolve the design tensions, we propose DiffKV, which builds on KV separation to carefully manage the ordering for keys and values. DiffKV manages keys using the conventional LSM-tree with *fully-sorted ordering* (within each level of the LSM-tree), while managing values with *partially-sorted ordering* with respect to the fully-sorted ordering of keys in a coordinated way for preserving high scan performance. We further propose fine-grained KV separation to differentiate KV pairs by size, so as to realize balanced performance under mixed workloads. Experimental results show that DiffKV can simultaneously achieve the best performance in all aspects among existing LSM-tree-optimized KV stores.

1 Introduction

Key-value (KV) storage, which abstracts data as KV pairs, becomes a critical storage paradigm for supporting a variety of applications, such as search engines [4, 11, 23, 53], distributed file systems [1, 28], data deduplication [18, 41], graph stores [7, 22, 37, 64], and OLTP/OLAP databases [3, 8, 11, 19, 30, 31, 33, 43, 50, 65]. Such storage paradigms mainly provide three operations: (i) *writes*, which insert KV pairs, (ii) *reads*, which retrieve the value of a single key, and (iii) *scans*, which retrieve the values over a key range. In particular, scans are essential operations for KV stores in various applications; for example, graph computation tasks may traverse multiples nodes or edges [2, 7, 37], and OLAP databases traverse multiple entries in a table for data filtering or aggregation [8, 30, 33, 50]. Thus, optimizations for scans have also been specifically studied in the literature [43, 55, 62, 65].

To better leverage the efficiency of sequential I/Os and preserve the data ordering for fast scans, modern KV stores (e.g., [10, 24, 27, 42, 52]) often adopt the *Log-Structured-Merge-tree (LSM-tree)* [46]. At a high level, the LSM-tree builds on three properties (see §2.1 for details): (i) it organizes KV pairs in a log-structured layout, in which updating KV pairs is treated as issuing sequential writes of KV pairs to persistent storage with high performance; (ii) it adopts a

multi-level structure that keeps KV pairs *fully sorted* within each level, so as to support efficient reads and scans without specialized in-memory index structures; and (iii) it mitigates the write overhead by gradually moving KV pairs from lower levels to higher levels via *compaction*, so as to maintain high storage scalability. However, the compaction incurs substantial amounts of I/Os, as the KV pairs in adjacent levels need to be retrieved and written back to maintain sorted ordering. It is well known that LSM-tree KV stores suffer from severe write and read amplifications, especially when the number of levels of the LSM-tree increases with the growing volume of KV pairs being managed [42, 52, 58].

To reduce the compaction overhead, a number of LSM-tree optimization techniques have been proposed in the literature. One direction of work is to relax the fully-sorted nature in each level of the LSM-tree, thereby alleviating the compaction overhead [17, 52, 55]. However, as the degree of fully-sorted ordering is relaxed, the scan performance also degrades. Another direction of work is based on *KV separation*, which separates the storage of keys and values by keeping only keys (in fully-sorted ordering) in the LSM-tree and performing value management in a dedicated storage area [10, 20, 38, 42, 49, 51, 63]. KV separation alleviates the compaction overhead as the LSM-tree size now significantly decreases without storing the values, and is particularly suited for practical KV workloads whose KV pairs are composed of large-size values [5, 9, 30, 38, 44, 59] (see §2.2 for details). However, it degrades the scan performance, especially for the values with small-to-medium sizes that are also common in practice [5, 9], since each scan needs to issue random I/Os to the values over a key range that are no longer fully sorted (in contrast, the random I/O overhead is amortized for large values). Also, KV separation incurs extra garbage collection (GC) overhead [10], thereby triggering additional I/O overhead beyond the compaction in the LSM-tree. In short, existing LSM-tree optimizations are still limited by tight performance tensions between reads/writes and scans, in terms of (i) the degrees of ordering in keys and values, and (ii) the management of KV pairs of varying sizes.

To this end, we design a novel KV store, DiffKV, that realizes balanced I/O performance on commodity storage devices (e.g., solid-state drives (SSDs)). Its main idea builds on the differentiated KV management in two aspects. First, DiffKV

differentiates the storage management of keys and values as in conventional KV separation, and takes one step further to carefully coordinate the differentiated management of the ordering for keys and values. Specifically, it keeps keys fully sorted in each level of the LSM-tree as in conventional KV separation for fast reads and scans, while keeping values *partially sorted*, such that the (partially-sorted) ordering of values is coordinated with respect to the (fully-sorted) ordering of keys. We design a new LSM-tree-like structure called the *vTree* for value management, such that the sorting of values in the *vTree* is triggered by the compaction of the LSM-tree. In this way, we limit the overhead of sorting values, yet we still maintain high scan performance via the partially-sorted ordering for values. Second, DiffKV differentiates the management of values via fine-grained KV separation, such that the KV pairs of different size groups are specifically managed for maintaining balanced performance under mixed workloads.

To the best of our knowledge, this is the first work that examines the differentiated ordering for KV pairs. Traditional LSM-tree KV stores without KV separation always couple keys and values together and only realize a single kind of ordering [24, 27, 52]. While existing KV separation designs [10, 20, 38, 42, 49, 51, 63] decouple keys and values, the values are unsorted, and they cannot be tuned to realize different degrees of ordering for balanced performance. Our main contributions are summarized as follows.

- We present DiffKV, which coordinates the differentiated management of ordering for keys and values, so as to simultaneously improve the performance of writes, reads, and scans. Specifically, DiffKV manages values in the *vTree* structure for the partially-sorted ordering of values.
- We propose multiple merge optimization techniques to reduce the sorting overhead in the *vTree*, and also develop a state-aware lazy GC scheme to realize high space efficiency and high performance.
- We propose fine-grained KV separation and differentiate the management of small, medium, and large KV pairs for optimizing mixed workloads. In addition to the LSM-tree and the *vTree*, we also propose a hotness-aware multi-log design for efficiently managing large KV pairs.
- We implement a DiffKV prototype atop Titan [51], an open-source KV store that implements KV separation with optimized techniques. Evaluation results show that DiffKV achieves the best performance in writes, reads, scans, and space utilization compared to state-of-the-art KV stores, including RocksDB [24], PebblesDB [52], and Titan [51].

We release the source code of our DiffKV prototype at <https://github.com/ustcadsl/diffkv>.

2 Background and Motivation

We first introduce the basics of an LSM-tree KV store. We then discuss the strengths and weaknesses of different LSM-tree optimizations to motivate our DiffKV design.

2.1 LSM-tree KV Store

Storage structure. Figure 1(a) depicts a simplified storage structure of a conventional LSM-tree KV store (e.g., LevelDB [27] and RocksDB [24]). An LSM-tree KV store comprises $n + 1$ levels on disk, denoted by L_0, L_1, \dots, L_n (from lowest to highest), and the capacity of a higher level L_i is a multiple (e.g., $10\times$ by default in LevelDB [27]) of that of a lower level L_{i-1} (where $1 \leq i \leq n$). It stores KV pairs in entirety as multiple disk files, called *SSTables*, in multiple levels. It also has two in-memory write buffers, namely *MemTable* and *Immutable MemTable*, and flushes the Immutable MemTable to level L_0 on disk with append-only writes. One main feature of the LSM-tree KV store is that all KV pairs in each of the levels from L_1 to L_n are *fully sorted* by keys to support fast scans, while KV pairs in L_0 are unsorted across different SSTables for fast flushes.

Write process. To write a KV pair, an LSM-tree KV store first inserts the KV pair into the MemTable, which keeps all buffered KV pairs sorted by keys in a skip-list. When the Memtable is full, it becomes an Immutable MemTable, which is then flushed to level L_0 as a new SSTable. The SSTable comprises the sorted KV pairs and some metadata (e.g., Bloom filters) for indexing. Meanwhile, the KV store generates a new MemTable to receive the subsequent new writes. When L_i is full (where $i \geq 0$), its SSTables will be integrated into L_{i+1} by a *compaction* operation. To compact an SSTable S from L_i into L_{i+1} , the KV store reads S and all SSTables in L_{i+1} that have overlapped key ranges with S , then sorts all KV pairs by keys and creates new SSTables. It finally writes them back into L_{i+1} . Thus, compaction induces to severe write amplification, which can reach up to a factor of $50\times$ [42].

Read process. To read a KV pair, an LSM-tree KV store first searches for the KV pair in memory. If the KV pair does not exist, the KV store performs binary search in each level of the LSM-tree, starting from the lowest level L_0 to the higher levels. For each level, it identifies an SSTable and checks its Bloom filter to see if the KV pair exists.

To scan KV pairs, the KV store first finds the starting key in each level. It then sequentially reads the KV pairs that fall in the queried range. It finally returns the set of KV pairs.

2.2 LSM-tree Optimizations and Limitations

We discuss two major classes of LSM-tree optimizations on how they reduce the compaction overhead of LSM-tree KV stores: (i) relaxing fully-sorted ordering [17, 52, 55] and (ii) KV separation [10, 20, 38, 42, 49, 51, 63]. Other types of optimizations are reviewed in §6.

Relaxing fully-sorted ordering. We consider PebblesDB [52], which realizes a *fragmented* LSM-tree, as a representative example, as shown in Figure 1(b). PebblesDB divides each level into several disjoint groups by *guards*, in which the key ranges of SSTables in the same group may overlap with each other. To compact a group of SSTables from L_i to

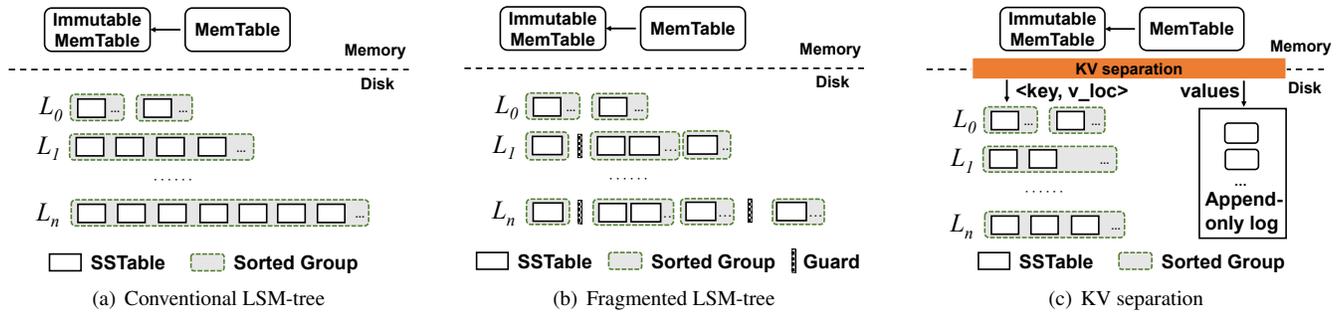

Figure 1: Overview of LSM-tree KV storage structure: (a) fully sorted within each level; (b) partially sorted within each level via multiple non-overlapping segments with guards; and (c) fully sorted for keys, unsorted for values.

L_{i+1} , PebblesDB only reads the SSTables within the group in L_i , sorts them to create new SSTables, and finally writes the new SSTables into L_{i+1} . In this case, a compaction operation in PebblesDB does not need to read SSTables from L_{i+1} , thereby greatly alleviating compaction overhead and write amplification. However, because of the overlapped key ranges of SSTables within each group, PebblesDB sacrifices scan performance. Although it can leverage multi-threading to issue reads in parallel, it incurs more CPU resources, while the improvement remains limited.

KV separation. Figure 1(c) illustrates the typical structure of KV separation in Wiskey [42] and Titan [51]. KV separation stores keys and values separately, in which keys and their references to values are treated as new KV pairs and stored in the LSM-tree, while the original values are separately stored in an append-only log, which is implemented as multiple blob files in Titan. For medium-to-large value sizes, as the keys and value references often have much smaller sizes than the original values. In this case, the total data volume in the LSM-tree is significantly reduced, so the compaction overhead and hence the write amplification are alleviated. In addition, a smaller LSM-tree reduces read amplification and hence improves read performance.

KV separation is a well-known optimization technique for LSM-tree KV stores, as KV pairs with large values sizes are commonly found in real-world KV workloads. For example, TiDB [30], a transactional database built atop a KV storage layer, maps every row of a database table into a KV pair whose value size can grow to hundreds of kilobytes. Atlas [38] maintains KV pairs of cloud storage with value sizes larger than 128 KB. Also, field studies [5, 44, 59] indicate that large-size values contribute to a considerable fraction of traffic in practical KV workloads, and the recent study by Facebook [9] shows that KV pairs for social graph data can have an average value size as large as 1 KB. Finally, the values with medium-to-large sizes (e.g., from 1 KB to 16 KB) are often chosen in the evaluation benchmarks of KV stores (e.g., [10, 42, 52]).

However, since KV separation writes values into an append-only log, the values of a consecutive range of keys are now scattered in different positions in the log. Thus, the scan oper-

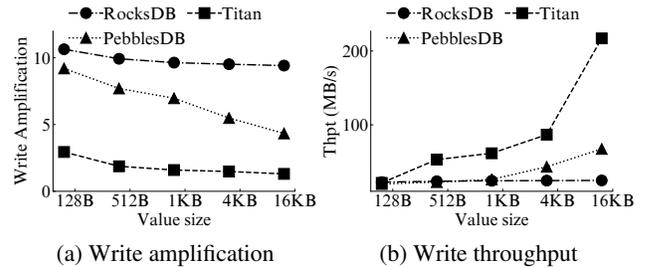

Figure 2: Write performance of RocksDB, PebblesDB, and Titan.

ations need to issue random reads to values, thereby leading to low scan performance in KV separation especially for the KV workloads whose values have small-to-medium sizes [5, 9] (e.g., in OLTP applications [5], more than 90% of values are smaller than 1 KB). Furthermore, KV separation needs to perform GC to reclaim the space of invalid values in the append-only log, and frequent GC operations incur extra I/O overhead [10].

2.3 Trade-off Analysis

We evaluate the design trade-offs of existing LSM-tree designs and optimizations. We consider three open-source KV stores: (i) RocksDB [24], which represents the state-of-the-art LSM-tree KV store with optimized performance; (ii) PebblesDB [52], which relaxes the fully-sorted ordering of each LSM-tree level for reduced compaction overhead; and (iii) Titan [51], which realizes KV separation with optimized implementation (e.g., managing values in multiple small Blob files instead of a large append-only log and using multi-threading to reduce GC overhead). We evaluate write amplification (i.e., the ratio of total write size to user write size) and performance, based on the testbed and configurations in §5.1.

Write performance. Figure 2 shows the write performance of loading a 100 GB database with different value sizes (varying from 128 bytes to 16 KB). From Figure 2(a), both PebblesDB and Titan significantly reduce the write amplification of RocksDB, and their write amplification ratios decrease as the value size increases. For example, for a value size of 16 KB, the write amplification ratios of RocksDB, PebblesDB, and Titan are $9.4\times$, $4.3\times$, and $1.3\times$, respectively.

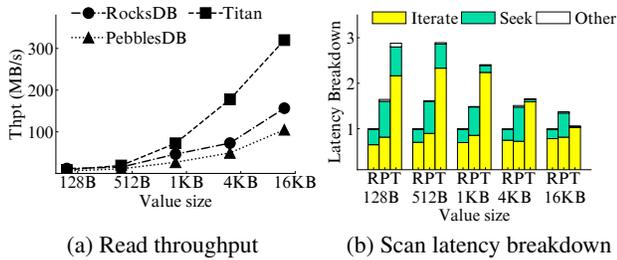

Figure 3: Read and scan performance of RocksDB (‘R’), PebblesDB (‘P’), and Titan (‘T’).

From Figure 2(b), both PebblesDB and Titan show higher write throughput than RocksDB due to the reduced write amplification. For example, for a value size of 16 KB, the write throughput gains of PebblesDB and Titan over RocksDB are $2.7\times$ and $8.7\times$, respectively. In short, the LSM-tree optimizations of relaxing fully-sorted ordering and KV separation are effective to reduce write amplification and hence increase write throughput, especially for large-size values.

Read and scan performance. Figure 3 shows the read and scan performance of RocksDB, PebblesDB, and Titan. For read performance, we issue read requests (i.e., random point queries) to a randomly loaded 100 GB KV store; for scan performance, we issue scan requests to 100 KV pairs. From Figure 3(a), relaxing fully-sorted ordering degrades the read performance, so the read throughput of PebblesDB is lower than that of RocksDB. Titan uses KV separation, which largely reduces the LSM-tree size, so its read throughput is evidently higher than that of RocksDB; for example, its throughput $2.0\times$ of that of RocksDB for a value size of 16 KB.

For scans, both PebblesDB and Titan perform worse than RocksDB, especially for small-to-medium size values. Figure 3(b) provides a latency breakdown for scans. For example, for a value size of 1 KB, the scan latencies of PebblesDB and Titan are $1.5\times$ and $2.4\times$ of that of RocksDB, respectively. Most of the scan time is spent on iteratively reading values (e.g., more than 90% for Titan). As the value size becomes larger (e.g., 16 KB), the differences of scan latencies among the KV stores are smaller, as accessing large-size values has smaller random read overhead. For the KV workloads that are dominated by small-size values [5, 9], the scan performance of PebblesDB and Titan will be limited in practice.

In short, existing LSM-tree designs and optimizations are subject to the performance trade-offs between reads/writes and scans. While relaxing the degree of ordering for values (e.g., using the fragmented LSM-tree or an unsorted append-only log in KV separation) reduces write amplification and improves write throughput, it sacrifices the scan performance, especially for values with small-to-medium sizes.

3 DiffKV Design

We present DiffKV, a novel LSM-tree KV store that aims for balanced performance in writes, reads, and scans.

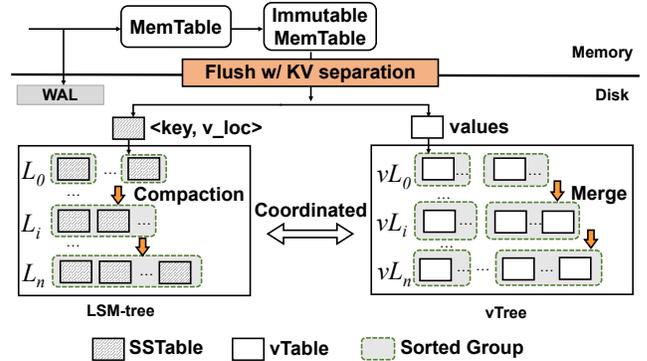

Figure 4: System overview.

3.1 System Overview

Figure 4 depicts the system architecture of DiffKV. DiffKV builds on KV separation for on-disk KV pairs, such that keys and values are decoupled during the flush of KV pairs from memory to disk and then they are separately stored. It also realizes *partially-sorted ordering* for values, so as to maintain high scan performance. To achieve this, DiffKV leverages a new LSM-tree-like multi-level tree, called the *vTree*, to manage values. As in the LSM-tree, the *vTree* comprises multiple levels, each of which can only be written in an append-only way. The difference between the *vTree* and the LSM-tree is that the *vTree* only stores values which are not necessarily fully sorted by their keys within each level; instead, they are allowed to be partially sorted for high scan performance.

To realize partially-sorted ordering for values, the *vTree* also necessitates a compaction-like operation as in the LSM-tree, which we call a *merge* operation to differentiate itself from a compaction operation in the LSM-tree. To reduce the merge overhead, DiffKV makes the compaction of the LSM-tree and the merge of the *vTree* be executed in a *coordinated* manner so as to reduce the overall overhead.

To make DiffKV compatible with existing LSM-tree store designs, it still follows the same in-memory data management as in conventional LSM-tree KV stores with an on-disk write-ahead log (WAL). Specifically, as depicted in Figure 4, DiffKV first writes KV pairs to the WAL, inserts them into the MemTable in memory, and finally flushes the Immutable MemTable to disk with KV separation.

3.2 Data Organization

The *vTree* adopts hierarchical data organization. It consists of multiple levels. Each level consists of *sorted groups*, and each sorted group further consists of multiple *vTables* (Figure 4). In the following, we elaborate their design details.

vTable. DiffKV organizes values as *vTables*, each of which has a fixed size (e.g., 8 MB by default). Note that each flush of an immutable MemTable may generate multiple *vTables* depending on the value size and MemTable size.

A *vTable* includes a *data area* that stores the values of KV pairs in a sorted order based on their keys, as well as

a *metadata area* that records the necessary metadata, such as the data size of the vTable, and the smallest and largest keys of the values in this vTable. Note that the Bloom filter is not required in the vTable (as opposed to the SSTable in the LSM-tree), since the values are still indexed by their keys in the LSM-tree. Thus, the metadata in each vTable has a very small size and brings limited storage overhead.

Sorted group. Each sorted group is a collection of vTables, and all vTables in a sorted group are fully sorted according to their corresponding keys. In other words, the key ranges of any two vTables in a sorted group have no overlaps. For ease of presentation, we also apply the concept of a sorted group for the LSM-tree, such that any set of SSTables in the LSM-tree that are fully sorted are also called a sorted group (e.g., all SSTables in the same level in the LSM-tree form a sorted group). In DiffKV, all vTables generated in one flush form a sorted group, so as to preserve the ordering of values in each immutable MemTable. We use the number of sorted groups as an indicator to measure the degree of ordering in the vTree. As the number of sorted groups increases, the degree of ordering decreases. In one extreme, if all SSTables/vTables form one sorted group, then we have the maximum degree of ordering, as all KV pairs are fully sorted.

vTree. The vTree consists of multiple levels, each of which is formed by multiple sorted groups. While the values in each sorted group are fully sorted, the values in a level of the vTree are not necessarily fully sorted, as they may belong to multiple sorted groups that have overlaps in the key range. As the vTree allows each level to have multiple sorted groups, a merge operation does not need to sort all values in successive two levels in the vTree; this alleviates the I/O overhead as opposed to the compaction in the LSM-tree.

3.3 Compaction-Triggered Merge

The vTree regularly performs merge operations to have partially-sorted ordering for values. Each merge reads a number of vTables and checks which values in the vTables remain valid. This can be done by querying the LSM-tree to retrieve the latest value location. Also, each merge needs to update the LSM-tree for the latest value locations of the valid values. To limit the merge overhead in the vTree, the merge operations in the vTree are not executed independently, but are triggered by the compaction operations in the LSM-tree in a coordinated manner. We call such a merge operation to be a *compaction-triggered merge* operation.

To explain the idea, we consider a simplified case in which we let each level in the vTree be coupled with only one level in the LSM-tree, and use L_i and vL_i to denote level i of the LSM-tree and vTree, respectively. If L_i and vL_i are correlated, then it means that for each KV pair, if the key is stored at level L_i in the LSM-tree, then the value of the KV pair can only be stored at level vL_i in the vTree. However, level vL_i in the vTree is not required to preserve the same fully-sorted ordering with its correlated level L_i in the LSM-tree.

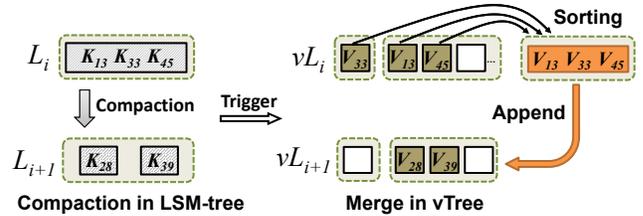

Figure 5: Compaction-triggered merge.

Figure 5 shows the idea of a compaction-triggered merge, which operates as follows. When a compaction operation is triggered to compact keys from L_i to L_{i+1} in the LSM-tree, it also triggers a merge operation that moves the corresponding values from vL_i to vL_{i+1} in the vTree. In the merge operations, there are two major issues: (i) which values should be involved in the merge and (ii) how to write back these values to level vL_{i+1} in the vTree. First, we merge only the values at level vL_i , and their corresponding keys must participate in the compaction in the LSM-tree. We call the value whose key participates in the compaction to be the *compaction-related value* for ease of presentation. Second, we reorganize all compaction-related values at level vL_i to generate new vTables and write these vTables to level vL_{i+1} in an append-only manner. For the example in Figure 5, the values $V_{33}, V_{13}, V_{45}, V_{28}, V_{39}$ are compaction-related values, and V_{33}, V_{13}, V_{45} will be involved in the merge, and finally appended to level vL_{i+1} after sorting.

Note that all values in the generated vTables in each merge are fully sorted; that is, they form only one single sorted group. However, we point out that the merge operation does not require to reorganize all vTables in both levels of vL_i and vL_{i+1} in the vTree. That is, when merging, a new sorted group is created in level vL_{i+1} with all vTables from level vL_i it. This avoids the rewrites of all values at level vL_{i+1} , thereby mitigating write amplification. In addition, the old vTables at vL_i will not be deleted during a merge, as they may still contain valid values, and they will be reclaimed later by GC.

The benefits of a compaction-triggered merge are two folds. First, merging only compaction-related values makes it very efficient to identify which values are still valid, as the corresponding keys also need to be read out from the LSM-tree during a compaction. In contrast, if the vTree is independent of the LSM-tree and triggers merge operations independently, then it needs to query the LSM-tree and compare the value locations to determine the validity of values, thereby inevitably incurring large query overhead. Second, as the locations of valid values are changed when generating new vTables during a merge operation, the LSM-tree needs to be updated accordingly to maintain the latest value locations. Since only the compaction-related values are merged, updating the value locations in the LSM-tree can be executed by directly updating the KV pairs participating in the compaction. Thus, the overhead of updating value locations can be hidden in the compaction operation as the compaction itself needs to rewrite the KV pairs in the LSM-tree.

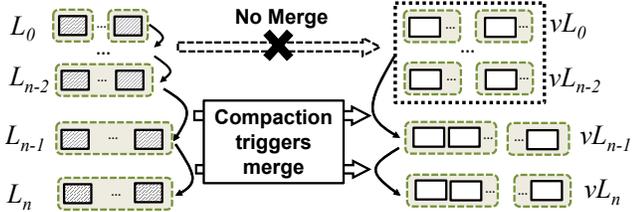

Figure 6: Lazy merge.

3.4 Merge Optimizations

Compaction-triggered merge operations incur limited merge overhead caused by checking the validity of values and writing back new value locations into the LSM-tree. However, letting each compaction operation trigger a merge operation may cause frequent merge operations. For example, if each level in the v Tree is correlated with only one level in the LSM-tree, then each compaction operation must trigger a merge operation in the v Tree. To further reduce the merge overhead in the v Tree, we propose two merge optimizations.

Lazy merge. We propose *lazy merge* to limit the merge frequency, and hence the merge overhead, in DiffKV. Our idea is to aggregate multiple lower levels in the v Tree as a single level, and correlate the aggregate level with multiple levels in the LSM-tree. Specifically, as depicted in Figure 6, we aggregate all levels vL_0, \dots, vL_{n-2} in the v Tree as a single level and correlate the aggregate level with levels from L_0 to L_{n-2} in the LSM-tree. Thus, any compaction between level L_0, \dots, L_{n-2} will not trigger a merge operation; in other words, the merge operations between level vL_0, \dots, vL_{n-2} will be delayed unless the values need to be merged into level vL_{n-1} .

Lazy merge significantly reduces the number of merge operations and the amount of data size being merged, but sacrifices the degree of ordering for the values in lower levels in the v Tree. Nevertheless, we argue that the sacrifice poses limited degradation to the scan performance. Recall that the LSM tree increases its capacity toward higher levels (e.g., the size of L_i is $10\times$ of that of L_{i-1} in LevelDB [27]) (§2.1). Thus, the last two levels L_{n-1} and L_n contain the majority of KV pairs. The uneven data distribution across levels implies that most values are actually retrieved from the last two levels of the v Tree for scans, so the degree of ordering of values in the last two levels is the dominant factor that determines the scan performance. In other words, the low levels of the v Tree only have limited impact on scan performance, and the frequent merge operations in the low levels do not help scan performance but instead incur large merge overhead.

Scan-optimized merge. We adjust the degree of ordering for values in the v Tree via scan-optimized merge, so as to maintain high scan performance. Recall that in a compaction-triggered merge operation, say merging the values from vL_i to vL_{i+1} , only the values in the lower level vL_i are reorganized and appended to the higher level vL_{i+1} , while the values in level vL_{i+1} are not involved in the merge operation and will

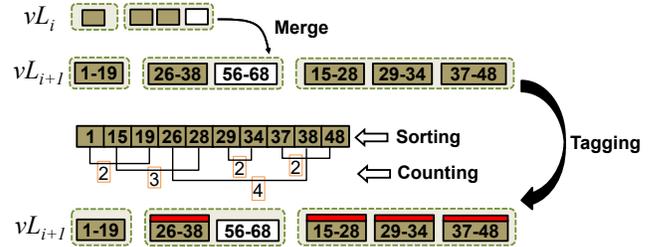

Figure 7: Scan-optimized merge.

not be sorted (§3.3). This append-only merge policy mitigates write amplification, but may result in too many sorted groups, which may have overlapped key ranges as values are not sorted across sorted groups. Thus, our idea is to find out the v Tables which have overlapped key ranges with many other v Tables, and also make them participate in the merge process regardless of which level they reside. With this, we can preserve a higher degree of ordering for values in the v Tree, and thus benefit the scan performance.

Figure 7 depicts the idea of scan-optimized merge. After the normal compaction-triggered merge, we further check the v Tables that contain compaction-related values at level vL_{i+1} . Our goal is to identify the set of v Tables that satisfy two conditions: (i) at least one v Table in the set has overlapped key range with others, and (ii) the number of v Tables (i.e., the set size) is larger than a pre-defined threshold, denoted by `max_sorted_run`. The rationale is that if such a set of v Tables exists, then the scan performance may degrade as these v Tables are not in a sorted order. We add a *scan optimization tag* for these v Tables, so that they will always participate in the next compaction-triggered merge and increase the degree of ordering for values in tagged v Tables.

To identify the set of v Tables for tagging, we first retrieve the start and end keys of each v Table containing compaction-related values at level vL_{i+1} , and sort these keys. For each checked v Table, we count the number of v Tables that have overlapped key ranges with it, and this can be done by scanning once the sorted key string. For example, as in Figure 7, consider a checked v Table [26-38]. By scanning the sorted string, we can count the number of start keys before key 38 (i.e., five in this case) and the number of end keys before key 26 (i.e., one in this case). By subtracting the two numbers, we can obtain the number of v Tables that have overlapped key ranges with v Table [26-38], which is four including itself (i.e., v Tables [15-28], [29-34], [37-48], and [26-38]). Finally, if the number of v Tables with overlapped key ranges is larger than the threshold `max_sorted_run`, then we add a scan optimization tag for all these v Tables to include them in the next compaction-triggered merge. We persist the optimization tags in a *manifest file*, which is already used by existing systems to track the version changes of KV pairs after each compaction; the persistence overhead is negligible.

Scan-optimized merge is an enhancement to compaction-triggered merge: a compaction-triggered merge operation only

appends values in a lower level to its next higher level, while a scan-optimized merge operation further includes certain values in the higher level into the merge to increase the degree of ordering of values in the vTree. Note that scan-optimized merge incurs limited merge overhead (see Figure 15 in §5.4) for two reasons. First, we allow each level in the vTree to have multiple sorted groups (i.e., the whole level is not necessarily fully sorted). Second, not all values in a tagged vTable participate in the merge, but instead only the compaction-related values are merged.

3.5 Garbage Collection

The vTree rewrites compaction-related values to new vTables (§3.3), so it necessitates garbage collection (GC) to reclaim the space of invalid values (in the LSM-tree, its invalid data is reclaimed via compaction). To reduce the GC overhead, we propose a *state-aware lazy approach* based on the amount of invalid values in each vTable.

State awareness. DiffKV tracks the amount of invalid values in each vTable in a hash table. Each time when a vTable participates in a merge operation, DiffKV counts the amount of values being retrieved from the vTable and updates the amount of invalid values in the old vTable in the hash table. It also inserts an entry for any new vTable in the hash table. The updates to the hash table are executed during a merge operation, so the overhead is limited. Also, each entry in the hash table only occupies few bytes for each vTable, so the memory overhead of the hash table is limited.

Lazy GC. DiffKV takes a lazy approach to limit the GC overhead. It selects a vTable as a GC candidate if the vTable has a fraction of invalid values greater than a predefined threshold (denoted by `gc.threshold`). Note that DiffKV does not immediately reclaim the candidate vTables; instead, it simply marks a *GC tag* for each candidate, and delays the GC until the next compaction-triggered merge. Specifically, if a vTable with a GC tag is involved in a compaction-triggered merge, the values contained in this vTable will always be rewritten to the next higher level (similar to scan-optimized merge).

Lazy GC avoids the extra overhead of querying the LSM-tree for the validity of values in the candidate vTable and updating the LSM-tree for the new locations of the valid values. It is now delayed to be executed together with the merge operation, so that the overhead of querying and updating the LSM-tree can be hidden within the merge operation.

3.6 Discussion

Optimizing compaction at L_0 . As KV separation is executed during flushes, SSTables at level L_0 in the LSM-tree may be very small, especially when KV pairs are large, so we propose a simple optimization called *selective compaction* to aggregate small SSTables at L_0 . Specifically, we trigger intra-level compaction which simply combines multiple small SSTables at L_0 to generate a new large one without merging with SSTables at L_1 . With selective compaction, the size of

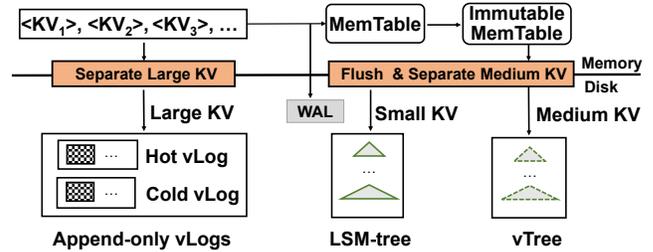

Figure 8: Fine-grained KV separation.

SSTables at L_0 will eventually become comparable to that of SSTables at L_1 , and hence no extra compaction overhead will be introduced due to KV separation.

Crash consistency. DiffKV is implemented on Titan (which builds on RocksDB) (§5), and provides the same level of consistency as RocksDB after system crashes. To guarantee data consistency, DiffKV uses a write-ahead log (WAL), and writes KV pairs to the WAL before writing to the MemTable. Also, DiffKV provides crash consistency for the hash table that records the amount of invalid data in each vTable (§3.5). As the hash table is updated after compaction, DiffKV appends the update information into the manifest file (§3.4) after compaction, so it can be restored when DiffKV recovers from a crash.

4 Fine-grained KV Separation

The benefit of KV separation is significant for large KV pairs, but diminishes for small KV pairs (§2.3). However, mixed workloads with varying value sizes are also common; for example, the value size may vary in a large range under the generalized Pareto distribution [25]. In this section, we further enhance DiffKV via fine-grained KV separation by distinguishing KV pairs by value sizes, so as to achieve balanced performance under mixed workloads.

4.1 Differentiated Value Management

DiffKV classifies KV pairs into three groups based on the value size, by using two parameters, namely `value_small` and `value_large`, as depicted in Figure 8. For KV pairs whose value size is larger than `value_large` (i.e., large KV pairs), DiffKV adopts KV separation, and manages values with a hotness-aware multi-log design called *vLogs*. For KV pairs whose value size is between `value_small` and `value_large` (i.e., medium KV pairs), DiffKV stores values in the vTree and keep both keys and value locations in the LSM-tree. For KV pairs whose value size is smaller than `value_small` (i.e., small KV pairs), DiffKV bypasses KV separation and stores the whole KV pairs directly in the LSM-tree. As a result, DiffKV achieves balanced performance for different value sizes.

Note that for large KV pairs, DiffKV adopts the workflow as in Wiskey [42], in which KV separation is performed before writing to MemTable (see Figure 8). Specifically, DiffKV directly flushes the values of large KV pairs into vLogs, treats their keys and value locations as new KV pairs, and writes

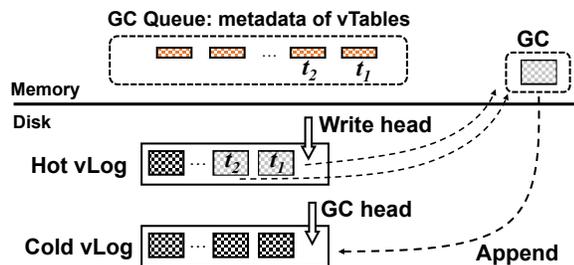

Figure 9: GC for vLogs.

them to MemTable as regular user data. The benefits of performing KV separation early for large KV pairs are two-fold. First, by directly flushing large-size values into vLogs and keeping only small-size value locations in the MemTable, we can save substantial memory space, while still guaranteeing high write performance due to large sequential I/Os. Second, as large-size values are first written to disk, there is no need to write them to the WAL, and this reduces the amount of I/Os. Note that for small and medium KV pairs, as well as the keys and value locations for large KV pairs, they still need to be written to the WAL so as to guarantee consistency (§3.6).

4.2 Hotness-aware vLogs

Structure of vLogs. A vLog is designed as a simple circular append-only log, which consists of a set of *unsorted vTables*. Unsorted vTables share a similar storage format with vTables described in §3.2, and the only difference is that values are written to *unsorted vTables* with append, so they are not sorted even within each unsorted vTable. The reason why we do this is because KV separation for large KV pairs is performed before writing to the MemTable, and values for large KV pairs are flushed to disk immediately after KV separation so as to avoid writing to WAL, so there is no way to sort the values in each vTable (see Figure 8). In fact, there is no need to sort these values as they have a large size, and hence they can already benefit from large I/Os without batched writes.

GC for vLogs. To reduce GC overhead, we leverage a hotness-aware design by employing a simple yet efficient parameter-less hot-cold separation scheme. As shown in Figure 9, we adopt two vLogs, namely a *hot vLog* and a *cold vLog*, to store hot and cold values, respectively. Each vLog has its own write frontier, and we call them *write head* and *GC head*, respectively. To realize hot-cold separation, the data from user writes are appended to the write head in the hot vLog, and the data from GC writes (i.e., the valid values that need to be written back after GC) are appended to the GC head in the cold vLog. The rationale is that the values reclaimed by GC are usually accessed less frequently than the recently written user data, so they can be regarded as cold data. One benefit of this design is that it is simple to implement, as no parameter is required to realize hot-cold identification. Clearly, we can also apply alternative hotness-aware classification schemes.

DiffKV employs a *greedy* algorithm to reduce GC cost, and the idea is to reclaim the unsorted vTables which have

the largest amount of invalid values. Specifically, DiffKV monitors the ratio of invalid values of each unsorted vTable during compaction, and maintains a GC queue in memory to track all candidate vTables, which are the unsorted vTables with the ratio of invalid values being greater than the threshold `gc_threshold`. Note that the GC queue only keeps the metadata of each unsorted vTable, and it is maintained in a descending order according to the ratio of invalid values. When GC is triggered, DiffKV simply selects unsorted vTables tracked in the queue head (e.g., t_1 , and t_2 in Figure 9), then appends the valid values in the selected vTables to the GC head in the cold vLog. For performance consideration, DiffKV implements GC as a background process with multiple GC threads.

5 Evaluation

In this section, we evaluate and compare DiffKV with the three state-of-the-art KV stores introduced in §2.3: RocksDB [24], PebblesDB [52], and Titan [51]. For fair comparisons with Titan, we also implement DiffKV based on it and our modifications contain around 2.1K lines of code.

5.1 Setup

Testbed. We conduct experiments on a single machine equipped with an 12-cores Intel Xeon E5-2650v4 CPU, 16 GB memory, and Samsung 860 EVO 480 GB SSD. The machine runs Ubuntu 18.04 LTS with Linux kernel 4.15.

Workload. We modify YCSB-C [48, 54], a C++ version of YCSB [14], to generate workloads based on the workload statistics in [9]. We fix the key size as 24 bytes, and configure the value size with the generalized Pareto distribution [29], whose probability density function is:

$$f(x) = (1/\sigma)(1 + k(x - \theta)/\sigma)^{-1-1/k} \quad (1)$$

where x represents the value size, k , θ , and σ are adjustable parameters. By default, we limit the maximum value size as 128 KB, and set $k = 0.92$, $\sigma = 226$, $\theta = 0$ by using the most common workload setting in [25]. Under this setting, the average value size is 1 KB.

System configuration. We refer to the official tuning manual for experimental verification [26]. For all KV stores, we use the recommended configuration by setting MemTable size as 64 MB, SSTable size as 16 MB, configure Bloom filters by setting 10 bits/key. Since our testbed machine has 12 cores, to speedup compactions and also limit overall CPU usage, we use 8 background threads for compaction by following the optimization tuning guide. We also allocate 8 GB memory for block cache and leave the rest for page cache in operating system. For Titan, as GC affects both space usage and foreground write performance, we consider three cases: (i) *no GC (No-GC)*, which achieves the best write performance, but incurs the largest space overhead; (ii) *background GC (BG-GC)*, in which GC is executed in the background without blocking foreground writes; and (iii) *foreground GC (FG-GC)*, in which a limit on space usage is set and GC may block

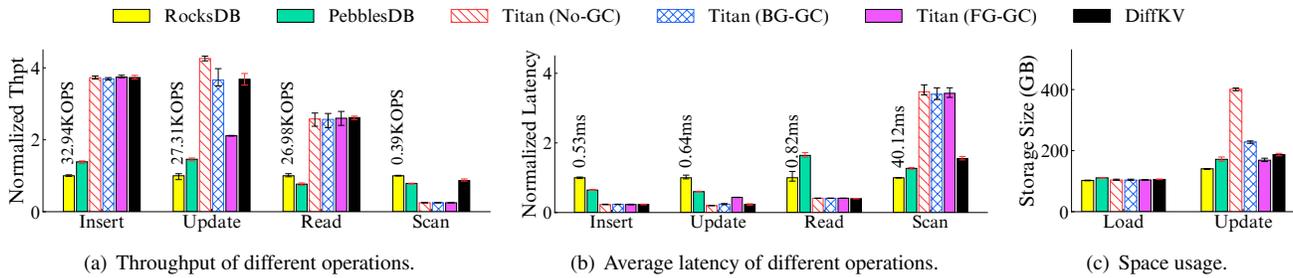

Figure 10: Microbenchmarks on RocksDB, PebblesDB, Titan, and DiffKV.

foreground writes if the free space drops below the predefined limit. For DiffKV, the two thresholds for differentiating small, medium, and large KV pairs are set as 128 bytes and 8 KB, respectively. We limit the vTable size as 8 MB, and set a GC tag to a vTable if it contains more than 30% invalid data. We study the impact of these parameters in §5.6. Each experiment was run at least five times.

5.2 Microbenchmarks

We first study the throughput and latency performance of various KV operations with the following workloads: (i) insert 10 GB KV pairs, (ii) update 300 GB KV pairs, (iii) read 10 GB KV pairs, and (iv) scan 10 GB KV pairs. We first randomly load 100 GB KV pairs, then issue the requests of each workload, and finally clear all KV pairs from the KV store to avoid interference. For scans, we use the widely used configuration for performance evaluation [8, 14, 43, 65], i.e., we issue 16 scan threads, each of which reads 100 KV pairs. We also study the impact of other scan settings in §5.5. By default, we use a Zipf distribution with the skewness parameter 0.9 for each workload. We also run our evaluation under uniform workloads and observe similar conclusions, so we omit the results in the interest of space.

Throughput. Figure 10(a) shows the throughput results, normalized with respect to the throughput of RocksDB for ease of comparison. Compared to RocksDB and PebblesDB, DiffKV achieves $3.8\times$ and $2.7\times$ insert throughput, $3.7\times$ and $2.3\times$ update throughput, $2.6\times$ and $3.4\times$ read throughput, respectively. Thus, DiffKV significantly improves both write and read throughput, with comparable scan performance.

Compared to Titan, DiffKV always improves the scan performance significantly, regardless of the GC policy used in Titan. For example, DiffKV achieves $3.2\times$ scan throughput over Titan. For write performance, even compared to the case of NO-GC (i.e., the case of best write performance for Titan), DiffKV still has similar write performance. Furthermore, compared to the case of using foreground GC in Titan, DiffKV achieves $1.7\times$ update throughput. Note that since the throughput results are evaluated in OPS, the throughput of scans is much lower than that of other operations.

Average latency. Figure 10(b) shows the latency results. Compared to RocksDB and PebblesDB, DiffKV reduces the latency of inserts, updates, and reads by up to 63.8%-78.1%,

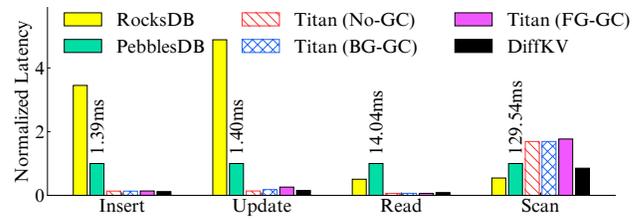

Figure 11: Tail latency of different operations.

Workload	Statistics
A (Update Heavy)	50% updates, 50% reads
B (Read Mostly)	5% updates, 95% reads
C (Read Only)	100% reads
D (Read Latest)	5% inserts, 95% reads
E (Scan Mostly)	5% inserts, 95% scans
F (Read-Modify-Write)	50% read-modify-write, 50% reads

Table 1: YCSB core workloads.

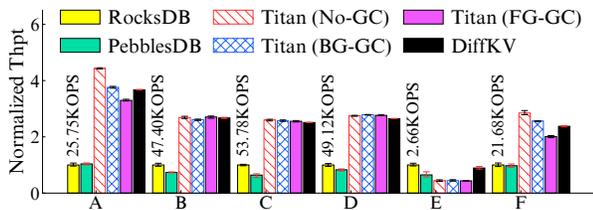

with a similar scan latency. Compared to Titan, DiffKV has similar latencies for inserts, writes, and reads, while reducing the scan latency by up to 43.2%.

Space usage. Figure 10(c) shows the space usage under GC, in which we randomly load 100 GB KV pairs and update 300 GB KV pairs with a Zipf distribution. As no GC is triggered in the load phase, all KV stores show the same space usage. However, after the update phase, Titan incurs large space usage if it disables GC or uses background GC only. DiffKV reduces space usage by up to 18%-53.7% compared to Titan (NO-GC) and Titan (BG-GC).

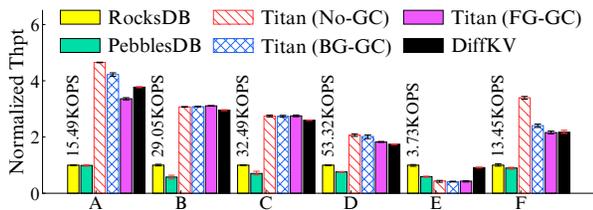

Tail Latency. We evaluate the 99-th percentile tail latency as shown in Figure 11. We normalize the results with respect to PebblesDB. Compared to RocksDB and PebblesDB, DiffKV has a much lower tail latency for inserts, updates, and reads. For example, it reduces the tail latency of inserts, updates, and reads of RocksDB by 96.5%, 94.3%, and 82.7%, respectively, while keeping similar tail latency for scans. Compared to Titan, DiffKV has a similar tail latency for inserts, updates and reads, but reduces the scan tail latency by 50.4%.

5.3 YCSB Evaluation

We show the performance of DiffKV under the YCSB workloads (Table 1). Each workload performs 100M operations on a randomly loaded 100 GB data store, other settings are the same as before. We consider both uniform distribution

(a) Zipfian workload.

(b) Uniform workload.

Figure 12: Performance under YCSB workloads.

and Zipf distribution with parameter 0.9, except workload D which reads the latest data as defined by the benchmark [14].

Throughput. Figure 12 shows the throughput results, normalized with respect to the throughput of RocksDB. Compared to RocksDB, DiffKV achieves 1.7-4.5 \times throughput for all read- or write-intensive workloads (i.e., all except workload E), and achieves similar performance under the scan-dominant workload E. Note that RocksDB has KV pairs fully sorted in each level, so it represents the best case in terms of scan performance. Compared to Titans, DiffKV achieves 2 \times scan throughput, while keeping similar performance under other workloads regardless of whether background GC or foreground GC are used. In short, DiffKV achieves balanced performance in all aspects.

Tail latency. Figure 13 shows the tail latency results. As YCSB workloads are mixed with different operations with highly different latencies, we show the tail latency of each type of operations. We normalize the results with respect to Titan (NO-GC). We observe a similar conclusion as in the case of microbenchmarks. That is, compared to RocksDB and PebblesDB, DiffKV significantly reduces the tail latency of inserts, updates and reads; compared to Titan, DiffKV reduces the tail latency of scans, so it always performs almost the best in all performance aspects.

Space usage. We show the space usage under YCSB workload A, which has 50% updates. We observe similar results as in Figure 10(c), i.e., DiffKV increases the space usage by 11.9% and 0.7% compared to RocksDB and PebblesDB, respectively. Also, the LSM-tree, v Tree, and v Logs incur 5%, 63.5%, and 31.5% of space in DiffKV, respectively.

5.4 Analysis on Merge Optimizations

We evaluate the merge optimization techniques of DiffKV (§3.3-§3.4) and show how they address the write-scan trade-

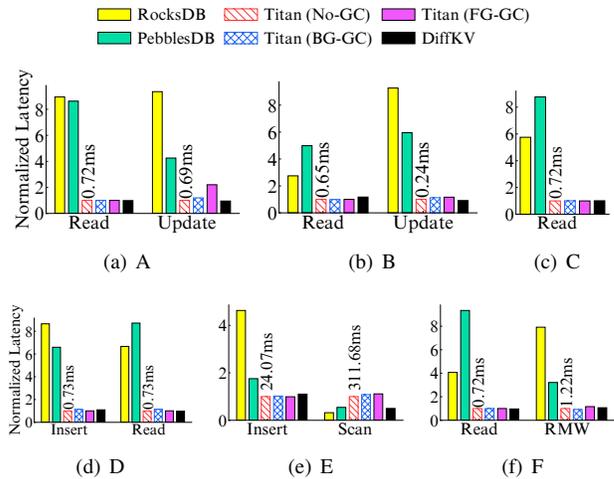

Figure 13: Tail latency of different ops under YCSB workloads.

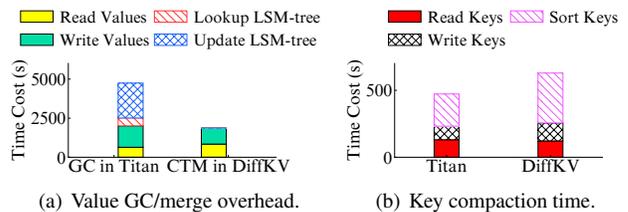

Figure 14: Impact of coordinated value management in DiffKV: it significantly reduces the value merge overhead, and slightly increases key compaction overhead.

off and realize the balanced performance for DiffKV.

We first compare the merge overhead in DiffKV with the GC overhead in Titan. Here, we deploy only the compaction-triggered-merge (CTM) in DiffKV and focus on the effectiveness of the coordinated design. Figure 14(a) shows the time cost breakdown for GC in Titan and merge in DiffKV. We issue a workload of updating 300 GB KV pairs with a Zipf distribution on a randomly loaded 100 GB KV store, using the default background GC for Titan. DiffKV costs much less time than Titan for value management, with a 60.7% reduction of time cost. The time saving mainly comes from the coordinated merge design, in which the overhead of looking up the LSM-tree and updating the new value locations to LSM-tree can be avoided via the compaction-triggered merge. However, as compaction must wait for the completion of the triggered merge, the compaction time slightly increases. Such an overhead can be mitigated via the merge optimizations (i.e., lazy merge and scan-optimized merge).

Figure 15 studies the impact of the merge optimizations. Lazy merge (LM) further reduces the number of merge operations and the amount of merged data size compared to using only the compaction-triggered merge (CTM), by 65.5% and 66.2%, respectively. However, it increases the number of sorted groups in v Tree, which is the key factor of influencing scan performance. For example, lazy merge adds up to 20% sorted groups in the last two levels. By further in-

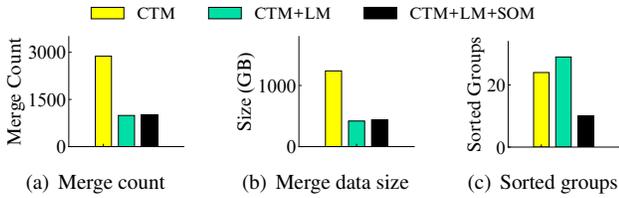

Figure 15: Impact of merge optimizations on merge overhead.

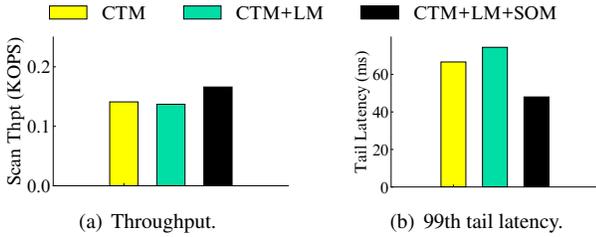

Figure 16: Scan performance.

corporating scan-optimized merge (SOM), the number of sorted groups reduces significantly, by up to 68% compared to lazy merge. Meanwhile, the merge overhead keeps almost the same. Due to the reduced number of sorted groups, the scan performance improves. For example, as shown in Figure 16, scan-optimized merge increases 18% of scan throughput and reduces 27% of the 99th tail latency compared to lazy merge. In summary, by combining lazy merge and scan-optimized merge with the coordinated design, DiffKV guarantees desired ordering for values with limited merge overhead, and hence achieves balanced performance in all aspects.

5.5 Scan Performance

Recall that the main benefit of DiffKV over Titan is its scan improvement. We further examine the scan performance by varying the *scan length* (i.e., the number of KV pairs read by each scan) and the number of scan threads (i.e., the number of threads initiated by clients for concurrent access).

Figure 17(a) shows the scan performance versus the scan length (from 20 to 10000), while fixing the total read size as 10 GB. As GC does not influence scan performance for Titan, we focus on only the case without GC. DiffKV significantly outperforms Titan, and as the scan length increases, the performance gain further increases. The reason is that Titan stores values in an unsorted manner and hence has poor scan performance, while DiffKV maintains a partial ordering for values. Even compared to RocksDB, which represents the optimum for scan, DiffKV still reaches 83% of scan throughput when the scan length is 20, and the ratio further increases to 96% when the scan length increases to 10000. Thus, DiffKV achieves similar scan performance with RocksDB.

Figure 17(b) studies the impact of the number of scan threads (from 8 to 64), while fixing the scan length as 100. DiffKV still significantly outperforms Titan, and achieves comparable performance with RocksDB under all settings.

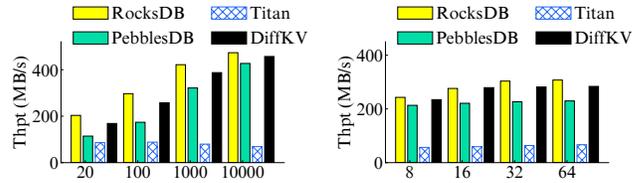

Figure 17: Scan performance under different settings.

Figure 17: Scan performance under different settings.

5.6 Tunable Parameters

We analyze the sensitivity of the parameters in DiffKV. First, the parameter `value_small` is used to differentiate small and medium KV pairs. In other words, for each value size, if KV separation brings no benefit to write, then we should treat this kind of KV pairs as small ones and keep them in the LSM-tree; otherwise, we should leverage KV separation and store values in `vTree`. Thus, to find an appropriate setting for parameter `value_small`, we compare the write performance of using the LSM-tree and the `vTree` under different value sizes. Figure 18(a) shows the load throughput versus the value size. When the value size is at least 128 bytes, using the `vTree` improves write performance (i.e., KV separation is beneficial). Thus, we set `value_small` as 128 bytes by default.

Second, we justify how to set an appropriate value for `value_large`, which influences both the write and scan performance. A smaller `value_large` means more KV pairs are regarded as large ones and stored in `vLogs`. We focus on a mixed workload generated with the default parameters (§5.1), and show the write and scan performance by varying `value_large` from 1 KB to 32 KB. As shown in Figure 18(b), when `value_large` increases from 8 KB to 32 KB, the marginal improvement of the scan performance is very limited. This implies that managing KV pairs whose value sizes are larger than or equal to 8 KB with `vLogs` only slightly degrades the scan performance. On the other hand, for write throughput, compared to the case of setting `value_large` as 1 KB, it already achieves around 80% of the throughput when the parameter is set as 8 KB. Thus, we set `value_large` as 8 KB by default.

Third, the parameter `max_sorted_run` controls the number of sorted groups in each of the last two levels in `vTree`, so it influences the scan performance and merge overhead, i.e., it determines the write-scan trade-off. Figure 18(c) shows the write-scan trade-off by varying `max_sorted_run` from 15 to one. Here, we run a workload which scans 10 GB data on a randomly loaded 100 GB data store and each scan requests 100 KV pairs. When there are more than 10 sorted groups in each level, both the write and scan performance change slowly, so we set `max_sorted_run` as 10 by default.

Finally, we study the impact of `gc_threshold` on write performance and space usage. Recall that a `vTable` will be set with a GC tag if its invalid data exceeds the threshold defined by `gc_threshold`, so a smaller `gc_threshold` means more frequent GC, and both the write performance and space usage should

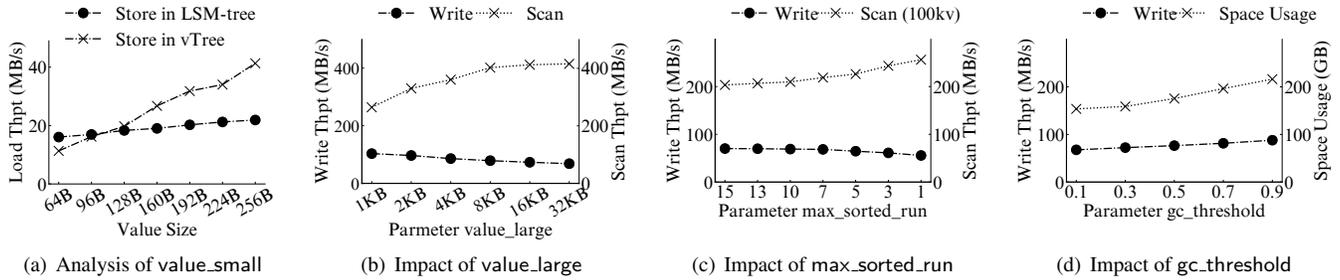

Figure 18: Empirical study on tunable parameters in DiffKV. Figure (a) justifies the setting of `value_small` by comparing the write performance of using LSM-tree and vTree under different value sizes. Figure (b) justifies the setting of `value_large` by studying its impact on write and scan performance. Figure (c) justifies the setting of `max_sorted_run`. Figure (d) shows the impact of `gc_threshold`.

decrease. Figure 18(d) shows the results. As `gc_threshold` increases, the increased write throughput becomes smaller. This implies that with the lazy GC, the impact of GC on write performance is limited. On the other hand, the space usage significantly increases (from 158.8 GB to 216.2 GB) when we increase `gc_threshold` from 0.3 to 0.9. Thus, we set `gc_threshold` as 0.3 by default.

6 Related Work

Research on KV stores has received a lot of attentions. In addition to building KV stores on new hardware like non-volatile memory [12, 13, 21, 34–36, 39, 44, 61] or characterizing real-world KV workloads [5, 9], many studies focus on optimizing the read/write performance of LSM-tree KV stores [6, 10, 15, 16, 32, 40, 42, 52, 56, 58, 62, 63].

Extensive efforts focus on reducing the compaction overhead of LSM-tree KV stores. One line of studies follows the idea of relaxing the fully-sorted ordering of KV pairs. PebblesDB [52] proposes a fragmented LSM-tree that relaxes the fully-sorted ordering of KV pairs by dividing each level into multiple non-overlapped segments and allowing KV pairs within each segment to be unsorted. dCompaction [47] delays compaction by constructing virtual SSTables that contain only metadata for multiple SSTables with overlapped ranges, and it can also be regarded as a relaxation of the fully-sorted ordering of KV pairs. Dostoevsky [17] introduces a lazy-leveling merge policy by adopting the leveling policy only for the last level and using tiering for other levels. The ideas of relaxing the fully-sorted ordering are also found in VT-Tree [57], LWC-tree [60], SlimDB [55], and SifrDB [45].

Another line of studies of mitigating the write amplification problem is KV separation. WiscKey [42] is the first work that proposes this technique by storing values in a separate append-only circular log, and Bourbon [15] extends WiscKey by integrating a learning approach for indexing the values. Based on KV separation, a lot of efforts are made to reduce the overhead of log management for values, especially the GC overhead [10, 20, 49, 51]. HashKV [10] leverages hash-based data grouping so as to reduce the GC cost of the circular log. BadgerDB [20] reuses the write-ahead log (WAL) as a value log, so as to save the data flush overhead. Titan [51] adopts KV

separation and leverage BLOB files for value management. We point out that all these studies follow the design of append-only logs for value management. In contrast, DiffKV proposes the vTree for maintaining the partially-sorted ordering for values, so as to realize balanced I/O performance.

Multiple studies also leverage hash indexing or optimize the Bloom filter to improve read and write performance. For hash indexing, LSM-trie [58] utilizes a hash-based trie structure to improve the performance for small KV pairs, while UniKV [63] unifies hash indexing and the LSM-tree to simultaneously improve both read and write performance. For the Bloom filter optimization, Monkey [16] proposes to differentiate Bloom filters between different levels; ElasticBF [40] further develops a fine-grained elastic Bloom filter scheme to improve read performance; SuRF [62] introduces a succinct range filter to optimize both reads and scans.

Unlike existing studies that usually possess performance trade-offs, DiffKV aims to realize balanced I/O performance by simultaneously improving the performance of writes, reads, and scans. DiffKV adopts KV separation, and takes one step further to adopt a new vTree structure with a coordinated design to realize the differentiated ordering for keys and values. It also adopts fine-grained KV separation, so as to realize balanced performance under mixed workloads.

7 Conclusion

In this paper, we propose to leverage differentiated ordering for keys and values to simultaneously achieve high performance for writes, reads, and scans. We develop DiffKV, which follows KV separation and utilizes a new structure vTree for value management with a partial ordering. By leveraging a coordinated design and multiple merge optimizations, DiffKV achieves efficient writes, reads, and scans with low storage cost, and thus realizes balanced performance in all aspects.

Abstract

The Zoned Namespace (ZNS) interface represents a new division of functionality between host software and flash-based SSDs. Current flash-based SSDs maintain the decades-old block interface, which comes at substantial expense in terms of capacity over-provisioning, DRAM for page mapping tables, garbage collection overheads, and host software complexity attempting to mitigate garbage collection. ZNS offers shelter from this ever-rising *block interface tax*.

This paper describes the ZNS interface and explains how it affects both SSD hardware/firmware and host software. By exposing flash erase block boundaries and write-ordering rules, the ZNS interface requires the host software to address these issues while continuing to manage media reliability within the SSD. We describe how storage software can be specialized to the semantics of the ZNS interface, often resulting in significant efficiency benefits. We show the work required to enable support for ZNS SSDs, and show how modified versions of `f2fs` and `RocksDB` take advantage of a ZNS SSD to achieve higher throughput and lower tail latency as compared to running on a block-interface SSD with identical physical hardware. For example, we find that the 99.9th-percentile random-read latency for our zone-specialized `RocksDB` is at least 2–4× lower on a ZNS SSD compared to a block-interface SSD, and the write throughput is 2× higher.

1 Introduction

The *block interface* presents storage devices as one-dimensional arrays of fixed-size logical data blocks that may be read, written, and overwritten in any order. Introduced initially to hide hard drive media characteristics and to simplify host software, the block interface worked well for many generations of storage devices and allowed great innovation on both sides of the storage device interface. There is a significant mismatch, however, between the block interface and current storage device characteristics.

For flash-based SSDs, the performance and operational costs of supporting the block interface are growing prohibitively [22]. These costs are due to a mismatch between the operations allowed and the nature of the underlying flash media. Although individual logical blocks can be written to flash, the medium must be erased at the granularity of larger

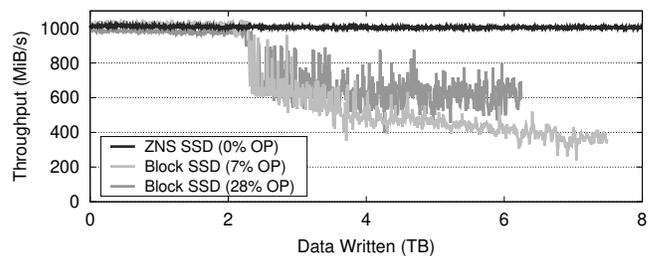

Figure 1: Throughput of a multi-threaded write workload that overwrites usable SSD capacity four times. The SSDs all have 2 TB raw media and share the same hardware platform.

units called *erase blocks*. The SSD’s Flash Translation Layer (FTL) hides this mismatch by using substantial DRAM for dynamic logical-to-physical page mapping structures, and by reserving substantial fractions (*over-provisioning*) of the drive’s media capacity to lower the garbage-collection overhead of erase-block data. Despite these efforts, garbage collection often results in throughput limitations [17], write-amplification [3], performance unpredictability [33, 64], and high tail latencies [16].

The NVMe Zoned Namespace Command Set specification [8], or ZNS for short, has recently been introduced as a new interface standard for flash-based SSDs. Instead of a single array of logical blocks, a ZNS SSD groups logical blocks into *zones*. A zone’s logical blocks can be read in random order but must be written sequentially, and a zone must be erased between rewrites. A ZNS SSD aligns zone and physical media boundaries, shifting the responsibility of data management to the host. This obviates the need for in-device garbage collection and the need for resource and capacity over-provisioning (OP). Further, ZNS hides device-specific reliability characteristics and media-management complexities from the host software.

Figure 1 illustrates some of the costs of the block interface and the corresponding potential benefits of ZNS. The three lines represent throughput for identical SSD hardware exposed as a ZNS SSD (0% OP) and as a block-interface SSD (measured with 7% OP and 28% OP), while concurrently overwriting the drive’s usable capacity 4 times. All three SSDs provide high throughput for the first 2TB (which is their raw capacity), but then the block-interface SSD expe-

periences a sharp drop in throughput as in-device garbage collection kicks in. As expected, due to the reduction in garbage collection overhead, 28% OP provides higher steady-state write throughput than 7% OP. The ZNS SSD sustains high throughput by avoiding in-device garbage collection and offers more usable capacity (see line length) by eliminating the need for over-provisioning.

This paper describes the ZNS interface and how it avoids the block interface tax (§2). We describe the responsibilities that ZNS devices jettison, enabling them to reduce performance unpredictability and significantly eliminate costs by reducing the need for in-device resources (§3.1). We also describe an expected consequence of ZNS: the host's responsibility for managing data in the granularity of erase blocks. Shifting FTL responsibilities to the host is less effective than integrating with the data mapping and placement logic of storage software, an approach we advocate (§3.2).

Our description of the consequences and guidelines that accompany ZNS adoption is grounded on a significant and concerted effort to introduce ZNS SSD support in the Linux kernel, the fio benchmark tool, the f2fs file system, and the RocksDB key-value store (§4). We describe the software modifications required in each use case, all of which have been released as open-source to foster the growth of a healthy community around the ZNS interface.

Our evaluation shows the following ZNS interface advantages. First, we demonstrate that a ZNS SSD achieves up to $2.7\times$ higher throughput than block-interface SSDs in a concurrent write workload, and up to 64% lower average random read latency even in the presence of writes (§5.1). Second, we show that RocksDB on f2fs running on ZNS SSD achieves at least $2\text{--}4\times$ lower 99.9th-percentile random read latency than RocksDB on file systems running on block-interface SSDs. RocksDB running directly on a ZNS SSD using ZenFS, a zone-aware backend we developed, achieves up to $2\times$ higher throughput than RocksDB on file systems running on block-interface SSDs (§5.2).

The paper consists of five key contributions. We present the first evaluation of a production ZNS SSD in a research paper, directly comparing it to a block-interface SSD using the same hardware platform, and optional multi-stream support. Second, we review the emerging ZNS standard and its relation to prior SSD interfaces. Third, we describe the lessons learned adapting host software layers to utilize ZNS SSDs. Fourth, we describe a set of changes spanning the whole storage stack to enable ZNS support, including changes to the Linux kernel, the f2fs file system, the Linux NVMe driver and Zoned Block Device subsystem, the fio benchmark tool, and the development of associated tooling. Fifth, we introduce ZenFS, a storage backend for RocksDB, to showcase the full performance of ZNS devices. All code changes are open-sourced and merged into the respective official codebases.

2 The Zoned Storage Model

For decades, storage devices have exposed their host capacity as a one-dimensional array of fixed-size data blocks. Through this *block interface*, data organized in a block could be read, written, or overwritten in any order. This interface was designed to closely track the characteristics of the most popular devices at the time: hard disk drives (HDDs). Over time, the semantics provided by this interface became an unwritten contract that applications came to depend on. Thus, when SSDs were introduced, they shipped with complex firmware (FTL) that made it possible to offer the same block interface semantics to applications even though they were not a natural fit for the underlying flash media.

The Zoned Storage model, originally introduced for Shingled Magnetic Recording (SMR) HDDs [19, 20, 35], was born out of the need to create storage devices free of the costs associated with block interface compatibility. We detail those costs with respect to SSDs (§2.1), and then continue to describe existing improvements to the block interface (§2.2) and the basic characteristics of zoned storage (§2.3).

2.1 The Block Interface Tax

Modern storage devices, such as SSDs and SMR HDDs, rely on recording technologies that are a mismatch for the block interface. This mismatch results in performance and operational costs. On a flash-based SSD, an empty flash page can be programmed on a write, but overwriting it requires an erase operation that can occur only at the granularity of an *erase block* (a set of one or more flash blocks, each comprising multiple pages). For an SSD to expose the block interface, an FTL must manage functionality such as in-place updates using a write-anywhere approach, mapping host logical block addresses (LBAs) to physical device pages, garbage collecting stale data, and ensuring even wear of erase blocks.

The FTL impacts performance and operational costs considerably. To avoid the media limitations for in-place updates, each LBA write is directed to the next available location. Thus, the host relinquishes control of physical data placement to the FTL implementation. Moreover, older, stale versions of the data must be garbage collected, leading to **performance unpredictability** [1, 10] for ongoing operations.

The need for garbage collection necessitates the allocation of physical resources on the device. This requires media to be over-provisioned by up to 28% of the total capacity, in order to stage data that are being moved between physical addresses. Additional DRAM is also required to maintain the volatile mappings between logical and physical addresses. Capacity over-provisioning and DRAM are the most expensive components in SSDs [18, 57], leading to **higher cost per gigabyte of usable capacity**.

2.2 Existing Tax-Reduction Strategies

Two major approaches for reducing the block interface tax have gained traction: SSDs with stream support (Stream

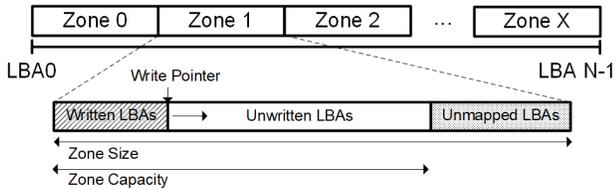

Figure 2: Zones within the LBA address space of a storage device. A write pointer per zone increases on successful writes, and is reset by issuing an explicit reset command.

SSDs) and Open-Channel SSDs (OCSSDs).

Stream SSDs allow the host to mark its write commands with a stream hint. The stream hint is interpreted by the Stream SSD, allowing it to differentiate incoming data onto distinct erase blocks [32] which *improves the overall SSD performance and media lifetime*. Stream SSDs require that the host carefully marks data with similar lifetimes in order to reduce garbage collection. If the host mixes data of different lifetimes into the same stream, Stream SSDs behave similarly to block-interface SSDs. A Stream SSD must carry the resources to manage such an event, so *Stream SSDs do not shed the costs of block-interface SSDs for extra media over-provisioning and DRAM*. We compare the performance of a Streams SSD with a ZNS SSD in §5.3.

Open-Channel SSDs allow host and SSD to collaborate through a set of contiguous LBA chunks [9, 38, 46, 60]. OCSSDs can expose these chunks such that they align with the physical erase block boundaries of the media. This eliminates in-device garbage collection overhead and reduces the cost of media over-provisioning and DRAM. With OCSSDs, the host is responsible for data placement. This includes underlying media reliability management such as wear-leveling, and specific media failure characteristics (depending on the OCSSD type). This has the potential to improve SSD performance and media lifetime over Stream SSDs, but *the host must manage differences across SSD implementations to guarantee durability*, making the interface hard to adopt and requiring continual software upkeep.

The ZNS interface, which we describe next, builds on the lessons of OCSSDs and SMR HDDs. It utilizes, and is compatible with, the zoned storage model defined in the ZAC/ZBC [28, 29] specifications. It adds features to take advantage of the characteristics of flash-based SSDs. ZNS aims to eliminate the mismatch between SSD media and the device interface. It also provides a media-agnostic next-generation storage interface by avoiding to directly manage media-specific characteristics like OCSSD [59].

2.3 Tax-free Storage with Zones

The fundamental building block of the zoned storage model is a *zone*. Each zone represents a region of the logical address space of the SSD that can be read arbitrarily but must be writ-

ten sequentially, and to enable new writes, must be explicitly reset. The write constraints are enforced by a per-zone state machine and a write pointer.

A per-zone *state machine* determines whether a given zone is writeable using the following states: EMPTY, OPEN, CLOSED, or FULL. Zones begin in the EMPTY state, transition to the OPEN state upon writes, and finally transition to FULL when fully written. The device may further impose an open zone limit on the number of zones that can simultaneously be in the OPEN state, e.g., due to device resource or media limitations. If the limit is reached and the host attempts to write to a new zone, another zone must be transitioned from the OPEN to the CLOSED state, freeing on-device resources such as write buffers. The CLOSED zone is still writeable, but must be transitioned to the OPEN state again before serving additional writes.

A zone’s *write pointer* designates the next writeable LBA within a writeable zone and is only valid in the EMPTY and OPEN states. Its value is updated upon each successful write to a zone. Any write commands issued by the host that (1) do not begin at the write pointer, or (2) write to a zone in the FULL state will fail to execute. When a zone is reset, through the reset zone command, the zone is transitioned to the EMPTY state, its write pointer is updated to the zone’s first LBA, and the previously written user data is no longer accessible. The zone’s state and write pointer eliminate the need for host software to keep track of the last LBA written to a zone simplifying recovery, e.g., after an improper shutdown.

Whilst the write constraints are fundamentally the same across zoned storage specifications, the ZNS interface introduces two concepts to cope with the characteristics of flash-based SSDs.

The *writeable zone capacity* attribute allows a zone to divide its LBAs into writeable and non-writeable, and allows a zone to have a writeable capacity smaller than the zone size. This enables the zone size of ZNS SSDs to align with the power-of-two zone size industry norm introduced with SMR HDDs. Figure 2 shows how zones can be laid out over the logical address space of a ZNS SSD.

The *active zone limit* adds a hard limit on zones that can be in either the OPEN or CLOSED state. Whereas SMR HDDs allow all zones to stay in a writeable state (i.e., CLOSED), the characteristics of flash-based media, such as program disturbs [15], require this quantity to be bounded for ZNS SSDs.

Although the ZNS interface increases the responsibilities of host software, our study shows various use cases can benefit from a set of techniques (§3.2) that ease its adoption.

3 Evolving towards ZNS

This section outlines aspects of ZNS SSDs that affect application performance, both in terms of hardware impact (§3.1) and adapting host applications to the ZNS interface (§3.2).

3.1 Hardware Impact

ZNS SSDs relinquish responsibilities traditionally carried out by the FTL, associated with supporting random writes. The ZNS interface enables the SSD to translate sequential zone writes into distinct erase blocks, thus eliminating the interface-media mismatch. Since random writes are disallowed by the interface and zones must be explicitly reset by the host, the data placement managed by the device occurs at the coarse-grained level of zones. This means that the SSD garbage collection routine responsible for moving valid data between erase blocks (to free up writeable capacity) becomes the responsibility of the host. This implies that write amplification on the device is eliminated, which eliminates the need for capacity over-provisioning, while also improving the overall performance and lifetime of the media [17, 23]. We quantify these benefits in §5.

While ZNS offers significant benefits for the end-user, it introduces the following tradeoffs in the design of the SSD's FTL.

Zone Sizing. There is a direct correlation between a zone's write capacity and the size of the erase block implemented by the SSD. In a block-interface SSD, the erase block size is selected such that data is striped across multiple flash dies, both to gain higher read/write performance, but also to protect against die-level and other media failures through per-stripe parity. It is not uncommon for SSDs to have a stripe that consists of flash blocks from 16-128 dies, which translates into a zone with writeable capacity from hundreds of megabytes to low single-digit gigabytes. Large zones reduce the degrees of freedom for data placement by the host, so we argue for the smallest zone size possible, where die-level protection is still provided, and adequate per-zone read/write performance is achieved at low I/O queue depths. If the end-user is willing to compromise on data reliability, the stripe-wide parity can be removed, and thus smaller writeable sizes can be achieved, but at the expense of host complexity, such as host-side parity calculation and deeper I/O queue depths to get the same performance as ZNS SSDs with larger zones or block-interface SSDs.

Mapping Table. In block-interface SSDs, the FTL maintains a fully-associative mapping table [21] between LBAs and their physical locations. This fine-grained mapping improves garbage collection performance, but the table size often requires 1GB of mappings per 1TB of media capacity. For consumer and enterprise SSDs, mappings are typically stored within device DRAM, whereas embedded SSDs may deploy a caching scheme at the expense of lower performance. Because ZNS SSD zone writes are required to be sequential, we can transition from complex, fully-associative mapping tables to coarse-grained mappings maintained either entirely at the erase block level [34] or in some hybrid fashion [31, 48]. As these mappings account for the largest usage of DRAM on an SSD, this can significantly reduce or even completely

eliminate the need for DRAM.

Device Resources. A set of resources is associated with each partially-written erase block (i.e., active zone). This set includes hardware resources, such as XOR engines, memory resources, such as SRAM or DRAM, and power capacitors to persist parity data following a power failure. The data and parity can range from hundreds of kilobytes to megabytes, e.g., due to two-step programming [13]. Due to these requirements and associated costs, ZNS SSDs are expected to have 8-32 active zones. Although the number of active zones can be further increased by adding extra power capacitors, utilizing DRAM for data movement, reduce parity requirements, or deploying a form of write-back cache (e.g., SLC).

3.2 Host Software Adoption

We now discuss three approaches for adapting host software to the ZNS interface. Applications that perform mostly sequential writes are prime candidates for adopting ZNS, such as Log Structure Merge (LSM) tree-based databases. Applications that primarily perform in-place updates are more challenging to support without fundamental modifications to core data structures [47].

Host-side FTL (HFTL). An HFTL acts as a mediator between (1) a ZNS SSD's write semantics and (2) applications performing random writes and in-place updates. The HFTL layer is similar to the responsibilities of the SSD FTL, but the HFTL layer manages only the translation mapping and associated garbage collection. Although it has less responsibility than an SSD FTL, an HFTL must manage its utilization of CPU and DRAM resources because it shares them with host applications. An HFTL makes it easier to integrate host-side information and enhances control of data placement and garbage collection, while also exposing the conventional block interface to applications. Existing work, such as dm-zoned [44], dm-zap [24], pblk [9], and SPDK's FTL [40], shows the feasibility and applicability of an HFTL, but only dm-zap currently supports ZNS SSDs.

File Systems. Higher-level storage interfaces (such as the POSIX file system interface) enable multiple applications to access storage by means of common file semantics. By integrating zones with higher layers of the storage stack, i.e., ensuring a primarily sequential workload, we eliminate the overhead that is otherwise associated with both HFTL and FTL data placement [30], as well as the indirection overhead [64] associated with them. This also allows additional data characteristics known to higher storage stack layers to be used to improve on-device data placement (at least to the degree that the application's actual workload allows this information to permeate to such layers).

The bulk of the file systems developed today primarily perform in-place writes and are generally difficult to adapt to the Zoned Storage model. Some file systems, however, such as f2fs [36], btrfs [53], and zfs [41] exhibit overly-sequential

write patterns and are already adapting so that they can support zones [4, 43]. Although not all of their writes are sequential (such as superblock and some metadata writes), file systems like these can be extended with strict log-structured writes [43], a floating superblock [4], and similar functionality to bridge the gap. These file systems effectively mimic the HFTL logic (with the LBA mapping table managed on-disk through metadata) while also implementing garbage collection to defragment data and free up space for new writes. Although zone support exists for f2fs and btrfs, they support only the zone model that is defined in ZAC/ZBC. As part of this work, we implement the necessary changes to f2fs to showcase the relative ease of supporting ZNS’s zone model, and evaluate its performance (§4.1).

End-to-End Data Placement. In an ideal world, zone-write semantics would be aligned with an application’s existing data structures. This would allow the highest degree of freedom by enabling the application to manage data placement, while at the same time eliminating indirection overheads from file-system and translation layers. While end-to-end data placement enables a collaboration between the application and ZNS SSD, and has the potential to achieve the best write amplification, throughput, and latency improvements, it is as daunting as interacting with raw block devices.

File semantics are a useful abstraction, and by forgoing them one must not only integrate zone support, but also provide tools for the user to perform inspection, error checking, and backup/restore operations. Like file systems, applications that exhibit sequential write patterns are prime candidates for end-to-end integration. This includes LSM-tree-based stores such as RocksDB, caching-based stores such as CacheLib [7], and object stores such as Ceph SeaStore [55]. To showcase the benefits of end-to-end integration, we introduce ZenFS, a new RocksDB zoned storage backend and compare it to both (1) the XFS file system and (2) the f2fs file system, with and without integrated ZNS support.

4 Implementation

We have added support to four major software projects to evaluate the benefits of ZNS. First, we made modifications to the Linux kernel to support ZNS SSDs. Second, we modified the f2fs file system to evaluate the benefits of zone integration at a higher-level storage stack layer. Third, we modified the fio [6] benchmark to support the newly added ZNS-specific attributes. Fourth, we developed ZenFS [25], a novel storage backend for RocksDB that allows control of data placement through zones, to evaluate the benefits of end-to-end integration for zoned storage. We describe the relatively few changes necessary to support ZNS when building upon the existing ZAC/ZBC support for the first three projects [5, 42, 52] (§4.1) and finally detail the architecture of ZenFS (§4.2).

Table 1 shows the lines modified for each software project. All the modifications have been contributed and accepted into the respective codebases [12, 25, 50, 51].

Project	Lines Added	Lines Removed
Linux Kernel	647	53
f2fs (kernel)	275	37
f2fs (mkfs tool)	189	15
fio	342	58
ZenFS (RocksDB)	3276	2
Total	4729	165

Table 1: Lines modified across projects to add ZNS support.

4.1 General Linux Support

The Linux kernel’s Zoned Block Device (ZBD) subsystem is an abstraction layer that provides a single unified zoned storage API on top of various zoned storage device types. It provides both an in-kernel API and an ioctl-based user-space API supporting device enumeration, report of zones, and zone management (e.g., zone reset). Applications such as fio utilize the user-space API to issue I/O requests that align with the write characteristics of the underlying zoned block device, regardless of its low-level interface.

To add ZNS support to the Linux kernel and the ZBD subsystem, we modified the NVMe device driver to enumerate and register ZNS SSDs with the ZBD subsystem. To support the ZNS SSD under evaluation, the ZBD subsystem API was further extended to expose the per zone capacity attribute and the active zones limit.

Zone Capacity. The kernel maintains an in-memory representation of zones (a set of zone descriptor data structures), which is managed solely by the host unless errors occur, in which case the zone descriptors should be refreshed from the specific disk. The zone descriptor data structure is extended with a new zone capacity attribute and versioning, allowing host applications to detect the availability of this new attribute.

Both fio and f2fs are updated to recognize the new data structure. Whereas fio simply had to avoid to issue write I/Os beyond the zone capacity, f2fs required additional changes.

f2fs manages capacity at the granularity of segments, typically 2MiB chunks. For zoned block devices f2fs manages multiple segments as a section, the size of which is aligned to the zone size. f2fs writes sequentially across a section’s segments, and partially writeable zones are not supported. To add support for the zone capacity attribute in f2fs, the kernel implementation, and associated f2fs-tools, two extra segment types are added to the three conventional segment types (i.e., free, open, and full): an *unusable* segment type that maps the unwriteable part of a zone, and a *partial* segment type that covers the case where a segment’s LBAs cross both the writeable and the unwriteable LBAs of a zone. The partial segment type explicitly allows optimizing for the case when segment chunk size and the zone capacity of a specific zone are unaligned, utilizing all of the writeable capacity of a zone.

To allow backward compatibility for SMR HDDs, which do not expose zone capacity, the zone capacity is initialized

to the zone size attribute.

Limiting Active Zones. Due to the nature of flash-based SSDs, there is a strict limit on the number of zones that can be active simultaneously, i.e., either in OPEN or CLOSED state. The limit is detected upon zoned block device enumeration, and exposed through the kernel and user-space APIs. SMR HDDs do not have such a limit and the attribute is initialized to zero (read: infinity).

No modifications were made to fio to support the limit, so it is the responsibility of the fio user to respect the active-limit constraint, which otherwise results in an I/O error when no more zones can be opened.

For f2fs, the limit is linked to the number of segments that can be open simultaneously. f2fs limits this to a maximum of 6, but can be reduced to align with the available active zone limit. This limit is set at the time the file system is created, and f2fs-tools is modified to check for the zone active limit, and if the zoned block device does not support enough active zones, the number of open segments is configured to align with what is available by the device.

f2fs requires its metadata to be stored on a conventional block device, necessitating a separate device. We do not directly address this in our modifications, as the evaluated ZNS SSD exposes a fraction of its capacity as a conventional block device. If this is not supported by the ZNS SSD, write-in-place functionality can be added similar to btrfs [4], or a small translation layer [24] can expose a limited set of zones on the ZNS SSD through the conventional block interface. Note that the Slack Space Recycling (SSR) feature (i.e., random writes) is disabled for all zoned storage devices, which decreases the overall performance. However, due to overall higher performance achieved by ZNS SSDs, we demonstrate superior performance to block-interface SSDs which have SSR enabled (§5.2).

4.2 RocksDB Zone Support

In this section we show how to adapt the popular key-value database RocksDB to perform end-to-end data placement onto zoned storage devices using the ZenFS storage backend. ZenFS takes advantage of the log-structured merge (LSM) tree [45] data structure of RocksDB that it uses to store and maintain its data, and its associated immutable sequential-only compaction process.

The LSM tree implementation consists of multiple levels, as shown in Figure 3. The first level (L_0) is managed in-memory and flushed to the level below periodically or when full. Intermediate updates between flushes are made durable using a Write-Ahead Log (WAL). The rest of the levels (L_1, \dots, L_n) are maintained on-disk. New or updated key-value data pairs are initially appended to L_0 , and upon flush the key-value data pairs are sorted by key, and then written to disk as a Sorted String Table (SST) file.

The size of a level is typically fitted to a multiple of the level above, and each level contains multiple SSTs with each

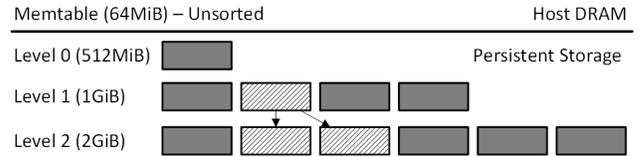

Figure 3: Data organization in RocksDB. Dark grey squares represent SSTs. Light grey with lines squares represent SSTs selected for compaction.

SST containing an ordered set of non-overlapping key-value data pairs. Through an explicit compaction process, an SST's key-value data pairs are merged from one level (L_i) to the next (L_{i+1}). The compaction process reads key-value data pairs from one or more SSTs and merges them with the key-value pairs from one or more SSTs in the next level. The merged result is stored in a new SST file and replaces the merged SSTs in the LSM tree. As a result of this process, SST files are immutable, written sequentially, and created/removed as a single unit. Furthermore, hot/cold data separation is achieved as key-value data pairs are merged into levels below.

RocksDB has support for separate storage backends through its file system wrapper API that is a unified abstraction for RocksDB to access its on-disk data. At its core, the wrapper API identifies data units, such as SST files or Write-Ahead Log (WAL), through a unique identifier (e.g., a filename) that maps to a byte-addressable linear address space (e.g., a file). Each identifier supports a set of operations (e.g., add, remove, current size, utilization) in addition to random access and sequential-only byte-addressable read and write semantics. These are closely related to file system semantics, where identifier and data is accessible through files, which is RocksDB's main storage backend. By using a file system that manages files and directories, RocksDB avoids managing file extents, buffering, and free space management, but also loses the ability to place data directly into zones, which prevents end-to-end data placement onto zones, and therefore reduces the overall performance.

4.2.1 ZenFS Architecture

The ZenFS storage backend implements a minimal on-disk file system and integrates it using RocksDB's file-wrapper API. It carefully places data into zones while respecting their access constraints, and collaborates with the device-side zone metadata on writes (e.g., write pointer), reducing complexity associated with durability. The main components of ZenFS are depicted in Figure 4 and described below.

Journaling and Data. ZenFS defines two types of zones: journal and data zones. The journal zones are used to recover the state of the file system, and maintains the superblock data structure, and mapping of WAL and data files to zones, whereas the data zones store the file content.

Extents. RocksDB's data files are mapped and written to a

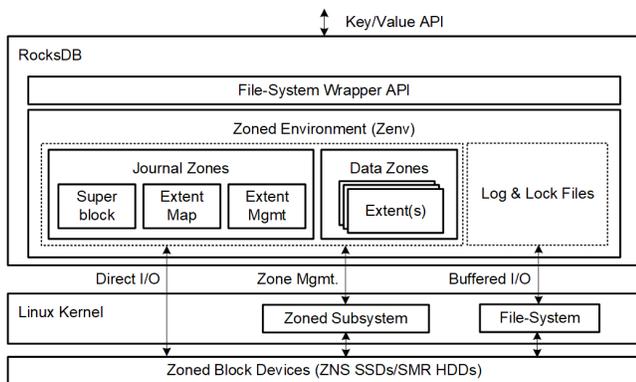

Figure 4: ZenFS Architecture

set of extents. An *extent* is a variable-sized, block-aligned, contiguous region that is written sequentially to a data zone, containing data associated to a specific identifier. Each zone can store multiple extents, but extents do not span zones. Extent allocation and deallocation events are recorded in an in-memory data structure and written to the journal when a file is closed or the data is requested to be persisted by RocksDB through an `fsync` call. The in-memory data structure keeps track of the mapping of extents to zones, and once all files with allocated extents in a zone has been deleted the zone can be reset and reused.

Superblock. The superblock data structure is the initial entry point when initializing and recovering ZenFS state from disk. The superblock contains a unique identifier for the current instance, magic value, and user options. A unique identifier (UUID) in the superblock allows the user to identify the file-system even if the order of block device enumeration on the system changes.

Journal. The responsibility of the journal is to maintain (1) the superblock and (2) the WAL and data file to zone translation mapping through extents.

The journal state is stored on dedicated journal zones, and is located on the first two non-offline zones of a device. At any point in time, one of the zones are selected as the active journal zone, and is the one that persists updates to the journal state. A journal zone has a header that is stored at the beginning of the specific zone. The header stores a sequence number (incremented each time a new journal zone is initialized), the superblock data structure, and a snapshot of the current journal state. After the header are stored, the remaining writable capacity of the zone is used to record updates to the journal.

To recover the journal state from disk, three steps are required: ① the first LBA for each of the two journal zones must be read to determine the sequence number of each, where the journal zone with the highest value is the current active zone; ② the full header of the active zone is read and initializes the initial superblock and journal state; and finally ③

SST file size	128 MiB	256 MiB	512 MiB
Write Amp.	11.9×	12.0×	12.0×
Runtime (s)	15,430	15,461	14,918
99.99 RW lat (ms)	102	102	105
99.99 RWL lat (ms)	77	73	73

Table 2: RocksDB’s write amplification and runtime during the *fillrandom* benchmark, and 99.99-th percentile tail latencies during the *readwhilewriting* benchmark with no rate limits (RW) and with writes rate-limited to 20 MiB/s (RWL), with different SST file sizes.

journal updates are applied to the header’s journal snapshot.

The amount of updates to apply is determined by the zone’s state, and its write pointer. If the zone is in the OPEN (or CLOSED) state, only records up to the current write pointer value are replayed to the journal, whereas if the zone is in the FULL state, all records stored after the header are replayed. Note that if the zone is full, after recovery a new active journal zone is selected and initialized to enable persisting journal updates.

The initial journal state is created and persisted by an external utility that is similar to existing file system tools that generate the initial on-disk state of a file system. It writes the initial sequence number, superblock data structure and an empty snapshot of the journal to the first journal zone. When ZenFS is initialized by RocksDB, the above recovery process is executed, after which it is ready for data accesses from RocksDB.

Writeable Capacity in Data Zones. Ideal allocation, resulting in maximum capacity usage over time, can only be achieved if file sizes are a multiple of the writeable capacity of a zone allowing file data to be completely separated in zones while filling all available capacity. File sizes can be configured in RocksDB, but the option is only a recommendation and sizes will vary depending on the results of compression and compaction processes, so exact sizes are not feasible. ZenFS addresses this by allowing a user-configurable limit for finishing data zones, specifying the percentage of the zone capacity remaining. This allows the user to specify a file size recommendation of, e.g., 95% of device’s zone capacity by setting the finish limit to 5%. This allows for the file size to vary within a limit and still achieve file separation by zones. If the file size variation is outside the specified limit, ZenFS will make sure that all available capacity is utilized by using its zone allocation algorithm (described below). Zone capacities are generally larger than the RocksDB recommended file size of 128 MiB and to make sure that increasing the file size does not increase RocksDB write amplification and read tail latencies we measured the impact on different file sizes. Table 2 shows that increasing SST file sizes does not significantly reduce performance.

Data Zone Selection. ZenFS employs a best-effort algorithm to select the best zone to store RocksDB data files. RocksDB separates the WAL and the SST levels by setting a write-lifetime hint for a file prior to writing to it. Upon the first write to a file, a data zone is allocated for storage. ZenFS tries first to find a zone based on the lifetime of the file and the max lifetime of the data stored in the zone. A match is only valid if the lifetime of the file is less than the oldest data stored in the zone to avoid prolonging the life of the data in the zone. If several matches are found, the closest match is used. If no matches are found, an empty zone is allocated. If the file fills up the remaining capacity of the allocated zone, another zone is allocated using the same algorithm. Note that the write life time hint is provided to any RocksDB storage backend, and is therefore also passed to other compatible file systems and can be used together with SSDs with stream support. We compare both approaches to pass hints in §5.3. *By using the ZenFS zone selection algorithm and the user-defined writeable capacity limits, the unused zone space or space amplification is kept at around 10%.*

Active Zone Limits. ZenFS must respect the active zone limits specified by the zoned block device. To run ZenFS, a minimum of three active zones are required, which are separately allocated to the journal, WAL, and compaction process. To improve performance, the user can control the number of concurrent compactions. Our experimentation has shown that by limiting the number of concurrent compactions, *RocksDB can work with as few as 6 active zones with restricted write performance*, while more than 12 active zones does not add any significant performance benefits.

Direct I/O and Buffered Writes. ZenFS leverages the fact that writes to SST files are sequential and immutable and performs direct I/O writes for SST files, bypassing the kernel page cache. For other files, such as the WAL, ZenFS buffers writes in memory and flushes the buffer when it is full, the file is closed, or when RocksDB requests a flush. If a flush is requested, the buffer is padded to the next block boundary and an extent with the number of valid bytes is stored in the journal. The padding results in a small amount of write amplification, but it is not unique to ZenFS, and is similarly done in conventional file system.

5 Evaluation

To evaluate the benefits and compare the performance of ZNS SSDs, we utilize a production SSD hardware platform that can expose itself as either a block-interface SSD or a ZNS SSD. As such, we enable an apples-to-apples comparison between the two interfaces. The block-interface SSD is formatted to have either 7% OP or 28% OP, and supports streams. ZNS SSD-specific details are shown in Table 3.

Our evaluation of ZNS is constructed around evaluating the following aspects:

- **Raw device I/O performance (§5.1).** We perform an

SSD Interface	Conv.	Conv.	ZNS
Media Capacity	2 TiB	2 TiB	2 TiB
Host Capacity	1.92 TB	1.60 TB	2 TB
Over-provisioning	7%	28%	0%
Placement Type	None	None	Zones
Max Active Zones	N/A	N/A	14
Zone Size	N/A	N/A	2048 MiB
Zone Capacity	N/A	N/A	1077 MiB

Table 3: Feature summary of the evaluated SSDs

apples-to-apples comparison between the block-interface SSDs and the ZNS SSD. We find that the ZNS SSD achieves higher concurrent write throughput and lower random read latency in the presence of writes.

- **End-to-end application performance (§5.2).** We compare the performance of RocksDB on a block-interface SSD running the XFS and f2fs file systems, with the performance of RocksDB when running on a ZNS SSD using our ZenFS backend. We find that RocksDB achieves up to 2× higher read and write throughput, and an order of magnitude lower random read tail latency when running over the ZNS SSD.
- **End-to-end performance comparison with SSD Streams (§5.3).** We compare the performance of the ZNS SSD with a Streams-enabled block-interface SSD, by running RocksDB on XFS and f2fs. We find that RocksDB achieves up to 44% higher throughput on ZNS and up to half the tail latency compared to the Stream SSD.

All experiments are performed on a Dell R7515 system with a 16-core AMD Epyc 7302P CPU and 128 GB of DRAM (8×16GB DDR4-3200Mhz). The baseline system configuration is an Ubuntu 20.04 distribution, updated to the 5.9 Linux kernel—the first version that includes our contributions as described in §4.1. RocksDB experiments were carried out on RocksDB 6.12 with ZenFS included as a backend storage plugin.

5.1 Raw I/O Characteristics

To ensure that the same workload is applied to both the block-interface SSD and ZNS SSDs, we divide the block-interface SSD address space into LBA ranges that have the same number of LBAs as the zone capacity exposed by the ZNS SSD. These zones, or LBA ranges, respect the same sequential write constraint as ZNS, but the zone reset is simulated by trimming the LBA range before writing. We measure performance after the SSD has reached its steady-state with a given workload.

Sustained Write Throughput. We evaluate SSD throughput to show the internal SSD garbage collection impact on throughput and its ability to consume host writes. The experiment issues 64KiB write I/Os to 4 zones. When one zone

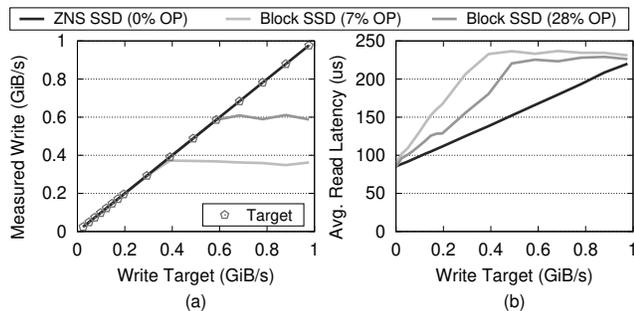

Figure 5: Measured (a) write throughput and (b) average random read latency during rate-limited writes.

is full, a new zone is chosen, reset, and written sequentially. While running the experiment, we measure the drive’s ability to reach a specific host write throughput target ranging from 0 to 1GiB/s. Figure 5 (a) shows the achieved write throughput for each write target. The block-interface SSDs sustain target writes up to 300MiB/s (0% OP) and 500MiB/s (28% OP), whereas the ZNS SSD sustains 1GiB/s. This aligns with the measured steady-state throughput shown in Figure 1, which shows that the block-interface SSDs achieve 370MiB/s (7% OP) and 590MiB/s (28% OP), respectively. The ZNS SSD with 0% OP, however, reaches 1010MiB/s. This is 1.7 – 2.7 \times higher write throughput, and 7 – 28% more storage capacity which is no longer required by the device-side garbage collection.

The ZNS SSD achieves higher throughput and lower write amplification as it can align writes onto distinct erase blocks and avoid garbage collection. The block-interface SSD mixes data onto the same erase block, which is ultimately garbage collected at separate points in time, increasing garbage collection overhead.

Random Reads and Writes. To demonstrate the reduced latency of random reads on a ZNS SSD, a second process is added to the previous experiment, which simultaneously performs random 4 KiB read I/Os across the SSD. We measure its average read latency while gradually increasing the host write target. Figure 5 (b) shows the average random read latency of the block-interface SSDs and the ZNS SSD. With no ongoing writes, both block-interface SSDs report a 4KiB read latency of 85 μ s. Compared to the SSDs with 7% and 28% OP, the random latency of the ZNS SSD is 19% and 5% lower at 50MiB/s write throughput, 45% and 16% lower at 150MiB/s write throughput, and finally 64% and 27% lower at 300MiB/s write throughput. The ZNS SSD’s throughput continues to increase linearly with the write target, unlike the block-interface SSDs.

5.2 RocksDB

Next, we demonstrate the performance improvements achieved by RocksDB when it runs on a ZNS SSD accessed either through f2fs with ZNS support added, or on top of our

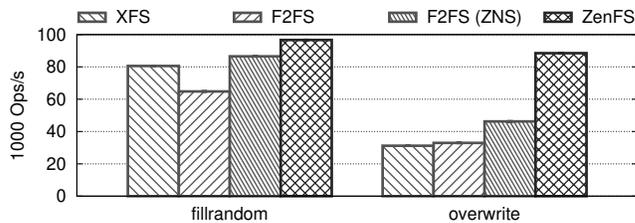

Figure 6: Throughput of RocksDB with write-heavy benchmarks— *fillrandom* followed by *overwrite* using the block-interface SSD with 28% OP and the ZNS SSD.

end-to-end optimized storage backend ZenFS. We compare these two setups against RocksDB running on XFS and f2fs using the block-interface SSD. f2fs supports both storage interfaces, allowing us to compare the impact of a file system running on top of a ZNS SSD. Furthermore, ZenFS is optimized for ZNS, showing the benefits of integrating data placement into an I/O intensive application.

Five workloads are executed for each setup. *fillrandom* is a write-intensive workload pre-conditioning the SSDs for follow-on benchmarks by issuing writes to fill drive capacity several times. Second, *overwrite* measures the overall performance when overwriting. Third, *readwhilewriting* performs random reads while writing. Fourth, *random reads* performs as described. Finally, *readwhilewriting* performs as described with the addition of write rate-limiting. The last three benchmarks are ran three times each and their results are averaged.

The benchmarks are scaled to 80% of the SSD. As a result, the actual over-provisioned space is 27% and 48% with respect to 7% OP and 28% OP. In the interest of space, we show mainly the 28% results, but show the performance difference for the write-heavy benchmarks and the rate-limited *readwhilewriting* benchmark. A 128 MiB target SST file size is used in all benchmarks except for the ZenFS workloads where the target file size is configured to align with the zone capacity.

Write Throughput. We first study the write throughput improvements, using two write-heavy benchmarks on the SSD with 28% OP and the ZNS SSD. First, we populate the database using the *fillrandom* benchmark with 3.8 billion 20B keys and 800B values (compressed to 400B). Then, we randomly overwrite all values using the *overwrite* benchmark.

Figure 6 shows the average throughput of the two benchmarks over the four setups. In the *fillrandom* benchmark, we report the average of write operations per second (ops/s) for each run and is executed from a clean state. Thus, the result is impacted by the lower garbage collection overhead until the SSD reaches a steady-state. As a result, the full write amplification impact can be first seen in the *overwrite* benchmark. Both benchmarks show the XFS and f2fs setups perform lower than f2fs (ZNS) and ZenFS. The most significant impact is seen in the *overwrite* benchmark, in which the garbage collection overhead heavily impacts the overall performance.

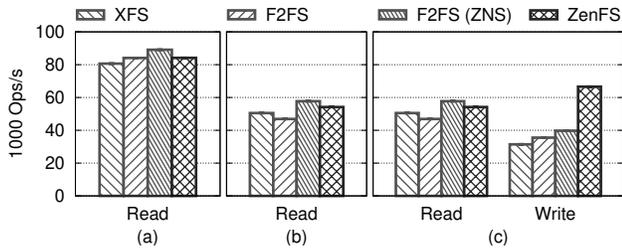

Figure 7: Throughput of RocksDB reads during (a) the *randomread* benchmark, (b) the *readwhilewriting* benchmark with writes rate-limited to 20 MiB/s and (c) the *readwhilewriting* benchmark with no write limits using the block-interface SSD with 28% OP and the ZNS SSD.

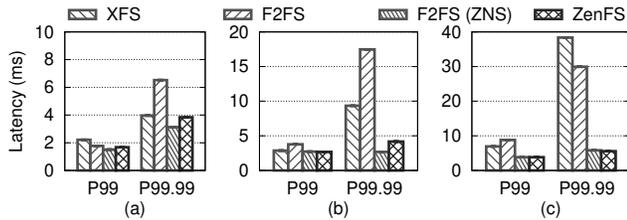

Figure 8: Latency of RocksDB reads during the (a) *randomread* benchmark, (b) the *readwhilewriting* benchmark with writes rate-limited to 20 MiB/s and (c) *readwhilewriting* benchmark with no write limits using the block-interface SSD with 28% OP and the ZNS SSD.

ZenFS is 183% faster than XFS, and f2fs (ZNS) performs 42% better than XFS and 33% better than f2fs.

While the performance of f2fs ZNS increases, the garbage collection overhead associated to large section size requires more data to be moved upon cleaning, which ultimately impacts the host-side garbage collection. To confirm, we measure the write amplification factor on the block-interface SSD, which is reported as $2.0\times$ for XFS, and $2.4\times$ for f2fs, whereas no device-side garbage collection (i.e., $1.0\times$) occurred for f2fs (ZNS) and ZenFS.

Read While Writing. As we have already shown (§5.1), the ZNS SSD achieves lower read latency during concurrent writes because there are no in-device garbage collection operations to interfere with reads during writes. We now demonstrate how this affects the latency of RocksDB read throughput using two read-intensive benchmarks: *randomread* and *readwhilewriting*. The first initiates 32 threads that perform a random reads of key-value pairs on a drive that has been pre-conditioned by the write-intensive benchmarks. The second initiates an extra thread that performs random overwrites, in addition to the 32 threads performing reads.

First, we run the *randomread* benchmark, next we run *readwhilewriting* while rate-limiting writes to 20 MiB/s (i.e., 25.6 Kops/s), and finally we run *readwhilewriting* with no rate-limiting of writes. We run each of these benchmarks for 30 minutes, two times, again in the same four setups as before,

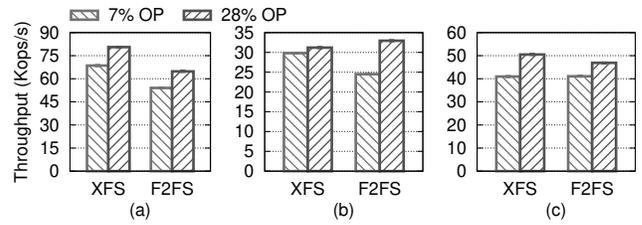

Figure 9: Throughput of RocksDB writes during (a) *fillrandom*, (b) *overwrite*, and (c) *readwhilewriting* benchmark, using the block-interface SSD with 7% OP, as well as 28% OP.

and report read/write throughput in Figure 7 and the average and tail read latencies per operation in Figure 8.

For the *randomread* benchmark, we observe that each combination achieves similar number of write ops/s and average latency, which is expected as there is no writes ongoing. However, the 99th percentile (P99) latencies show that ZenFS is 25% lower than XFS, and 6% lower than f2fs, while f2fs (ZNS) has 32% lower latency than XFS and 16% lower than f2fs.

Next, we study the throughput when performing rate-limited writes. We first notice that only ZenFS is able to sustain 20MiB/s writes while reading, with the other file systems are doing 15% less writes. f2fs (ZNS) performs the most read ops/s, followed by ZenFS, f2fs and XFS. Furthermore, we observe that ZenFS and f2fs (ZNS) have the lowest average latencies, and are able to achieve P99.9 read latencies that are $2\times$ and $4\times$ lower than for XFS and f2fs, respectively.

Finally, we remove the write rate-limit, and then measure the overall impact. Removing the write limit allows ZenFS to achieve $2\times$ the write ops/s compared to f2fs and XFS on consumer SSDs at higher level of read ops/s. f2fs (ZNS) achieves the highest amount of read ops/s and significantly higher write throughput than XFS and f2fs. The P99.99 read tail latencies stand out for ZenFS and f2fs (ZNS) which are an order of magnitude lower than f2fs and XFS.

Impact of Capacity Over-Provisioning. We also evaluate the impact of SSD capacity over-provisioning on RocksDB performance. Whereas block-interface SSDs thrive on unused capacity, as garbage collection is improved and thereby lowering its write amplification factor. The ZNS SSD do not exhibit this behavior and can use all available capacity, while still maintaining a write amplification factor of $\sim 1\times$.

Figure 9 shows the measured number of operations per second for XFS and f2fs when executing the *fillrandom*, *overwrite*, and rate-limited *readwhilewriting* benchmarks. The benchmarks are executed with 7% OP and 28% OP, respectively. For the *fillrandom* benchmark, an improvement between 14% and 16% in overall operations is seen, whereas in the *overwrite* benchmark, XFS only sees a modest 4% improvement, while f2fs is improved by 25%. Finally, in the *readwhilewriting* benchmark we see an improvement between

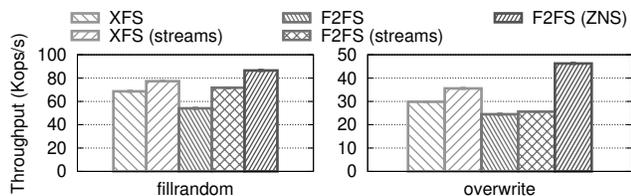

Figure 10: The throughput of RocksDB during the *fillrandom* and *overwrite* benchmarks when executing on an block-interface SSD with 7% OP and stream support.

12% and 18% for f2fs and XFS. While the overall throughput is important, the latency is as well. For XFS, the tail latency improves by 30% and by 23% for P99 and P99.9. Thus, if latency is more important than throughput, then one must budget with addition over-provisioning to lower the overall latency caused by extra garbage collection.

5.3 Streams

Finally, we evaluate the performance of a block-interface SSD with stream support against the performance of a ZNS SSD.

Figure 10 shows the throughput of the *fillrandom* and *overwrite* benchmarks executing on top of a block-interface SSD with 7% OP and with streams enabled or disabled on top of XFS and f2fs. RocksDB on XFS shows higher throughput by 11% and 16% with Streams on *fillrandom* and *overwrite* respectively. RocksDB on f2fs shows higher throughput by 24% and 4% with Streams on *fillrandom* and *overwrite* respectively. f2fs (ZNS) achieves 17% and 44% higher throughput compared to f2fs on a block-interface SSD with Streams for *fillrandom* and *overwrite* respectively.

Furthermore, the P99 latency for f2fs drops from 9,435 μ s to 6,529 μ s with Streams support. This is very close to ZenFS’s P99 latency during the same benchmark of 3,734 μ s. We therefore find that RocksDB achieves up to 44% higher throughput on ZNS and close to half the tail latency compared to a block-interface SSD with streams [56].

6 Related Work

This section covers related work on host-device collaboration, research platforms, and key-value store designs. This section covers work that was not already covered as necessary background (§2.2).

Host-Device Collaboration. Significant research has gone into optimizing the storage interface between host and SSD. Josephson et al. implement DFS [30], a host-side file system tightly integrated with the underlying hardware. SDF [46] exposes individual flash dies to the host through a custom-designed storage controller, and FlashBlox [26] uses dedicated channels and dies for each application to improve isolation. Application-Managed Flash [38] defines an interface based on fixed-size segments that can be written sequentially and reset by a trim operation. ZNS does not fix the number of erase blocks per zone, which allows the SSD implementation

to map erase blocks dynamically to zones. Zhang et al. examine sharing the responsibility of data placement by enabling the SSD to notify the host upon data relocation events [67]. ZNS provides a path to have both high performance and low cost, while leaving the reliability and coarse-grained management to the device.

Research Platforms. Various SSD hardware [14, 37, 58] and software [11, 39, 66] platforms have been developed over the years to expose the characteristics inherent to SSDs [10, 23]. This enables key research on storage interfaces [30, 54, 63] and makes it possible to improve upon the block device interface [27, 62]. Each of these works target specific optimizations and platforms, enabling the storage community to build on them. ZNS is built upon these advancements, each of which has enabled further exploration of the block interface design space.

Key-value Store Designs. Previous work introduces multiple key-value store designs for non-block interfaces. LOCS [61] takes end-to-end design to the extreme and modifies LevelDB to leverage the channel parallelism in OCSSDs. Unlike LOCS, which is tied to a specific OCSSD platform, ZenFS targets the general zone interface and thereby enables RocksDB to run on both ZNS SSDs and HM-SMR HDDs. Similarly, SMRDB [49], GearDB [65], and BlueFS [2] target strictly HM-SMR HDDs and are therefore unable to take the advantage of ZNS extensions and run on ZNS SSDs.

Conclusion

ZNS enables higher performance and lower-cost-per-byte flash-based SSDs. By shifting responsibility for managing data organization within erase blocks from FTLs to host software, ZNS eliminates in-device LBA-to-page maps, garbage collection and over-provisioning. Our experiments with ZNS-specialized f2fs and RocksDB implementations show substantial improvements in write throughput, read tail latency, and write-amplification when compared to conventional FTLs running on identical SSD hardware.

Acknowledgments

We thank the 22 anonymous reviewers, and our shepherd Ethan Miller for their help improving the presentation of this paper. We thank the members and companies of the PDL Consortium: Amazon, Facebook, Google, Hewlett Packard Enterprise, Hitachi Ltd., IBM Research, Intel Corporation, Microsoft Research, NetApp, Inc., Oracle Corporation, Pure Storage, Salesforce, Samsung Semiconductor Inc., Seagate Technology, Two Sigma, and Western Digital for their interest, insights, feedback, and support. Abstract

DM-cache is a component of the device mapper of Linux kernel, which has been widely used to map SSDs and HDDs onto higher-level virtual block devices that take fast SSDs as a cache for slow HDDs to achieve high I/O performance at low monetary cost. While enjoying the benefit of persistent caching where SSDs accelerate normal I/O without affecting durability, the current design of DM-cache suffers from long crash recovery times (at the scale of hours) and low availability. This is because its metadata of dirty bits has to be *asynchronously* persisted for high I/O performance, which consequently causes *all* cached data on SSDs to be assumed dirty and to be recovered after the system is restarted.

This paper presents MapperX, a novel extension to DM-cache that uses an on-disk adaptive bit-tree (ABT) to *synchronously* maintain the metadata of dirty bits in a hierarchical manner. Leveraging spatial locality of block writes, MapperX achieves controlled metadata persistence overhead with fast crash recovery by adaptively adding/deleting leaves in the ABT where different levels represent the states of blocks with different granularity. We have implemented MapperX for Linux DM-cache module. Experimental results show that the MapperX based hybrid storage device outperforms the original DM-cache based hybrid device by orders of magnitude in crash recovery times while only introducing negligible metadata persistence overhead.

1 Introduction

SSDs (solid state drives) are preferable to HDDs (hard disk drives) in building cloud storage systems [11, 31, 33, 35, 43, 44, 51, 65, 66] as SSDs significantly outperform HDDs in random small I/O [13, 14, 26, 27, 40] which is dominant in the cloud [44, 48]. Since currently SSDs are still much more expensive than HDDs, in recent years we see a trend of adopting HDD-SSD hybrid storage for high I/O performance at low monetary cost. For instance, URSA [38] is a distributed block storage system which stores primary

replicas on SSDs and replicates backup replicas on HDDs; and SSHD [28] integrates a small SSD inside a large HDD of which the SSD acts as a cache.

As the demand of HDD-SSD hybrid storage increases, Linux kernel has supported users to combine HDDs and SSDs to jointly provide virtual block storage service. DM-cache [5] is a component of the device mapper [4] in the kernel, which has been widely used in industry to map SSDs and HDDs onto higher-level virtual block devices that take fast SSDs as a cache for slow HDDs. DM-cache records the mapping between SSDs and HDDs for each cached block in its metadata. When DM-cache adopts the default writeback mode, a block write will go only to the SSD cache and get acknowledged after being marked dirty, so that the dirty block could be *demoted* from the SSD cache to the HDD later in a batch for accelerating random small I/O. Linux kernel also provides other modules (Bcache [3] and Flashcache [9]) which have similar functionalities with DM-cache.

While enjoying the performance benefit of persistent caching without affecting data durability [68], in the current design of DM-cache and its variations the metadata of dirty bits has to be *asynchronously* persisted (with a hard-coded period of one second), otherwise the synchronous update overhead of the metadata for each write would be overwhelming. Unfortunately, asynchronous metadata update causes *all* cached data on SSDs to be assumed dirty once the system crashes and gets restarted, which results in long crash recovery times and consequently low availability. For example, in our production storage cluster we use DM-cache to combine SSDs with HDDs for hybrid block storage, and it will take more than two hours (depending on the locality of workloads) to recover from a crash even if most cached blocks are clean. The low availability caused by asynchronous metadata update prevents Linux kernel's hybrid storage mechanisms from being widely applied in availability-sensitive scenarios.

To address this problem, in this paper we present MapperX, a novel extension to DM-cache that uses an on-

disk adaptive bit-tree (ABT) to *synchronously* maintain the metadata of dirty bits in a hierarchical manner. Workloads in the cloud usually have adequate write locality [36, 38, 48], which can be exploited to use one bit to represent the state of a range of consecutive blocks and thus effectively reduce the number of actual persistence operations for synchronous metadata update. Leveraging spatial locality of block writes, MapperX achieves controlled metadata persistence overhead with fast crash recovery by adaptively adding/deleting leaves at different levels in the ABT, which represent the states of blocks with different granularity.

We have implemented MapperX for Linux DM-cache module. Experimental results show that for workloads with certain localities the MapperX based hybrid storage device outperforms the original DM-cache based hybrid device by orders of magnitude in crash recovery times while only introducing negligible metadata persistence overhead.

The rest of this paper is organized as follows. Section 2 introduces the background and problem of DM-cache. Section 3 presents the design of MapperX. Section 4 evaluates the performance of MapperX and compares it with the original DM-cache. Section 5 discusses related work. And finally Section 6 concludes the paper.

2 Background

2.1 DM-Cache Overview

DM-cache is a component of the Linux kernel’s device mapper, a volume management framework that allows various mappings to be created between physical and virtual block devices. DM-cache allows one or more fast flash-based SSDs (cache devices) to act as a cache for one or more slower mechanical HDDs (origin devices). In this section we briefly introduce the basic caching mechanism of DM-cache.

Like most cache solutions, DM-cache has three operating modes, namely, *writeback*, *writethrough*, and *passthrough*, among which only the default *writeback* mode can accelerate small writes (by asynchronously persisting SSD-cached data to HDDs). In this paper we focus on DM-cache’s *writeback* mode. Linux provides DM-cache with various (plug-in) cache policy modules, such as multi-queue (MQ) and stochastic multi-queue (SMQ), to determine which blocks (and when) should be migrated from an HDD to an SSD (a.k.a. *promoted*) or from an SSD to an HDD (a.k.a. *demoted*). The cache policy is orthogonal to this paper, and we simply adopt the default SMQ policy which performs the best for most workloads.

DM-cache can use either the SSD cache device or a separate metadata device to store its metadata, which includes the mapping (between the cached blocks on SSDs and the original blocks on HDDs) and the dirty bits, as well as other policy-related metadata such as per-block hit counts. DM-cache adopts a fixed (but configurable before cache creation)

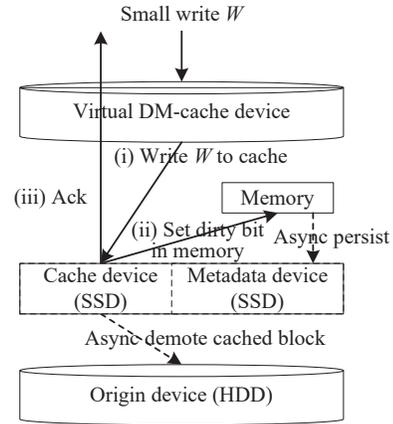

Figure 1: DM-cache maps HDDs and SSDs onto higher level virtual block devices.

block size typically between 32KB and 1MB.

Consider a small write to a virtual DM-cache device in the *writeback* mode.

If the target block is already in the SSD cache, then as shown in Fig. 1, (i) the new data (W) is written to the SSD, (ii) the corresponding bit of the block is set dirty in memory, and (iii) the write is acknowledged. The cached block will be asynchronously persisted to the HDD according to the cache policy. There are two kinds of metadata: the metadata for the cached block’s mapping (between SSD and HDD) already exists and thus needs no persistence; and the metadata for the block’s dirty bit has to be *asynchronously* persisted (one persistence per second by default), because once being synchronously persisted this update will be on the critical path of writing W which would greatly affect the performance of cached writes, as demonstrated in the next subsection. In original DM-cache the persistence of dirty bits is not for crash recovery but for (e.g., battery-backed) graceful shutdown which happens after dirty bits are (incrementally) persisted, so that up-to-date dirty-bit metadata can be read after reboot.

If the target block is not yet in the cache, then the processing is slightly complex: when the write is not aligned with a block, the block needs to be first promoted to the cache with the first kind of (mapping) metadata being persisted, after which the processing is the same as cached block writes. Note that the mapping metadata must be synchronously updated, in which case the synchronous update of the dirty-bit metadata is less harmful because the number of metadata writes only increases from one to two. In contrast, if the mapping metadata needs no update then the number of metadata writes *sharply* increases from zero to one. Mapping metadata update is largely decided by the locality of the workloads together with the replacement policy. Generally speaking, higher locality of writes causes less changes of mapping metadata which makes synchronous dirty-bit per-

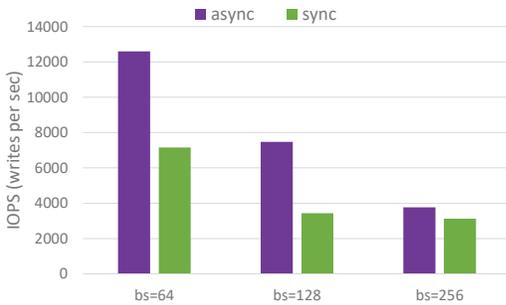

Figure 2: Synchronous updates of dirty bits severely affect the I/O performance, evaluated using one HDD + one SSD.

sistence have higher negative impact on the performance of cached writes, and vice versa.

2.2 The Main Drawback of DM-Cache

To demonstrate the runtime performance problem of persisting dirty bit for each write, we compare the IOPS of DM-cache with synchronous and asynchronous updates, respectively. We use `fiio` to perform random writes (`rw = randwrite`) and evaluate the IOPS (writes per second) with `iodepth=16`, using various cache block sizes ranging from 64 KB to 256 KB. The `fiio` write sizes are the same as the catch block sizes. The result (Fig. 2) shows that the performance is severely affected when adopting synchronous update for dirty-bit metadata, causing several times IOPS degradation. The high overhead prevents synchronous update of dirty-bit metadata from being adopted by DM-cache.

Unfortunately, asynchronous metadata update causes *all* cached data on SSDs to be assumed dirty once the system crashes and gets restarted, which results in long crash recovery times and consequently low availability. For example, in our production block storage system where we use DM-cache to combine multiple SSDs with multiple HDDs on each storage machine, it takes more than two hours (depending on the workloads) to recover from a power failure (by demoting all cached blocks) even if most blocks are clean. The low availability (caused by asynchronous metadata update) prevents Linux’s HDD-SSD hybrid cache mechanisms (like DM-cache) from being widely applied in availability-sensitive scenarios.

3 MapperX Design

3.1 Synchronous Metadata Update

The timing of dirty-bit metadata update is a dilemma for HDD-SSD hybrid devices. The asynchronous update mechanism periodically updates dirty bits for not affecting normal writes but suffers from long crash recovery time (since all SSD-cached blocks have to be assumed dirty and get recovered even if most of them are clean); while the

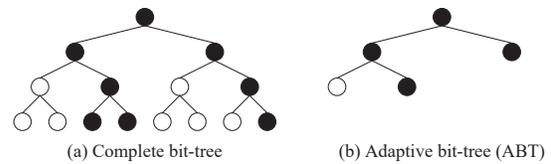

Figure 3: MapperX maintains an on-disk adaptive bit-tree (ABT), a summary of the complete bit-tree (CBT) of which the leaves represent the states of all HDD blocks. Black nodes represent dirty = `true`. ABT is *synchronously* updated for each write, but most updates do not need persistence to SSD since one bit represents a set of consecutive blocks.

synchronous update mechanism keeps all dirty bits up-to-date for fast crash recovery but greatly increases the latency of cached writes. Although the-state-of-the-art caching solution (DM-cache) adopts asynchronous update for high I/O performance, in this paper we propose to take the synchronous update mechanism for fast crash recovery.

The challenge is that there is no trade-offs for the timing of dirty-bit metadata update, because once the metadata is asynchronously updated even only one outdated bit state would require demotion of all cached blocks to ensure data durability after crash recovery. To address this challenge, our key idea is to adjust the granularity, instead of the timing, of dirty-bit metadata update to smoothly trade off between normal I/O performance and crash recovery time.

Workloads in the cloud usually have adequate write locality which can be leveraged to use one bit to represent the state of a range of consecutive blocks, as long as we can (roughly) know the effective range of the bit. Note that false positives of the effective range are not critical: if one clean block is wrongly included in the effective range of a dirty bit, the price is simply an unnecessary demotion of that block in crash recovery.

There is an in-memory bitmap that precisely records the state of every block. We first extend the in-memory bitmap to a (logical) hierarchical complete bit-tree or CBT (as shown in Fig. 3(left)), where the leaves are the bits of the bitmap and each inner node is the disjunction of its direct children. Then, MapperX maintains a *summary* of the CBT on the metadata device, which we refer to as on-disk *adaptive bit-tree* (ABT), as shown in Fig. 3(right). The ABT is synchronously updated for each write request, but most updates do not cause disk writes for metadata persistence, as discussed below. Each inner node of the ABT represents a range of consecutive blocks, and thus only the first dirty block within the range causes a write to the metadata device and subsequent writes of blocks in the range need no persistence. Initially, the ABT only has a root node representing the states of *all* cache blocks, which will change from clean to dirty after the first block write.

MapperX proposes a synchronous ABT update mecha-

Algorithm 1 Synchronous bit-tree update of MapperX

```
1: procedure BITTREEUPDATE(Block  $b$ , Adaptive bit-  
   tree  $abt$ )  
2:   Update in-memory bitmap by  $b$   
3:   Calculate affected inner nodes of complete bit-tree  
   ( $cbt$ ) ▷ Dirty if any child dirty, clean if all children clean  
4:   if  $b$  causes leaf node  $L$  of  $abt$  to become dirty then  
5:     Update  $abt$  on disk according to  $cbt$   
6:   end if  
7:   return SUCCESS  
8: end procedure  
  
9: procedure PERIODICADJUST(Period  $p$ , SLA  $n$ , Adap-  
   tive bit-tree  $abt$ )  
10:   $W \leftarrow$  total number of client writes during  $p$   
11:   $N \leftarrow$  total number of metadata writes during  $p$   
12:  if  $N/W \geq 1/10^n$  then ▷ Too many metadata writes  
13:     $parents \leftarrow$  all direct parents of the leaves in  $abt$   
14:     $target\_parent \leftarrow$  the parent from  $parents$  which  
    has experienced the most metadata writes during  $p$   
15:    Delete all children of  $target\_parent$  in  $abt$   
16:  else  
17:     $target\_leaf \leftarrow$  the leaf from all leaf nodes of  $abt$   
    which has experienced the least metadata writes in  $p$   
18:    Generate  $d$  children for  $target\_leaf$  in  $abt$  and  
    set their states according to  $cbt$  ▷  $d$  is the degree of  $abt$   
19:  end if  
20:  return SUCCESS  
21: end procedure
```

nism (Algorithm 1), which can adaptively adjust the metadata persistence frequency. The basic idea is to control the effective range of the corresponding bits of the leaves (i.e., the granularity of metadata update) by adding/deleting leaves in the ABT. Leaves at higher levels (farther from the root) in the ABT represent the states of a smaller range of blocks and thus increasing the levels of the ABT will increase the metadata persistence overhead while reducing the expected recovery time, and vice versa. When adding child leaves to an existing leaf node, the information about which children are dirty can be obtained from the logical CBT (calculated from the in-memory bitmap).

Since the user-perceived I/O performance is usually described as tail latencies, e.g., 99.9th percentile latency guarantee requires only one out of 1000 writes can be affected by dirty-bit metadata update, we use the number of nines (n) of the SLA (service-level agreement) to control the summary levels of the ABT.

The BITTREEUPDATE procedure first updates the in-memory bitmap and calculates the affected nodes in the complete bit-tree (Lines 2~3). Then, if the current block write causes a leaf node to change from clean to dirty, we will persist the updated ABT (Lines 4~6).

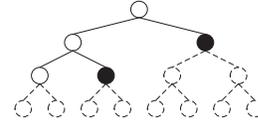

Figure 4: Example of a virtual ABT (degree $d = 2$, level $m = 4$) stored in a flat bit array for the actual ABT (Fig. 3(left)). For $d^{m-1} = 8$ leaves (representing 8 blocks), there are totally $\sum_{i=0}^{m-1} d^i = \frac{d^m-1}{d-1} = 15$ nodes in the tree, which can be stored using 15 bits (0010 1000 0000 000).

The PERIODICADJUST procedure decides whether to add or delete leaf nodes in the ABT according to the statistics of the last period (p). The period is configurable and by default set as one second. If there are too many metadata writes compared to the SLA in p , then we will remove all the children of the parent that has experienced the most metadata writes during p (Lines 12~15). Otherwise we will add children to the leaf node that has experienced the least metadata writes during p (Lines 16~18). Similar to the original DM-cache, MapperX can synchronously or asynchronously update the ABT (without add/deleting leaves) when the dirty blocks are demoted to the HDD.

3.2 Fast Crash Recovery

Since the ABT is synchronously updated for every write request, the leaf nodes in the ABT has no false negatives for dirty states. That is, when a leaf is not dirty, each of the blocks it represents are guaranteed to be not dirty and we can safely skip these blocks in crash recovery. Therefore, the recovery procedure of MapperX-based DM-cache devices is straightforward: for each dirty leaf L of the ABT, demote all SSD-cached blocks of L to the HDD.

3.3 Implementation

We have implemented MapperX on CentOS 7 by augmenting the original DM-cache with BITTREEUPDATE and PERIODICADJUST in Algorithm 1, and realizing the in-memory CBT and the on-disk ABT structures in Fig. 3.

In order not to introduce extra storage overhead, we reuse DM-cache's four-byte dirty-bit metadata structure of each cached block, of which DM-cache uses only the last two bits (a dirty bit and a valid bit) leaving the first 30 bits available for MapperX. We organize the first 30 bits of all cached blocks' metadata structures into a flat bit array. To minimize the update overhead of adding/deleting leaves, we store ABT as the virtual ABT or V-ABT (Fig. 4) which has the same numbers of levels and leaves as the CBT but where only the ABT's *dirty leaves* are 1 and all other inner/leaf nodes are 0. We use the flat bit array for statically representing the states of all inner/leaf nodes in the V-ABT (each bit for one node started from the root in a breadth-first manner).

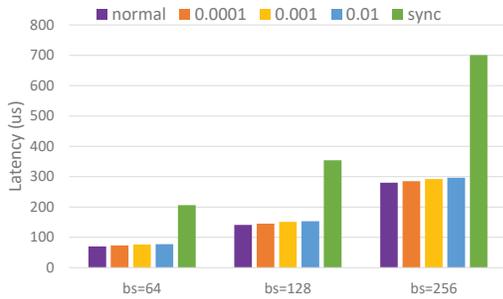

Figure 5: MapperX ($\beta = 0.01, 0.001, 0.0001$) vs. DM-cache (normal) in mean latency.

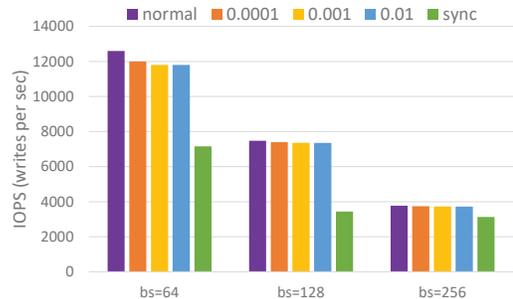

Figure 7: MapperX ($\beta = 0.01, 0.001, 0.0001$) vs. DM-cache (normal) in IOPS (writes per sec).

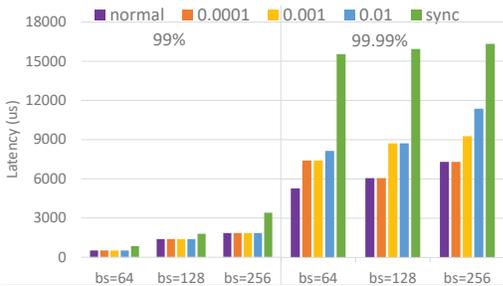

Figure 6: MapperX ($\beta = 0.01, 0.001, 0.0001$) vs. DM-cache (normal) in tail latency.

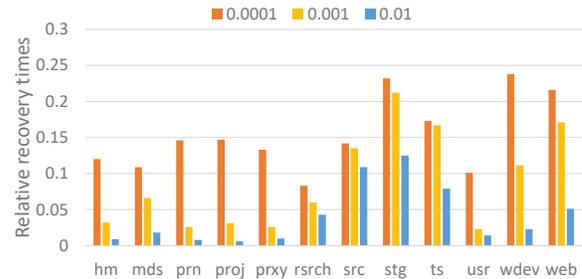

Figure 8: Recovery times of MapperX ($\beta = 0.01, 0.001, 0.0001$) relative to DM-cache for MSR traces.

4 Evaluation

Our test machine has an Intel gold 6240 36-core 2.60GHz CPU and 64GB RAM, running CentOS 7. The machine has one SATA 7200RPM 2TB HDD and one NVMe 400GB SSD. We configure the DM-cache virtual block device with 1TB HDD storage device, 128GB SSD cache device, and 1GB SSD metadata device. The client runs the `fiio` benchmark tool [8] to perform random writes (`rw=randwrite`) that all hit the SSD cache for three hundred seconds. Note that cache miss should be avoided in this test because otherwise the poor performance of HDD storage would dominate the overall performance making MapperX and DM-cache have no difference.

4.1 Micro Benchmarks

We first compare the latency of random writes of MapperX and DM-cache. The cache block size (bs) is 64KB \sim 256KB, and the `fiio` write block size is equal to the cache block size. The degree of the tree is $d = 4$. We evaluate the latency using one `fiio` thread with `iodepth = 1`. We use β to represent the expected ratio of metadata writes to all writes (i.e., $\beta = 1/10^n$ where n is the SLA) and set $\beta = 0.01, 0.001, 0.0001$, respectively. We set `max_level = 7` (maximum number of levels), which limits the ABT to have $d^{\text{max_level}} = 16K$ leaves each representing 1024, 512, and 256 blocks for $bs = 64\text{KB}, 128\text{KB},$ and 256KB (for the 1TB HDD storage),

respectively. The original DM-cache adopts asynchronous metadata update (which equals to set `max_level = 1`). The results are shown in Fig. 5 and Fig. 6 respectively for the mean and tail latencies. The results show that the latency overhead of MapperX slightly increases as β increases from 0.0001 to 0.01, but the overhead is small compared to the original DM-cache.

We compare the IOPS (number of writes per second) of random writes of MapperX and DM-cache. The configuration is the same as that in the latency test except that we use one `fiio` thread with `iodepth = 16`. The result is shown in Fig. 7, where MapperX has similar IOPS with DM-cache, which proves that the IOPS overhead of MapperX is small compared to the original DM-cache. Note that higher latency does not necessarily cause lower throughput (and vice versa), because NVMe SSD supports high parallelism which enables it to mask I/O delays with parallel I/O requests flying over the wire and waiting in the pipeline.

4.2 Trace-Driven Evaluation

We compare the recovery performance of MapperX ($bs = 128$) and the original DM-cache, using the public I/O traces from Microsoft Research [1] that capture block-level I/O (below the filesystem cache) of various desktop/server applications running for one week. The result is shown in Fig. 8, where the original DM-cache has to recover all the cached blocks because of its asynchronous dirty-bit metadata

update. In contrast, MapperX only needs to recover much fewer blocks owing to its synchronous dirty-bit metadata update. For example, the recovery time of MapperX with $\beta = 0.01$ for the proj trace is only 0.6% that of DM-cache. Generally speaking, less locality leads to fewer ABT levels, fewer normal-time ABT updates, and longer crash recovery time (due to higher false-positive rates), with the design of the original DM-cache at the extreme end.

5 Related Work & Discussion

DM-cache [5], Bcache [3] and Flashcache [9] are Linux kernel modules which are used to combine fast SSDs with slow HDDs as a virtual block device. The difference is that Bcache utilizes a btree cache structure, while Flashcache's cache is structured as a set-associative hash table. LVM-cache [12] is built on top of DM-cache using logical volumes to avoid calculation of block offsets and sizes. DM-cache can also be used as the client-side local storage for caching of virtual machines in storage area networks (SANs).

DM-cache and its variations asynchronously update dirty bits and thus cannot recover from crashes with up-to-date dirty-bit information. Consequently, all cached blocks on SSD have to be assumed dirty, which makes cached blocks have to be written to HDD. In contrast, MapperX uses ABT to synchronously update dirty bits, providing flexibility of whether to write dirty data to HDD on recovery. Since recovery from crashes takes time, it is natural for MapperX to take a little more time (usually several minutes depending on the volume of dirty data) for demotion.

In addition to DM-cache/LVM-cache/Bcache/Flashcache provided by Linux kernel, several SSD-HDD hybrid designs use SSD as a cache layer. For example, Nitro [37] designs a capacity-optimized SSD cache for primary storage. Solid State Hybrid Drives (SSHD [28]) integrate an SSD inside a traditional HDD and realize SSD cache in a way similar to Nitro. URSA [38] is a distributed block storage system which stores primary replicas on SSDs and replicates backup replicas on HDDs. Griffin [60] designs a hybrid storage device that uses HDDs as a write cache for SSDs to extend SSD lifetimes. Compared to these studies, MapperX mainly focuses on the tradeoff between normal write performance and recovery times, using the ABT to adaptively adjust the range represented by the leaves.

Journal [38] based metadata write is inefficient [63] for DM-cache because of expensive write ordering [22]. For consistency, journal-based solutions always impose ordering constraint on writes (e.g., data \rightarrow sync \rightarrow metadata \rightarrow sync) [21], which both increases latency and decreases throughput. In DM-cache and MapperX, if the blocks are already in the cache then the writes need not update the mapping metadata, so they only need one SSD write for DM-cache (Fig. 1) and (if ABT unchanged) for MapperX.

Log-structured solutions [24] are inefficient for DM-

cache, because log-style writing always causes changes of the SSD-HDD mapping metadata (due to new block allocation) which has to be updated even for cache-hit write requests. In contrast, this can be avoided by DM-cache and MapperX for cache-hit write requests when mapping metadata keeps unchanged, where only one metadata write is needed (Fig. 1). Moreover, garbage collection (GC) [49] for old versions is expensive for log-structured systems.

Hardware-based, out-of-band solutions [17] require special hardware and driver supports with high programming complexity, and recently-emerging open-channel SSDs [7] are not readily available. As far as we know, large cloud providers that own millions of SSDs only have a few thousands SSDs with open-channel customization support. Further, synchronous update of SSD page states can be viewed as a special case of ABT where each leaf represents a page. This is inefficient for workloads with good locality where page states frequently change: writing a page back to HDD requires to synchronously change its state (clean) on SSD, which can be avoided by ABT if the higher-level node state keeps unchanged (dirty). On the other hand, NVM (non-volatile memory) [6] based solutions [15, 19, 20, 62, 71] are promising but expensive. NVM is still uncommon in the cloud, and the relatively-small NVM is expected to be used in more critical scenarios.

6 Conclusion

This paper presents MapperX, a novel extension to DM-cache that uses an on-disk bit-tree to *synchronously* persist the dirty-bit metadata in a hierarchical manner. Experimental results show that MapperX significantly outperforms DM-cache in crash recovery times while only introducing negligible metadata write overhead. In our future work, we will apply EC [34, 39, 45, 55, 70] for ABT, study the impact of MapperX on durability and consistency [30, 32, 46, 52, 58], apply ABT in distributed file systems [21, 23, 29, 36, 50, 53, 56, 59] and object storage systems [2, 16, 47, 64, 67], apply bloom filters [25, 42, 57, 61, 69] and compression [18, 41, 54] in ABT, and improve ABT's adjustment policy.

The source code of MapperX is available at [10].

Exploring the Design Space of Page Management for Multi-Tiered Memory Systems

Jonghyeon Kim, Wonkyo Choe, and Jeongseob Ahn
Ajou University

Abstract

With the arrival of tiered memory systems comprising various types of memory, such as DRAM and SCM, the operating system support for memory management is becoming increasingly important. However, the way that operating systems currently manage pages was designed under the assumption that all the memory has the same capabilities based on DRAM. This oversimplification leads to non-optimal memory usage in tiered memory systems. This study performs an in-depth analysis of page management schemes in the current Linux design extending NUMA to support systems equipped with both DRAM and SCM (Intel’s DCPMM). In such multi-tiered memory systems, we find that the critical factor in performance is not only the *access locality* but also the *access tier* of memory. When considering both characteristics, there are several alternatives to page placement. However, current operating systems only prioritize access locality. This paper explores the design space of page management schemes, called *AutoTiering*, to use multi-tiered memory systems effectively. Our evaluation results show that our proposed techniques can significantly improve performance for various workloads, compared to the stock Linux kernel, by unlocking the potential of the multi-tiered memory hierarchy.

1 Introduction

With the advent of in-memory computing, such as data analytics, key-value stores, and graph processing, the demand for high-density DRAM has been steadily increasing in recent years [27]. However, due to the challenge of scaling DRAM density, a new class of memory has received attention to bridge the performance gap between DRAM and SSD. For example, Intel recently unveiled its non-volatile memory based on 3D Xpoint technology, called Optane DC Persistent Memory Module (DCPMM) that provides more density than DRAM while outperforming flash-based SSDs [23]. Cloud vendors such as Google, Oracle, Microsoft, and Baidu have adopted such storage class memory (SCM) in their cloud services [4, 14, 17, 25].

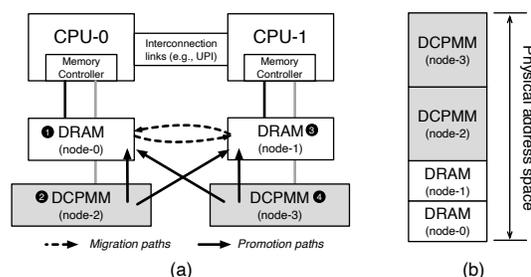

Figure 1: Software-managed tiered memory system augmented on the NUMA architecture

Since modern server systems are built with the Non-Uniform Memory Access (NUMA) architecture, future large-memory systems will take the shape of tiered memory augmented on traditional NUMA architecture, called *multi-tiered memory*. Figure 1 presents a real-world multi-tiered memory system used throughout this study. Each compute chip has two types of memory: DRAM (upper-tier) and Intel’s DCPMM (lower-tier). We configure both DRAM and DCPMM to be fully exposed to software as memory.

This paper presents that the recent advancement in Linux [15] and tiered memory studies [16, 20, 35] do not lead to optimal page placement in multi-tiered memory systems. As the new class of memory becomes part of the main memory, the critical factor in performance is not only the *access locality* but also the *access tier* of memory. However, current page placement schemes have been established for DRAM-only NUMA architecture and only consider locality between threads and memory [2, 8, 12, 13, 21, 38]. As a result, the current design is far from exploiting the potential benefits of multi-tiered memory systems. For example, suppose the local DRAM becomes full when promoting pages from the lower-tier (DCPMM) to the upper-tier (DRAM) memory. In this case, the current state of the art leaves the page on the lower-tier memory, regardless of the availability of the remote DRAM (of the upper-tier). Such a decision is reasonable for DRAM-only NUMA systems because there is no difference between alternatives. However, in multi-tiered memory sys-

tems, we cannot consider every possible alternative equivalent to the *access tier*. When placing pages, the access tier of memory should be considered before the access locality because the access tier has a more significant impact on performance.

This limitation motivates us to revisit the page management schemes of the commodity OSes and explore the design space of page management for multi-tiered memory systems. In this study, we introduce a set of new page management schemes. Our first scheme, called *AutoTiering-CPM*, conservatively looks for promotion or migration alternatives using the access tier and locality metric when failing to find the best memory node (e.g., local DRAM).

Although this conservative approach can achieve better performance by considering alternatives, such a design does not unlock the full potential of software-managed tiered memory. To effectively utilize the limited capacity of upper-tier memory, we design a page reclamation scheme tailored to multi-tiered memory systems. Our second technique is opportunistic page promotion or migration, called *AutoTiering-OPM*, which judiciously demotes pages from the upper-tier memory. To reclaim effectively, we predict the *least accessed page* as a victim in the upper-tier memory by estimating the access frequency of pages. When deciding on which page to promote, our OPM compares the page with the victim to determine which is relatively more accessed. With OPM, we can achieve better effectiveness of the upper-tier memory while reducing the memory accesses to the lower-tier memory.

Unless there is a free space in the upper-tier memory, a promotion operation waits until the completion of a demotion operation. To hide the latency of demoting pages from the critical path, we reserve a set of free pages in the upper-tier memory to serve the promotion requests immediately. When the number of reserved pages exceeds a threshold, our *kdemoted* wakes up and reclaims the least accessed page to the free page pool in the background. *kdemoted* differs from the traditional reclamation because it is only responsible for demoting pages to the lower-tier memory and not storage.

In this study, we implement our proposed schemes on top of Linux kernel v5.3. We take advantage of the AutoNUMA facility, which periodically scans memory pages and marks them inaccessible to capture non-local DRAM accesses. Once the pages are reaccessed, it incurs a page fault, called *NUMA hinting page fault*. We take the NUMA faults as demand signals for the page promotion from the DCPMM nodes or the migration from the remote DRAM node. We build the access history per page with the fault-based facility and use this information when demoting pages.

The experimental results show that our *AutoTiering* can significantly improve the performance of various applications. *GraphMat* and *graph500* show performance increases around $2.3\times$ and $6.9\times$, respectively, compared with the baseline Linux kernel [15]. Most of the SPECaccel workloads show a $2\times$ speedup. Compared to Intel’s recent approach [36], our performance improvement shows up to a $3.5\times$ speedup.

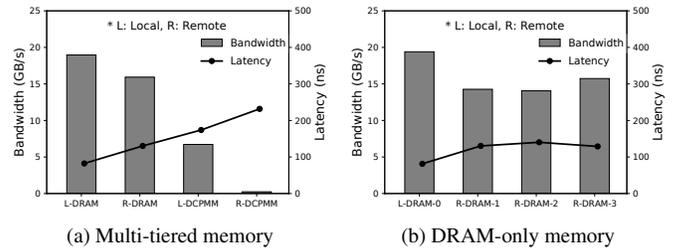

Figure 2: Memory access latency and bandwidth for multi-tiered and DRAM-only memory systems

2 Background and Motivation

2.1 Large Memory Systems

Data centers typically employ multi-chip NUMA architecture to scale up the performance of commodity servers with high core counts and memory capacity. Although this can increase the number of DIMM slots per server, scaling DRAM density is still a significant obstacle. It poses challenges in cost-effectively constructing large memory systems. Meanwhile, since SCM offers byte-addressable and non-volatile properties, it is gaining traction to bridge the performance gap between DRAM and SSD. Intel recently released the 3D XPoint non-volatile memory (DCPMM) that can be installed on DIMM without modification [23]. Many cloud vendors such as Google, Microsoft, Oracle, and Baidu have adopted Intel’s DCPMM in their cloud services [4, 14, 17, 25]. Recently, Samsung has revealed a CXL (Compute Express Link) based DRAM module attached to the system, forming tiered memory systems [1]. Since such new type of memory is not as fast as DRAM, they cannot replace DRAM entirely. Instead, future computer systems will offer a form of tiered memory architecture with DRAM and SCM.

In this study, we take advantage of DCPMM as a new tier between DRAM and SSD. Intel DCPMM provides two types of tiered memory systems that can be categorized as hardware-assisted or software-managed. In hardware-assisted mode, DCPMM is exposed to software as the main memory while DRAM acts as a hardware-managed cache, non-visible to the software. The memory controller automatically places frequently accessed data on the DRAM cache, while the rest of the data is kept on a large capacity but slow DCPMM. On the other hand, with the operating system support, both DRAM and DCPMM can be exposed as normal memory and visible to software, tiering memory into fast and slow [15]. We call this a software-managed tiered memory system. In this environment, operating system support is supposed to effectively use both DRAM and DCPMM because the full control is given to software. This paper focuses on system software aspects of tiered memory systems by understanding how the hardware is organized.

2.2 Performance Characteristics

We describe the distinct performance characteristics of a software-managed tiered memory system that runs with the Linux operating system. Figure 1 presents the system organization used in this study. There are two CPU sockets in the system. For each CPU socket, one DRAM node and one DCPMM node are attached. The entire physical address space is comprised of both the DRAM and DCPMM nodes.

In multi-tiered memory systems, the critical factors in performance are not only the *access locality* but also the *access tier* of memory. Figure 2a shows read access latency and bandwidth for each of the four memory nodes measured from MLC [18]. Accessing the local DRAM outperforms the other three memory nodes, which is well established in traditional NUMA architecture. On the other hand, we observe that local DCPMM (L-DCPMM) is slower than that of remote DRAM (R-DRAM) due to the device characteristics. This is in stark contrast with the conventional wisdom that local memory is always faster than remote memory. Note that we also observe a similar pattern in a bandwidth measurement.

Similarly, Figure 2b shows the same type of evaluation over the four CPU (Intel Xeon Gold 6242) sockets with DRAM-only systems. There is no significant difference in latency and bandwidth for access to any remote DRAM nodes. Due to this, placing pages on the remote DRAM nodes in DRAM-only systems is a relatively simple task.

These distinct characteristics motivate us to explore the design space of page management in operating systems. The operating systems need to have the ability to (re)locate memory efficiently and dynamically by understanding the performance characteristics of multi-tiered memory systems. Unlike the DRAM-only systems, not all the remote memory nodes can be considered equal due to the access tier.

2.3 OS Support of Multi-Tiered Memory

The multi-tiered memory hierarchy that is the focus of this paper is distinct from traditional two-tiered memory. Nevertheless, the current Linux still relies on the existing NUMA framework to support multi-tiered memory systems. Such limited OS support makes the page placement sub-optimal in multi-tiered memory architectures. Although we can redefine the NUMA distance table according to the access latency, it does not exploit the full potential of the multi-tiered memory systems. First, Linux classifies memory nodes as either local or remote in a binary way. When promoting or migrating pages, several alternatives among the remote nodes are not considered at all. Second, the Linux does not support demoting (or reclaiming) pages from the upper-tier to the lower-tier memory. In this study, we revisit page placement strategy by considering performance characteristics across access-tier as well as access-locality.

3 Analysis of Page Management to Multi-Tiered Memory Systems

In this section, we investigate existing page management techniques of Linux that have been designed for DRAM-only NUMA systems. Then, we identify the lack of sufficient support for tiered memory systems. Although AutoNUMA [33] can be used for such multi-tiered memory, we observe that it fails to take full advantage of the multi-tiered memory.

3.1 Initial Page Placement

With the introduction of storage class memory (e.g., Optane DCPMM) in main memory, conventional page placement based only on the access locality has a negative impact on performance because the most critical factor in performance is not only the locality but also the memory tier. Meanwhile, current page placement schemes in operating systems have been well established for DRAM-based NUMA architecture, considering the access locality *only* between threads and memory [8, 13, 21]. In Linux, the default page allocation policy tries to use local memory as much as possible to minimize the performance penalty incurred by accessing remote memory. Only if there is no free space in the local memory, the memory allocator looks for free space on a remote memory node known as a *fallback path* [9].

As a result, the default (*local-first*) allocation policy is considered harmful in multi-tiered memory systems. The numbers in Figure 1a present the order used in the default fallback path when a thread runs on CPU-0, considering only the physical distance. If the *local-DRAM* node does not have enough free space, the memory allocator examines the fallback path to determine which memory node the allocation request should be sent. We anticipate that the allocator should ask the *remote DRAM* node to get a free page because this node provides better performance than the local DCPMM node. Surprisingly, however, the fallback path in the state-of-the-art Linux kernel indicates the local DCPMM (lower-tier). It had not taken into account the distinct characteristic that the memory type is more sensitive to performance than the access locality in multi-tiered memory systems.

Problem: If the local DRAM is full, the fallback prioritizes allocating from the local DCPMM (lower-tier), even though the remote DRAM (upper-tier) performs better.

3.2 Dynamic Placement

Although initial page placement plays a crucial role in the given memory space, the decision may not represent optimal performance because it depends on the memory access traffic at runtime. To adjust the placement of pages according to access patterns, the AutoNUMA facility has been included as part of Linux, automatically migrating pages to a mem-

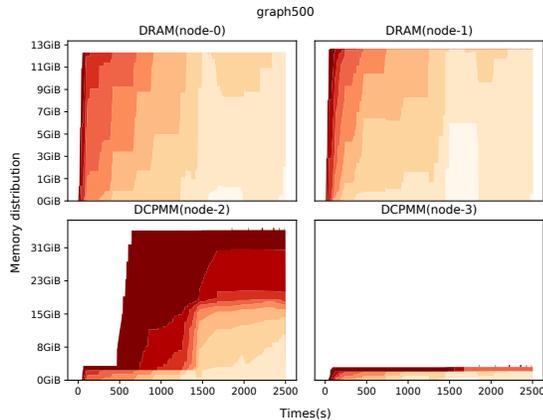

Figure 3: Page distribution and access intensity of `graph500` across memory nodes (Darker colors refer to pages that are accessed relatively more frequently.)

ory node closer to the thread running at runtime [33]. The operating system examines the access locality to find whether the accessed page is placed on the local memory or remote memory. If this is on the remote memory, the page is migrated to the local memory to avoid the remote accesses for subsequent requests. This approach improves the performance of applications running on DRAM-only NUMA systems.

However, we find that the current design does not exploit the advantages of the multi-tiered memory hierarchy. Figure 3 presents memory usage across the memory nodes for `graph500` with the 128GB dataset as time goes by. The detailed experimental setup is explained in Section 5. First, we notice that the upper-tier memory is *ineffectively* used because more frequently accessed pages (dark red) mainly reside in the lower-tier memory (`node-2`). In contrast, less frequently accessed pages are placed on the upper-tier memory¹. The primary reason for this is that the current memory management does not allow page promotion or migration to the upper-tier memory when there is no free space. Although such a design decision is reasonable for DRAM-only systems, we need to reconsider this assumption for multi-tiered memory systems. Figure 4 depicts three cases whereby AutoNUMA encountered page promotion or migration failure due to lack of free space in local DRAM.

Even though the page promotion or migration cannot be made to the best memory node satisfying the access tier as well as the access locality, there are effective alternatives to placement in multi-tiered memory systems. When page promotion fails from remote DCPMM to local DRAM, for example, we have two possible workarounds: placing the page either on the remote DRAM or on the local DCPMM.

Problem: Pages in the lower-tier are not promoted when the upper-tier is fully utilized.

¹Section 4.2.1 explains how we estimate the access frequency.

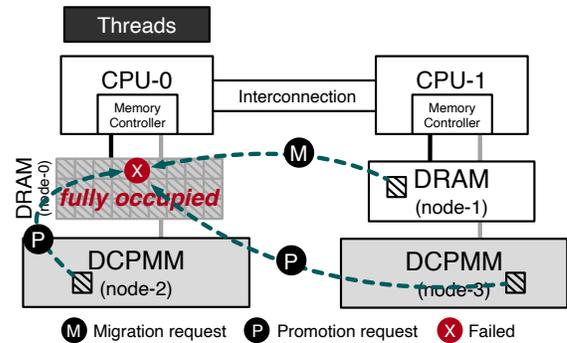

Figure 4: Page promotion and migration failure cases (Promotion: lower-tier \rightarrow upper-tier, Migration: movement between the same tier)

Second, we observe the *skewed* page distribution across the memory nodes in the lower-tier memory. This is because the page movement to CPU-less nodes (DCPMM) is not considered in the current Linux operating systems. Since the traditional OSes were designed under the assumption that memory access performance is highly affected by the access locality between CPU and memory nodes, moving pages to CPU-less nodes does not occur. Only if the destination upper-tier memory has free space, the pages residing in the CPU-less node (lower-tier memory) can be promoted through AutoNUMA. Figure 1a shows arrows all the possible page promotion and migration paths that the stock Linux kernel currently supports. Even though the upper-tier memory is full, so that the operating system cannot place pages on the preferred access tier, we need to be able to preserve the access locality in the lower-tier memory by freely allowing page movement across any CPU-less nodes.

Problem: Pages are never migrated to the CPU-less (lower-tier) nodes due to a NUMA policy that does not apply to multi-tiered memory systems.

3.3 Page Reclamation

The current page reclamation is also designed for DRAM-only systems backed by storage-based swap devices rather than tiered memory systems. Traditionally, `kswapd` reclaims the inactive pages in memory directly to the storage regardless of the memory tier when the memory node is exhausted. It would make sense to reclaim pages in the lower-tier memory to the storage device. However, this is not a desirable solution for the upper-tier memory pages when the lower-tier has enough space. This limitation is intertwined with the two problems explained in Section 3.2.

Problem: Frequently accessed pages from the lower-tier cannot be promoted without demoting less frequently accessed pages from the upper-tier.

Problem / limitation	Our solution	Section
Allocation fallback does not consider the access tier Pages are not promoted when upper-tier is full	Promotion or migration to alternatives	4.1
Pages are never demoted or reclaimed to lower-tier memory	Demotion for the least-accessed pages	4.2
Page classification is too coarse-grained (binary)	Fine-grained access history estimation	4.2.1
Page reclamation to lower-tier & to storage needs to be decoupled	Foreground promotion & background demotion	4.3

Table 1: Problems with current page management implementation, and our solutions

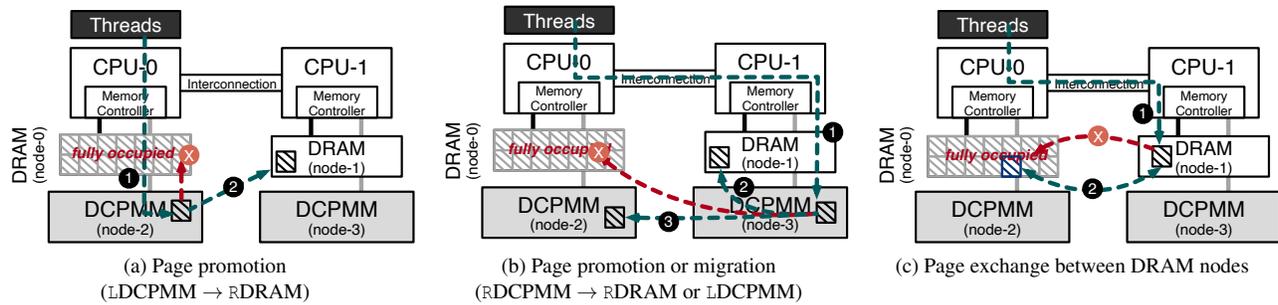

Figure 5: Our conservative design: exploiting multi-tiered memory hierarchy (L: Local, R: Remote)

In Linux operating systems, part of the virtual address space for each process can be mapped, either the `file-backed` or the `anonymous` region. The pages in the `file-backed` region contain the contents of an existing file(s) on memory so that subsequent file I/O operations of the same file can be replaced with memory access. On the other hand, pages belonging to the `anonymous` region do not represent any file contents. This is used for keeping arbitrary data on memory (e.g., `malloc`). For each memory region, the Linux operating system classifies memory pages into `active` or `inactive`. The kernel has inactive lists containing pages that might not be in use while keeping recently accessed pages on the active list. However, the current page classification is too conservative to precisely differentiate which pages are frequently or less frequently accessed from the active and inactive lists.

Problem: Binary page classification (either active or inactive) is too coarse-grained to be used for tiering.

Last, current page reclamation is very carefully performed in the background to hide the cost of accessing the storage devices from the critical path. In tiered memory systems, however, the cost of demoting pages to the lower-tier memory is cheaper than that of swapping out pages to the storage. We need to decouple the demotion to the lower-tier memory from traditional reclaim to the storage.

4 Automatic Multi-Tiered Memory

This section explores the design space of page management to tiered memory systems. The goal of our page management is to extract the full advantage of multi-tiered memory to im-

prove the performance of large-memory applications. To keep our design simple, we base our design on the AutoNUMA facility. Table 1 summarizes the supported mechanisms for each design space. In the following subsections, we explain the design and implementation of each scheme.

4.1 Exploiting Multi-Tiered Memory

As depicted in Figure 4, we take the NUMA fault as a demand signal for page promotion or migration from the DCPMM nodes or the remote DRAM node. Note that the current AutoNUMA deals with the promotion and migration requests only if the upper-tier (local DRAM) memory has free space. Otherwise, the request is discarded, and the faulted page remains in the original memory. When the local DRAM is fully occupied, our proposed design allows the pages to be promoted or migrated into the next best memory node in the multi-tiered memory hierarchy. This approach can exploit the advantage of the multi-tiered memory hierarchy, providing higher performance than the stock Linux kernel.

Figure 5 describes how we react when the local DRAM is full. There are three sources of demand for page migration or promotion to local DRAM in the multi-tier memory system. The multi-tier hierarchy opens up new opportunities to design memory placement. First, (5a) when the faulted page resides in the local DCPMM (1), we promote the page to the remote DRAM as the second best location (2). Since the remote DRAM provides lower latency and higher bandwidth than local DCPMM, we can improve the performance of applications to which memory was initially allocated in the lower-tier memory. Second, (5b) if the faulted page resides in the remote DCPMM (1), we have two alternatives to ex-

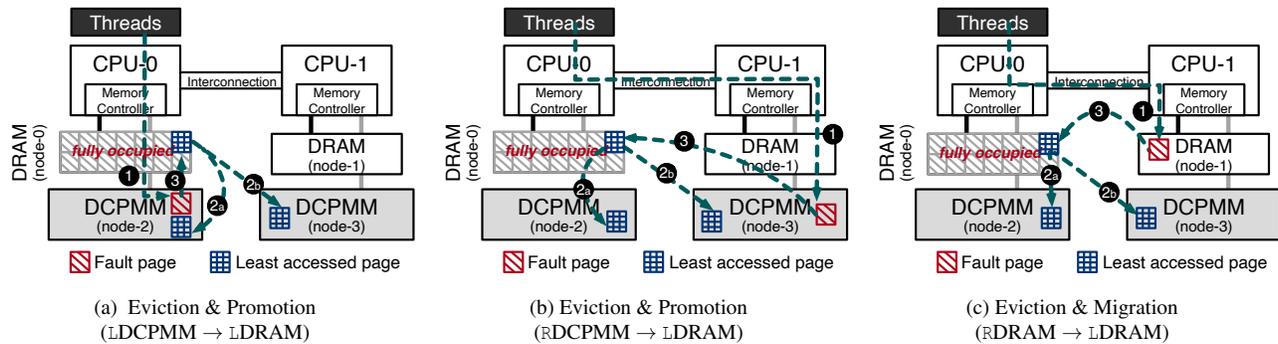

Figure 6: Our progressive design: opportunistic page promotion and migration with page eviction (L: Local, R: Remote)

exploit the advantage of the multi-tier memory hierarchy. We attempt to promote the page to the remote DRAM (2). If the remote DRAM also does not have free space, we try to migrate the page to the local DCPMM (3). Unlike the stock Linux kernel, our modified kernel supports migrating the page to CPU-less nodes (local DCPMM). We call this *AutoTiering Conservative Promotion and Migration (CPM)*. Last, (5c) the faulted page is in the remote DRAM (1). This means that the page is already in the second best location. The existing AutoNUMA is unable to complete the page migration operations between the upper-tier memory nodes. As a result, it leads to sub-optimal performance. In such a case, we consider the page exchange option to satisfy the demand for memory affinity (2). The prior study proposed the page exchange mechanism for tiered memory [35]. We repurpose the mechanism to resolve the migration failures between the same tier memory nodes as well. Internally, for each memory node, we keep track of which pages fail to be migrated. We then leverage this information to determine the migration demand that can be resolved with the exchange operation. We call this *AutoTiering CPM with Exchange (CPMX)*.

Since this design does not require significant changes in the existing Linux operating system, it is easily integrated on top of the AutoNUMA facility. We anticipate that our conservative design can be a practical solution for such software-managed tiered memory systems.

4.2 Opportunistic Promotion and Migration

As we design a conservative approach for finding the best alternative, this is limited to extracting the full performance benefit of software-managed tiered memory. In our conservative design, frequently used pages can reside in the lower-tier (DCPMM) memory while the upper-tier (DRAM) memory holds infrequently accessed data. To relieve such undesirable memory placement, we explore a progressive strategy, opportunistically demoting a page from the upper-tier memory to create free space. This is the main difference between conservative and progressive designs. By demoting a page, the request for page promotion can be successful. For page de-

motion to be effective, we need to have the ability to select a page that is highly unlikely to be reused within a short time. Otherwise, the wrong selection can have a negative impact on performance. We explain how we select a page for the demotion in the following subsection (4.2.1).

Figure 6 depicts how our progressive approach works with page demotion. When the NUMA page fault occurs (1), we find the least accessed page from the upper-tier (local DRAM) memory and compare the access frequency of the least accessed page with the faulted page. If the selected page is relatively less frequently accessed than the faulted page, we demote the selected page to place the faulted page on the higher-tier memory node. Otherwise, we prevent page promotion or migration requests to keep the upper-tier memory with more frequently accessed pages.

To promote a page from either local DCPMM (6a) or remote DCPMM (6b), we demote the least accessed page selected to the lower-tier memory (2a or 2b). The destination of the demoted page depends on where the page was previously accessed to preserve the locality. After that, (3) we can finally promote the page to the local DRAM node. In addition, Figure 6c shows how the page migration request from the remote DRAM is made. We call this *AutoTiering Opportunistic Promotion and Migration (OPM)*.

We further optimize our progressive design by fusing demotion and promotion (or migration) into one exchange operation, called *AutoTiering OPM with Exchange (OPMX)*. When the destination of the demotion is equal to the source of the promotion or migration, we leverage the exchange operation instead of individual promotion and migration. For example (6a), if we need to demote a selected page into the local DCPMM (2a) and promote the page to the local DRAM (3), two individual operations are fused. The exchange operation eliminates unnecessary page allocation and free operations.

In case we cannot find a page to be demoted from the upper-tier memory, we try to promote the page to the next best location - the remote DRAM - as would normally be the case. Since we are conducting page promotion and migration opportunistically, we can reduce excessive page promotion

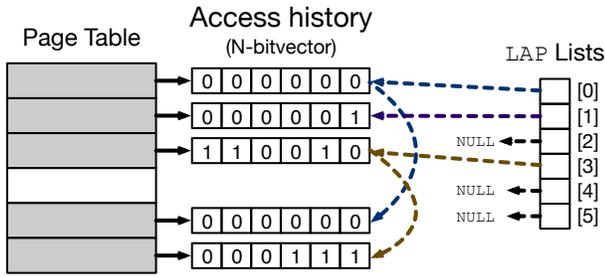

Figure 7: Maintaining least accessed page lists

and demotion that incurs performance overhead associated with page table manipulation and TLB shutdowns.

4.2.1 Predicting the Least Accessed Page

To make the progressive design effective, our goal is to find the least accessed page from the upper-tier memory. As explained in Section 3.3, the Linux operating system separates memory into file-backed and anonymous pages as LRU lists. When page promotion or migration fails due to lack of free space on the upper-tier memory, we investigate the pages from the file-backed region preferentially and move on to the anonymous region if we are unable to find the least accessed page from the file-backed region.

① **File-backed pages:** We examine whether we can make free space by demoting a page belonging to the file-backed region. As file-backed pages are maintained in two LRU lists, active and inactive, we regard the oldest page in the inactive list as the least accessed page. Whenever the file-backed pages are reaccessed (e.g., `sys_read` or `sys_write`), the operating system marks the page as accessed and moves it into the active list. Since the operating system can track the access of file-backed pages, we estimate the least accessed page by looking at the inactive list. If not, we move on to the active list. Note that we preserve the portion of the page cache configured in the kernel parameter (e.g., `vfs_cache_pressure`). If we cannot find a reusable space in the file-backed region, then we look for a page in the anonymous region as a fallback path.

② **Anonymous pages:** On the other hand, we keep the access (fault) information per page to select the least accessed page in the anonymous region judiciously. To minimize the monitoring overhead, we leverage the page scan facility used for AutoNUMA, keeping track of whether the pages are accessed or not during a given time window. Then we build the access history for each page with an N bit-vector. This means that we maintain up to the last N -time access history. We set N to 8. Based on the access history, we classify the pages into N levels (Least Accessed Page lists), where N is the number of bits that are set, as shown in Figure 7. Once page demotion is required, we find one of the pages in the LAP [0] list because those pages have not been accessed the last N times. If the LAP [0] list is empty, then we try to find

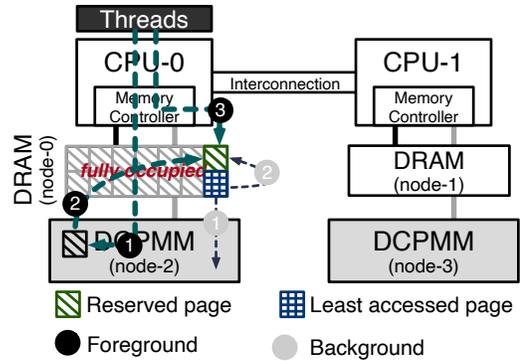

Figure 8: Hiding latency of page demotion with our `kdemoted`

a page from the LAP [1] list, and so on. After that, we can select the least accessed page in the upper-tier memory and conduct page demotion to the lower-tier memory.

4.3 Hiding Latency of Page Demotion

To enforce page promotion, we are supposed to demote a page from the target node. Before completing the page demotion, we cannot proceed with the promotion request due to a lack of space. The fault handling time is the sum of the two operations in the critical path: page demotion and promotion. To remove page demotion from the critical path, we explore a software optimization technique.

We keep a page pool of a few reserved pages. We empirically determine the reserved pages to 16 and 4 for 4KB and 2MB, respectively. The reserved pages allow us to immediately serve the promotion request without requiring the demotion process, even though the upper-tier memory is full. This approach is more cost-effective than the page exchange scheme [35] because it hides the latency of the page demotion in the critical path. Page demotion to the lower-tier memory takes longer than page promotion to the upper-tier memory because the storage-class memory used for lower-tier memory provides better read performance than write performance. To efficiently demote pages in the background, we maintain a new kernel thread called `kdemoted`, demoting the least accessed pages in a batch. Once the number of reserved pages reaches below a certain threshold, we wake the kernel thread to start the demotion process. The threshold is set to 4 through sensitivity studies.

Figure 8 depicts how simple optimization hides the latency of the page demotion. For every promotion request (1), the page can be promoted even when the upper-tier memory is full (2). After completing the promotion, the NUMA fault handler is returned without the demotion process, and future accesses to the page (3) will take place on the upper-tier memory. Meanwhile, `kdemoted` demotes the least accessed pages as needed in a batch (1) to reclaim the memory pool (2). We call this *OPM-BD (Background Demotion)*.

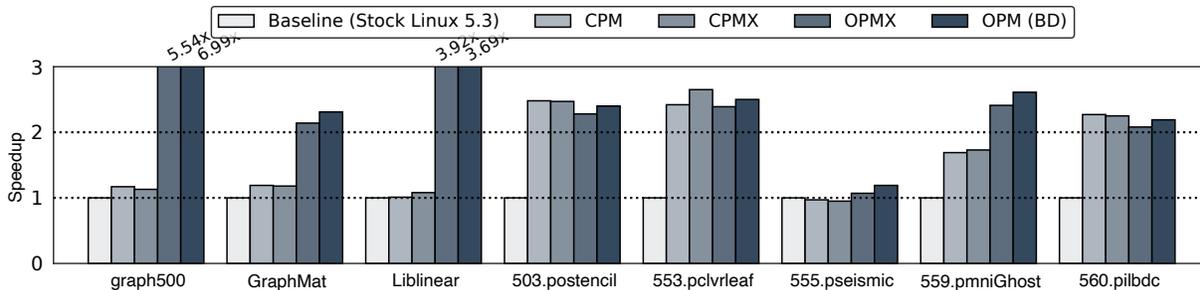

Figure 9: Speedup of our conservative (CPM and CPMX) and progressive (OPMX and OPM (BD)) schemes

5 Evaluation

5.1 Experimental Setup

To evaluate our proposed scheme, we use a NUMA server equipped with two Intel Xeon Gold 5218 processors and compose a multi-tiered memory hierarchy with a 16GB DDR4-2666 DIMM and a 128GB Intel Optane DC Persistent Memory (DCPMM) for each CPU socket. The server system has a total of 32GB DRAM and 256GB DCPMM as the main memory. To minimize measurement variability, we disable HW features, including Hyper-Threading, DVFS, Turbo-Boost, and prefetches. We use the Linux kernel 5.3 and Ubuntu 18.04 server as our baseline and implement our proposed schemes on top of the kernel. Our code is available at <https://github.com/csl-ajou/AutoTiering>. We run benchmarks from graph500, SpecACCEL (OpenMP), GraphMat [32], and Liblinear [22] used in recent large memory systems [2, 35]. We configure them for all the benchmarks to use all 32 cores across two sockets and more than 64GB of memory to sufficiently stress the multi-tiered memory system. Since the page size can affect performance in various ways, we evaluate performance for the large page (2MB) as well as the base page (4KB).

5.2 Experimental Results

Performance with our conservative approach (CPM):

Figure 9 presents the speedup results over the stock Linux kernel (first bar). Note that AutoNUMA is enabled in the default Linux kernel. The second bar in Figure 9 presents the speedup with our conservative promotion and migration (CPM), and the third bar shows performance changes when the conservative exchange is applied (CPMX). For most of the workloads we evaluate, we can see significant performance improvement with our CPM. In 503.postencil, 553.pclvrleaf, and 560.pilbdc, the speedup is over 2x, compared to the baseline. Also, 559.pmniGhost shows 1.6x performance improvement. Our conservative design (CPM) can promote pages from the lower-tier (DCPMM) memory nodes to the remote DRAM node even though the locality is not preserved because the remote DRAM is faster than the local DCPMM. We

can also migrate pages between the two DCPMM nodes to better access locality when accessing the lower-tier memory. As a result, we can utilize the multi-tiered memory systems more efficiently, leading to performance improvement.

For graph500 and GraphMat, we look at that the speedup is around 17% and 19%, respectively. GraphMat and Liblinear read the large dataset from file to its in-memory data structure. The file-backed pages occupy a significant portion of the DRAM nodes, while the crucial data structures reside in the DCPMM nodes. After that, it performs the Pagerank algorithm for analytics. Unfortunately, we could not observe that kswapd is invoked to free the inactive file-backed pages. Thus, our CPM and CPMX do not have the opportunity to utilize the DRAM nodes effectively.

On the other hand, we observe that the performance of 555.pseismic is not improved at all. This shows that the memory placement is well balanced across the upper-tier and lower-tier memory in the baseline. As a result, we could not exploit the promotion and migration opportunities.

Performance with our progressive approach (OPM):

We look at further improvement with our progressive design described in Section 4.2, which finds the least accessed page from the upper-tier (local DRAM) node and demotes that to the lower-tier memory. As shown in Figure 9, OPMX exhibits better performance than CPMX for most of the workloads. In particular, graph500, GraphMat, Liblinear, and 559.pmniGhost show significant speedup over CPMX. The performance of 503.postencil, 553.pclvrleaf, and 560.pilbdc is slightly degraded, by about 7 to 8%. 560.pilbdc fails to amortize the overhead of page promotion and demotion, and 553.pclvrleaf shows that the opportunity for page exchange is reduced.

We analyze the running behavior of graph500 to understand performance improvement. Before performing the core graph algorithm, it generates a lot of intermediate data that occupies the DRAM space. As a result, the baseline and our CPMX spend most of the time accessing the lower-tier memory while running BFS (Breadth-First Search). Interestingly, it exhibits the memory access locality on a small part of the address space, even though the whole address space is huge. With OPMX, we can demote the less frequently accessed data

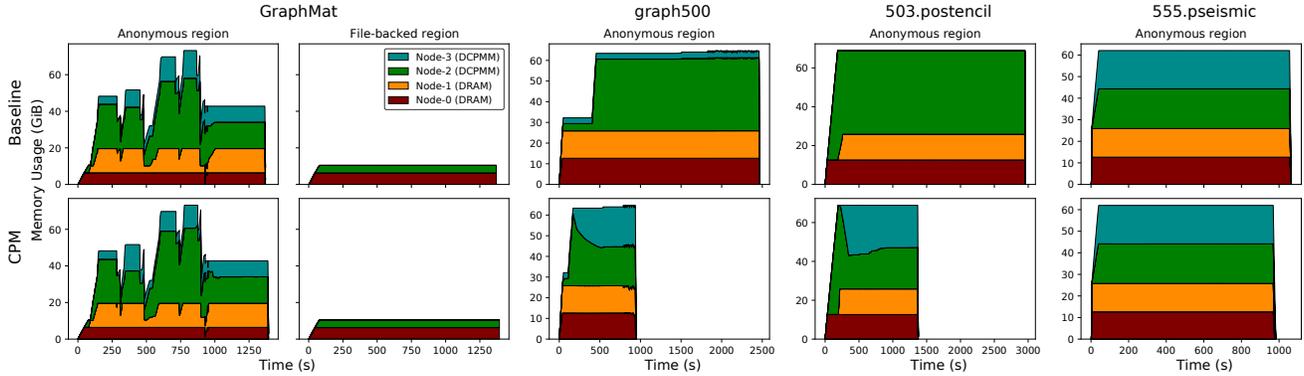

Figure 10: Memory usage across DRAM and DCPMM nodes (Baseline vs. CPM)

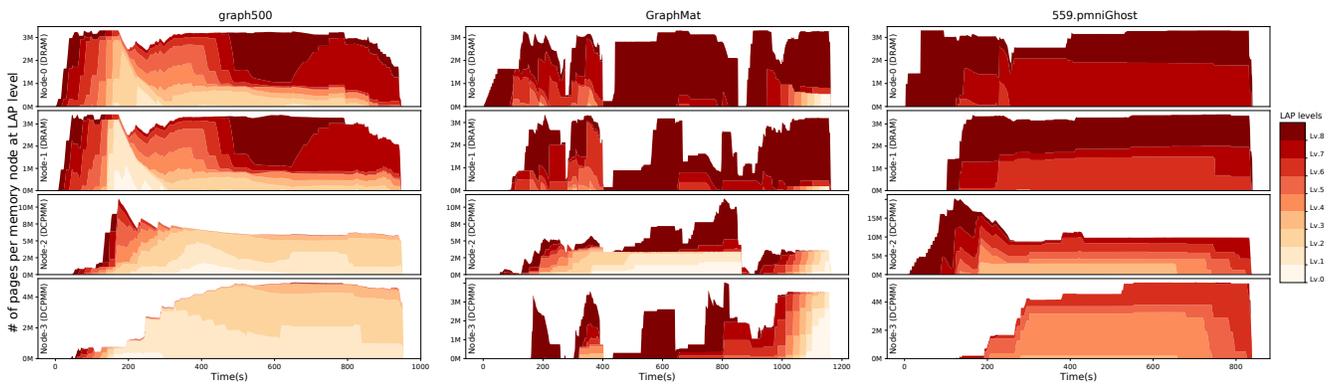

Figure 11: Estimated access frequency of pages corresponding to the LAP levels

to the lower-tier memory and utilize the upper-tier memory space for more frequently accessed data. Therefore, we can increase performance drastically.

For GraphMat, we see significant performance improvement comes from the demotion of file-backed pages. By default, the file-backed page is initially placed on the inactive list. After the page is reaccessed, it moves from the inactive to the active list. By demoting the least accessed page from the file-backed pages, we can improve the utilization of the upper-tier memory.

With OPM(BD), we can further improve the performance of most workloads. The improvement for graph500 and GraphMat is considerable compared to OPMX. 555.pseismic and 559.pmniGhost show marked improvement, and the other SPEC workloads also restore the degraded performance from the exchange version. Meanwhile, Liblinear shows degraded performance slightly.

Distribution of memory usage: We analyze how multi-tiered memory is utilized as time goes by. Figure 10 compares the memory usage for the baseline and our progressive design for selected workloads, which are beneficial from our CPM. For the three SPEC workloads, the lower-tier memory is more well balanced with CPM. This is because we allow pages to be migrated to the CPU-less node. Even though CPM is unable

to satisfy the required access tier, it can preserve the access locality in the lower-tier memory.

For GraphMat, the performance improvement is relatively small compared to the SPEC workloads, and 555.pseismic is not improved. The reason is that the baseline already keeps the memory balance across lower-tier DIMMs. In the next paragraph, we look at the effectiveness of our OPM-based schemes for those two workloads.

Effectiveness of LAP classification: To evaluate the effectiveness of our LAP scheme, we decompose all the pages into each LAP level and build a histogram as time goes by. Figure 11 presents the selected three workloads that show significant improvement with OPMX compared to CPM. For graph500, GraphMat, and 559.pmniGhost, the relatively frequently accessed pages (dark red) corresponding to level 7 or 8 are placed on DRAM nodes, while DCPMM nodes serve the relatively less accessed pages. This result shows that our OPMX can be effective for applications whose working set fits in the upper-tier memory.

The additional space for keeping the access history (8b), two pointers for lists (16B), page frame number (8B), and last faulted CPU number (1B) is required for each page to enable our LAP scheme. Compared to the baseline, we require 32 bytes of metadata per page due to 8 bytes alignment, and it

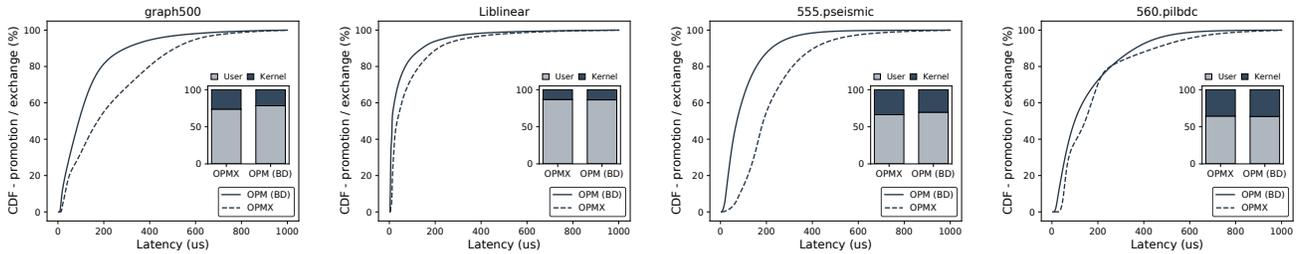

Figure 12: Cumulative distribution function (CDF) of page promotion and migration with OPMX and OPM (BD)

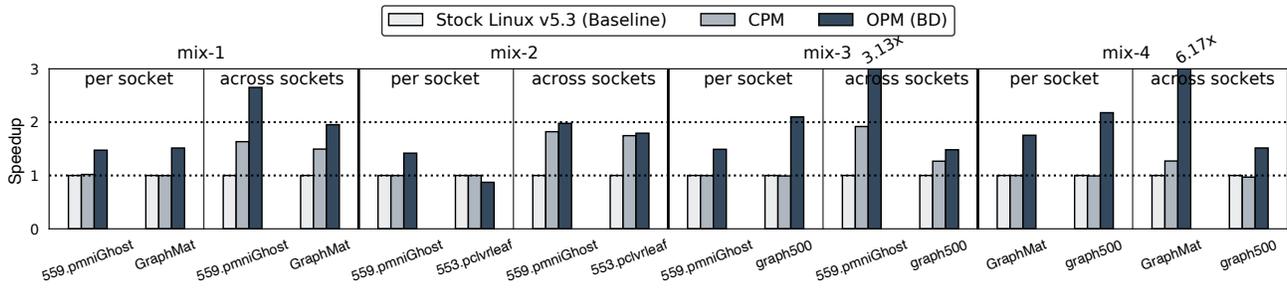

Figure 13: Speedup of multi-programmed execution scenarios

results in an extra 288MB for the system memory of 32GB DRAM with 256GB DCPMM. It slightly decreases the effective DRAM memory space by 0.91%.

Latency hiding with background demotion: We measure promotion and exchange latency distribution in the page fault path with `ftrace` and the kernel and user time. Figure 12 presents the latency CDF serving a page promotion for OPM (BD) and a page exchange for OPMX. The solid line is for the distribution, including the latency hiding scheme (OPM (BD)), and the dashed line is for the OPMX scheme. The fault latency varies for both schemes. We observe that OPM (BD) shows better latency distribution for all the workloads than the exchange version because the demotion is off the critical path. Especially, `graph500` and `555.pseismic` are beneficial to the background demotion.

On the other hand, the end performance of `Liblinear` is not improved with the background demotion shown in Figure 9. Even though the latency is reduced, the kernel execution time is not significantly changed. This is due to the possibility of incurring memory access contentions across the application threads and the background kernel thread. We plan to resolve the undesired background demotion case with rigorous scheduling of `kdemoted` in our future work.

Performance with multi-programmed workloads: We evaluate how well our proposed schemes work for multi-programmed workloads in two scenarios, `per socket` and `across sockets`. Figure 13 shows the speedup with CPM and OPM (BD) when two applications run on the same server. We mimic four multi-programmed scenarios (`mix-1` to 4)

with the combination of the workloads. When isolating the applications based on sockets (`per socket`), CPM does not provide any performance improvements as expected because it lacks the opportunity to exploit the multi-hierarchy of memory. On the other hand, we can observe significant performance improvement with OPM (BD) for all cases except for `553.pclvrleaf` in `mix-2` as more frequently accessed pages can be placed on the upper-tier memory. When allowing the applications to run across sockets, these may not effectively utilize the upper-tier memory nodes because the memory usage across the threads of applications is not evenly distributed. In the `across sockets` setting, we observe that CPM can be useful by exploiting the multi-tiered memory hierarchy. In addition, OPM (BD) can further improve performance, compared to CPM, for all the cases.

Working-set sensitivity: Figure 14 presents the performance by varying the working-set size from 32GB to 160GB for selected workloads. We observe that the performance of `graph500` and `559.pmnigHost` is significantly improved by both CPM and OPM (BD). For `503.postencil` and `553.pclvrleaf`, however, OPM (BD) and CPM show similar performance improvements as the working-set size increases. As explained in the LAP classification paragraph, most of the pages are evenly accessed in those benchmarks less beneficial to OPM (BD). Note that the speedup with our approach is significant and still effective compared to stock Linux (Baseline). Since the other workloads, such as `GraphMat` and `Liblinear`, have fixed problem input sizes, we could not evaluate the working-set sensitivity for the workloads.

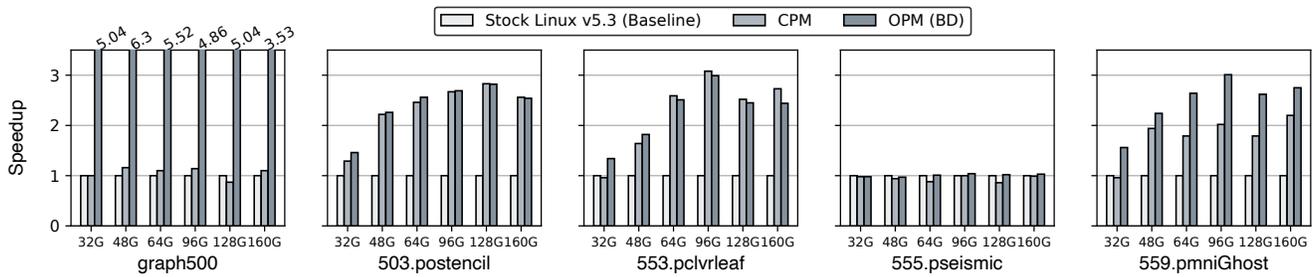

Figure 14: Performance speedup by varying the working-set size from 32GB to 160GB

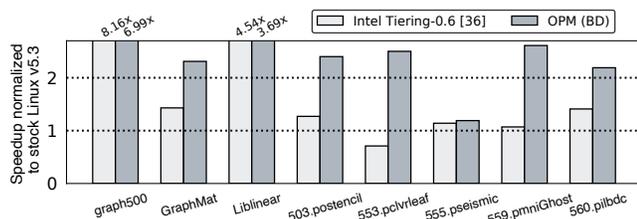

Figure 15: Performance comparison: OPM(BD) and Tiering v0.6 [36]

Performance comparison with prior studies: Figure 15 presents the performance comparison results with a recent proposal from Intel called Tiering v0.6 [36]. Note that Tiering v0.6 is based on Linux kernel version 5.9 but not merged into the mainline. We show that our OPM(BD) outperforms the performance of Tiering v0.6 for most of the workloads.

For the anonymous memory region, Tiering v0.6 supports the page promotion to the upper-tier memory by extending the AutoNUMA framework. Through the monitoring facility, they investigate whether the page is accessed during the last two consecutive scans or not. If so, they consider the page is hot and promote it. On the other hand, our OPM(BD) maintains access history for the last N (8) times. The decision is more accurate than looking at the previous two accesses.

Besides, Tiering v0.6 inherits the same limitation from the traditional AutoNUMA. Once the local DRAM becomes full, it is allowed to promote the page to neither the remote DRAM nor the local DCPMM. Instead, `kswapd` is triggered to reclaim pages to lower-tier memory. In contrast, our LAP scheme makes the upper-tier memory better utilized by opportunistically performing promotion and demotion.

For `graph500`, we observe that Tiering v0.6 performs better than OPM(BD). Our scheme outperforms the time for building graphs before execution, but while traversing the graph, `graph500` with OPM(BD) accesses more pages in the lower-tier memory compared to Tiering v0.6. In `Liblinear`, it shows that Tiering v0.6 more aggressively demotes the file-backed pages, leading to better utilization of the upper-tier memory.

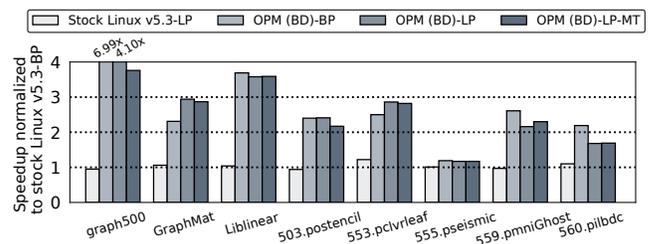

Figure 16: Speedup with large page (LP) over base page (BP)

Performance with large page: To minimize the overhead of TLB misses for large memory applications, modern computer systems provide large page options. Figure 16 shows the speedup results when we leverage the large page (2MB) instead of the base page size (4KB). For `GraphMat` and `553.pclvrleaf`, the performance improvement with large pages can be observed in the OPM(BD) scheme. On the other hand, most of the workloads do not present a significant difference. `559.pmniGhost` and `560.pilbdc` exhibit degraded performance. When analyzing the LAP histogram for the SPEC workloads with the large page, our scheme can quickly separate pages into the LAP levels compared to the base page. However, there is performance degradation because the overhead of page demotion increases when moving the large pages. To reduce the overhead, we take advantage of the multi-threaded (MT) version of copying pages [35]. `559.pmniGhost` only shows improved performance, but the other workloads become even worse. As mentioned in the earlier paragraph (*Latency hiding*), we will further investigate how our scheme can be extended to mitigate the performance overhead in our future work.

6 Related Work

There have been significant efforts throughout hardware and software to use tiered (or heterogeneous) memory systems effectively. We compare our scheme with prior approaches. First, most previous studies focused on designing page migration mechanisms and policies on two-tiered memory systems [3, 10, 11, 19, 20, 24, 26, 29, 35]. Unlike the prior work, this study extends the problem space to the tiered memory

augmented on traditional NUMA architecture, called multi-tiered memory systems. As there are several alternatives to page placement in multi-tiered memory systems, this paper exploits such opportunities when placing, promoting, and demoting pages. Second, *AutoTiering* does not differentiate pages into hot and cold with a predefined threshold used in prior work [3, 19, 20]. In this study, promotion and demotion decisions are made on the relative access frequency and recency across the memory tier. To estimate page access activities, we rely on the AutoNUMA facility. Last, we use a real-world infrastructure to evaluate our proposed ideas based on Intel's Optane Persistent Memory (DCPMM), which has attracted recent attention. Prior work emulated or simulated two-tiered memory systems based on DRAM [3, 11, 19, 20, 35]. Although real-world storage-class memory (SCM) shows asymmetry in read and write performance, it was not correctly modeled in emulating tiered memory with DRAM.

Below, we describe previous software efforts in the OS community. To understand the heterogeneity of memory systems in Linux, the ACPI 6.2 specification introduced heterogeneous memory attributes tables (HMAT) to provide users with performance information for various memory types [39]. Since the Linux kernel 5.0-rc1, the persistent memory (here, Intel's DCPMM) can be used as volatile main memory, although it is slower than DRAM [15]. It can provide abundant main memory space, but the policy and mechanism supporting tiered memory hierarchy are in infancy. Recently, a new memory allocator for hardware-managed DRAM cache known as shuffle page allocator introduced in the Linux kernel [34]. However, it is not enough to extract the full performance of tiered memory because it does not consider the distance between memory nodes and NUMA typologies. Also, there have been efforts to efficiently support page migration between fast and slow memory, but these still rely on active and inactive list management [5, 16, 30] and have not been merged into the mainline of the Linux kernel until now. In the Windows operating system, they measure the cost of various page operations when the system is initialized through `MiComputeNumaCost` and build a table like the NUMA distance of Linux, but this reflects the access costs [37]. Due to limited information for Windows OS, we could not find how they work for multi-tiered memory.

Researchers in the architecture community introduced hardware techniques to effectively utilize two-tiered memory systems while minimizing the performance overhead in estimating access frequency [7, 28, 29, 31]. Choe et al. suggested memory allocation schemes for the hardware-assisted multi-tiered memory systems where the DRAM nodes are invisible to software [6]. Except for that, none of the work considered the case of multi-tiered memory systems. The overheads such as tracking and migrating pages can be reduced significantly by architectural support, but the flexibility of making decisions for promotion and demotion considering placement alternatives is limited.

7 Conclusion

This work explored a set of new page management schemes called *AutoTiering*, which benefit from multi-tiered memory systems. We found that the Linux operating system focuses on the access locality posed by NUMA, rather than the memory tier. However, in multi-tiered memory systems, the cost of accessing memory is not proportional to solely the locality. We comprehensively addressed the diverse aspects of utilizing the multi-tiered memory systems by considering two factors: the access tier and locality. We built a proof of concept with a real-world tiered memory system. Our evaluation showed significant performance improvements in various benchmarks than the stock Linux kernel version 5.3 and the previous approach from Intel's Tiering v0.6.

Future tiered-memory systems are expected to be more diverse and heterogeneous. To make our approach more general, we can maintain a table describing possible alternatives to placement. While initializing memory in the operating system, we can measure actual performance across memory nodes. With such a new table, *AutoTiering* can adjust where pages need to be promoted, demoted, or migrated adaptively, as explained, without a static decision.

A Fast and Flexible Hardware-based Virtualization Mechanism for Computational Storage Devices

Dongup Kwon, Dongryeong Kim, Junehyuk Boo, Wonsik Lee, and Jangwoo Kim*
*Department of Electrical and Computer Engineering
Seoul National University*

Abstract

A *computational storage* device incorporating a computation unit inside or near its storage unit is a highly promising technology to maximize a storage server’s performance. However, to apply such computational storage devices and take their full potential in virtualized environments, server architects must resolve a fundamental challenge: *cost-effective virtualization*. This critical challenge can be directly addressed by the following questions: (1) how to virtualize two different hardware units (i.e., computation and storage) and (2) how to integrate them to construct virtual computational storage devices, and (3) how to provide them to users. However, the existing methods for computational storage virtualization severely suffer from their low performance and high costs due to the lack of hardware-assisted virtualization support.

In this work, we propose *FCSV-Engine*, an FPGA card designed to maximize the performance and cost-effectiveness of computational storage virtualization. FCSV-Engine introduces three key ideas to achieve the design goals. First, it achieves high virtualization performance by applying *hardware-assisted virtualization* to both computation and storage units. Second, it further improves the performance by applying *hardware-assisted resource orchestration* for the virtualized units. Third, it achieves high cost-effectiveness by *dynamically constructing and scheduling* virtual computational storage devices. To the best of our knowledge, this is the first work to implement a hardware-assisted virtualization mechanism for modern computational storage devices.

1 Introduction

A modern *computational storage* device incorporating a computation unit inside or near its storage unit is becoming a highly promising solution for high-performance storage servers as it can minimize the data movement overhead with *near-storage processing* [10, 15, 17, 21, 27, 33, 35, 39]. A server equipped with a computational storage device can offload

*Corresponding author.

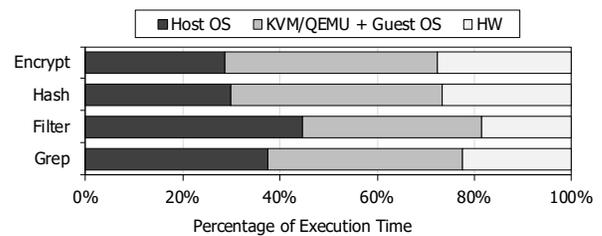

Figure 1: Percentage of execution time spent on a paravirtualized computational storage device.

data-intensive routines to the computation unit and enable it to access the data stored in the storage unit without software intervention. For example, current off-the-shelf computational storage devices incorporate high-end field-programmable gate arrays (FPGAs) for computations and adopt an NVM Express (NVMe) storage protocol to allow the FPGAs to directly access the solid-state drives (SSDs) [6, 24, 33, 35].

In addition to the advances in the hardware devices, recent studies have proposed flexible FPGA overlay architectures and POSIX-like APIs to improve the usability of modern computational storage devices [33, 35]. Their stream-based overlay architectures contain user-specified operators (e.g., stream processing units) and activate them selectively through an in-FPGA crossbar switch and control logic. At the same time, their custom software stacks provide abstraction layers to hide the complexity of the underlying FPGA implementations. For example, a recent computational storage implementation takes advantage of Linux file and pipe abstractions to allow users to easily orchestrate their near-storage processing [35].

However, the existing virtualization mechanisms for computational storage severely suffer from their low performance and high costs. First, the software-based virtualization mechanisms (e.g., paravirtualization) cannot take full advantage of near-storage processing due to their (1) heavy hypervisor and host OS stacks to emulate virtual computational storage devices and (2) indirect resource orchestration mechanisms via guest and host OSes. To profile the software overhead of paravirtualized computational storage devices, we measured the

end-to-end execution time of near-storage processing benchmarks on a virtual machine (VM). The near-storage processing benchmarks read 4-KB pages from an NVMe SSD and perform four different stream operations (*encryption, hash, filter, grep*) on an FPGA. Figure 1 shows the percentage of execution time spent on the paravirtualized near-storage processing benchmarks. The hypervisor and guest/host OSes account for a significant portion of their overall execution time (72%–81%) due to the software-centric device emulation and resource orchestration.

Second, the existing virtualization mechanisms which statically allocate both computation and storage units for each VM will incur high hardware costs due to the inefficient use of the shared device resources. (1) The existing SSD-FPGA coupled architectures suffer from their limited scalability when multiple VMs share a single computational storage device. For example, concurrently running many VMs and their near-storage processing workloads on a single computational storage device result in the performance bottleneck at the single shared SSD. (2) Moreover, their static resource allocation methods cannot handle the dynamic behavior of VM workloads efficiently, which incurs the extra costs for the additional hardware resources to meet quality-of-service (QoS) requirements.

In this paper, we propose FlexCSV, a new hardware virtualization mechanism to maximize the performance and cost-effectiveness of computational storage virtualization. FlexCSV combines the following key ideas. First, FlexCSV implements *hardware-assisted virtualization and resource orchestration*. Through a standard single-root I/O virtualization (SR-IOV) layer at the hardware level, FlexCSV provides a fast and host-bypassing virtualization stack and allows multiple VMs to exploit near-storage processing capabilities. In addition, FlexCSV manages user-requested stream operations at the hardware level to mitigate the software burden to orchestrate near-storage processing.

Second, FlexCSV achieves high cost-effectiveness by *dynamically constructing and scheduling both computation and storage units*. To improve its scalability, FlexCSV adopts an SSD-FPGA decoupled architecture and allows the FPGA accelerator card to construct many virtual computational storage devices with multiple PCI Express (PCIe) attached SSDs. Moreover, its dynamic resource allocation from a shared hardware operator pool and partial reconfiguration support can capture the dynamic behavior of VM workloads and reduce QoS violations significantly at minimum hardware costs.

For evaluation, we implemented our FlexCSV prototype on a Xilinx FPGA accelerator card [7], NVMe SSDs [3], and an existing KVM/QEMU virtualization stack [4, 5]. We implemented a hardware-assisted virtualization stack for computational storage on the same FPGA card and connected its hardware modules through advanced extensible interface (AXI) interconnects. An in-FPGA AXI crossbar switch orchestrates data movements between the processing units and

the FPGA’s on-board DRAM. In this work, we implemented eight hardware near-storage processing operators and allowed them to be shared by four VMs.

Our experimental results show that our FlexCSV prototype obtains 2.0x–2.8x higher near-storage processing performance in virtualized environments than the existing software-centric virtualization mechanisms. Moreover, FlexCSV’s SSD-FPGA decoupled architecture can connect four PCIe-attached SSDs and provide 3x more scalable performance over the coupled computational storage architectures. Through its dynamic resource allocation for both computation and storage units, FlexCSV can reduce QoS violations significantly at minimum hardware costs when a computation storage device is oversubscribed by many VMs.

In summary, we make the following contributions:

- **Novel virtualization stack for computational storage:** We propose a fast and flexible hardware-assisted virtualization mechanism for modern computational storage devices.
- **High performance:** FlexCSV achieves high virtualization performance by bypassing software stacks and leveraging near-storage processing.
- **High cost-effectiveness:** FlexCSV achieves high hardware cost-effectiveness by dynamically constructing and scheduling both computation and storage units at minimum costs.
- **Prototyping:** We implement and evaluate our FlexCSV prototype with off-the-shelf devices and open-source software virtualization stacks.

2 Background

2.1 SSD-FPGA Computational Storage

2.1.1 Hardware Architecture

SSD-FPGA hardware platform. A modern computational storage device incorporates its computation and storage units together and couples them through an on-board interconnect [24, 33, 35]. Figure 2 (bottom) shows the typical hardware platform of modern SSD-FPGA computational storage devices. It utilizes an FPGA for computations and allows it to directly access an attached NVMe SSD. For near-storage data processing, it also supports peer-to-peer (P2P) data communications between the computation and storage units through its internal switches (e.g., on-board PCIe switch). For example, by exposing an FPGA’s DRAM space to an SSD and implementing a routing policy in an internal crossbar switch, a computational storage device can enable the computation and storage units to exchange data directly without software arbitration [35].

FPGA overlay architecture. The FPGA overlay architectures implemented on computational storage devices offer programmable near-storage processing [33, 35]. They consist

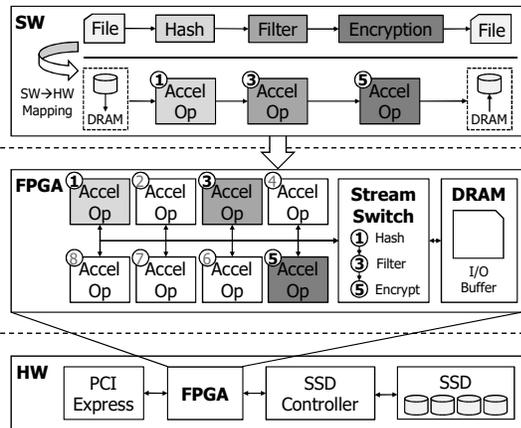

Figure 2: Full software and hardware stacks for a modern FPGA-based computational storage device.

of reconfigurable operators, crossbar stream switches, and on-board DRAM. The *operators* are reconfigurable stream processing units, and each of them can be selectively activated to configure full stream operations. The on-board crossbar switches orchestrate data movements between the operators and the FPGA’s DRAM. Figure 2 (middle) shows an example overlay architecture for programmable near-storage processing. This overlay architecture contains eight operators and three of them are activated to serve the user-specified stream workloads (hash, filter, encryption). Then, a routing policy is installed in the stream switch to properly route an incoming data stream to the target operators (hash→filter→encryption) or DRAM buffers.

The FPGA overlay architectures also implement storage interfaces to allow their operators to directly access storage units [24,33,35]. Modern computational storage devices adopt an NVMe standard storage protocol to offer fast and parallel storage access [24]. NVMe has the following key advantages. First, NVMe supports multiple I/O queues to fully utilize the high-bandwidth storage units. NVMe can run multiple storage operations concurrently by assigning separate NVMe submission queue (SQ)/completion queue (CQ) pairs to different processing cores. Second, NVMe enables fast storage operations by minimizing the number of memory-mapped I/O (MMIO) operations. For example, NVMe devices expose a set of SQ/CQ doorbell registers and require only a single MMIO write operation (i.e., doorbell register write) to submit storage operations or to notify their completions.

2.1.2 Software Support

Abstraction layer. To improve the usability of near-storage processing in modern computational storage devices, recent studies provide custom software stacks utilizing Linux file and pipe abstractions and allow users to easily orchestrate near-storage processing [33,35]. Their software stacks expose the operators implemented on their FPGA overlay architec-

```

1  typedef struct {
2      ap_uint<64> data;
3      ap_uint<4> dest;
4      ap_uint<1> last;
5  } stream_data;
6  typedef hls::stream<stream_data> stream_t;
7
8  void accel_unit(
9      stream_t &in, stream_t &out, ap_uint<4> dest){
10     stream_data input, output;
11     do {
12         input = in.read();
13         output.data = process(input, data);
14         output.dest = dest;
15         out.write(output);
16     } while (!input.last);
17 }

```

Listing 1: Example HLS code for an operator implemented on an FPGA overlay architecture.

tures as executable files to an OS. Then, a user program can initiate near-storage processing through POSIX-like APIs or a pipe command from data to executable (i.e., operator) files. Figure 2 (top) shows an example user program and its software-to-hardware mapping process. In this example, the application performs a hash→filter→encryption stream operation on the input file stored in the computational storage device. In this way, the software support can hide the complexity of the underlying FPGA implementations and coordinate user-specified near-storage data processing.

High-level synthesis support for operators. The software support also allows users to customize operators using an FPGA’s reconfigurability and high-level synthesis (HLS) tools [35]. Listing 1 shows an HLS code snippet to implement an example `accel_unit` operator. First, users can define a stream data structure. In this example, `dest` and `last` signals are delivered along with a data stream. The `dest` field indicates its next destination operator and the `last` field indicates a last word in the data stream. Second, users can define the input and output ports of an operator. In this example, the `accel_unit` module has the `in/out` data stream ports and the `dest` configuration register to determine its next destination operator. This example operator reads a word through the `in` stream port and forwards it through the `out` stream port after manipulating the `dest` field of the output stream.

2.2 I/O Virtualization

2.2.1 Software-based Virtualization

The existing software-based I/O virtualization presents virtual device instances and enables device sharing across multiple VMs. *Full virtualization*, which is one of the software-based virtualization mechanisms, utilizes a trap-and-emulate approach to provide virtual device instances to VMs without changing the guest OSes. However, this virtualization mechanism significantly suffers from excessive VM exits when

guest OSes access their virtual device resources.

In contrast to full virtualization, *paravirtualization* enables efficient virtual device emulation by creating VM-friendly virtual device interfaces between guest OSes and hypervisors (e.g., virtio [34]). This paravirtualization mechanism incurs a fewer number of VM exits by minimizing MMIO operations for device access, but it still relies on software traps to a hypervisor and CPU mode switches. Moreover, guest OSes should be aware that they are being virtualized and modified to interact with a hypervisor in this efficient manner.

To virtualize modern fast and high-bandwidth devices, recent *sidecore approaches* dedicate multiple CPU cores for device emulation [29, 38]. As dedicated sidecores in the host software keep polling guest I/O operations via shared memory regions, VMs do not have to incur VM exits to submit device operations. In this way, the sidecore approaches minimize the performance overhead incurred by VM exits and CPU context switches [23]. However, the sidecore approaches demand a large amount of computing resources of a host server machine to execute their polling-based device emulation [22, 25, 29].

2.2.2 Hardware-assisted Virtualization

To overcome the performance overhead and host inefficiency of the software-based virtualization mechanisms, hardware-assisted virtualization mechanisms allow guest OSes to access target PCIe devices directly without any software arbitration. To enable the direct assignment of PCIe devices (i.e., *passthrough* virtualization), an I/O memory management unit (IOMMU) and its direct memory access (DMA) and interrupt remapping mechanisms are introduced. The DMA remapping mechanism allows DMA operations from virtual devices to be accomplished with guest physical addresses. Similarly, the interrupt remapping mechanism translates interrupt vectors caused by the virtualized devices into VM contexts. However, this approach requires a physical device to be exclusively assigned to a single VM and does not support device sharing across multiple VMs.

To address such shortcomings, PCIe SR-IOV allows a physical device to be shared by many VMs at the hardware level. An SR-IOV capable device presents multiple physical functions (PFs) and virtual functions (VFs) (i.e., virtual device instances) at the device interface. Since VFs have separate PCIe configuration registers, including base address registers (BARs), SR-IOV can enforce resource isolation while serving multiple VMs. Moreover, an SR-IOV capable device implements how to multiplex itself at its internal bridge module and thus does not rely on any host software to multiplex its virtual device instances.

3 Motivation

The increasing density and performance of modern computation and storage devices create new opportunities for

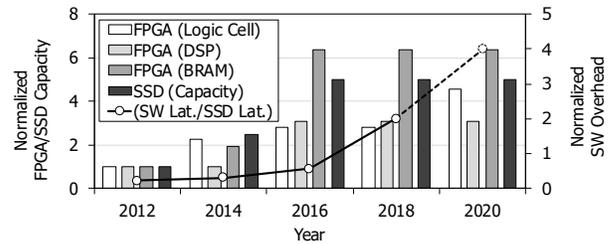

Figure 3: Increasing resource density and performance of FPGA and SSD products over time [3, 8]. The data are normalized to the values at 2012. The latency of the SW stack is set to 20 μs [30, 33], and the current SSD access time is assumed to be 5 μs based on recent studies [33, 41].

virtualization. Figure 3 shows the increase in SSD capacity and FPGA resources over the recent eight years. The available commodity SSD and FPGA resources have increased 3x–6x over the years, which creates a high potential to serve many VMs on a single computational storage device [19, 22, 25, 29, 40]. Furthermore, the significant improvements in storage device access time (65 μs \rightarrow 5 μs [33]) have moved the performance bottlenecks to the software stacks.

However, the existing software-based SSD and FPGA virtualization mechanisms have the following limitations when providing near-storage processing between the virtualized computation and storage units. First, the software-based virtualization mechanisms cannot take full advantage of near-storage processing due to their indirect device-control and data paths to emulate virtual computational storage devices. Second, their static resource allocation for each VM incurs high hardware costs due to the inefficient use of the shared device resources.

3.1 Indirect Device-Control and Data Paths

Employing software-centric virtualization to SSD and FPGA devices separately suffers from indirect device-control and data paths between the virtualized hardware units and fails to take full advantage of near-storage processing. To measure the software overhead of paravirtualized SSD and FPGA operations, we implemented a virtio-based virtualization stack on KVM/QEMU and profiled the end-to-end execution time of SSD-FPGA near-storage processing. Figure 4 shows two software-centric implementations for computational storage virtualization. In the full software implementation, SSD and FPGA operations involve VM exits and traps to a hypervisor. In the optimized software implementation, accessing an SSD from a VM can bypass the hypervisor and host OS stacks through to an IOMMU and SR-IOV support. However, utilizing an FPGA still relies on the software-centric virtualization mechanisms and suffers from the software-side performance overhead. Moreover, since a guest OS cannot obtain host physical addresses of the FPGA’s BARs, its input and output data must be transferred via the guest and host OS stacks.

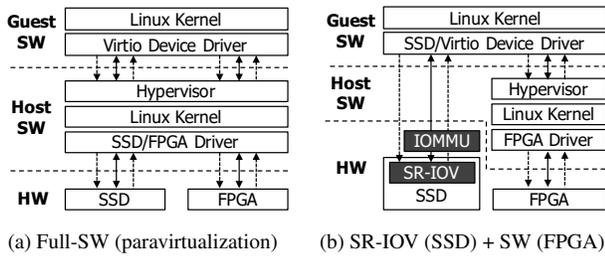

Figure 4: Software-centric virtualization mechanisms for computational storage.

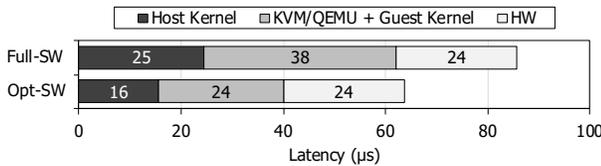

Figure 5: Execution time spent on a paravirtualized computational storage device with SW-centric virtualization implementations.

Figure 5 shows the execution time spent in paravirtualized SSD-FPGA near-storage processing. The benchmark reads a 4-KB page from the NVMe SSD and executes Blowfish encryption [28] on the FPGA. To emulate a coupled computational storage device, we installed an Intel Optane SSD [3] and Xilinx Alveo U250 FPGA [7] and connected them through PCIe Gen-3 lanes. The SSD read latency is $10 \mu\text{s}$, and the encryption operation takes $14 \mu\text{s}$ to process the 4-KB data. In this environment, the hypervisor and guest/host OSes account for a significant portion of overall execution time due to the software-centric device emulation and resource orchestration. The optimized software virtualization implementation mitigates host OS overhead because the SSD access bypasses the host software. Also, as there is no need for KVM/QEMU to emulate the SSD, the hypervisor and guest kernel overhead also decrease. However, the overhead for the virtual FPGA emulation and the data movements between the virtualized units still remains.

3.2 SSD-FPGA Coupled Architecture

An SSD-FPGA coupled computational storage architecture severely suffers from its limited scalability due to its board-level SSD-FPGA integration [6, 17, 33, 35]. Such tight device integration makes it challenging to merge diverse SSD-FPGA resource combinations into a single device while supporting direct device-control and data paths among all the consolidated devices. Moreover, their architectural limitations become increasingly apparent as the gaps between SSD and FPGA resource capacity and performance increase.

For example, concurrently executing many VMs and their near-storage processing workloads on a computational stor-

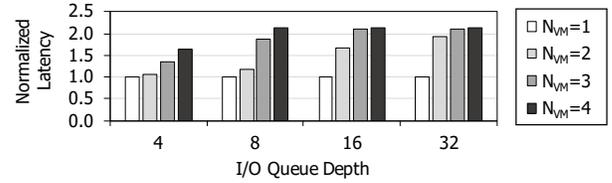

Figure 6: Performance comparison of near-storage processing with the increasing number of SSD-contending VMs and queue depth. The results are normalized to the single-VM latency. N_{VM} indicates the number of concurrently running VMs.

age device can lead to the performance bottleneck at the single shared SSD. To show the performance impact of resource contention in a coupled architecture, we emulated an on-board consolidated storage unit by dedicating an NVMe SSD to an FPGA board through PCIe P2P. In this experiment, we implemented an example operator whose throughput is 100 MB/s and measured the end-to-end latency on a target VM with the increasing number of I/O-intensive VMs and their block I/O intensities (i.e., queue depth). Figure 6 shows the normalized end-to-end latency of the target near-storage processing on the coupled architecture. When two or more I/O-intensive VMs share the SSD, the near-storage processing latency becomes 2.1x slower than the single-VM execution case. When the VMs demand higher I/O performance by increasing the queue depth, the target VM and its near-storage processing suffer from the more severe resource contention.

3.3 Static SSD/FPGA Resource Allocation

Static resource allocation and scheduling for both computation and storage units will incur high hardware costs because they cannot handle the dynamic behavior of VM workloads efficiently. To motivate dynamic resource allocation and scheduling, we implemented two hardware operators on an FPGA and allowed each of them to serve two VMs using time multiplexing. Following the resource-sharing mechanisms proposed by prior FPGA virtualization studies [19, 26], we oversubscribed the hardware operators but statically assigned them to a specific set of VMs.

Figure 7 shows the latency cumulative distribution function of the four VM workloads with the static resource allocation strategy. In this experiment, we executed four VMs concurrently and generated VM workloads by following Poisson distribution with different expected request rates (λ). For the first two VMs (VM_1, VM_2), we generated near-storage processing workloads with the same execution time and wait time ($T_{exec} = T_{wait}, \lambda_A = \frac{1}{T_{exec} + T_{wait}} = \frac{1}{2T}$). For the other two VMs (VM_3, VM_4), we generated workloads with a longer period between near-storage processing invocations ($\lambda_B = \frac{1}{16T}$). The result demonstrates that the static operator allocation scheme cannot guarantee a target QoS with the skewed workloads. When the VM_1 and VM_2 share the same operator and invoke

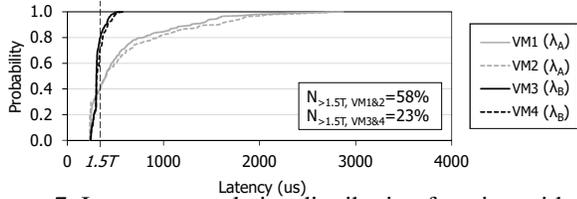

Figure 7: Latency cumulative distribution function with two oversubscribed hardware operators and four VMs.

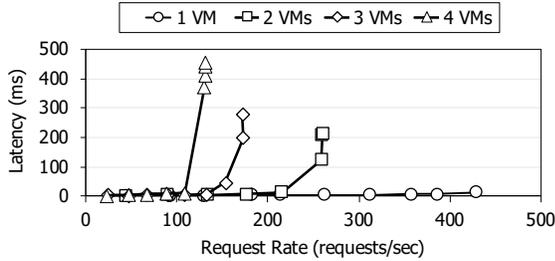

Figure 8: Operator latency with the increasing number of VMs and their request rate.

near-storage processing with a high request rate (λ_A), they severely suffer from a larger number of QoS violations ($> 1.5 \times T_{exec}$) than the other VM group (λ_B) due to the severe resource contention between the VMs.

The static resource allocation and scheduling mechanisms can lead to unacceptable QoS levels with the increasing number of VMs. Figure 8 shows the average latency of an encryption operator with varying request rates. If the total request rate does not exceed the maximum throughput of the operator, the operator can serve the requests within a reasonable latency bound. For example, when the four VMs submit requests at a rate of 50 requests per second each, the operator will show reasonable latency bound and the VMs will not suffer from the unexpected delay. However, when the total request rate exceeds the maximum throughput, the operator latency and the number of QoS violations increase quickly.

4 Design and Implementation

4.1 FlexCSV Architecture

In this work, we propose FlexCSV, a fast and cost-effective virtualization mechanism for computational storage devices. Its key idea is to implement *FCSV-Engine*, an FPGA card designed to maximize the performance and cost-effectiveness of computational storage virtualization. Figure 9 shows the *FCSV-Engine* architecture and its main hardware components. *FCSV-Engine* implements (1) a hardware-assisted virtualization layer based on PCIe SR-IOV, (2) a hardware-level direct device-orchestration mechanism, (3) an SSD-FPGA decoupled architecture, and (4) dynamic resource allocation through its operator renaming and partial reconfiguration support.

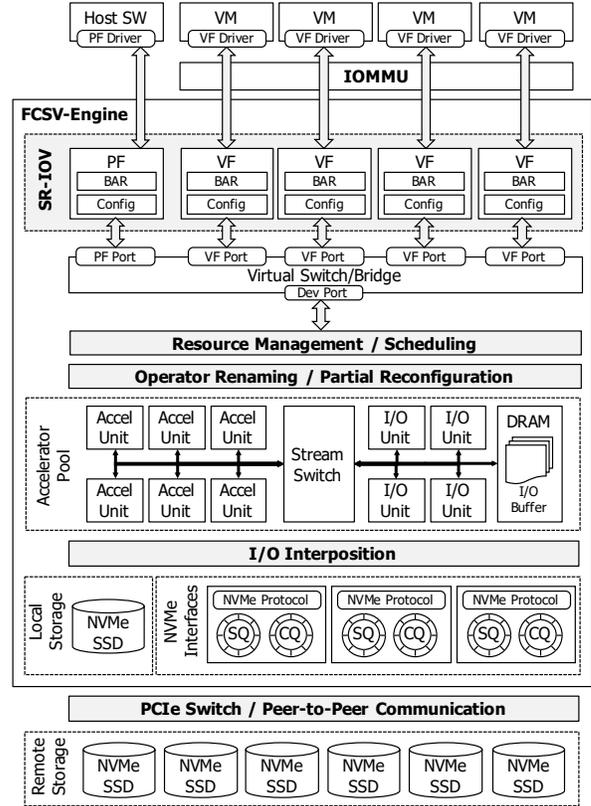

Figure 9: *FCSV-Engine* architecture.

4.2 Hardware-assisted Virtualization

4.2.1 SR-IOV and VM Isolation

To mitigate the software overhead in computational storage virtualization, *FCSV-Engine* offers hardware-assisted virtualization under a standard PCIe SR-IOV layer. By incorporating SR-IOV, *FCSV-Engine* can virtualize itself at the hardware level and each VF can be assigned exclusively to a VM for the direct access. Another advantage is that SR-IOV does not demand extra server CPU cores for polling guest I/O activities and indirect interrupt injections, which enables even more scalable and cost-effective server configurations than the conventional software-centric virtualization mechanisms (e.g., trap-and-emulate, sidecore). In this work, we utilize a single SR-IOV implementation at *FCSV-Engine* to virtualize both computation and storage units. This design choice minimizes the server costs for purchasing and operating SR-IOV supported computation and storage devices.

In addition, we utilize non-overlapping address translation to *FCSV-Engine*'s internal address space (i.e., PCIe-to-AXI address translation) to guarantee isolated execution of multiple VMs. *FCSV-Engine* allocates a disjoint set of memory regions and assigns different AXI address ranges for each VF so that near-storage processing requests from two different VMs do not interfere with each other. For example, we statically partition *FCSV-Engine*'s on-chip memory and off-chip

DRAM regions, and apply different offset values to MMIO requests from the VMs. Similarly, we allocate a different set of available interrupt vectors of FCSV-Engine for each VM. In this work, we allocate eight interrupt vectors per VM, and each vector is dedicated to a single completion queue of FlexCSV device driver running on a guest OS.

4.2.2 Device Interface

FCSV-Engine implements a multi-queue device interface and a doorbell mechanism to interact with guest OSEs. For this multi-queue device interface, we arrange FCSV-Engine’s PCIe BAR regions for doorbell registers of virtual FCSV-Engine instances (i.e., each VF). From the software side, FCSV-Engine’s device driver installed on a guest OS allocates multiple SQ/CQ pairs and initializes the doorbell registers mapped at FCSV-Engine’s BARs. FCSV-Engine’s device driver then delivers the guest physical addresses of the allocated queue pairs to FCSV-Engine. The number of queue pairs is dictated by FCSV-Engine’s BAR configuration and FPGA on-chip resource budgets. In this work, we create eight queue pairs per VM so that the same number of virtual CPUs can offload near-storage processing in parallel.

FCSV-Engine polls its on-chip memory space for doorbell registers using its host interfaces. To serve near-storage processing requests from multiple VMs concurrently, we instantiate multiple host interfaces and dedicate them to each VF. They get newly updated doorbell values by polling the doorbell register regions and utilize an internal DMA engine and an IOMMU to access a target SQ in guests’ memory space. By incorporating an IOMMU and its guest-to-host address translation mechanism, each virtual FCSV-Engine instance can safely access target queue pairs allocated in the guest memory space without software intervention. Alternatively, FCSV-Engine can manage a guest-to-host address mapping table in itself, but this design incurs significant VM memory overhead to store the translation tables for every VM.

4.3 Hardware-level Resource Orchestration

4.3.1 Near-storage Processing Command

To offload resource orchestration routines to FCSV-Engine, FlexCSV extends a standard NVMe protocol and defines a new command format for near-storage processing. FlexCSV’s NVMe-extended computational storage protocol minimizes software modifications to support near-storage processing in virtualized environments. Since major cloud providers are allowing NVMe storage devices to be used as primary storage for VMs, our NVMe-extended protocol can be easily applied in modern cloud and datacenter infrastructures.

Figure 10 shows a near-storage processing command structure. First, `op_chain` specifies which operators should be activated and the target stream order of the activated operators. For this, every operator type implemented on an FPGA

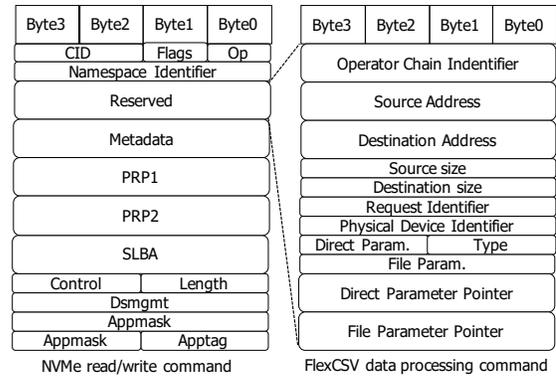

Figure 10: Near-storage processing command in FlexCSV.

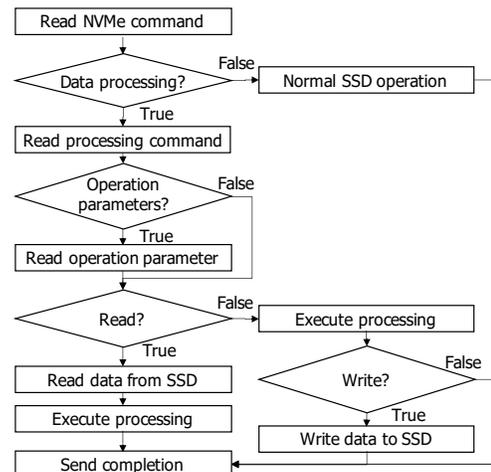

Figure 11: Control flow in FCSV-Engine.

has a unique identifier. `src_addr/size` and `dst_addr/size` represent the addresses and sizes of the source and destination in the FPGA’s DRAM space. Additionally, if an operator needs parameters to process, a user can carry the parameters either directly or indirectly with `direct_param` or `file_param` fields. A user can also manage dependency between near-storage processing commands by manipulating a `request_id` field. If a request contains the same `rid` as in the previous requests, the current request cannot be issued before the earlier requests finish their near-storage processing. `type` determines whether a current request involves storage access or not.

4.3.2 Resource Orchestration

FCSV-Engine involves a resource orchestration mechanism to manage both computation and storage resources. To orchestrate two different hardware units without frequent software-hardware crossings, FCSV-Engine schedules user-requested computation and storage operations at the hardware level. Figure 11 shows the hardware-level scheduling mechanism. First, FCSV-Engine identifies a newly issued command by polling submission doorbell registers. If the command re-

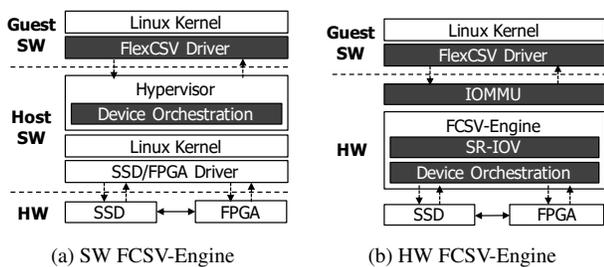

Figure 12: FCSV-Engine implemented in SW and HW.

quires near-storage processing, FCSV-Engine reads the data processing command and saves its contexts (e.g., source/destination FPGA DRAM addresses). After that, FCSV-Engine manipulates the DMA buffer addresses of the received NVMe command so that the SSD can transfer the user-requested data to/from the FPGA’s DRAM. FCSV-Engine also enforces a correct order of computation and storage operations depending on the direction of user-requested data movements (i.e., read or write) and target operators.

FCSV-Engine executes user-requested stream data processing without software orchestration. In contrast to the existing static routing mechanisms, FCSV-Engine adopts a dynamic routing mechanism between hardware operators. For this, FCSV-Engine’s control logic determines the order and routing path dynamically when it executes near-storage processing. FCSV-Engine parses the `op_chain` field of a data processing command and reserves the shortest routing path by manipulating the `dest` configuration registers of the user-requested operators. The operators then manipulate the `dest` field of the output stream data and FCSV-Engine’s internal crossbar switch redirects the incoming stream to the correct next operator. If the requested operators are used and their paths are already reserved, FCSV-Engine stalls their executions until the earlier requests finish their near-storage processing.

4.3.3 Software FCSV-Engine

FCSV-Engine’s resource orchestration mechanism can be implemented at the hypervisor level, but it still suffers from frequent software-hardware layer crossings to orchestrate two different hardware units. Figure 12 illustrates the software and hardware FCSV-Engine implementations. In the software implementation, a guest OS can leverage an NVMe-extended near-storage processing protocol and thus reduce the number of guest-host layer transitions. It also allows a device to directly transfer data to another device’s internal memory by manipulating the DMA buffer addresses to the target device memory addresses. However, this design suffers from the inevitable hypervisor and host OS overhead due to the indirect orchestration for SSD and FPGA devices and a large number of software-hardware layer transitions.

Because of the indirect resource orchestration routines through the host software (e.g., MMIO, interrupt), the soft-

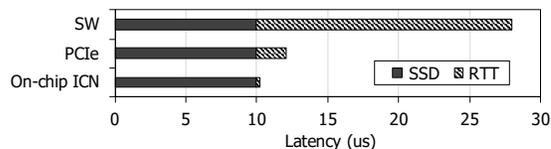

Figure 13: Storage latency and round-trip time through SW, PCIe, and on-chip ICN.

ware FCSV-Engine implementation fails to achieve the full potential of near-storage processing [21]. To profile the performance overhead of the software FCSV-Engine implementation, we measured the SSD access latency through (1) the host software, (2) PCIe P2P, and (3) on-chip interconnect (ICN). Figure 13 shows their round-trip time for access to an Intel Optane SSD. The result indicates that the major performance bottleneck is moved to the software stacks when the host software manages a device operation. Such performance overhead will get worse when we exploit near-storage processing between faster computation and storage units. On the other hand, the round-trip time of the PCIe P2P and on-chip ICN is still much faster than the software MMIO and interrupt mechanisms.

4.4 SSD-FPGA Decoupled Architecture

In this work, we introduce a decoupled computational storage architecture for scalable near-storage processing with multiple PCIe-attached SSDs. To allow multiple NVMe SSDs to combine with FCSV-Engine through PCIe P2P, the host software remaps their queue pairs onto FCSV-Engine’s BAR regions. By doing so, the decoupled storage units can seamlessly exchange NVMe commands and their completions with FCSV-Engine. The SSDs are unaware of being interacting with FCSV-Engine, but an external PCIe switch delivers their PCIe read and write transactions to FCSV-Engine directly. In addition, FlexCSV can nicely scale with a large number of PCIe-attached SSDs leveraging its large on-chip memory space. As a result, FlexCSV can mitigate the performance bottleneck at a single FPGA or SSD by flexibly combining PCIe-attached computation and storage devices in the same server.

Moreover, FCSV-Engine implements PCIe message arbitration and transaction modules to encapsulate local NVMe requests (e.g., NVMe doorbell write) with PCIe transactions and allow multiple storage interfaces to share a single PCIe/DMA IP core. In this arbitration module, FCSV-Engine leverages PCIe transaction queues for each VM and adopts a round-robin algorithm to serve PCIe access from multiple VMs. The PCIe transaction module translates an internal AXI address to an associated host physical address (e.g., AXI-to-PCIe address translation). For this address translation, the PCIe/DMA IP core manages an AXI-to-PCIe address mapping table. The current Xilinx-provided PCIe/DMA IP core supports up to six mapping entries, and this design point can be a serial

	Critical Path		FPGA Resource Usage		
	Submission	Completion	LUT	FF	BRAM
Static	656 ns	72 ns	20370	6702	11
Renaming	728 ns	96 ns	20693	6892	11

Table 1: Renaming overhead analysis.

point when it handles concurrent near-storage processing from many VMs.

4.5 Dynamic Resource Allocation

4.5.1 Operator Renaming

To maximize the hardware resource efficiency, FCSV-Engine implements dynamic resource allocation through its operator renaming support. FCSV-Engine implements a shared operator pool and dynamically maps user-requested operations onto available physical operators. In this way, FCSV-Engine can quickly capture the dynamic behavior of VM workloads and thus reduce QoS violations significantly. Our current resource scheduling mechanism is similar to a resource availability-based FCFS algorithm because we focus more on cost-effectiveness and resource utilization of computation and storage units. However, we can also improve storage fairness and performance by adopting more fairness-oriented scheduling methods [16, 36].

In the renaming stage, every operator request from VMs is mapped onto physical operators via an operator renaming table. The operator renaming table manages the availability of physically implemented operators. FCSV-Engine looks up the renaming table to find and allocate available physical instances of user-requested operators. If it succeeds in allocating the physical operators, the scheduler executes near-storage processing and manipulates the operator renaming table to record the resource allocation status. When the requested near-storage processing finishes, the scheduler collects the completions from all the activated operators and deallocates the recorded resources by manipulating the renaming table.

We measured the area and performance overhead when the operator renaming mechanism is implemented in FCSV-Engine’s scheduler module. We first implemented the scheduler without the renaming capabilities in which virtual operators have a one-to-one mapping with physical operators, and implemented operator renaming logic on top of it. In this work, our operator renaming logic can remap a virtual operator onto four physical operator instances. Table 1 shows the increase in the area and critical path for our operator renaming logic. The area overhead is 2%–4% and the total critical path overhead is around 100 ns, which is negligible compared to the original scheduler area and operator delay.

4.5.2 Operator Partial Reconfiguration

Partial reconfiguration (PR) support for FPGA operators further improves the hardware utilization by capturing the dy-

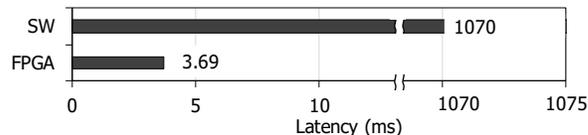

Figure 14: Partial reconfiguration latency with the host software and an FPGA.

	CLB LUTs	CLB Registers	Block RAM Tiles	Clock speed
FCSV-Engine	313,069 (18%)	487,333 (14%)	441 (16%)	250 MHz
PCIe / SR-IOV	46,970	51,487	61	
DRAM	18,592	20,817	26	
Host Interface (4 VMs)	74,886	124,761	266	
Storage Interface	22,927	39,403	39	
Scheduler	2,507	3,050	4	
Interconnect	115,073	203,827	0	
Others	32,114	43,988	45	

Table 2: FCSV-Engine FPGA resource utilization.

amic behavior of VM workloads. If there exist enough operator slots to serve all requested near-storage processing workloads, their target operators can be assigned to available slots in FCSV-Engine’s operator pool. However, if the demand from near-storage processing workloads exceeds the maximum number of operator slots, they can be partially reconfigured to serve the current user requests. As a result, such a dynamic resource allocation mechanism enables the FPGA to support more operators than its physical resource limit.

Figure 14 shows the latency of partially reconfiguring the FPGA operators from the host software and from the FPGA itself. Reconfiguration from the host software incurs long latency because the software has to send the bitstream from the host DRAM to the FPGA. Alternatively, to achieve agile operator reconfiguration, we can store the partial bitstreams in the FPGA DRAM and implement a PR controller to allow the FPGA to reconfigure its operator slots. In this way, the PR latency is reduced by 99.7% and the scheduler in FCSV-Engine can dynamically generate the operators on demand with low overhead.

5 Evaluation

5.1 Experimental Setup

To evaluate FlexCSV, we implemented our FCSV-Engine prototype on a Xilinx Alveo U250 board and installed its SW support on the Linux KVM/QEMU virtualization stack. Our FCSV-Engine prototype provides eight stream-based operators with the partial reconfiguration support and allows the operators to be shared by four VMs through the hardware-assisted virtualization and resource allocation mechanisms.

Operators	LUTs	Registers	BRAMs	Performance
Encryption (E) [28]	38,031	19,246	168	211 MB/s
Decryption (D) [28]	37,655	19,126	168	212 MB/s
Hash (H) [37]	50,620	13,541	0	285 MB/s
Aggregate (A) [35]	2,292	1,539	2	4.70 GB/s
Filter (F) [35]	41,823	5,428	116	278 MB/s
Grep (G) [15]	37,288	5,647	6	426 MB/s
KNN (K) [32]	14,052	4,091	8	4.22 GB/s
Bitmap (B) [33]	63,570	5,588	31	4.24 GB/s

Table 3: Operators’ FPGA resource utilization.

To enable FCSV-Engine to interact with CPUs and PCIe-attached NVMe SSDs, we utilized Xilinx-provided PCIe and DMA engine implementations (PCIe Gen3 4-lane, 4 GB/s per direction) [9] and configured VFs to virtualize FCSV-Engine itself. For intermediate data buffers between computation and storage units, FCSV-Engine leverages its on-board DDR4 DRAM and on-chip AXI-stream FIFO queues.

Table 2 shows FCSV-Engine’s FPGA resource utilization using Xilinx Vivado and HLS (v2019.2). The on-chip interconnect logic consumes the major portion of FPGA LUTs and registers as it connects all the VFs (i.e., host interfaces for each VM) and operators through all-to-all crossbars. On the other hand, the host and storage interfaces consume many on-chip memory tiles for their device register regions of the NVMe-extended protocol (e.g., doorbell registers) and for NVMe I/O queue regions to orchestrate PCIe-attached NVMe SSDs. Note that the FPGA has enough remaining resources to add more operator slots for near-storage processing.

Our software-hardware full-system prototype is built on a host server with two Intel’s Xeon Gold 5118 CPUs, each with 12 physical cores running at 2.3 GHz, and 256-GB DDR4 DRAM (Supermicro SuperServer 4029GP-TRT2). The host server machine is equipped with four Intel Optane 900P NVMe SSDs and connects them to FCSV-Engine through PCIe Gen3 4-lane interconnects (4 GB/s per direction). The Optane SSD can offer up to 550k IOPS in random-read and 500k IOPS in random-write with 10 μ s latency. For software support, we installed a Ubuntu 18.04 OS and Linux kernel (version 5.3) on VMs and implemented custom FCSV-Engine’s device driver.

To generate various near-storage processing scenarios, we implemented eight representative computational storage operations from the previous FPGA acceleration and near-storage processing studies [15, 28, 32, 33, 35, 37]. We utilized the Xilinx HLS tool (v2019.2) to generate their hardware operators. The implemented hardware operators perform stream operations through 512-bit input and output data links (16 GB/s interconnect bandwidth with 250-MHz clock frequency). In this work, we dedicated 4x more on-chip bandwidth than the configured PCIe link capability (4 GB/s per direction) to avoid the bottleneck at the on-chip crossbars and to obtain the full potential of near-storage processing in multi-VM workloads. However, the proper data stream width may vary depending

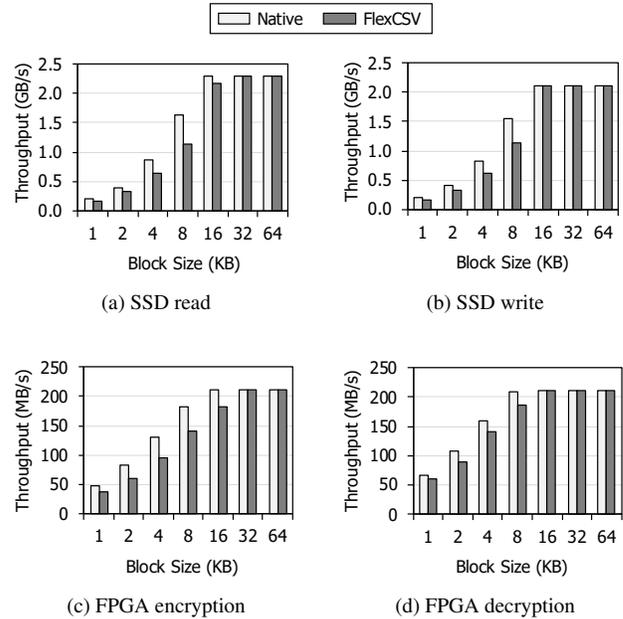

Figure 15: SSD and FPGA operation performance with different virtualization mechanisms.

on the target operators and resource budgets.

The FPGA operators have a broad spectrum of resource utilization and data-processing throughput based on their algorithm complexity and synthesis strategies. Table 3 shows the benchmarks and their FPGA implementation results. The Blowfish data encryption and decryption operators consume a large number of registers, but demonstrate the lowest data processing performance among the benchmarks. On the other hand, the aggregate, K-nearest neighbors (KNN), and bitmap operators show the highest ideal performance due to their algorithmic simplicity.

5.2 Device Virtualization Performance

In this experiment, we measured the performance of the hardware-assisted virtualization mechanism and compared it with the native device performance. For this evaluation, we installed the SSD and FPGA devices through PCIe and implemented the Blowfish encryption and decryption operators [28] on the FPGA. To fairly compare the performance for both device types, we measured the performance of the computation and storage units separately. To measure the storage performance, we ran flexible I/O tester (FIO) [2] in both native and FlexCSV virtualization environments with an increasing data block size. In contrast, we leveraged the NVMe-extended protocol to measure the FPGA virtualization performance without invoking storage operations. Similar to the storage benchmarks, the FPGA benchmarks measured the end-to-end performance in both native and FlexCSV environments with an increasing data block size.

The experimental results show that our FCSV-Engine prototype delivers near-native NVMe SSD and FPGA performance.

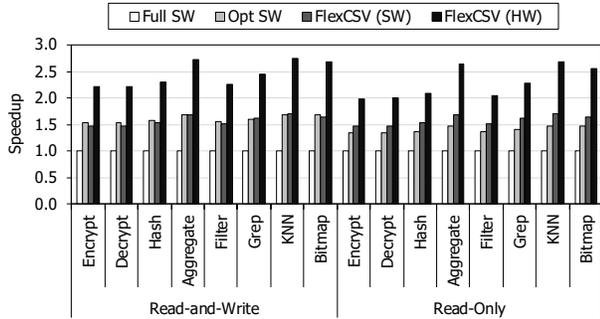

Figure 16: Speedup comparison in various virtualized environments.

Figure 15 shows the native and virtualized SSD and FPGA acceleration performance. Due to the hardware-assisted virtualization mechanism (including SR-IOV), FCSV-Engine can achieve the near-native performance when utilizing both SSD and FPGA devices in virtualized environments. Moreover, as the block size increases, the native and virtualized executions of the SSD and FPGA operators demonstrate the ideal bare-metal throughput (explained in Section 5.1 and Table 3). The increasing data block size further mitigates the software overhead by merging multiple near-storage processing requests using NVMe’s scatter-gather list (SGL) support.

5.3 Near-Storage Processing Performance

In this experiment, we measured the performance of the near-storage processing benchmarks through existing software stacks and FlexCSV virtualization mechanisms. For this evaluation, we generated a 4-GB dataset as an input file of near-storage processing, and each benchmark running on a guest OS divides the dataset into multiple 4-KB blocks and iterates them to cover the total dataset size. To compare the speedup values over the existing software-centric mechanisms, we also executed the same near-storage processing benchmarks on the paravirtualization schemes with and without SR-IOV support at the SSD side (described in Figure 4). In addition, we measured the performance of software FCSV-Engine (described in Figure 12) to highlight the benefits of FlexCSV’s hardware-level resource orchestration.

Each near-storage processing benchmark listed in Table 3 is executed in two VM workload scenarios. The first scenario reads a data block from the SSD directly, performs data processing using the FPGA’s stream operator, and writes its output data to the SSD (read-and-write). The other scenario, on the other hand, follows the same routines for every data block, but does not write back the output data for further near-storage processing (read-only).

The experimental results show that FlexCSV can achieve 2.1x (geomean) faster near-storage processing in virtualized environments over the software virtualization mechanisms. Figure 16 shows the speedup values compared to the full software virtualization mechanism. In contrast to the software-

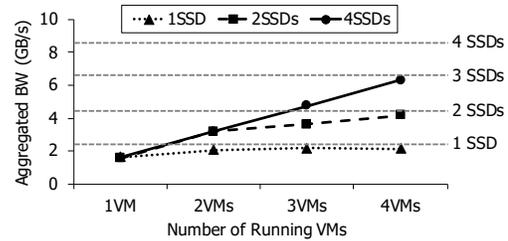

Figure 17: The aggregated bandwidth with a different number of VMs and SSDs.

based virtualization mechanisms, FlexCSV allows the VM to access the underlying devices and orchestrates the data movements between the virtualized units without any software intervention. The encryption and decryption benchmarks obtain 2.2x speedup (33 MB/s→72 MB/s) in the read-and-write case and 2x speedup (48 MB/s→95 MB/s) in the read-only case. The KNN benchmark, which shows the highest speedup values among the benchmarks, achieves 2.8x speedup over the full software virtualization (38 MB/s→105MB/s in the read-and-write case). Compared to the software FCSV-Engine implementation, the hardware FCSV-Engine implementation achieves 1.4x speedup on average.

5.4 Multi-SSD Performance

In this work, we evaluated FlexCSV’s decoupled architecture by executing an I/O-intensive VM workload with an increasing number of VMs and PCIe-attached SSDs. The result is shown in Figure 17. In this experiment, the VMs utilize about 2 GB/s storage bandwidth, similar to the maximum bandwidth of a single SSD. A single SSD can meet the performance requirements of a single VM workload as there is no storage interference. However, when we utilize a single SSD and run two or more VMs, the aggregate bandwidth of all the VMs is limited by a single SSD. So, the tightly-coupled architectures suffer from such bandwidth imbalances and unexpected delays as the available storage bandwidth cannot be scaled easily. However, with the FPGA and SSD decoupled, the required bandwidth of multiple VMs can be met by adding more SSDs. In this work, FCSV-Engine supports attaching up to four SSDs to a single FPGA and achieves the scalable performance with the increasing number of VMs and SSDs.

5.5 Dynamic Resource Scheduling

In this experiment, we evaluated the effectiveness of FCSV-Engine’s dynamic resource allocation and scheduling mechanisms. For this evaluation, we ran four VMs concurrently and generated the VM workload by following Poisson distribution with diverse expected request rates ($\lambda = \frac{1}{T} = \frac{1}{T_{exec} + T_{wait}}$). We ran four VMs and grouped the VMs into two groups (A, B) that have different request rates (T_{wait}/T_{exec}). After that,

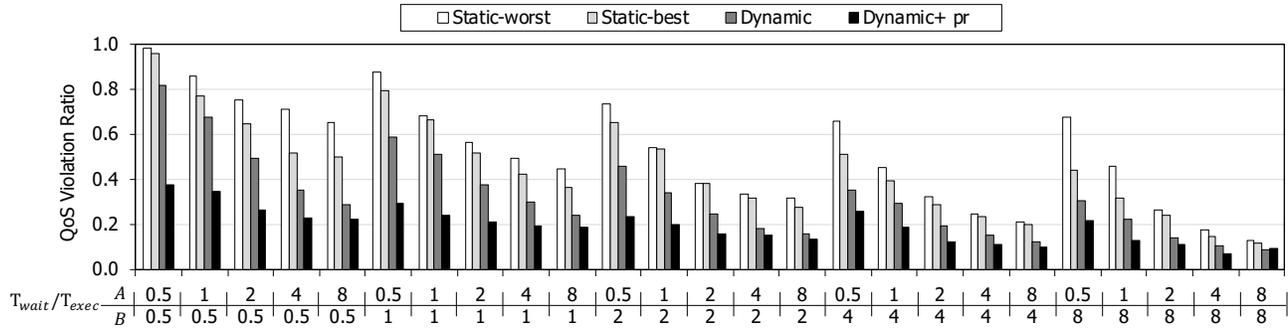

Figure 18: QoS violation ratios with different request rates from multiple VMs.

we compared their QoS violation ratios with four different resource scheduling strategies: (1) static-worst, (2) static-best, (3) dynamic, and (4) dynamic + partial reconfiguration (dynamic+pr). The static-worst, static-best, and dynamic scheduling methods utilize two physical operators, and dynamic+pr can support up to four physical operators through partial reconfiguration. The VMs in the experiment perform an encryption operation with near-storage processing capabilities.

Figure 18 shows the QoS violation ratios ($> 1.5 \times T_{exec}$) with diverse request rate combinations of the two VM groups. Except when the request rate between the two groups is the same, the static-best scheduling methods achieve lower the QoS violation ratios compared to the static-worst method. Also, the dynamic scheduling significantly lowers the QoS violation ratios over the static-worst and static-best strategies for all the workload scenarios. When both VM groups invoke the operators frequently (e.g., $[A=0.5, B=0.5]$), FCSV-Engine can increase the number of available operators using its partial reconfiguration support and further reduce the QoS violation ratios. If the request rate is low (e.g., $[A=4, B=8]$), the dynamic scheduling can drop QoS violations, but increasing the number of operators has a minor impact.

6 Related Work

Near-storage processing. Recent near-storage processing studies have proposed flexible FPGA overlay architectures and improved the usability of computational storage devices [33, 35]. Their FPGA overlay architectures can implement user-specified operators and activate them selectively through the crossbar switches and control logic. Also, their custom software stacks provide abstraction layers to hide the complexity of the underlying FPGA implementations.

NVMe SSD virtualization. NVMe virtualization becomes one of the most critical components in cloud environments to meet the performance demand from modern server workloads. For example, Amazon Web Services (AWS) accelerates I/O virtualization through dedicated hardware components. To make full use of its parallel and high-performance storage protocol, storage performance development kit (SPDK) vhost-

nvme extends the SPDK library to provide virtual NVMe controllers to QEMU-based VMs [38]. Similarly, another implementation provides a mediated passthrough mechanism in kernel space with an active polling mode [29]. In addition, current hardware-assisted virtualization studies demonstrate offloading NVMe virtualization stacks to a programmable FPGA or SmartNIC device [22, 25].

FPGA virtualization. The existing FPGA virtualization studies introduce abstractions for FPGA logic cell and interconnection components [19, 20, 40]. First, user logic is encapsulated in flexible operators to be dynamically scaled and remapped to the physical fabric. Second, the host software manages the mapping between operators and physical FPGAs. To enable flexible mapping, high-level operators encapsulate information to enable the host software to generate new FPGA implementations on demand. Moreover, the host software maintains a registry to hide the latency of partial reconfiguration for dynamic scalability.

7 Conclusion

In this work, we propose a fast, flexible, and cost-effective mechanism to virtualize computational storage devices. The key idea is to use FCSV-Engine, an FPGA card designed to maximize the performance and cost-effectiveness of computational storage virtualization. It achieves high virtualization performance by applying hardware-assisted virtualization and resource orchestration. In addition, it achieves high cost-effectiveness by dynamically constructing many virtual computational storage devices and scheduling their near-storage processing at the hardware level.

Abstract

CPU schedulers such as the Linux Completely Fair Scheduler try to allocate equal shares of the CPU performance to tasks of equal priority by allocating equal CPU time as a technique to improve quality of service for individual tasks. Recently, CPUs have, however, become power-limited to the point where different subsets of the instruction set allow for different operating frequencies depending on the complexity of the instructions. In particular, Intel CPUs with support for AVX2 and AVX-512 instructions often reduce their frequency when these 256-bit and 512-bit SIMD instructions are used in order to prevent excessive power consumption. This frequency reduction often impacts other less power-intensive processes, in which case equal allocation of CPU time results in unequal performance and a substantial lack of performance isolation.

We describe a modification to existing schedulers to restore fairness for workloads involving tasks which execute complex power-intensive instructions. In particular, we present a technique to identify AVX2/AVX-512 tasks responsible for frequency reduction, and we modify CPU time accounting to increase the priority of other tasks slowed down by these AVX2/AVX-512 tasks. Whereas previously non-AVX applications running in parallel to AVX-512 applications were slowed down by 24.9% on average, our prototype reduces the performance difference between non-AVX tasks and AVX-512 tasks in such scenarios to 5.4% on average, with a similar improvement for workloads involving AVX2 applications.

1 Introduction

One common requirement for schedulers is to provide an acceptable quality of service to the tasks in the system [7]. Fair schedulers evenly share CPU performance among the tasks or groups of tasks in the system to achieve good quality of service for all tasks [15]. In the past, it was commonly assumed that even shares of the CPU time result in even shares of CPU performance. The Linux Completely Fair Scheduler [20], for

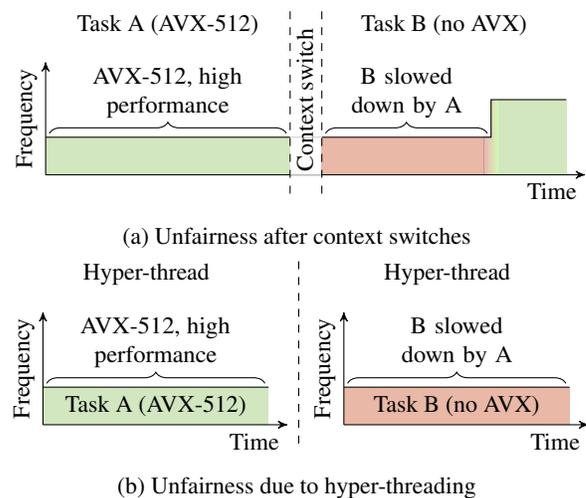

Figure 1: With AVX2 and AVX-512, equal CPU time shares do not translate into fair shares of CPU performance. AVX2 and AVX-512 cause the CPU core to reduce its frequency which can affect other non-AVX tasks. In these situations, our prototype would increase the priority of task B to achieve improved fairness. In this figure, the two frequencies represent the non-AVX and AVX-512 turbo levels.

example, always executes the task with the lowest CPU time used (scaled by priority) to allocate equal shares of CPU time to individual tasks.

In systems with dynamic voltage and frequency scaling (DVFS), the assumption that equal CPU time results in equal performance does not hold. Reduced frequencies affect the performance of applications differently depending on how memory-limited the applications are, and techniques have been developed to include this effect when distributing CPU time [14]. Such techniques have not found their way into common operating systems, though, most likely because fairness mostly matters when system utilization is high, in which case operating systems rarely reduce the CPU frequency.

Recent CPUs, however, have started to use autonomous DVFS outside of the control of the operating system to prevent excessive power consumption. In the last years, transistor scaling has increased power density, leading to a situation where the performance of recent CPUs is largely limited by their power consumption [28]. One common technique to improve CPU performance in this power-limited design regime is to use additional transistors to implement specialized accelerators which remain inactive most of the time. CPU cores can operate at high frequencies while the accelerators are inactive, whereas use of the accelerators requires a temporary frequency reduction to prevent excessive power draw. This adaptation of the CPU frequency to meet thermal and power supply constraints increases individual cores' frequencies to always utilize their whole power budget but also decreases frequencies if the cores risk overheating or instability, similar to techniques such as Turbo Boost [1] which increases the frequency of the whole processor when some cores are idle.

Recent Intel CPUs provide an example for such behavior where low-power code is executed at increased frequencies. For some workloads, these CPUs provide a substantial performance advantage over previous CPU generations due to the introduction of the AVX2 and AVX-512 SIMD instruction sets [6] which support operations on up to 512-bit vector registers. The large difference in power consumption between AVX2/AVX-512 instructions and other instructions, however, requires individual CPU cores to reduce their frequency while they execute AVX2 and AVX-512 code, whereas other less power-intensive code is executed at higher frequencies [23]. As an example, the Intel Xeon Gold 6130 server CPU executes non-AVX code at an all-core turbo frequency of 2.8 GHz, whereas AVX2 and AVX-512 code is executed at 2.4 GHz and 1.9 GHz, respectively [4].

If only AVX2 or AVX-512 code would be selectively slowed down, no problem for fair schedulers would arise. Only tasks *choosing* to execute AVX2 or AVX-512 code would be slowed down and the increased throughput of these instructions would more than compensate the frequency reduction. However, the impact of the lower frequency is not limited to the AVX2 and AVX-512 code responsible for the reduction [10]. In two scenarios, the frequency reduction also affects other potentially unrelated tasks:

1. Context switches: When the CPU switches from an AVX2 or AVX-512 task to a non-AVX task, the CPU waits for a fixed timeout before restoring the standard frequency [5]. Such a delay is sensible as it limits worst-case overhead due to frequent clock changes. The following task is consequently slowed down as well.
2. Hyper-threading: When one hyper-thread executes either AVX2 or AVX-512 code, the whole physical core needs to reduce its frequency, so any code running on the other hyper-thread is affected as well even if it does not execute AVX2 or AVX-512 instructions [10]. This effect

has shown to be particularly prominent, with workloads often being slowed down by more than 15% when executed alongside an AVX-512 application on Linux [10].

As shown in Figure 1, when contemporary fair schedulers allocate the same share of CPU time to AVX2/AVX-512 tasks which cause a frequency reduction as to other tasks which are also affected by the reduced frequencies, the latter would receive a substantially reduced share of the system's performance. This unfairness and the resulting performance reduction is particularly problematic for tasks with soft real-time requirements and for multi-tenant systems where individual users commonly pay to receive a specific share of the CPU time. While these effects are currently only observed on systems with recent Intel CPUs, we expect future power-limited systems to show similar behavior as outlined above.

In this paper, we show that for these systems it is necessary to rethink our notions of scheduling fairness. In particular, we show that equal CPU time, minimal effects on quality of service, and fair distribution of CPU performance are mutually exclusive goals. We do so by describing a scheduler that is commonly able to achieve the latter when some tasks – called *victim tasks* in the following – are negatively affected by a frequency reduction caused by other tasks.

We present a concrete implementation of this design for Intel systems and AVX2 and AVX-512 instructions. Our approach mitigates the performance impact of frequency reduction via modified CPU time accounting where the CPU time of victim tasks is scaled according to the decrease in CPU frequency (Sections 3). We show how victim tasks can often be recognized by the lack of characteristic register accesses (Section 4). Variable turbo frequencies complicate calculating the actually experienced frequency reduction, so we show how on Intel systems the average frequency reduction during a scheduling time slice can be calculated using only two configurable performance counters and a cycle counter (Section 5). As the load balancing mechanism of the Linux CFS scheduler prevents achieving fairness, we describe an implementation of our design based on the Linux MuQSS scheduler modified to use the CFS scheduling algorithm (Section 6). Our evaluation based on a range of real-world applications shows that our prototype has close to zero runtime overhead, yet is able to improve the fairness in workloads with AVX2 and AVX-512, reducing the performance difference between two applications from 24.9% to 5.4% if one of the applications uses AVX-512 (Section 7). Finally, we discuss different fairness criteria, showing how our approach can be modified to achieve even stronger performance isolation (Section 8), as well as the limitations of our approach (Section 9).

2 AVX Frequency Reduction

To mitigate the unfairness caused by power-intensive instructions, we first need to know which instructions cause the

CPU to reduce its frequency and by how much the frequency is reduced. Our prototype targets the AVX2 and AVX-512 instruction sets. Both are categorized by Intel into “heavy” and “light” instructions, where the former consist of all floating point instructions as well as multiplication instructions, whereas the latter consist of all other instructions [5]. In the default CPU configuration at the maximum non-AVX frequency, all light and heavy instructions have the potential to draw excessive current, which causes voltage drops and system instability. During execution of all these instructions, the CPU therefore increases its voltage to allow for increased currents [8].

Not all 256-bit and 512-bit instructions, however, also cause a frequency change. CPUs with support for AVX-512 provide three different frequency ranges named “non-AVX frequencies”, “AVX2 frequencies”, and “AVX-512 frequencies” [5]. Unlike the name suggests, “AVX-512 frequencies” are not triggered by arbitrary 512-bit instructions but rather only by 512-bit heavy instructions. Similarly, “AVX2 frequencies” are triggered by 512-bit light instructions and 256-bit heavy instructions. Short stretches of AVX2/AVX-512 instructions or long code sections with infrequent AVX2/AVX-512 instructions may cause less frequency reduction or may not cause any change in frequency at all [18]. After the last AVX2/AVX-512 instruction requiring the frequency reduction, the CPU waits for 670 μ s before reverting to a higher frequency [11].

3 Frequency Reduction Compensation

As described in Section 1, there are two situations in which tasks executing AVX2 and AVX-512 code can slow other tasks down [10]. First, the delay before the CPU reverts to a higher frequency means that after a context switch away from an AVX2/AVX-512 task the next task continues to execute at the lower frequency. Second, in a system with hyper-threading both hyper-threads of a physical core share the same frequency, thus a AVX2/AVX-512 task executing on one hyper-thread slows down the task executing on the other hyper-thread.

In a situation where the frequency reduction caused by power-intensive instructions is not limited to tasks executing such instructions, CPU time is not proportional to performance anymore and existing schedulers which allocate equal CPU time to tasks of equal priority fail to provide a fair distribution of CPU performance. In this paper, we take relative application performance compared to isolated execution as the main metric for fairness and consider a distribution of CPU performance “fair” if each task receives the same fraction of the CPU performance that it would receive if it was executing on the CPU alone. In a system without frequency changes and with two tasks, for example, each task would obtain 50% of the performance of the task executed in isolation. If one of the tasks executes power-intensive instructions and the other one does not, however, only the latter task (i.e., the

victim task) is affected by the resulting *remote frequency reduction overhead* [11] and receives a lower share of the CPU performance. Note that AVX2/AVX-512 tasks themselves, for example, can be assumed to obtain full CPU performance despite executing at reduced frequencies. They profit from the increased throughput of AVX2 and AVX-512 – applications have little reason to use complex power-intensive instructions if their speedup does not outweigh the frequency reduction.

Current schedulers allocate equal CPU time to individual tasks even though only some are affected by remote AVX overhead, resulting in compromised performance isolation. Some existing techniques using consumed energy as the basis for scheduling [22, 26, 31] may be applicable to solve this problem (see Section 8 for a discussion of these and other scheduling criteria). Such approaches are, however, not viable on current hardware as the CPUs lack interfaces required for sufficiently accurate energy models.

In this paper, we instead propose *frequency reduction compensation* as a simple technique to modify existing fair schedulers to reduce the impact of frequency reduction on the performance of victim tasks. To increase the performance share allocated to these tasks, we propose modifying CPU time accounting to take the performance reduction into account. If less CPU time is credited to a task, the scheduler will automatically schedule the task more often to make up for the perceived CPU time inequality. For victim tasks, we scale the CPU time credited to the tasks by the ratio between the actual average CPU frequency and the frequency at which the tasks could be executed if they were executed in isolation, so that this virtual CPU time matches the CPU throughput experienced by the tasks. The scheduler will then automatically mitigate the performance impact experienced by victim tasks to the point where all tasks receive equal shares of CPU performance. Such frequency reduction can be applied to all scheduling algorithms based on CPU time. In the following sections, we first describe how to identify victim tasks (Section 4) and then describe how to calculate the performance impact due to the frequency reduction (Section 5) before we describe important details in our implementation of the techniques (Section 6).

4 Attribution of Frequency Changes

Any scaling of the virtual CPU time must be limited to victim tasks, as only those tasks are supposed to be executed more frequently. First, we therefore need to identify whether a task is a victim task, i.e., whether it is affected by excessive frequency reduction caused by other tasks.

On recent Intel CPUs, it is trivial to determine whether the CPU frequency was reduced, as the CPUs provide performance events to count the cycles spent at AVX2 and AVX-512 frequency levels [5]. The CPUs do not provide a mechanism for the operating system to detect whether a code region triggers frequency reduction or not, though [11]. While the perfor-

mance events can be used to detect frequency level transitions, they cannot be used to identify the hyper-thread which caused a physical core to reduce its frequency. Also, during the time after a context switch the counters do not provide information about whether the current task could be executed at a higher frequency.

We therefore detect power-intensive code based on register accesses – many complex instruction set extensions introduce additional architectural registers, so accesses to these registers signal such power-intensive code. In our prototype, we use an approach found in previous work that uses a trap-based mechanism to identify AVX-512 code [10]: When the OS clears the `ZMM_Hi256` and `Hi16_ZMM` bits in the `XCR0` register, context switching for 512-bit vector registers is disabled [2, p. 13-1ff] and AVX-512 instructions trigger undefined instruction exceptions [2, p. 14-34].

Whereas previous work uses this mechanism to permanently disable AVX-512 on select CPU cores [10], we extend the mechanism to AVX2, yet we only trap the first 256-bit or 512-bit register access within a time slice to detect whether the task uses AVX2/AVX-512. At each context switch, we test whether the next task has valid 256-bit or 512-bit register content and flag the task as an AVX2/AVX-512 task if it does. If there is no valid 512-bit register state, we prevent further 512-bit register accesses as described above. If there is no valid 256-bit register state, either, we clear the `AVX` bit in the `XCR0` register as well to make future AVX2 instructions trigger exceptions. Then, if 256-bit registers are not enabled when the undefined instruction exception handler is called, we simply re-enable those registers, flag the current task as an AVX2 task and continue execution. Similarly, if 256-bit registers are already enabled but 512-bit registers are not, we enable 512-bit registers and flag the current task as an AVX-512 task. During the next scheduler invocation, we can test whether the previous task was marked as an AVX2 or AVX-512 task to determine whether to apply frequency reduction compensation.

Note that this implementation triggers two exceptions for the first AVX-512 instruction after a context switch. A more optimized implementation can reduce overhead by checking the register size of the trapped instruction and, if it accesses 512-bit registers, enabling both AVX2 and AVX-512 at once.

As Gottschlag et al. discuss, such a mechanism is not a precise indicator of whether code requires a frequency reduction [10]. As described in Section 2, the conditions for a frequency change are much more complex, so the mechanism can cause false positives as not all 256-bit and 512-bit register accesses cause a transition to AVX2/AVX-512 frequencies. Victim tasks using light AVX2/AVX-512 instructions may therefore not benefit from frequency reduction compensation even if the tasks themselves do not require reduced frequencies. In addition, AVX supports 256-bit registers as well, so our approach cannot cleanly distinguish AVX and AVX2. We discuss the impact of this limitation in Section 9.1.

4.1 CPU Feature Detection

One problem of disabling AVX2 and AVX-512 instructions via changes in the `XCR0` register is that this change breaks CPU feature detection in most applications. Intel states that before using any AVX instructions programs should first read the `XCR0` register via the `XGETBV` instruction and test whether AVX2 and AVX-512 are supported by the OS and then execute the `CPUID` instruction to test whether the required instructions are available [2, p. 14-15]. Related work suggests that this problem can be solved by virtualizing the `CPUID` instruction [10]. Recent Intel CPUs indeed provide an MSR that can be used to disable `CPUID`. However, we found it impossible to trap the `XGETBV` instruction without also disabling all vector instructions including widely used instruction set extensions such as SSE.

Instead, we propose patching all executables to replace the `XGETBV` instructions with an invalid instruction. In the invalid instruction exception handler, the kernel can then emulate `XGETBV` before returning to the application. We have verified this technique to be functional, and the additional exception causes minimal overhead given that most applications only determine the available CPU features once at startup.

In our evaluation, we wanted to compare our prototype to a stock Linux kernel, where we would not be able to execute such modified applications as the kernel lacks support for virtualization of `XGETBV`. As described in Section 7, we therefore did not integrate the technique into our prototype and instead manually modified the applications to assume that AVX2 and AVX-512 were available.

5 Calculation of the Performance Impact

Whenever a victim task has been identified, CPU time accounting for the task has to be scaled to increase the share of actual CPU time allocated to that task. As described above, the scaling has to occur in proportion to the performance impact. If we assume that the workload is CPU-bound, the performance impact p during a single scheduler time slice is defined by the ratio between the average CPU frequency experienced by the task and the average ideal CPU frequency at which the task could have been executed in isolation:

$$p = \frac{f_{\text{measured}}}{f_{\text{ideal}}} \quad (1)$$

In the case of Intel CPUs, the ideal frequency is the non-AVX frequency for non-AVX tasks and the AVX2 frequency for tasks which accessed 256-bit registers during the time slice. Note that memory-bound workloads suffer less from frequency reduction. We discuss the impact of this limitation in Section 9.2.

Whereas the average CPU frequency during a time slice is easily measurable, the ideal CPU frequency is not. Both non-AVX frequency and AVX2 frequency depend on the turbo

level which is selected by the CPU depending on the number of active cores. The number of active cores, however, can change at any point during the time slice, so counting the active cores during scheduler invocations is not sufficient to get a high-quality estimate of the average ideal frequency. Instead, we need to determine the average turbo level throughout the whole time slice. To determine the turbo level, we compare the measured frequency against each frequency expected had the chip operated at one particular turbo level during the time slice. If the measured frequency matches one of the expected frequencies, we can assume the corresponding turbo level. Else, the calculation of the ideal frequency has to be made via linear interpolation between the closest turbo levels.

As a first step, we calculate the expected frequency at a given turbo level for the measured amount of cycles spent at AVX2 and AVX-512 frequency levels. Assuming that during a time slice of length t_{total} the system spends t_i time at frequency f_i , the average frequency during the time slice can be calculated as follows:

$$f = \frac{1}{t_{\text{total}}} \sum t_i f_i \quad (2)$$

In the following, we assume that f_0 is the non-AVX frequency at the given turbo level, whereas f_1 and f_2 are the AVX2 and AVX-512 frequencies, respectively. These frequencies are published by Intel for their server CPUs [4]. As we count the cycles instead of the time spent at the three frequency levels, we substitute $t_i = c_i/f_i$ where c_i are the cycles at frequency f_i . We arrive at the following equation:

$$f(c_0, c_1, c_2) = \frac{f_0 f_1 f_2 (c_0 + c_1 + c_2)}{f_1 f_2 c_0 + f_0 f_2 c_1 + f_0 f_1 c_2} \quad (3)$$

$c_{\text{total}} = c_0 + c_1 + c_2$ is the total CPU cycle count and can be measured via a fixed-function performance counter, so only two programmable performance counters are required. If we further substitute $c_0 = c_{\text{total}} - c_1 - c_2$ as well as $r_1 = c_1/c_{\text{total}}$ and $r_2 = c_2/c_{\text{total}}$ as the ratio between the cycles spent at AVX2/AVX-512 frequencies and the total cycle count, we arrive at the final formula for the expected frequency at a specific turbo level:

$$f(r_1, r_2) = \frac{f_0 f_1 f_2}{(f_0 - f_1) f_2 r_1 + (f_0 - f_2) f_1 r_2 + f_1 f_2} \quad (4)$$

While calculating this formula requires a division, all frequencies lie within the same order of magnitude, so the formula can be calculated using fixed-point arithmetic and no floating-point arithmetic is required. The two-dimensional case of this formula for a Xeon Gold 6130 CPU under the assumption that $r_1 = 0$ – the system did not spend any time at the AVX2 frequency level – is shown in Figure 2.

At the end of each time slice, the scheduler measures the cycles spent at AVX2 and AVX-512 frequency levels as well as the average actual frequency. The formula above is then

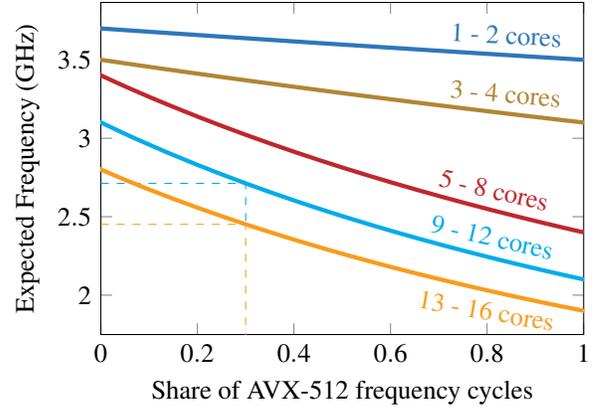

Figure 2: For a given amount of AVX2 and AVX-512 cycles during a time slice, the expected frequencies at the different turbo levels can be compared with the actual measured CPU frequency to determine the turbo level of the CPU. For example, if during a time slice 30% of all cycles were spent at the AVX-512 frequency level while an average frequency of 2.5 GHz was measured, the system likely spent most of the time at the lowest turbo level and some time at the second lowest as indicated by the dashed lines.

applied to the cycles to calculate the expected frequencies for the given number of AVX2/AVX-512 cycles at the different turbo levels. For each turbo level, the scheduler also calculates $f(0, 0)$ as the ideal frequency for non-AVX tasks and $f(r_1, 0)$ as the ideal frequency for AVX2 tasks.¹

The expected frequencies at the different turbo levels can then be compared to the measured actual frequency to determine the turbo level of the CPU, and that turbo level is used to determine the ideal frequency for the current task. If, as mentioned above, the measured frequency matches neither of the expected frequencies, linear interpolation is applied to determine the ideal frequency. The resulting ideal frequency can then be inserted into equation (1) to obtain the scaling factor for the task’s CPU time.

6 Implementation

We base the implementation of our design on the MuQSS scheduler [16], modified to use the scheduling policy of the CFS scheduler for enhanced fairness. We initially intended to use the CFS scheduler [20] as it provides particularly strict fairness for non-AVX workloads. While we show that the main scheduling policy of CFS is well-suited to our design, the implementation of CFS is not.

CFS measures the accumulated *virtual runtime* of each task, which is the actual CPU time multiplied by a priority factor [20]. The runqueue is sorted by the virtual runtime of

¹These calculations can be performed once at startup.

the tasks, and the scheduler always schedules the task with the lowest virtual runtime to ensure that all tasks are given an equal share of the CPU time. Changes to the virtual runtime as described above therefore cause preferential scheduling of victim tasks which counteracts the unfairness caused by AVX frequency reduction.

Our design, however, is incompatible with the current implementation of CFS. CFS maintains one separate runqueue per logical CPU, so any frequency reduction compensation for victim tasks only changes their priority within the runqueue of their current logical CPU. If, for example, one hyper-thread only executes AVX2/AVX-512 tasks, whereas the other only executes non-AVX tasks, the latter tasks only compete against each other during scheduling and there is no preferential treatment compared to the AVX2/AVX-512 tasks.

Frequent load balancing might improve the fairness in such a situation if an idle or more lightly loaded CPU would fetch and execute victim tasks first. In CFS, however, different cores can have different virtual runtime ranges and virtual runtimes are normalized during load balancing, so the virtual runtime advantage gained by victim tasks is often lost if tasks are migrated to a different logical CPU.

Rewriting CFS so that runtimes of tasks from different logical CPUs are comparable and introducing fast load balancing based on these runtimes is likely possible without introducing much overhead. However, we deemed the task too complex for our limited resources, so we based our implementation on the simpler MuQSS scheduler [16] which is a scheduler for Linux based on virtual deadlines. MuQSS differs from CFS in that it performs load balancing as part of the main scheduler function so that logical CPUs very frequently try to fetch tasks from other more heavily loaded CPUs.

Our tests, however, showed that MuQSS is often less fair than CFS even when no AVX2/AVX-512 is involved. We therefore replaced the deadline-based scheduling policy of MuQSS with the CPU-time-based policy of CFS, resulting in a hybrid of CFS scheduling policy and MuQSS load balancing. We then extended the policy with frequency reduction compensation as described in the previous sections. Unlike CFS, we do not perform full renormalization of the virtual runtime of tasks during load balancing. Instead, when a CPU selects a task from a different CPU, we simply limit the virtual runtime advantage the incoming task can have compared to the CPU's current lowest virtual runtime to prevent starvation of other tasks.

7 Evaluation

We evaluate our prototype to show to which degree our design can improve fairness and to determine the limitations of the design. The evaluation is conducted on a system with an Intel Xeon Gold 6130 CPU, 24 GiB of 2666 MHz DDR4 RAM, the Fedora 31 operating system, and the Linux 5.9 kernel (with the CFS scheduler or with our modified scheduler

based on MuQSS). As benchmarks for our evaluation, we use the nginx web server, most benchmarks from the Parsec 3.0 benchmark suite², as well as the Linux kernel build benchmark from the Phoronix Test Suite 9.0.1 (called “kernel-build” below). These benchmarks serve as potential victim tasks for frequency reduction compensation. In our experiments, the background application responsible for AVX frequency reduction is the x265 video encoder as it provides support for AVX-512 [29]. As described in Section 4.1, we did not implement our mechanism for CPU feature detection as part of our prototype as it would have made comparisons to an unmodified kernel much more difficult. Instead, we patch x265 to assume that AVX-512 is always available. All experiments are repeated ten times. MuQSS can be configured to share runqueues between multiple logical CPUs, and we selected runqueue sharing between hyper-thread siblings as we expected this setting to further help with the load-balancing issues described in the last section. As we show in Section 7.4, however, this setting does not seem to have much impact on the results.

7.1 Fairness

The main goal of our scheduler is to improve the fairness in a system where some tasks cause AVX frequency reduction and the performance of other tasks is affected. Fairness, in this case, means that equal CPU performance is available to the individual tasks. It is difficult to measure such fairness directly. Simply measuring the completion time of two applications when executing individually and then measuring the completion time of each application while both are executed at the same time does not yield the expected results. In particular, in a system with hyper-threading, two hyper-threads share CPU resources, and different applications may suffer differently from contention on these shared resources. An application with a large degree of instruction-level parallelism (ILP) may be able to utilize all available CPU resources when executed in isolation, but not when executed in parallel with a second application, whereas an application with little ILP may not be affected as much by other applications if the CPU resources are shared in a fair fashion. This and similar effects make it difficult to measure the unfairness caused by AVX frequency reduction.

We therefore choose a different, more indirect approach. Our experimental setup consists of two applications, a non-AVX foreground application of which we measure the completion time³, and a background application (the x265 video encoder as described above) which can be configured to use

²We excluded raytrace as it failed to finish even on a system with CFS and x264 as it showed too much variation in all experiments to provide meaningful results.

³Note that to generate HTTP requests for nginx we use the wrk2 benchmark client which has a constant benchmark duration. For the nginx benchmark, we therefore substitute the completion time with the inverse of the web server throughput (i.e., the time required per HTTP request).

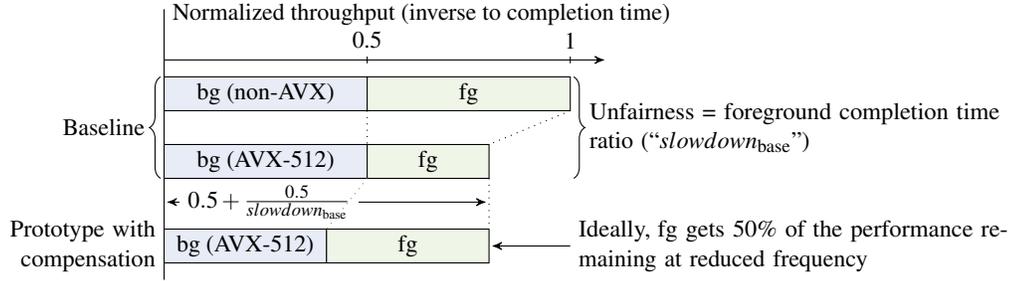

Figure 3: To calculate the fairness achieved by our prototype, we have to take into account that less overall CPU performance is available due to AVX-induced frequency reduction. Each application is supposed to be allocated half of that reduced performance.

either AVX, AVX2, or AVX-512 instructions. We start four instances of x265 with 8 threads each as otherwise x265 would not be able to utilize all available logical CPUs. Note that the completion time of x265 does not change much for the different instruction sets and that AVX, AVX2, and AVX-512 instructions are executed on the same functional units of the CPU core. Therefore, we avoid the problems described above and completion time differences for the foreground application should be representative of the AVX frequency reduction.

In a first experiment, which we call the *baseline experiment*, we execute the applications using our modified scheduler but without all code for frequency reduction compensation.⁴ We calculate the slowdown due to reduced frequencies as the completion time of the foreground application when the background application uses AVX2/AVX-512 divided by the completion time when the background application only uses AVX which does reduce the CPU frequency:

$$slowdown_{base,AVX-512} = \frac{t_{base,AVX-512}}{t_{base,AVX}} \quad (5)$$

$$slowdown_{base,AVX2} = \frac{t_{base,AVX2}}{t_{base,AVX}} \quad (6)$$

In this experiment, the slowdown provides a good metric for unfairness as no slowdown ($slowdown_{base} = 1$) means that the foreground application received the same share of CPU throughput irrespective of the choice of instructions:

$$unfairness_{base} = slowdown_{base} - 1 \quad (7)$$

We then repeat identical completion time measurements in a *prototype experiment* where we include frequency reduction compensation. As Figure 3 shows, in this case calculating the unfairness is slightly more complex. In a completely fair situation, both x265 and the foreground application would receive 50% of the CPU performance. However, overall CPU performance is reduced when x265 uses AVX2 or AVX-512, so 50%

⁴We did not compare our prototype to CFS directly as we wanted to isolate the impact of frequency reduction compensation. Related work shows that CFS does not prevent AVX2/AVX-512 tasks from slowing other tasks down [10], either, which violates the fairness definition used by this paper.

of this reduced performance are less than 50% of the CPU performance without any frequency reduction. Consequently, even with complete fairness, the foreground application still runs somewhat slower if x265 reduces the CPU frequency.

As Figure 3 shows, a slowdown during the baseline experiment of $slowdown_{base}$ results in a remaining CPU performance of $perf_{cpu} = 0.5 + 0.5/slowdown_{base}$ of the original performance. We can use this information to calculate the unfairness in the prototype experiment using the slowdown in this experiment $slowdown_{proto}$ as well as $slowdown_{base}$. If we, as in the baseline experiment, define the unfairness as the ratio between the completion time of the background application and the foreground application and then substitute the time with the inverse of the throughput, we get the following formula:

$$unfairness_{proto} = \frac{tp_{bg}}{tp_{fg}} - 1 = \frac{perf_{cpu} - tp_{fg}}{tp_{fg}} - 1 \quad (8)$$

As shown in Figure 3 the throughput of the foreground application is $tp_{fg} = 0.5/slowdown_{proto}$. Inserting into equation (8) and simplifying yields the following formula which we use in the next sections to calculate the remaining unfairness in our prototype:

$$unfairness_{proto} = slowdown_{proto} + \frac{slowdown_{proto}}{slowdown_{base}} - 2 \quad (9)$$

7.1.1 Benchmark Results

Figure 4 shows the results of the experiments described above. It can immediately be seen that our prototype greatly reduces the unfairness between the two applications. Whereas the baseline system shows an average unfairness of 7.9% for AVX2 and 24.9% for AVX-512, these numbers are reduced to 2.5% and 5.4% by our prototype, respectively.

Some benchmarks show substantially worse results than others, though. In particular, the blackscholes and dedup benchmarks show a high degree of unfairness even with our prototype. An analysis of these benchmarks shows that the benchmarks are not able to scale to all logical CPUs of the system. The blackscholes benchmark, in particular, contains long

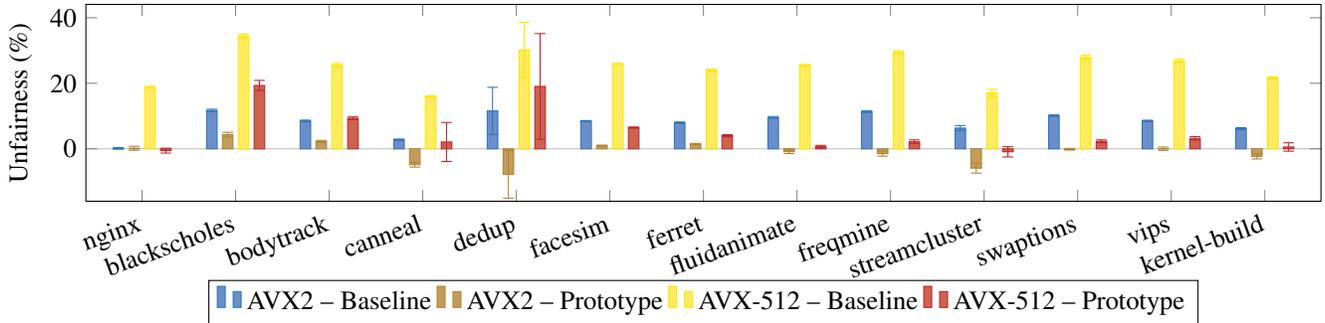

Figure 4: Unfairness for applications executed alongside x265 – for most workloads, our scheduler greatly reduces the unfairness between AVX2/AVX-512 applications and other applications executed in parallel. For AVX2, the unfairness was reduced from 7.9% (blue bars) to 2.5% (brown bars) on average, and for AVX-512 from 24.9% (yellow bars) to 5.4% (red bars).

serial phases where only one thread was active. In this case, the baseline setup already allocates almost one full logical CPU to the application. Therefore, our prototype is ineffective as it is not able to provide much more CPU time due to the lack of additional runnable threads.

This result also shows the main limitation of our approach. While overall our prototype is able to greatly increase fairness, the central mechanism – i.e., increasing the priority of victim tasks – is only effective if an increased priority translates into increased CPU time. This is not the case if an application already receives as much CPU time as it can utilize. Similarly, our approach also fails if victim application and AVX2/AVX-512 application are restricted to non-overlapping sets of logical CPUs, for example, via non-overlapping affinity masks, but effectively share physical cores via hyper-threading.

7.1.2 Synthetic Workload

Our methodology to measure the fairness for real-world applications relies on unusually complex indirect calculation of the target metric. Although the results of our experiments seem consistent, we therefore conduct an additional direct measurement of the fairness in a purely synthetic workload. For this experiment, our foreground application simply consists of 32 threads which together execute a fixed amount of 256-bit fused multiply-add (FMA) instructions requiring AVX2 frequencies, whereas the background application similarly executes a fixed amount of 512-bit FMA instructions at AVX-512 frequencies. As the two applications use very similar CPU resources, the resource contention effects described in Section 7.1 should affect both equally and should therefore not influence the observed fairness.

We try to choose the number of instructions executed by the two applications so that both require the same time if executed in isolation. We then perform a direct measurement of the fairness by comparing the completion time of the applications when executed in parallel at the same time. After one of the application finishes, we immediately start it a second time

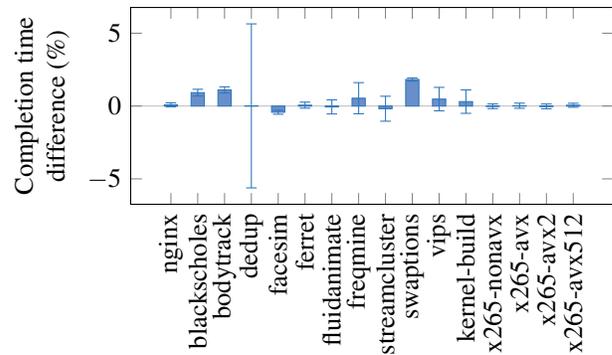

Figure 5: Our prototype causes almost no overhead when compared to a scheduler without frequency reduction compensation.

to prevent situations where only one application is running, as it then receives substantially more CPU resources. The increased throughput during that phase would mean that the measured completion time difference would not be representative for the unfairness during parallel execution.

In this setup, equal completion times are an indicator that both applications received equal shares of CPU performance. Our prototype provides almost perfect fairness. Whereas on a system without frequency reduction compensation the completion times differ by 19.2%, only a completion time difference of 0.5% remains in our prototype.

7.2 Overhead

While frequency reduction compensation can reduce the performance impact of AVX2/AVX-512 tasks on other tasks, the required modifications to the operating system can also cause overhead. In particular, the modified scheduler algorithm is executed many times per second on each core. The additional code not only increases the time spent in the scheduler itself

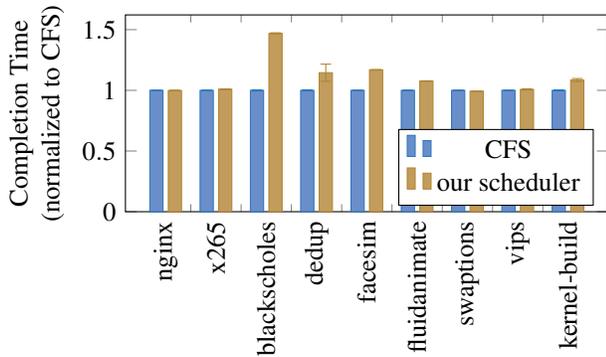

Figure 6: Our scheduler mostly provides competitive performance compared to CFS.

but also the cache footprint of the scheduler. Furthermore, the design triggers additional exceptions to detect 256-bit and 512-bit register accesses.

Most of the overhead, however, is only generated under specific circumstances. For example, the frequency impact of AVX2/AVX-512 is only calculated when the code detects a reduced frequency level at some point during the last time slice. The exceptions to detect AVX2 and AVX-512 tasks only affect such tasks and are triggered at most once per scheduler time slice.

To determine the overhead caused by our prototype, we measure the completion time of a range of benchmarks when executed in our prototype. We compare this time to the time when the benchmarks are executed with the same scheduler but without the code for frequency reduction compensation. The benchmarks include the nginx, Parsec, and PTS benchmarks used in Section 7.1 as well as the x265 video encoder as an example of an application using AVX2 or AVX-512 instructions. Due to the large variance of the dedup benchmark, we execute it 100 times to reduce the chance of misleading results.

Figure 5 shows the results of this experiment. The highest average overhead is measured for swaptions and amounted to 1.82%. All other benchmarks show less overhead, with an average overhead across all benchmarks of only 0.3%. We expect this overhead to be acceptable in most scenarios. In particular, the experiment shows that the additional exceptions to detect AVX2/AVX-512 code do not cause substantial overhead, as can be seen by the low overhead for the AVX benchmarks.

7.3 Comparison With CFS

In all experiments described above, the baseline for our measurements is our own scheduler, with the code for frequency reduction compensation removed at compile time. Even though our scheduler implements the same basic algo-

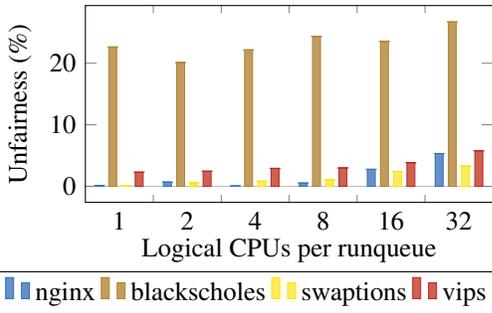

rithm as CFS, it provides a radically different implementation based on MuQSS. While MuQSS has been shown to provide similar performance as CFS [17], the implementation differences would have likely had an impact on the behavior of the benchmarks. Because we did not directly compare our MuQSS-based prototype to CFS in the experiments above, we show that the underlying scheduler – MuQSS modified to use the CFS policy, but without frequency reduction compensation – provides performance competitive to CFS. We execute a subset of the benchmarks with these two schedulers comparing the completion times.

Figure 6 shows the completion times of the benchmarks when executed with our scheduler normalized to the completion times with CFS. For most benchmarks, our scheduler causes at most 17% overhead when compared with CFS. This range matches the performance reported for unmodified MuQSS [17]. We used perf to measure the instructions per cycle (IPC) as an effort to determine the reason for the overhead. Overall, the IPC differences were much smaller than the overhead, with no clear correlation between the two, which shows that ineffective caching due to the fast load balancing required by our approach is not the main reason for the overhead. Implementing a suitable load balancing mechanism in other schedulers such as CFS is therefore unlikely to have substantial negative impact.

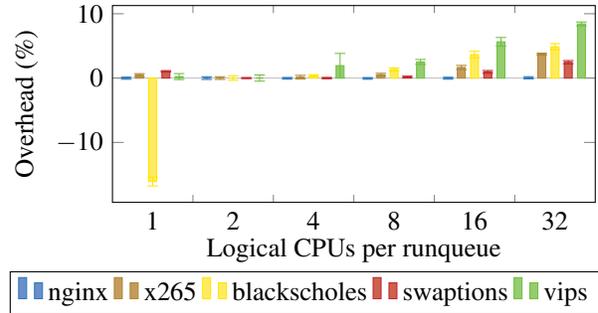

7.4 Runqueue Sharing

As described in Section 6, our implementation relies either on runqueues shared between multiple logical CPUs or on quick load balancing as otherwise the scheduler would often not have a choice between enough tasks to be able to effectively implement prioritization of victim tasks. The MuQSS scheduler used as the basis for our implementation provides both flexible runqueue sharing options as well as quick load balancing. As we want to determine whether shared runqueues were required for our approach to be effective, we measure the fairness for a subset of the benchmarks and with runqueues shared between different numbers of logical CPUs. The results of this experiment are visualized in Figure 7a, where we show the unfairness when AVX frequency compensation is enabled. Note that sharing runqueues between cores increases lock contention and potentially has a negative impact on throughput, so we also measure the overhead compared to a setup with runqueues shared between two logical CPUs. The results of this experiment are shown in Figure 7b.

Counterintuitively, sharing runqueues beyond sibling hyperthreads does not appear to have any beneficial impact on our prototype, which shows that the load balancing mechanism of our scheduler is able to provide all CPUs with enough choices so that they are able to prioritize victim tasks. The runqueue sharing options do result in slightly different throughput, however, with most benchmarks performing best if runqueues are shared between two logical CPUs. We assume blackscholes

(a) Remaining unfairness due to AVX-512 frequency reduction in our prototype (parallel execution with x265)

(b) Overhead for different runqueue sharing options compared to sharing among two logical CPUs (without frequency reduction compensation)

Figure 7: Our scheduler can share runqueues between a flexible number of CPU cores. While sharing runqueues between sibling hyper-threads – i.e., between two logical CPUs – provided the highest performance for most workloads, other configurations caused additional overhead and did not provide improved fairness.

benefits from improved cache efficiency when executed without shared runqueues. Note that despite the potential for such results the default option for MuQSS is to share one runqueue among all multicore siblings (i.e., 32 logical CPUs on our system).⁵

8 Fairness Criteria

Our evaluation shows that equal distribution of CPU time as implemented by contemporary schedulers fails to achieve its goal, which is to allocate equal CPU performance to individual tasks to improve performance isolation. We therefore propose AVX frequency compensation as a technique for fairer distribution of performance. While equal performance in terms of equal slowdown due to remote AVX overhead is an intuitive fairness definition, it is by far not the only one. We have identified two main dimensions spanning the design space of such definitions.

First, while current schedulers build upon CPU time as the main metric for fairness and we base our approach on a notion of CPU throughput, other metrics may be viable. One alternative would be to base scheduling on energy as a first-class operating system resource as suggested by related work [22, 26, 31]. Similar to our approach, such designs could penalize applications using power-intensive instructions such as AVX2 or AVX-512. While energy-based scheduling can therefore likely also solve the problem covered by this paper, it is not viable on current hardware. The CPU power model used by existing approaches either does not differentiate between executed instructions [22, 31] or uses the performance monitoring unit and requires a careful choice of performance events from which the energy can be derived with sufficient accuracy [24]. Current CPUs, however, do not provide any

⁵<https://github.com/ckolivas/linux/blob/5.9-muqss/kernel/Kconfig.MuQSS#L3>

sufficiently specific performance events for the relevant set of AVX2 and AVX-512 instructions [3, p. 19-3ff].⁶ If future hardware provides a reliable method to estimate energy usage of individual logical CPUs, energy-based scheduling may prove to be a more effective solution than our approach.

Second, the effects of CPU power management can be compensated to different degrees, ranging from no compensation at all as implemented by most current operating systems to full compensation where only power-intensive tasks are affected by frequency reduction overhead. The latter provides a degree of performance isolation that is often desired in multi-tenant systems where customers pay for specific CPU performance. However, it also actively penalizes use of accelerators or similar specialized hardware, even though such code is often more energy-efficient due to the resulting speedup [6]. Our approach implements a compromise between performance isolation and incentives to use energy-efficient accelerators: Our definition of fair distribution of CPU performance means that the frequency reduction overhead is equally shared by low-power tasks as well as the high-power tasks which caused the overhead. In the future, we envision metadata such as the CPU quota information provided by Linux cgroups to be used to choose the appropriate type of frequency reduction compensation on a task-by-task basis.

As part of such a more flexible approach, our scheduler can easily be modified to support different degrees of performance isolation. As a possible variant, we changed our scheduler to not only reduce the CPU time credited to the victim task according to the frequency reduction but to also add an identical amount to the CPU time credited to the last AVX2 or AVX-512 task executed on the physical core. Whereas the original scheduler only reduced the performance impact on non-AVX tasks by a third during the benchmarks described

⁶While the CPUs provide performance events for floating point AVX2/AVX-512 instructions, other instructions are not covered.

above, this modification foregoes fairness and allocates more CPU time to victim processes, thereby achieving an average reduction by 70%, with many benchmarks experiencing a far lower performance impact.

9 Limitations

Our evaluation demonstrates that our scheduler modifications greatly improve fairness for workloads consisting of AVX2/AVX-512 tasks and non-AVX tasks. For many of the scenarios we test, our prototype achieves 10 times better fairness than a scheduler without frequency reduction compensation. This improvement comes at near-zero cost: As we show, frequency reduction compensation has almost no overhead, and it only contributes 329 additional lines of code to our prototype. While our design therefore provides a practical solution as-is, with substantial improvements over existing schedulers, it has a number of limitations, some of which are caused by limitations of the underlying hardware. We discuss these limitations below and sketch improvements of the design where applicable.

9.1 Detection of AVX2 and AVX-512

As our design tries to increase the CPU time share of tasks which suffer from AVX frequency reduction even though they do not have to be executed at reduced frequencies, correct attribution of reduced frequencies to AVX2/AVX-512 tasks is a central part of our design. We use and extend an existing approach [10] where the CPU is configured to trigger an exception when 256-bit and 512-bit registers are accessed. This simple policy does not match the actual conditions for reduced frequencies which are substantially more complex [5, 18]. Often, usage of 256-bit and 512-bit registers is detected even though a task does not actually require the respective AVX2 and AVX-512 frequency levels. Yet, our prototype assumes that a lower frequency level is required whenever a task accesses the corresponding registers.

If, for example, a task executes light AVX-512 instructions, our prototype never applies any compensation even if the task could be executed at AVX2 frequencies as shown in Section 2. Similarly, for tasks with light AVX2 instructions which are able to execute at non-AVX frequencies, our prototype only compensates the difference between AVX2 and AVX-512 frequencies. To the best of our knowledge, there is no better hardware interface available to detect power-intensive AVX2/AVX-512 code sections. In our case, however, it is important to note that the mechanism does not cause any false negatives and therefore results in a conservative implementation where applications are never unfairly rewarded for a frequency reduction they caused themselves.

In the future, an improved software mechanism to detect AVX2/AVX-512 code may improve accuracy. For example, the operating system could scan executable pages for 256-bit

and 512-bit operations and categorize them. Then, instead of the current register-based mechanism, the OS could selectively unmap all pages containing instructions which may cause a transition to AVX2/AVX-512 frequencies to detect AVX2/AVX-512 tasks via page faults.

9.2 Memory-Bound Processes

As described in Section 5, our prototype currently assumes that performance is proportional to CPU frequency when deriving the performance impact from the calculated frequency reduction. This is an assumption that is found in related work as well [12]. The assumption is incorrect for memory-bound tasks, however. Memory latency does not increase when the CPU frequency is reduced, so memory-heavy applications suffer less from reduced frequencies [13]. Unequal performance impact due to different sensitivity to frequency changes has been identified as a challenge for fair scheduling [14].

In our case, the result is that memory-bound tasks may be given more than their fair share of the system's performance if frequency reduction compensation is applied. Consequently, the negative impact on the AVX2/AVX-512 tasks causing the frequency reduction is increased, as they in turn are allocated less than their fair share of CPU performance. This negative impact, however, is bounded: The AVX2/AVX-512 tasks always receive at least as much CPU performance as they would if all other tasks were completely CPU-bound.

In the future, our design could be extended with a more accurate performance model which takes memory accesses into account, similar to DTS [14] which has shown that better DVFS performance models can greatly increase fairness. Many such models have been described in the literature [21]. It has been shown that often very few performance counters suffice to characterize the workload and to predict performance at other CPU frequencies [25, 27]. As described in Section 5, our current technique to determine the performance impact requires at least two of the four configurable performance counters of each logical CPU (one for AVX-512 and one for AVX2 frequency level cycles) as well as a fixed-function CPU cycle counter.⁷ The two remaining configurable counters can be used to determine how memory-heavy the workload is and to implement a better performance model.

10 Related Work

To the best of our knowledge, our approach is the first fair scheduler for workloads involving AVX2 and AVX-512 tasks. However, there have been scheduling algorithms for software-controlled DVFS and there have been other techniques to mitigate the performance impact caused by AVX frequency

⁷Currently, the prototype uses three configurable performance counters. The third counter is used to determine the total number of elapsed CPU cycles and can be replaced with a fixed-function counter.

reduction. In the following section, we describe the corresponding related work and lay out the differences to our approach.

10.1 Fair Scheduling and DVFS

Existing work on fair schedulers for systems with DVFS has focused on software-controlled DVFS where the operating system chooses the CPU frequency. Two main issues affecting fairness arise from such DVFS:

1. CPU quotas are commonly expressed in terms of CPU time, and a fixed CPU time quota translates into less performance when the system is running at a reduced frequency. Hagimont et al. [12] discuss the interaction between load-based CPU frequency selection and fixed and flexible CPU time quotas. Whereas fixed CPU time quotas result in reduced fairness and insufficient CPU throughput, flexible CPU time quotas commonly prevent any frequency reduction.

Hypervisors often implement CPU time quotas in the form of credit schedulers. To solve the problems stemming from DVFS, the time per credit can be scaled by the CPU frequency and frequency selection can be modified to take flexible CPU quotas into account [12]. In this work, we use a similar approach where we implement scaling within CPU time accounting. Our work differs, though, in that we focus on hardware-controlled DVFS and on unfairness problems where one task reduces the CPU frequency experienced by another task. This scenario requires different techniques to identify the tasks affected by unfair scheduling and to determine the scale of the resulting performance impact.

In Section 8, we discussed that CPU time is not the only possible metric for scheduling. Credit schedulers in particular have been modified to scale the time per credit based on power consumption [30]. While such policies could improve fairness in workloads with AVX2 and AVX-512, the required fine-grained accurate power models cannot be constructed on current hardware for the reasons outlined above.

2. Programs suffer from the same frequency reduction to different degrees depending on how memory-heavy the programs are. Jia et al. [14] show how this affects fairness when the operating system reduces the CPU frequency. They suggest dynamic time-slice scaling (DTS) to achieve level performance, where the operating system determines the performance impact of DVFS on applications and scales time-slices accordingly. Our work solves a different problem – unfairness caused by hardware-controlled DVFS – yet uses a very similar mechanism. Instead of time-slice scaling, we modify CPU time accounting as it requires fewer modifications to the CFS

scheduling algorithm. In general, we argue, though, that the approach of DTS is orthogonal to our design. As we describe in Section 9.2, we currently assume that all tasks are affected equally by frequency reduction, so estimates of the actual performance impact as conducted by DTS can further improve the fairness of our approach.

10.2 Core Specialization

In this work, we describe a scheduler which compensates AVX frequency reduction to improve fairness. An alternative approach would be to prevent AVX frequency reduction whenever possible, as less AVX frequency reduction might also lead to improved fairness. One such technique to prevent AVX frequency reduction is to use core scheduling to limit co-scheduling of AVX-512 and non-AVX-512 tasks [19]. Similarly, core specialization [10] restricts scheduling of AVX-512 tasks to a subset of the system’s CPU cores. While, in contrast to our approach, both techniques can potentially improve overall system throughput if they achieve higher average CPU frequencies, they have the potential to cause substantial overhead. Core scheduling leaves hyper-threads idle if necessary [19], which may cause reduced utilization of CPU resources. Similarly, an earlier version of core specialization was shown to cause substantial overhead when tasks frequently had to be migrated between cores [9]. We present an approach that is far less intrusive and has less potential to cause overhead. We therefore believe that our approach is applicable to a wider range of situations.

11 Conclusion

When power-intensive instructions are executed, power-limited CPUs may have to temporarily reduce their frequency to prevent excessive power consumption. Often, this frequency reduction also affects tasks that do not execute such power-intensive instructions. Therefore, as we demonstrate, these systems require new approaches to fair scheduling.

Recent Intel CPUs with support for AVX2 and AVX-512 show such behavior, and in this work we describe a technique to identify victim tasks whose performance is affected by other AVX2/AVX-512 tasks. We describe a modification to CPU time accounting where the CPU time credited to these victim tasks is scaled according to the frequency reduction experienced by the tasks. The change causes fair schedulers based on CPU time to prioritize the tasks to the degree where they receive their fair share of CPU performance again. Our prototype is able to reduce the unfairness from 7.9% to 2.5% on average for workloads involving AVX2 applications and from 24.9% to 5.4% for AVX-512.

RCS Lab, University of Waterloo

Abstract

This paper presents Schedulable Kqueue (SKQ), a new design to FreeBSD Kqueue that improves application tail latency and low-latency throughput. SKQ introduces a new scalable architecture and event scheduling. We provide multiple scheduling policies that improve cache locality and reduce workload imbalance. SKQ also enables applications to prioritize processing latency-sensitive requests over regular requests.

In the RocksDB benchmark, SKQ reduces tail latency by up to $1022\times$ and extends the low-latency throughput by $27.4\times$. SKQ also closes the gap between traditional OS kernel networking and a state-of-the-art kernel-bypass networking system by 83.7% for an imbalanced workload.

1 Introduction

Applications and hardware have evolved tremendously. Modern server applications span hundreds to thousands of nodes across the data center to serve user requests. The depth and breadth of the service tree cause users to experience request latency dominated by the tail latency of any node in an application [11]. Advancements in storage and networking are making low latency services possible [2]. Recent research systems propose using kernel-bypass and custom dataplanes to reduce latency [3, 19, 23, 36].

However, most applications in data centers are still built directly on top of traditional OSes and employ an event-driven approach, which uses an event loop that polls the kernel's event subsystem. Even popular user-level threading systems internally depend on kernel event subsystems to dispatch events efficiently across user-level threads, e.g., Go language [16] and Arachne [37].

Event subsystems in traditional OSes such as *Kqueue* [27] in FreeBSD and Mac OS X, *epoll* [29] in Linux, *IO Completion Ports* (IOCP) [9] in Windows and *Event Completion Framework* [4] in Solaris were developed nearly 20 years ago, predating many innovations in modern hardware. These event subsystems undermine features such as receive side scaling

(RSS) [8] that can improve scalability and latency. Userspace event libraries, e.g., *libevent* [32], are influenced by event subsystems and propagate these issues. Research systems such as *Megapipe* [17] and *Affinity-Accept* [34] improve event subsystems but only solve part of the problem.

The evolution of modern server applications and hardware inspired us to revisit event facilities in traditional OS kernels to address the latency problem. Improving tail latency in a traditional OS is challenging. Unlike kernel-bypass and custom dataplanes, existing kernels are multipurpose and complex. Kernel event facilities tightly integrate with many subsystems including storage, network, and process management. Furthermore, we must carefully tradeoff our system's overhead with the performance benefit to the rest of the system.

This paper presents Schedulable Kqueue (SKQ), a novel event notification facility based on FreeBSD Kqueue that provides a more flexible abstraction, and allows applications to use features of modern hardware. SKQ improves tail latency and extends low-latency throughput. SKQ introduces a new architecture with improved scalability, fine-grained event scheduling and event delivery control. Application threads share a single, scalable SKQ instance, which automatically schedules events across all threads. While improvements to kernel event notification facilities have been proposed [17, 34], SKQ differentiates itself with the following contributions:

- SKQ offers multiple application-controlled scheduling policies to improve cache locality and workload imbalance. We present guidelines for policy selection in § 4.3.
- SKQ presents explicit control over event delivery including event pinning and prioritization.
- SKQ has been extensively tested and deployed on production servers. We also developed event libraries to facilitate integration in existing applications.

We evaluate SKQ with microbenchmarks and multiple real world workloads with different characteristics. We examine workloads with uniform and non-uniform request service times, and IO-bound workloads. In microbenchmarks, we

show that SKQ reduces lock contention, improves cache locality and multicore scalability. In our RocksDB [14] benchmark running the Facebook ZippyDB workload, SKQ extends the low-latency throughput by 27.4× and reduces latency by up to 1022×. Event prioritization allows a saturated server to service low-latency requests to a high priority client with 8× lower latency while having little performance impact on other clients. Additionally, SKQ closes the gap between traditional OS kernel networking and a state-of-the-art kernel-bypass networking system by 83.7% for an imbalanced workload.

2 Background and Related Work

SKQ was motivated by the design and performance problems with existing event subsystems. While our observations hold on popular platforms, i.e., Linux `epoll` and Windows IOCP, we will explain everything in the context of FreeBSD Kqueue.

Sources of Latency: Li et al. [28] studied several server applications and identified multiple factors in the OS that contribute to high tail latency. The authors suggested reducing background tasks, pinning threads to cores and avoiding NUMA effects. Even after following all the recommendations, we found two additional factors that lead to high tail latency.

One factor is cache misses due to receive side scaling (RSS) [8] found in modern NICs. RSS creates a send and a receive NIC queue per core and distributes connections across them using hash functions. Recent implementations of RSS also load balance by migrating groups of connections between cores. However, applications are unable to detect this and will process the connection on the original core, losing connection affinity and causing cache misses. In our Memcached benchmark, we found that up to 77% of total L2 cache misses are due to improper connection affinity and are avoidable. SKQ maintains connection affinity and follows connection migration with the *CPU affinity* scheduling policy.

Another factor is workload imbalance that arises from differences in request service time and suboptimal connection distribution across worker threads. Workload imbalance over-saturates some worker threads while under-saturating others. To put this into perspective, we measured the difference in total processing time between the most and least busy threads in two workloads. In Memcached, a uniform workload, we measured a 2.8% difference. In a GIS application with a Zipf-like service time distribution, we measured a 46% difference. As a result, the GIS application's tail latency increases much faster than Memcached as a function of throughput. SKQ offers scheduling policies to minimize workload imbalance.

Event-Driven Models: Most modern event-driven applications use either the *1:1 model* or the *1:N model*.

Applications using the 1:1 model create one Kqueue per thread where connections are assigned to thread private Kqueues. This model scales well and maintains connection affinity. However, the 1:1 model suffers from two problems.

First, it hinders efficient event migration. Moving events between Kqueues requires two system calls that remove events from the source Kqueue and add them to the target Kqueue. This migration process also involves multiple kernel and userspace locks, leading to poor scalability. Second, this model interacts poorly with RSS in modern NICs as applications cannot detect nor react to RSS connection migration.

The 1:N model means all threads share a single Kqueue and process connections in a round-robin fashion. This model maximizes CPU utilization and simplifies event scheduling, but suffers from two problems. First, the model leads to lock contention on multicore machines (see § 6). Second, the model does not preserve connection affinity as each connection is processed by different threads, which results in cache misses. As a result, applications and event libraries have mostly avoided the 1:N model except for a few low-throughput services [25].

SKQ uses a hybrid architecture that offers the best of both worlds through our event scheduler. SKQ exposes a 1:N model to applications for efficient event scheduling and delivery while internally using a 1:1 model for multicore scalability.

Need for Application Control: Applications often need to deliver events to a specific thread. For example, one thread needs to notify another thread of control events. Kqueue does not provide applications using the 1:N model with fine-grained event delivery control. SKQ allows applications to pin events to specific threads.

SKQ also introduces application controlled event prioritization, which allows applications to prioritize latency-sensitive events over batch-processing events. To our knowledge, no existing kernel event subsystem supports event prioritization. The latest generation NICs provide hardware support for event prioritization with application device queues (ADQs) [20]. SKQ can be used with ADQs to improve event prioritization throughout the networking stack.

RFS, RPS and Intel Flow Director: Receive Flow Steering (RFS) [12] and Receive Packet Steering (RPS) [6] are Linux networking stack features. RFS improves connection locality by enabling the kernel to process packets on the core where the corresponding application thread is running. RPS is a software implementation of hardware RSS, which provides hash-based packet distribution across cores. Intel Flow Director [18] is a hardware implementation of RFS. SKQ eliminates the need for RFS with the *CPU affinity* policy.

io_uring: `io_uring` [7] is a recent Linux kernel feature that enables efficient asynchronous IO and avoids system call overhead via polling. Each `io_uring` object uses a single submission queue and a single completion queue for kernel-user communications. However, `io_uring` does not provide event scheduling between threads, which is the goal of SKQ.

FreeBSD offers the `lio_listio` [41] interface for asynchronous IO, which batches rather than eliminates system calls. We benchmarked the benefit of `lio_listio` combined with SKQ to improve low-latency throughput by roughly 40%,

compared to 19.8% with SKQ alone on our web server benchmark (§ 6.7). Our techniques are also applicable to `io_uring`.

Windows IOCP: Windows IOCP is functionally similar to Kqueue and provides a developer friendly API for blocking IOs when used with the 1:N model [10, 38]. Each IOCP internally uses one event queue and provides a concurrency parameter to limit the number of running threads. Threads beyond this limit block until a running thread sleeps on an unrelated IO operation (e.g. disk IO) [9]. IOCP also suffers from lock contention at high core counts because of the 1:N model. As a result, only applications with long running requests, such as Exchange and MSSQL [25], use the 1:N model.

MegaPipe: MegaPipe [17] permanently affinizes accepted connections to threads to improve cache affinity. MegaPipe internally uses the 1:1 model. Prior to MegaPipe, Affinity-Accept [34] and Chronos [26] also suggest maintaining connection affinity. MegaPipe delivers socket data along with triggered connections to reduce system call overhead.

SKQ's *queue affinity* scheduling policy is similar to MegaPipe's behavior. However, queue affinity is inferior to CPU affinity that takes into account connection migration in kernel and NICs. MegaPipe was developed much earlier when connection migration was less frequent due to the maturity of RSS implementations.

Custom Networking Stack: Arrakis [35], Chronos [26], DPDK [19], F-Stack [40], IX [3], and mTCP [22] use kernel-bypass to reduce system calls and/or kernel networking stack processing overhead. Other systems such as Snap [30], Shinjuku [23], and ZygOS [36] apply thread scheduling on custom dataplanes. Shenango [33] implements user-level scheduling on top of DPDK and uses work stealing for load balancing.

SKQ differs from the systems above in three ways. First, SKQ schedules events between threads rather than threads between cores. Second, SKQ offers control over event delivery and scheduling policies in addition to work stealing. Last, SKQ is implemented in a traditional OS where most server applications are still being developed. SKQ enables applications to gain performance benefit with minimal changes. The systems above however generally suffer from adoption issues.

3 Design Overview

Modern applications require increasingly better multicore scalability, cache locality and scheduling support. FreeBSD Kqueue was designed to solve the C10K [24] problem. Server applications are now running with many cores and millions, rather than thousands, of clients. The changes in applications' scale and requirements require us to revisit Kqueue's design.

The current design presents three major issues. First, using Kqueue in the 1:N model results in scalability bottlenecks due to lock contention in some multithreaded applications with as few as 4 threads. Second, we observed cache misses and load imbalances that could not be solved. Finally, Kqueue processes events in FIFO order and lacks event prioritization.

SKQ is designed with three primary goals: scalability, event scheduling, and event prioritization. SKQ is also designed to be compatible with the Kqueue API.

- **Scalability:** SKQ scales to multicore machines and a large number of events. Our design allows a single SKQ to efficiently schedule events to multiple threads with little overhead and lock contention.
- **Event Scheduling:** SKQ implements scheduling policies that improve cache locality and minimize workload imbalance. Applications can select policies based on workload characteristics to minimize tail latency.
- **Event Prioritization:** SKQ enables applications to prioritize processing high priority events versus regular events, with minimal performance impact.

One major challenge is providing low overhead scheduling as any overhead can impact application performance. To put this in perspective, for Memcached, an increase in processing times of 150 cycles would result in a 1% drop in peak throughput, while a single L3 cache miss reduces throughput by 2.7%. Scheduling introduces unavoidable overhead due to statistics collection and making scheduling decisions.

3.1 Kqueue

The Kqueue API consists of two system calls. The `kqueue()` system call creates a Kqueue kernel object and returns a file descriptor. The `kevent()` system call handles event registration, update and delivery.

Applications manipulate events by calling `kevent()` on a Kqueue object with the file descriptor of a kernel object and the type of event to monitor (e.g. read availability on a socket). For event registration, the target Kqueue object allocates a *knote* to track the information and the state of the registered event. For fast lookups, all knotes on a Kqueue are kept in a hash table in the Kqueue object.

Upon creation, the knote is also attached to the kernel object of interest. In FreeBSD, all kernel objects supported by Kqueue maintain a list of attached knotes. When the kernel object triggers an event, it activates all attached knotes by notifying their corresponding Kqueue objects.

Kqueue enqueues activated knotes into a single event queue protected by a giant lock. Application threads retrieve events with the `kevent()` system call and a userspace buffer used to hold the returned events. Internally, all threads acquire the giant lock and dequeue knotes from the event queue.

One correctness guarantee that a shared Kqueue provides is to avoid returning an event that is being processed by a thread to another thread. For example, a shared Kqueue must not notify more than one thread of read availability on the same socket, otherwise a race may occur. Kqueue achieves this guarantee by relying on application threads marking shared events as *dispatch events*, which instruct Kqueue to disable the event after returning it to the application. Once an application

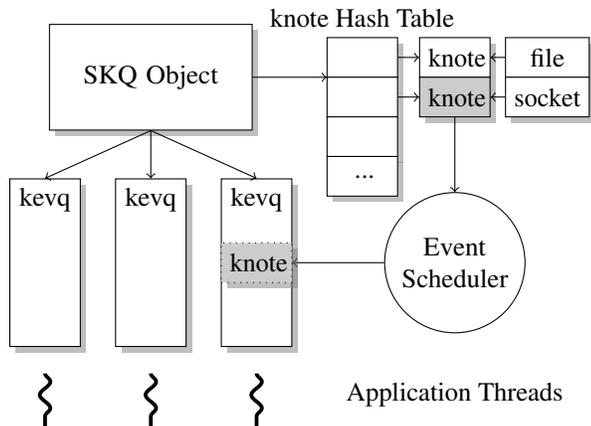

Figure 1: System Overview. SKQ creates thread private kevm to reduce lock contention and introduces an event scheduler. In this diagram a socket activated a knote and the event scheduler enqueued it into a specific kevm based on an application defined scheduling policy.

thread finishes processing a shared event, the thread must call `kevent()` to re-enable the event so it can trigger again.

Both the single event queue design and frequent event enabling/disabling cause lock contention. Therefore, a Kqueue is rarely shared between threads in an application. Additionally, using a single event queue hinders optimizing for cache locality [17,34]. User-level scheduling is difficult as migrating knotes between Kqueues is cumbersome and inefficient.

3.2 SKQ

SKQ provides applications with event scheduling and delivery controls by sharing a single scalable instance between all application threads. Figure 1 shows the overall architecture. SKQ extends Kqueue in three main ways: employing a new scalable design, offering event scheduling and delivery control, and optimizing the event lifecycle. Additionally, SKQ maintains a compatibility mode that exhibits the same behavior as Kqueue.

Scalability: SKQ improves multicore scalability and enables efficient event scheduling by introducing a new internal, lightweight, per-thread *kevm* structure. Each SKQ creates one kevm for each application thread, which is an event queue that holds knotes assigned to the corresponding thread.

When applications query events, each worker thread locks and retrieves knotes from its private kevm, eliminating a major source of contention on the giant Kqueue lock. Furthermore, kevm allow SKQ to quickly schedule events between lightweight internal structures instead of kernel objects. Implementing event scheduling between kernel objects requires extra locking (e.g. file descriptor locks) and complicates resource cleanup. SKQ approximates the benefit of the 1:N model without scalability bottlenecks or poor cache affinity

through scheduling on top of an internal 1:1 model.

When an SKQ is destroyed, all of its kevm are destroyed. If a thread exits while an SKQ is still active, only the exiting thread's kevm is drained and destroyed. Knotes already queued to the kevm are rescheduled to other available threads.

Applications are allowed to create multiple SKQs at a time, meaning each application thread can correspond to multiple kevm belonging to different SKQs. We use a hash table that maintains the mapping from kevm to their respective SKQs in the kernel thread object.

The per-thread design allows SKQ to more easily handle applications that spawn greater or fewer threads than available cores, and thread migration. While it might seem natural to use a per-core design, some applications process blocking IO calls and have more threads than cores. Applications with fewer threads than cores would require extra handling to prevent events from being left on cores with no threads.

Event Scheduling and Delivery Control: SKQ introduces an event scheduler to schedule knotes both passively and actively. Upon event activation, the event scheduler determines the target kevm of the activated knote based on the selected scheduling policy. When a kevm has no active knotes, the kevm also actively tries to steal knotes from other kevm. Applications can control the scheduling policy via `ioctl()` and new per-event flags for pinning and priorities.

SKQ also allows applications to mark individual events as high priority. SKQ favors returning high priority events first. Two tunables are provided to control the exact behavior. Applications can adjust the tunables based on their requirements. We elaborate on both features in § 4.

Optimized Event Lifecycle: We optimize SKQ's event handling to eliminate the need of re-enabling events after processing and to improve scheduling fairness.

SKQ adds a processing flag to knotes and a processing queue to kevm. Each processing queue holds knotes returned to the application from the last `kevent()` call. SKQ marks these knotes as processing, which can be scheduled to a different kevm although they are temporarily ignored by event queries. When the original thread finishes processing events, it calls `kevent()` again, which releases all knotes on its processing queue so they can be returned by future event queries.

Applications do not need to re-enable events because SKQ marks them as processing in the kernel and will not deliver them to other threads until the original thread releases them. This optimization improves scheduling fairness as processing events are always scheduled on activation rather than after the original thread returns, preserving the relative order of arrival.

4 Event Scheduling Policies

The event scheduler selects the kevm for an activated knote based on the scheduling policy. SKQ offers two categories of scheduling policies that improve cache locality and reduce

workload imbalance, which can be combined. Additionally, applications can pin events to threads and prioritize events.

We originally planned to provide a single policy that would perform well for all workloads. However, we realized from our experiments that the best scheduling policy is application and workload dependent (§ 4.3 describes policy selection). To this end, SKQ provides applications with control over scheduling policy to better meet the developer and user needs.

The biggest challenge is balancing the overhead and the optimality of making scheduling decisions. Since the event scheduler runs on every event activation, we must minimize the overhead so that the cost of scheduling does not overshadow its benefit. Towards this goal, we carefully designed SKQ while considering the impact of lock contention, CPU overhead and cache footprint.

4.1 Cache Locality Policies

Cache misses are detrimental to applications. For example, a read request in Memcached takes about 15k cycles from the NIC receiving the request to sending the response on our machine, while a L3 cache miss takes 400 cycles. This means that each cache miss increases processing time by 2.67% and correspondingly reduces throughput. SKQ provides two policies to help applications improve cache locality.

Both policies use our *kqdom* structure, which is a multi-level N-ary tree that mirrors the system's cache and memory topology, and keeps track of the core affinity of all kevs. Each *kqdom* leaf node corresponds to a core and contains a list of local kevs. Each *kqdom* level represents a shared cache level. During initialization, each SKQ creates a private *kqdom*. When an SKQ object registers a thread, the kevs is inserted into the corresponding *kqdom* leaf node. When the CPU scheduler reschedules a thread to a different core, the kevs is also moved to the new *kqdom* leaf node.

On a multi-socket machine, a *kqdom* typically contains 3 levels. The top level nodes represent different NUMA domains. The second level contains all cores that share the last-level cache within a NUMA domain. The third level consists of leaf nodes corresponding to a core containing hyperthreads.

Queue Affinity: The *queue affinity* policy always delivers events to the core where the event first triggered, which reduces userspace cache misses by maintaining affinity.

When a knote is activated for the first time, SKQ stores the corresponding *kqdom* leaf node in the knote. On subsequent activations, the event scheduler queues the knote to a kevs in the same *kqdom* leaf node. When multiple kevs are present in the same *kqdom* leaf node, a random kevs is selected. However, when connections migrate, this policy results in more cache misses in the kernel.

CPU Affinity: The *CPU affinity* policy delivers events to the application threads local to the triggering core. For network sockets, the policy always queues knotes to the core that received the NIC interrupt and processed the packet.

This policy improves cache locality within the kernel. Before an event activation, the networking stack has already processed the incoming packet, which pulls socket buffers and metadata into the local core's cache. CPU affinity policy keeps these cache lines local so subsequent reads and writes in userspace will more likely result in cache hits.

Furthermore, CPU affinity cooperates well with all sources of connection migration including RSS. After a connection migrates to a different core, the policy follows the migration and queues the event to a kevs on the new core. This reduces the cache misses caused by the application and kernel processing the event on different cores. This also reduces kevs lock contention during event activation as cores will deliver events to their local kevs from the packet processing, rather than competing to deliver events to the same kevs.

4.2 Workload Balancing Policies

Workload imbalance is another major cause of suboptimal performance. An imbalanced load distribution leads to resource under-utilization where some worker threads are idling whereas others are overloaded. We implement two policies that mitigate imbalances.

Best of Two: The *best of two* policy load balances events between threads by randomly selecting two kevs and choosing the kevs with a lower expected wait time. Mitzenmacher [31] shows that this policy offers good optimality. Expected wait time $E[t]$ refers to the wait time before the activated knote is serviced by an application thread.

For each kevs, we maintain the number of knotes currently queued n_{cur} , the number of knotes returned to userspace of the last *kevent()* call n_{ret} , the timestamp of the last *kevent()* call t_{ret} , and a moving average of the processing time in cycles per knote t_{avg} . We use an exponential moving average with $\alpha = 0.05$, hence $t'_{avg} = 0.05 * t_{new} + 0.95 * t_{avg}$, which we found to react fast enough while smoothing out workload behavior and noise from interrupts and scheduling. When applications finish processing a knote and return it to SKQ via *kevent()*, the moving average is updated.

On knote activation, the event scheduler calculates the expected wait time with $E[t] = t_{ret} + t_{avg} * (n_{ret} + n_{cur})$ for both selected kevs. Finally, the event scheduler enqueues the knote to the kevs with earlier $E[t]$.

A potential issue is that a thread may unexpectedly stall in userspace. In this case, $E[t]$ can lag far behind and be in the past. To prevent the event scheduler from assigning too many knotes to the thread, we set t_{ret} to $MAX(t_{ret}, t_{cur} - t_{avg} * n_{ret})$, where t_{cur} is the current timestamp.

Work Stealing: Work stealing allows idle threads to steal knotes from another thread's kevs. Unlike other scheduling policies, work stealing operates during the dequeuing of knotes rather than knote activation. When a thread has no knotes to process, it normally blocks until some knotes arrive. With work stealing enabled, instead of blocking, the idle

thread picks a random victim ke_{vq} and tries to steal knotes. The system will periodically retry until either new knotes arrive or at least one knote is stolen. Applications can control the maximum stolen knotes per attempt (defaults to 1).

In order to reduce the overhead and lock contention of work stealing, we use trylocks to check the availability of the victim ke_{vq} and knotes. The idle thread first trylocks the victim ke_{vq}. If the victim ke_{vq} is busy, the idle thread sleeps for a fixed amount of time then retries. Otherwise, the idle thread scans the victim ke_{vq} for knotes. We use the same trylock technique to probe each knote, skipping knotes that are undergoing changes (e.g., being scheduled). To avoid locking the victim ke_{vq} for too long, we bound the maximum number of scanned knotes to twice the maximum stolen knotes.

Another issue is thrashing that can occur because of lock ordering issues. When a knote is stolen by an idle thread it is moved to the idle thread's ke_{vq}. For a short window of time we must drop all ke_{vq} locks to not violate lock ordering. This allows another thread to steal events from the idle thread before it can process any stolen knotes. This causes thrashing of events as they can bounce around due to this race. We added a flag to denote whether it is stolen. Knotes with the flag set are skipped during work stealing. The flag is cleared after the stolen knote is processed by the idle thread.

Our measurements show that for applicable workloads, work stealing improves the latency response and reduces tail latency (see § 6.5). We also observe negligible lock contention because of the trylock optimization using FreeBSD *lockstat*. Our earlier implementation did not employ the trylock optimization that caused work stealing to increase the overall latency in some workloads due to the aforementioned issues.

Hybrid Policies: SKQ allows applications to combine cache locality policies with workload balancing policies. In this case, the event scheduler picks the first ke_{vq} according to the cache locality policy, and then uses best of two to pick a second ke_{vq} from the rest. The expected wait time of both selected ke_{vqs} are then compared with a constant cache miss penalty applied to the ke_{vq} selected by best of two. While the cache miss penalty of migrating to a random core is both application and workload dependent, in our experiments we found a constant penalty was enough to prevent unnecessary migration when the imbalance was not significant.

Work stealing can be used with other policy combinations as it operates during knote dequeuing. In our experiments, hybrid policies that combine all three scheduling options comprise the best-performing policies for imbalanced workloads.

4.3 Policy Selection Criteria

Policy selection is based on the application's workload characteristics. Applications with uniform and low response times should use the CPU affinity policy to maximize cache affinity. Applications with imbalanced or IO-heavy workloads should use the hybrid policy consisting of CPU affinity and best of

two with work stealing to balance the threads and extend low-latency throughput. The rationale is discussed in § 6.

4.4 Fine-grained Event Delivery Controls

Besides scheduling, SKQ allows applications to control event delivery on a per-event level. We currently offer two controls to handle event pinning and event prioritization.

Event Pinning: SKQ allows applications to pin individual events to specific threads. Application threads use the affinity flag for each event during event registration. The flag ensures that the event is always delivered to the registering thread.

This is useful to applications where threads communicate based on pipes or user events. For example, in Memcached, the main thread uses a pipe to communicate control messages to each worker thread. Scheduling these events between threads would break the notification system.

Event Prioritization: Event prioritization enables applications to prioritize latency-sensitive traffic such as end user requests over batch processing. SKQ defines two event priority levels: regular and high priority. By default, all registered events are of regular priority. Applications can promote an event to high priority by setting the high priority flag.

In each ke_{vq}, we maintain a separate event queue for high priority knotes. During event activation, the event scheduler queues activated knotes to their corresponding queue. During event queries, `kevent()` prioritizes dequeuing knotes from the high priority queue. The remaining space left in the userspace buffer is filled with regular priority events.

Our design also addresses two potential problems of event prioritization. First, too many high priority events may cause starvation. To prevent starvation, we introduced the *rtshare* parameter that controls the maximum percentage of returned high priority events. For example, an *rtshare* of 80 means at most 8 high priority events out of 10 total events will be returned to the application per `kevent()` call.

Second, if `kevent()` returns too many events per call, which is common at high throughput, the application thread might spend a long time processing all events, postponing the delivery of newly arrived high priority events. To address this issue, applications can set the *rtfreq* parameter to control the number of `kevent()` calls a thread should perform per second, bounding the latency of high priority events. SKQ dynamically limits the number of events returned to the application based on the average processing time statistics.

Applications gain the full benefit of event prioritization by tuning *rtshare* and *rtfreq* based on workload characteristics and user requirements. In our benchmark, we observed an 8× tail latency improvement of a high priority client at peak throughput with little impact on regular clients.

5 Implementation

We implemented SKQ in FreeBSD 13 (commit 04816a1) with ~3000 source lines of code (SLOC). We also developed two SKQ event libraries *libevent-skq* and *libsq* for easy adoption in ~1700 SLOC. *libevent-skq* is compatible with *libevent* and solves its limitation with concurrent event processing on a single event base. *libsq* uses a custom API with reduced lock contention and system call batching via *lio_listio* (disabled in our evaluation). Additionally, we implemented a custom webserver in ~1000 SLOC on top of *libsq* that conforms with HTTP/1.1 as defined in RFCs 7230–7237 [21].

6 Evaluation

We evaluate our system using microbenchmarks and four applications. We choose workloads based on their request service time characteristics, e.g. Memcached has a uniform request service time whereas RocksDB displays workload imbalance. We also measure the event prioritization benefit and compare SKQ with Shenango, a kernel-bypass system.

All server applications run on a server with dual 2.1 GHz Intel Skylake-SP Silver 4116 with an Intel X722 10 GbE NIC. The workload generating clients run on 6 identical Skylake machines and 4 additional machines with dual Intel Xeon E5-2680 and a Mellanox ConnectX-3 10 GbE. Turbo boost is disabled on all machines to minimize measurement error. Hyperthreading is enabled with one application thread per core and NIC interrupts scheduled to the adjacent hyperthread as recommended by NIC vendors.

In all experiments we use 12 server threads, 12 client threads and 12 connections per client thread. Each run consists of a 5-second warmup followed by a 25-second measurement. All threads are pinned to the first socket. The measurement client establishes one connection per thread to probe the server response time. Each data point is obtained as the average of three runs and all results are statistically significant.

In the following sections, *vanilla* refers to multiple SKQs (the 1:1 model) to isolate the scheduling benefit. We do this because SKQ in compatibility mode provides a modest performance improvement over Kqueue (§ 6.2).

6.1 Scalability

We built a benchmark that generates events via UNIX pipes to measure the scalability of Kqueue/SKQ. Each client thread establishes 12 pipe pairs and sends requests with a constant processing time of 5 μ s. We run four configurations in total while varying the number of threads.

Shared SKQ scales linearly and on par with both multiple Kqueues and multiple SKQs. We see a constant throughput increase with each additional core, since all three setups have little lock contention and SKQ schedules events with low overhead. Shared Kqueue starts to contend after 4 cores. At

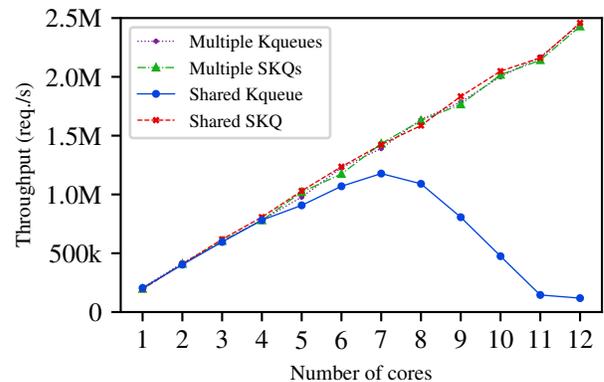

Figure 2: The impact of adding cores on various configurations’ peak throughput. Shared refers to the 1:N model while Multiple refers to the 1:1 model. We use the CPU affinity policy for shared SKQ.

12 cores, shared Kqueue only achieves 4.8% of the throughput of other configurations. This reduction in throughput comes from lock contention in Kqueue. Additional experiments show that the result of shared Kqueue is workload dependent. For requests with very short processing time, the giant Kqueue lock is the main source of contention. The lock contention decreases as the processing time increases.

We use FreeBSD *lockstat* [15] to compare the lock contention of shared Kqueue with SKQ at maximum throughput with 12 cores. The result shows that shared Kqueue has significantly higher lock contention due to threads competing for the single event queue and the giant lock.

For shared Kqueue, the top three contending system locks belong to Kqueue, which comprise 69% of total lock contention. Shared SKQ displays much lower contention with the worst contending SKQ lock ranked the 4th in the system. The top three contending SKQ locks only comprise 12% of total lock contention.

By breaking up Kqueue’s giant lock and introducing thread private *kevqs*, SKQ significantly lowers the lock contention at high core counts, achieving much better scalability.

CPU Affinity vs. Queue Affinity: In our benchmarks, CPU affinity performs on par or better than queue affinity. As we mentioned before, this is due to connection migration, which breaks connection affinity with queue affinity. *Thus, we consider CPU affinity superior to queue affinity in general and will omit queue affinity from further discussions.*

6.2 Multiple SKQs vs. Multiple Kqueues

Figure 3 shows the latency response of an unmodified Memcached using multiple Kqueues vs. multiple SKQs (the 1:1 model). We improve tail latency at throughputs between 750k–1.1M req./s. At maximum throughput, we lower tail latency by 33%. The improvement comes from the new SKQ archi-

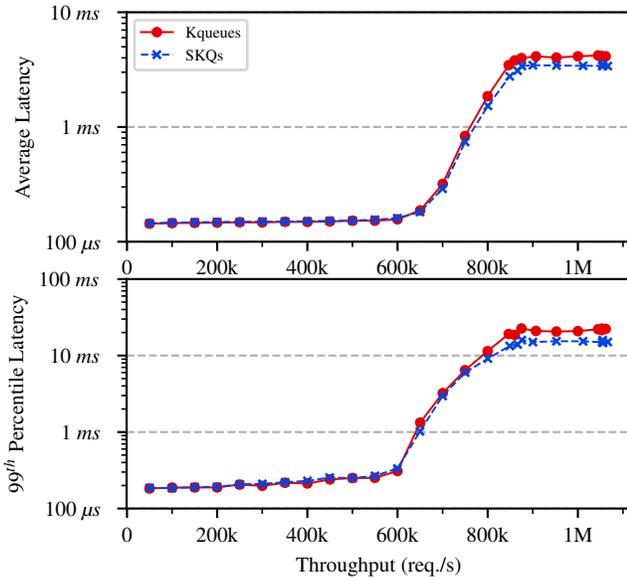

Figure 3: The latency response of Memcached using multiple SKQs vs. multiple Kqueues. SKQ lowers the tail latency by 33% at high throughput due to fine-grained locking.

ecture and fine-grained locking.

Throughout the evaluation, "vanilla" refers to multiple SKQs (the 1:1 model) to accurately measure the benefit of our scheduling policies. This isolates the improvement due to architectural changes.

6.3 Cache Miss Analysis

We use an RPC echo service to understand how cache locality policies affect cache miss rates. Figure 4 shows the latency response for an RPC echo client while varying throughput against three different policies. Both CPU and queue affinity outperform vanilla above 500k req./s. At 580k req./s, both policies show the maximum benefit over the vanilla with a $6.8\times$ ($269\ \mu\text{s}$ vs. $1839\ \mu\text{s}$) lower tail latency and 20% more low-latency throughput (585k req./s vs. 487k req./s).

Using CPU performance counters, we analyze the cache behavior to understand where the benefit comes from. Table 1 shows the L2 cache misses at 580k req./s broken down by various kernel code paths.

Both scheduling policies significantly reduce L2 cache misses in the TCP input/output path and event query path. The TCP input path includes receive-side packet processing, while the TCP output path includes processing the socket buffer into packets. The event query path is all the code executed during `kevent()` calls to retrieve events. In all paths, SKQ outperforms as both cache locality policies preserve cache affinity better, thus reducing cache misses.

The vanilla configuration of Memcached (see § 6.4) is typical of other applications that ignore cache affinity information

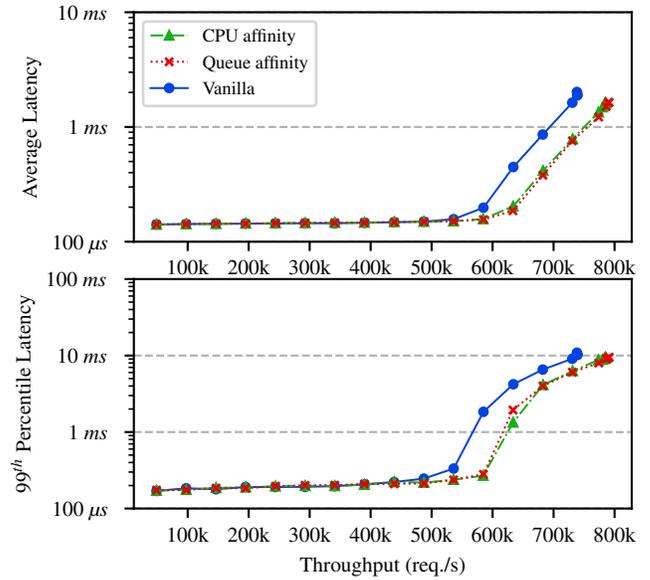

Figure 4: Cache locality policies' latency improvements of a lightweight RPC echo endpoint.

Policy	TCP input	TCP output	Event activation	Event query	Total
CPU	252k	15k	63k	166k	496k
Queue	343k	33k	95k	250k	721k
Vanilla	828k	76k	45k	1235k	2184k

Table 1: L2 data cache misses collected using hardware performance counters for 20 s running at 580k req./s. TCP input/output refer to the packet transmit and receive path, event activation includes event activation and scheduling, and event query is the application retrieving events with `kevent()`.

(unavailable in userspace) and use a round-robin assignment of connections to worker threads. As a result, vanilla contains many mismatched connections, i.e. connections processed by the kernel on one core but processed by an application thread on a different core, leading to more cache misses and worse tail latency.

In the event activation path, vanilla has fewer cache misses than our scheduling policies. This is expected as both policies require extra scheduling logic and accesses to new data structures like the `kqdom`. However, the cache miss difference is minor in comparison to the other three code paths and has little impact on the overall performance.

CPU affinity has fewer cache misses compared to queue affinity. This is due to connection migration between cores. Recall that the queue affinity policy does not follow the migration. In this workload, the difference is minor enough to not show a significant latency difference.

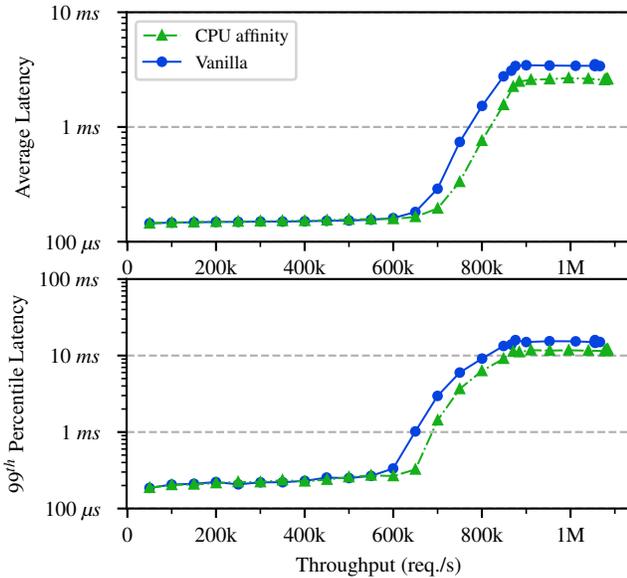

Figure 5: The latency response of Memcached using vanilla and our cache affinity policies. The CPU affinity policy increases low-latency throughput and exhibits lower tail latency in medium to high throughput range.

6.4 Memcached

We benchmark Memcached using Mutilate with the Facebook ETC workload [1]. Figure 5 shows the latency response of the best-performing policy. The largest latency gap occurs at 640k req./s where CPU affinity had $3\times$ lower latency than vanilla. With a maximum tail latency of $320\mu\text{s}$, SKQ effectively increases 9% of low-latency throughput (650k req./s vs. 600k req./s). At high load, SKQ achieves 5% higher throughput and 26% lower tail latency.

Mutilate’s request service time distribution is nearly uniform as it only issues GET and PUT requests. We measure the total time each worker thread spent processing requests in userspace at maximum throughput. The thread with the highest processing time spent 2.8% more than that of the thread with the lowest processing time, indicating that load imbalance is insignificant among worker threads.

With a uniform and balanced workload, cache locality policies offer cache affinity without the scheduling overhead of the load balancing policies. Besides preserving cache locality, there is little that can be done in the kernel event subsystem to improve the performance of Memcached without optimizing the application itself, e.g. reducing lock contention [26].

6.5 Application Server

Server applications often need to service client connections with different latency characteristics, e.g. connections that issue only light requests vs. heavy requests. To investigate the benefit of SKQ on such workloads, we developed a GIS appli-

cation server with a Zipf-like distribution of request service times that models MyBikeRoutes-OSM traffic [39].

In this benchmark, each client issues requests that are either light, medium or heavy computation tasks (approximately $10\mu\text{s}$, $50\mu\text{s}$ and $200\mu\text{s}$). Each client connection is assigned to perform a single task. The overall connection characteristics follow a Zipf-like distribution consisting of 95% light, 4% medium and 1% heavy connections. We collect the latency response of all the policies.

Figure 6 shows the most interesting policies. The hybrid policy (CPU affinity and best of two with work stealing) has 6% lower peak throughput compared to vanilla due to the overhead of scheduling. However, the hybrid policy provides much lower tail latency and more low-latency throughput at mid range. At 460k req./s, the hybrid policy reached the largest gap of $9.9\times$ lower tail latency and $3.4\times$ lower average latency. For a maximum tail latency of $280\mu\text{s}$, the hybrid policy extends the low-latency throughput by $3\times$. It is also worth noting that the hybrid policies show benefit even at low throughput. The analysis is further discussed in § 6.6.

To quantify the imbalances, we again measure the total amount of time each worker thread spent processing events in userspace at 460k req./s (the largest gap) for both vanilla and the hybrid policy. The percent difference between the busiest and the least busy thread is 46.1% for vanilla and 1.4% for the hybrid policy. This shows that the hybrid policy significantly reduced the workload imbalance between threads.

Work Stealing: Figure 6 shows the latency response of best of two with and without work stealing. Although best of two mitigates the imbalance to some extent, work stealing further shifts the curve outward, providing lower tail latency and more low-latency throughput. This is because while best of two balances the threads according to statistics at event activation time, work stealing enables SKQ to react faster and respond immediately to runtime changes and imbalance.

Hybrid Policy: Figure 6 also shows that a hybrid policy of CPU affinity and best of two with work stealing further extends the low latency throughput. This is because CPU affinity also considers cache locality. The hybrid policy always considers the thread with the better cache locality, and prefers it unless best of two shows substantial benefit.

6.6 RocksDB

RocksDB is a fast and persistent embeddable key-value store. Cao et al. [5] characterized and modeled several Facebook workloads that use RocksDB as the backend. We developed a frontend to RocksDB that services GET, SEEK and PUT requests. In this benchmark, we use the same client configuration as the ZippyDB (prefix_dist) model specified by Cao. We place the RocksDB directory on a memory backed file system and preload it with 50M keys.

Unlike Memcached, the ZippyDB workload presents heavy imbalances due to its 3% SEEK requests. As an experiment,

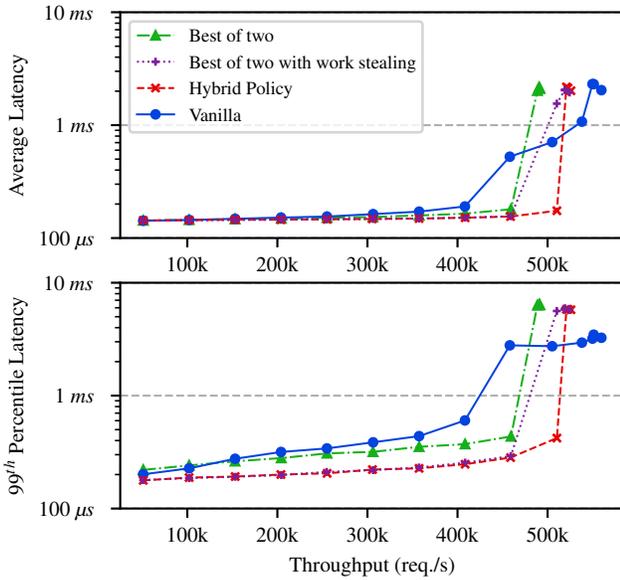

Figure 6: The latency response of the application server using various policies. The hybrid policy refers to CPU affinity and best of two with work stealing. All workload balancing policies lower the latency to different extents.

we eliminate all SEEK requests from the workload and observed $5.85\times$ higher maximum throughput (737k req./s vs. 126k req./s). Figures 7 and 8 show the latency data over full and low throughput range. At low throughput, the tail latency of vanilla starts to increase at only 2.3k req./s whereas the hybrid policy (CPU affinity and best of two with work stealing) stays flat. This indicates extreme imbalances in the workload and is in line with what Cao reported.

Despite a lower peak throughput, the hybrid policy extends the low-latency throughput by $27.4\times$ (63k req./s vs. 2.3k req./s). The largest latency gap occurs at 63k req./s where the hybrid policy achieves $1022\times$ (263 μ s vs. 269 μ s) lower tail latency. This benchmark demonstrates SKQ’s benefit to highly imbalanced workloads.

Unlike the GIS application workload where connections have a fixed request type, RocksDB connections all have the same request service time distribution. At low throughput, heavy SEEK requests are relatively rare where they can still be handled in time and do not queue up. In the GIS application, even a few misassigned heavy connections could overload a thread at low throughput, which is why the hybrid policy showed benefit earlier.

6.7 Web Server

So far we showed the benefit of SKQ on both balanced and imbalanced in-memory workloads. In this benchmark, we use our custom web server to demonstrate how SKQ improves IO-heavy workloads.

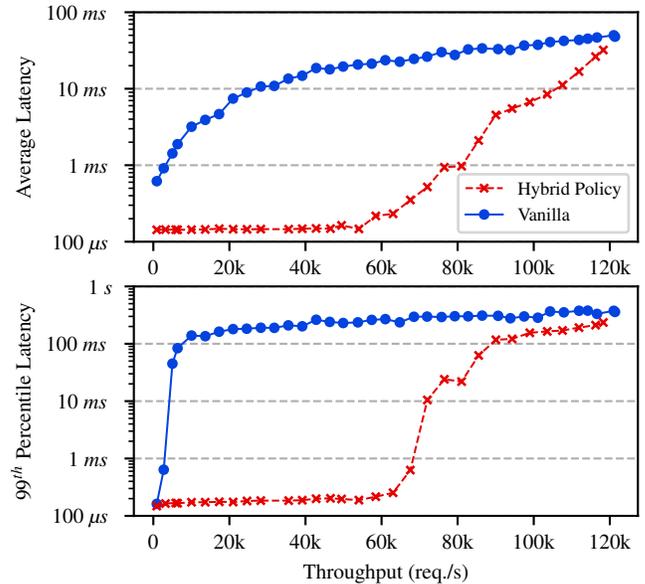

Figure 7: The latency response of RocksDB using the Facebook ZippyDB workload. The hybrid policy refers to CPU affinity and best of two with work stealing. SKQ significantly improves the low-latency throughput.

The web server is configured to service HTTP requests of small HTML pages (~ 640 bytes) without caching residing on a HDD. Figure 9 shows the results of the best-performing policy. Similar to other imbalanced benchmarks, the hybrid policy has marginally lower peak throughput, but provides 19.8% higher low-latency throughput with 300 μ s maximum tail latency. The biggest tail latency improvement occurs at 341k req./s where vanilla has $3.6\times$ higher tail latency (1386 μ s vs 384 μ s). We can see that SKQ also offers benefit on heavy, uniform IO workloads.

In this benchmark, clients request web pages of similar size, which is a uniform IO workload. However, the web server benefits most from a workload balancing policy. This is because IO requests have high variance in latency. Some HTML pages might be in the file system buffer cache whereas others need to be read from the hard disk. This results in different access times and leads to an imbalanced workload. However, compared to our RocksDB and application server benchmark, IO does not induce as much imbalance. Thus, the web server benchmark shows less benefit than the other imbalanced workloads.

6.8 Event Prioritization

This benchmark demonstrates the effect of event prioritization on a lightweight high priority client. We use the same workload distribution as the application server.

The measurement client is assigned regular priority in the first experiment but high priority in the second experiment.

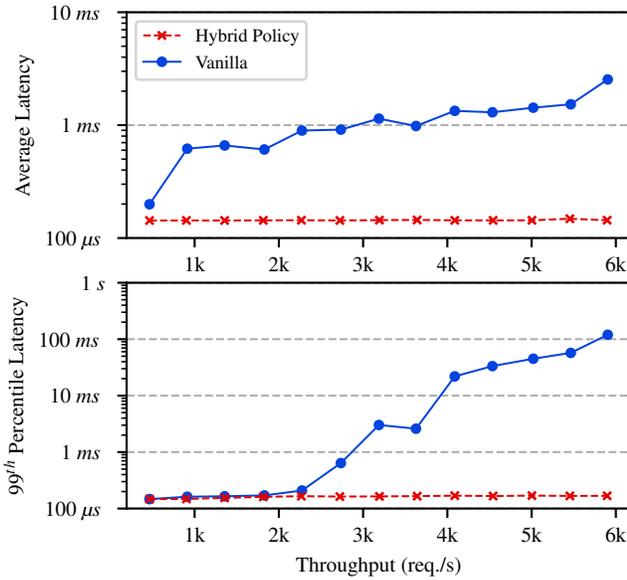

Figure 8: The low throughput latency response of Figure 7. Vanilla’s latency rises at very low throughput.

The measurement client also sends 30000 lightweight requests per second to probe the latency. We set `rtfreq` to be 10000 so that server threads call `kevent()` every 100 μ s. `rtshare` is left at 100 to let SKQ pass back as many high priority events as possible. We measure the latency experienced by the measurement client in both settings and the regular clients’ latency in the second experiment.

Figure 10 shows the latency response. At peak throughput, the high priority client’s throughput comprises 5% of all traffic. The high priority measurement client’s tail latency only increases by $1.2\times$ (371 μ s) than that at low throughput (263 μ s) whereas the regular priority measurement client’s tail latency increases by almost $10\times$ (2656 μ s). In addition, the regular clients did not experience increased latency due to the addition of the high priority client but the server did lose 0.9% maximum throughput. This benchmark shows that event prioritization enables the server to service a lightweight, high priority client with low tail latency while having minimal impact on regular clients even when the server is fully loaded.

The tunables (`rtshare`, `rtfreq`, high priority client’s request rate) used are specifically tuned for this workload. Blindly changing the tunables to meet unrealistic goals only lead to decreased performance. For example, if the request rate of the high priority client is too high, it will experience increased latency as serving a large amount of high priority requests with low latency without starvation is difficult. Furthermore, using inappropriate `rtshare` and `rtfreq` may cause starvation or priority loss. Therefore, we do not offer recommended values for the tunables as they are highly situational.

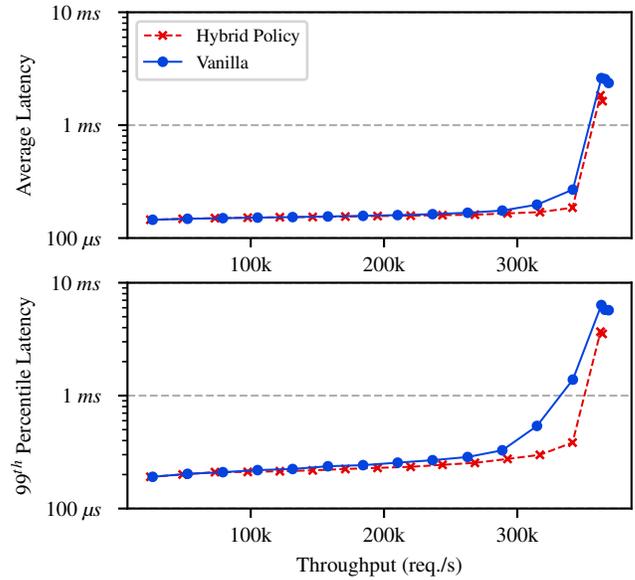

Figure 9: The latency response of our web server with file caching turned off. The hybrid policy refers to CPU affinity and best of two with work stealing. SKQ provides more low-latency throughput for IO-heavy workloads.

6.9 Comparing with a Kernel-bypass System

We compare SKQ with the state-of-the-art kernel-bypass system Shenango to illustrate the benefits and tradeoffs. We also considered porting SKQ to F-Stack, a kernel-bypass library based on FreeBSD’s networking stack. Unfortunately, F-Stack does not support multithreading within a single instance [13]. While outperforming kernel-bypass techniques in a traditional OS is unlikely without significant advances in hardware and software, we can still narrow the performance gap.

We built Shenango on Debian 10 running on a Skylake machine with an Intel 82599 NIC as Shenango only supports two modified NIC drivers in DPDK. We use one Skylake machine as the measuring client and six Skylake machines as workload generation clients. We benchmark three synthetic workloads with different request service time distributions: two with uniform distribution (10 μ s, 20 μ s) and one with imbalanced Zipf-like distribution (85% 10 μ s, 12% 50 μ s, 3% 200 μ s). We compare how each system maximizes the low-latency throughput (<150 μ s 99th percentile latency).

This comparison is unfair due to vastly different approaches and environments. First, Shenango implements a custom networking stack using DPDK and user-level scheduling, both of which bypass the Linux kernel. SKQ only redesigns the event subsystem in FreeBSD. Second, Shenango’s TCP stack is a research prototype and lacks TCP features such as congestion control, while SKQ uses FreeBSD’s networking stack.

In Figure 11, at 10 μ s request service time, Shenango shows $1.67\times$ higher low-latency throughput than SKQ. However,

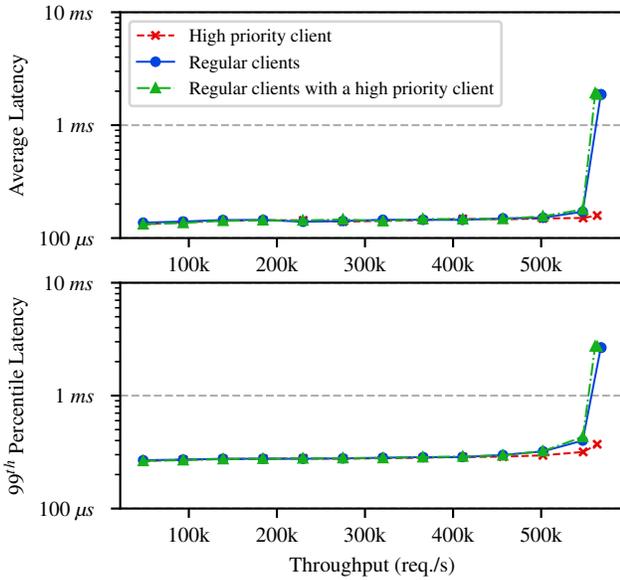

Figure 10: The latency response of two runs where the measurement client is marked as high priority vs. regular priority. The server services a high priority client with low latency while having little impact on other clients at peak throughput.

for 20 μ s request service time, Shenango only achieves $1.5\times$ higher low-latency throughput. This is because system call overhead comprises a larger fraction of time when the request service time is low. Heavier requests mask system call overhead as applications spend more time in userspace.

For the imbalanced workload, Shenango shows less benefit than uniform workloads – only 16.7% higher low-latency throughput than SKQ. This gap is lower because of the longer average service times and correspondingly lower OS overhead. SKQ achieves a result very close to Shenango as we measure nearly no load imbalance (§ 6.5). We also measure the latency response of vanilla, i.e., multiple SKQs, and found that SKQ closes the gap between vanilla and Shenango by 83.7%.

Kernel-bypassing shows bigger improvements when the request service time is low and uniform. For imbalanced workloads and heavier requests, the benefit of kernel-bypassing diminishes compared to kernel event scheduling.

Additionally, Shenango suffers from difficult adoption. First, Shenango requires changes to the threading model, synchronization and networking APIs. Porting complex applications such as RocksDB proved to be challenging. SKQ requires less invasive changes and affects only one system call. As a comparison, Shenango’s Memcached results in ~ 1200 SLOC changed whereas SKQ’s Memcached modifies only ~ 200 SLOC, including SKQ statistics collection and exposing SKQ controls to configuration files. Second, Shenango requires DPDK and patching NIC drivers, which increases maintenance effort. SKQ is built into the kernel and supports all NICs supported by the operating system.

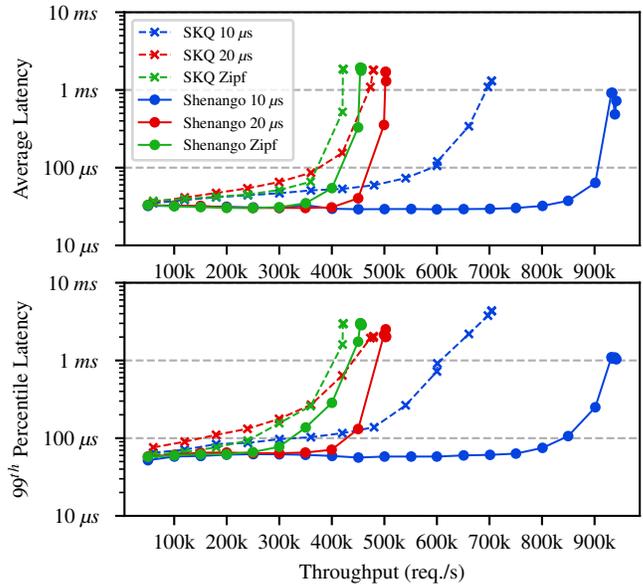

Figure 11: The latency response of three workloads running on Shenango and SKQ. SKQ uses CPU affinity scheduling policy for 10 μ s, 20 μ s benchmarks; CPU affinity and best of two with work stealing for the Zipf-like benchmark.

7 Conclusions

SKQ revisits existing kernel event facilities and provides a practical solution to the latency problem for applications running in traditional OSes. SKQ offers novel features and a production quality implementation that has been developed over the course of nearly two years. We show significant performance gains in applications by only revisiting kernel event subsystems. This suggests that there are still optimization opportunities in traditional OS kernels.

Availability

All of our code and scripts to run experiments are available at <https://rcs.uwaterloo.ca/skq/>.

A Linux Kernel Implementation of the Homa Transport Protocol

John Ousterhout
Stanford University

Abstract

Homa/Linux is a Linux kernel module that implements the Homa transport protocol. Measurements of Homa/Linux reconfirm Homa's superior performance compared to TCP and DCTCP. In a cluster benchmark with 40 nodes, Homa/Linux provided lower latency than both TCP and DCTCP for all message sizes; for short messages, Homa's 99th percentile tail latency was 7–83x lower than TCP and DCTCP. The benchmarks also show that Homa has eliminated network congestion as a significant performance limitation. Both tail latency and throughput are now limited by software overheads, particularly software congestion caused by imperfect load balancing of the protocol stack across cores. Another factor of 5–10x in performance can be achieved if software overheads can be eliminated in the future.

1 Introduction

Montazeri et al. recently introduced a new network transport protocol for datacenters called Homa [25]. Homa uses network priority queues and receiver-driven packet scheduling to favor shorter messages and eliminate congestion at host downlinks. Homa reduces latency significantly, especially for short messages under high network loads. Montazeri et al. demonstrated tail latencies almost 100x better than the best prior measurements of transport protocols that included TCP, DCTCP [1], Infiniband, HULL [2], PIAS [4], and NDP [15].

However, the original evaluation of Homa was done in a research setting, based partly on simulations and partly on a user-level implementation (with kernel bypass) in the RAM-Cloud storage system [29]. The implementation did not support general applications, and it was difficult to compare it fairly to a kernel TCP implementation, since the user-level implementation of Homa avoided the high software overheads imposed on TCP by the kernel. As a result, the original Homa work left open questions about whether the protocol's benefits could be achieved in a more practical setting.

This paper describes Homa/Linux, a Linux kernel module that implements Homa. I undertook the development of Homa/Linux with three goals: first, to understand how the overheads of a kernel implementation affect Homa's implementation and performance; second, to measure how a kernel version of Homa performs compared to a mature and widely used implementation of TCP and DCTCP; and third, to create a practical implementation of Homa to encourage its use in real applications and evaluate its benefits for production datacenter workloads.

This paper makes two contributions. First, Homa/Linux demonstrates that it is possible to build a competitive production implementation of Homa. Homa/Linux outperforms both TCP and DCTCP by a wide margin, confirming the results in [25]. Using four of the Montazeri workloads and considering short messages under high network loads, P99 (99th percentile) latency under Homa/Linux is 7–83x lower than TCP and DCTCP. All message sizes under all workloads experience lower latency with Homa than either TCP or DCTCP, both at the median at P99. In most cases Homa's P99 latency is lower than the median for TCP and DCTCP. Homa needs only a few priority levels to achieve high performance, and it outperforms TCP and DCTCP even with only one priority level.

Second, this work provides a case study of the challenges in building a performant transport protocol in the high-overhead environment of the Linux kernel. Homa/Linux had to address a variety of issues, such as batching, load balancing, and real-time processing. Homa eliminates almost all network congestion, but software congestion is becoming more problematic as more and more cores must be harnessed to keep up with increasing network speeds. In Homa/Linux, software overheads are now the primary factor limiting performance. This paper quantifies those overheads. For example, at least 18 cores will be required to drive a 100 Gbps network in both directions, and distributing protocol processing across multiple cores increases software overheads by 2–3x.

Although Homa/Linux provides much better performance than TCP, its latency and small-message throughput are still 5–10x worse than raw network speeds. Section 7 argues that this gap cannot be reduced significantly as long as transports are implemented in software. To harness future networks' full performance potential, protocols such as Homa will probably need to be implemented in hardware. This will require new NIC architectures to be developed.

2 Homa Summary

This section summarizes the key elements of the Homa protocol; see Montazeri et al. [25] for details and discussion. Homa is designed as a transport for RPC frameworks in datacenters. It is optimized for networks with one-way hardware latencies as low as 1–2 μ s and aims to provide the lowest possible tail latency for short messages, even when operating at high network load with a mix of message lengths. It does so by minimizing the latency impact of congestion at the network edge (host downlinks). Homa also eliminates head-of-line block-

ing that occurs when small messages are delayed behind large ones in TCP streams. Homa does not explicitly deal with congestion in the network core (see Section 8).

SRPT and messages. Homa implements an approximation of SRPT (shortest remaining processing time), prioritizing shorter messages over longer ones. SRPT is most beneficial for short messages, but it also improves latency for large messages compared to the fair sharing approach used in protocols such as TCP. This is because SRPT produces run-to-completion behavior: once a message becomes highest priority, it will remain highest priority until it completes (unless new messages arrive).

Receiver-driven packet scheduling. In Homa, each receiver collects information about all of its incoming messages and schedules incoming packet transmissions. The first few packets of each message (*unscheduled packets*) are transmitted unilaterally by the sender, but the remaining *scheduled packets* are sent only in response to *grants* from the receiver. The number of unscheduled packets is typically chosen to cover the round-trip time, so that an unloaded server can return the first grant before the last unscheduled packet has been sent. This allows messages to use the full network bandwidth in an unloaded system. The grant mechanism allows receivers to limit congestion at their downlinks; buffer buildup occurs only if many senders transmit unscheduled packets simultaneously to the same destination (*incast*). I use the term *RTTbytes* to describe the number of unscheduled bytes, following Montazeri et al.; its role is analogous to windows in other protocols.

In-network priority queues. Homa takes advantage of the priority queues in modern network switches (typically 8 or 16 for each egress port). It divides the priority levels into two groups: the highest levels are used for unscheduled packets, and the lower levels for scheduled ones. Within each group, shorter messages get higher priorities. Receivers choose the priorities for all of their incoming traffic. For scheduled packets, the receiver specifies priorities “just in time” using grants. For unscheduled packets, the receiver specifies in advance the range of message lengths for each priority level; it disseminates new assignments occasionally as its workload changes.

The fraction of priority levels allocated for unscheduled packets is chosen to match the fraction of all incoming bytes that are in unscheduled packets. The cutoffs between unscheduled priorities are assigned so that each priority level is used for about the same number of incoming bytes.

Sender-side SRPT. Homa nodes also implement SRPT when transmitting: given multiple messages with packets to transmit, a sender should transmit packets for the message with the fewest remaining bytes. To do this, Homa must limit the rate at which outgoing packets are passed to the NIC to ensure that long queues do not build up in the NIC (these would delay packets from new shorter messages).

Overcommitment. When a receiver issues a grant there is no guarantee that the sender will immediately transmit the granted packets. In order to keep its downlink fully loaded,

receivers thus grant simultaneously to multiple incoming messages; this is called *overcommitment* since it overcommits the downlink and may result in buffering at the switch. Scheduled priority levels are allocated to ensure SRPT among the messages being granted, so overcommitment does not affect the latency of the highest priority message. The degree of overcommitment is typically in the range of 5–10, which is chosen as a balance between excessive buffer buildup (if too large) and inefficient use of downlink bandwidth (if too small).

3 Homa/Linux API

TCP’s connection-oriented socket API is a poor match for Homa, and for datacenter applications in general. The first problem is TCP’s streaming nature, which means that it has no notion of message boundaries. This is problematic for Homa, which needs message lengths to implement SRPT. Streams are also awkward for most datacenter applications, which communicate via messages. These applications must impose their own message structure on TCP streams; this adds nontrivial complexity, given that a read might return only part of a message, or parts of several messages. It is difficult to share a TCP stream between multiple reading threads (e.g., in a server), since reads don’t necessarily return dispatchable units (entire messages).

Streams also have the disadvantage of enforcing FIFO ordering on their messages. As a result, long messages can severely delay short ones that follow them. This head-of-line blocking is one of the primary sources of tail latency measured for TCP in Section 5.

A second problem with TCP sockets is that they are connection oriented, with long-lived state for each peer that an application communicates with. Connections are undesirable in datacenters because applications can have hundreds or thousands of them, resulting in high space and time overheads. Some applications have resorted to proxies or other forms of connection pooling [32] to reduce the overheads. It seems to be an article of faith in the networking community that connections are necessary for desirable properties such as reliable delivery and congestion control, but in fact all of these properties can be achieved without connections.

Because of these issues, Homa/Linux provides a message-based API. Specifically, it implements *remote procedure calls* (RPCs). Each RPC consists of a *request* message sent from a client to a server, followed by a corresponding *response* message in return. An RPC protocol has two advantages over a pure messaging approach. First, the response serves as acknowledgment for the request, reducing the number of packets that must be processed. Second, it results in a deeper interface [28] because the transport can implement the timers and retries needed to ensure end-to-end completion. In a pure messaging protocol, timeouts must be implemented by applications (the protocol can ensure that individual messages are delivered, but cannot ensure that servers generate responses).

Homa/Linux has no notion of connections, only RPCs. A client can use a single socket for simultaneous communication

```

int socket(AF_INET, SOCK_DGRAM, IPPROTO_HOMA);
int bind(int sockfd, const struct sockaddr *addr,
        socklen_t addrlen);
int close(int sockfd);

int homa_send(int sockfd, const void *request,
             size_t reqlen,
             const struct sockaddr *dest_addr,
             socklen_t addrlen, uint64_t *id);
int homa_recv(int sockfd, void *buf, size_t len,
             int flags, struct sockaddr *src_addr,
             socklen_t addrlen, uint64_t *id);
int homa_reply(int sockfd, const void *response,
             size_t resplen,
             const struct sockaddr *dest_addr,
             socklen_t addrlen, uint64_t id);

```

Figure 1: The API provided by Homa for applications; `socket`, `bind`, and `close` are existing Linux system calls.

with any number of servers. A server can use a single socket to receive requests from any number of clients, to reply to client requests, and to issue its own requests as a client. Homa/Linux maintains state only for active RPCs (rarely more than a few at a time). This eliminates the overheads associated with connections.

Each Homa RPC is independent. Any number of RPCs may be active simultaneously for a given socket. If a client issues multiple concurrent RPCs, they may complete in any order; this eliminates the TCP's head-of-line blocking problem. If order matters among concurrent RPCs, Homa clients can add their own sequence numbers to messages.

Figure 1 shows Homa/Linux's system call interface. The existing `socket` and `close` calls are used to create and delete Homa sockets; Homa/Linux defines a new protocol type `IPPROTO_HOMA`. If a socket is going to receive incoming requests, the existing `bind` call is used to associate the socket with a well-known port number. There is no need to invoke `bind` for client sockets; Homa/Linux automatically assigns port numbers for them from the upper half of the 16-bit port space.

Homa/Linux defines three new functions: `homa_send`, `homa_recv`, and `homa_reply`. All are implemented via `ioctl`s on the Homa socket; Homa/Linux does not add new system calls to Linux. A client invokes `homa_send` to issue a request; it returns a 64-bit unique identifier for the RPC, which can be used to wait for the corresponding response. `homa_recv` receives incoming messages; it returns a message and its unique identifier. The arguments to `homa_recv` can restrict it to return only requests, only responses, or only a response with a given identifier. `homa_reply` is used by servers to send responses; it is similar to `homa_send` except that the RPC identifier is an input argument.

The Homa/Linux API is not backwards-compatible with existing applications based on TCP or UDP sockets, due to the API's need for explicit RPC ids. However, most datacenter applications are layered on a few RPC frameworks such as gRPC [12] or Apache Thrift [34]; adding Homa support to them should enable transparent usage by many applications.

Homa/Linux ensures reliable delivery of messages and

eventual completion of each RPC issued by a client. An RPC fails only if the server becomes nonresponsive or there is no socket matching the port in the request. There is no limit on the processing time for an RPC.

4 Implementation

Homa/Linux is a dynamically loadable Linux kernel module; it does not require any changes to Linux itself. The current version runs on Linux version 5.4.80 and contains about 10,000 lines of heavily commented C code. Source for Homa/Linux is freely available on GitHub along with unit tests, instrumentation tools, and all of the benchmarks discussed in this paper [16]. The module was implemented with the goal of achieving production quality, and I believe the current version is mature enough to run a variety of applications.

Most of the implementation effort for Homa/Linux focused on three obstacles to high performance. The first is the high cost of pushing a packet through the protocol stack. This cost is particularly high in Linux, due to its many layers and features. To amortize the protocol stack overheads, packets must be collected into batches, so that the stack traversal cost is only incurred once per batch. Unfortunately, batching necessarily incurs latency, since the first packet in a batch must be delayed until the last is available. Larger batches can be processed more efficiently, but incur a larger latency penalty.

The second obstacle is that a single core is too slow to handle all the protocol processing for a modern high-speed network, especially for small packets. This problem is worsening over time, since network speeds are increasing rapidly while CPU speeds are not. A transport protocol must be able to balance its load across a large number of cores. Even so, small-packet performance will be severely limited by software overheads; for example, neither Homa nor TCP can utilize more than about one-third of the bandwidth of a 25 Gbps network for short-message workloads, even with 20 cores. The greatest challenge with load balancing is software congestion in the form of hot spots that form when too much work is assigned to one core; even after considerable optimization, hot spots remain the single greatest source of tail latency for Homa/Linux.

The third obstacle to high performance is real-time processing. In the case of Homa, real-time processing is needed to implement a transmit rate limiter as discussed in Section 4.3. Implementing such a mechanism, which requires response times on the order of a few microseconds, is challenging in the Linux kernel and creates additional software overheads.

These problems are likely to occur in any transport protocol, and Linux contains mechanisms to facilitate both batching and load-balancing. However, the Linux mechanisms are biased towards TCP, even when implemented in code that is ostensibly protocol independent. To implement Homa efficiently, it was necessary to reshape Homa/Linux to fit the existing mechanisms. In some cases, Homa/Linux subverts the mechanisms to achieve results that are not possible with TCP.

One recurring issue is that TCP depends on in-order processing of a stream's packets. This requires flow-consistent

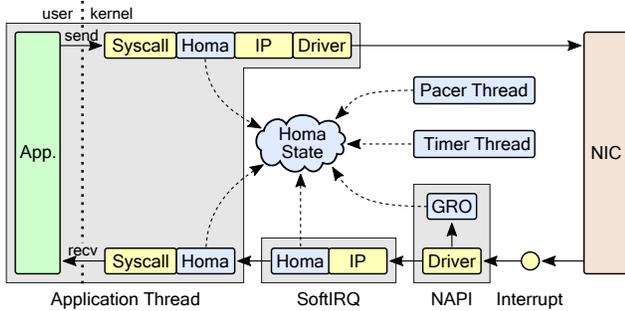

Figure 2: Structure of Homa/Linux. Homa components are shown in blue; existing Linux kernel modules are in yellow. Gray areas represent different cores. Only the primary sending and receiving paths are shown; other Homa elements such as the pacer thread and timer thread also transmit packets.

routing in the network, and also requires consistency in protocol processing on the hosts: for example, to preserve packet order, each packet of a flow must pass through the same set of cores. Homa does not require packets to be processed in order; by relaxing this constraint it can achieve better batching and load balancing. As a result, Homa/Linux attempts to bypass TCP’s constraints; this is not always easy or clean, since the constraints tend to be enforced by Linux.

The rest of the section discusses these three primary issues in detail, plus a few other smaller issues. The design described here evolved over about two years and was driven by extensive performance measurements. For example, throughput for Homa/Linux improved by about 3x over this process (the initial version did not implement batching). Space limitations prevent inclusion of the detailed measurements.

4.1 Packet flow and batching

Figure 2 shows the major components of Homa and the basic packet flow for sending and receiving messages. Homa exists as a layer just above IP in the Linux networking stack, parallel to TCP and UDP; the packet flow discussed in this section is similar to that for TCP and UDP. Homa packets are encapsulated as IPv4 datagrams.

The basic path for packet transmission is shown in the top part of Figure 2. When an application invokes `homa_send` or `homa_reply`, the resulting `ioctl` kernel call is dispatched to Homa/Linux. Homa/Linux copies the message data from user space into packet buffers and passes the first few packets to the IP stack, which eventually calls a device driver to transmit the packets.

Linux offers two mechanisms for batching on the transmit path: TSO (TCP Segmentation Offload) and GSO (Generic Segmentation Offload). In either case, the transport protocol creates a single large packet (up to 64 KB) for stack traversal. Once the packet reaches the device driver it is broken up into smaller segments for transmission. With TSO the segmentation occurs in the NIC. For NICs that don’t support TSO, or for protocols that cannot use TSO, GSO can perform segmentation in software, just above the driver layer. Homa/Linux currently supports TSO but not GSO. TSO assumes that packets have TCP headers, so Homa packet headers mimic the

TCP fields that TSO depends on. Unfortunately, TSO and GSO enable batching only for data packets that are part of the same message. For short messages and control packets, each transmitted packet must traverse the protocol stack independently.

The receive path is shown at the bottom of Figure 2. When an interrupt occurs, the interrupt handler doesn’t actually read packets; instead, it schedules an *NAPI* action to execute driver code. NAPI actions execute at interrupt level on the same core that received the interrupt, just before returning from the interrupt and with interrupts reenabled. To avoid high overheads associated with interrupts, the NAPI layer polls the NIC for more packets until it reaches either a packet count limit or a time limit.

Once the NAPI layer has finished collecting packets, it passes them to the *SoftIRQ* layer, where they work their way through the networking and IP layers, eventually reaching Homa. Homa performs protocol processing and message re-assembly. When a message is complete, Homa signals the waiting application thread (or queues the message if there are no waiting threads); the application thread copies the message data to user space and then returns from the `homa_recv` system call. *SoftIRQ* code executes in the same fashion as NAPI (at interrupt level with interrupts enabled) but it may run on a different core than the NAPI code (see Section 4.2).

Before forwarding incoming packets to *SoftIRQ*, the NAPI layer organizes them into batches. It does this by passing each packet to a transport-specific function using a mechanism called GRO (Generic Receive Offload). The transport-specific GRO function decides how to group packets into batches. For TCP, each batch contains packets from a single flow (this ensures that all packets from a flow go to the same core for *SoftIRQ*). Unfortunately, protocol-independent GRO code partially segregates batches by flow before invoking the transport-specific function. This segregation is neither necessary nor desirable for Homa. Fortunately, I found a way for Homa/Linux to defeat the GRO segregation and collect all incoming packets into a single batch (see the Appendix for details). This allows Homa to batch more aggressively than TCP, and is one of the reasons Homa has higher throughput for short messages (in TCP, each short message becomes a separate batch).

4.2 Load balancing

As mentioned in the introduction to this section, the networking subsystem must distribute load across multiple cores to keep up with a high-speed network. Load balancing is easy for packet output, because the output stack executes entirely on the sending thread’s core, with a separate NIC channel per core. The Linux scheduler balances threads across cores, and this distributes the packet transmission load as well.

The remainder of this section focuses on packet input, where Linux employs two different load balancers. The first is RSS, which runs in NICs and distributes incoming packets across cores for NAPI processing using a hash of packet

header fields. This hash function ensures that all packets from a given flow are assigned to the same core, as required by TCP. The second load balancer runs in the NAPI layer: after incoming packets have been grouped into batches, the NAPI layer chooses a SoftIRQ core for each batch. It does this using another hash function on header fields of the first packet in each batch; the hash is different from the one used by the NIC, but it ensures that all batches for a given flow are delegated to the same SoftIRQ core.

Input load balancing is problematic because it results in hot spots. Hot spots occur because the Linux scheduler's load balancer is unaware of the networking subsystem. For example, the NAPI layer can consume a core for hundreds of microseconds when a burst of packets arrives for a single long message. Short messages can still be processed through the NAPI and SoftIRQ layers on other cores, but if a message's target thread is assigned to the core processing the local burst, it will not run until after the burst is handled. This form of hot spot is the primary contributor to P99 tail latency in Homa/Linux.

Homa exacerbates this form of hot spot because it tries to use the entire incoming link bandwidth for one message at a time. TCP's fair-sharing scheduler tends to divide incoming bandwidth among multiple flows, which will probably be processed on different cores, so this form of hot spot is less likely to occur. Increasing packet size does not help, because NAPI polls for more packets: if the MTU increases then NAPI will spend less time processing packets but more time polling.

Homa/Linux has been unable to eliminate NAPI-thread conflicts because it has no control over the RSS hash function in the NICs. Hot spots can also occur with the SoftIRQ layer, where it conflicts with either application threads or NAPI. I eliminated most of these hot spots by repurposing an alternate mechanism for SoftIRQ core selection (the socket flow table, which steers packets to a specific application thread's core) so that Homa's GRO function can select a specific SoftIRQ core for each packet batch. After experimenting with several policies, I settled on one that records for each core the most recent time when it processed a Homa packet at either NAPI or SoftIRQ level. To choose a SoftIRQ core, NAPI consults the times for the next few cores after the one where it is running (in circular order) and selects the one with the oldest time. This policy has two desirable properties. First, it avoids conflicts between NAPI and SoftIRQ. Second, it tends to distribute SoftIRQ batches across multiple cores, so that no single core is occupied continuously: this leaves time for application threads to execute on each core. This policy improved Homa's P99 latency by about a factor of 2x.

I experimented with using core affinity to reduce conflicts between application threads and NAPI/SoftIRQ threads. For example, I tried partitioning the cores, with one set used exclusively for application threads and the others for NAPI and SoftIRQ processing. However, I was unable to find a configuration where core affinity improved tail latency.

A second problem with load balancing is that it hurts performance at low load. At low load it is best to concentrate

all processing on a single core: ideally, RSS should be disabled so that all interrupts pass through a single core, and that same core should execute both the NAPI and SoftIRQ layers. This maximizes cache locality, eliminates inter-core synchronization, eliminates the overhead of cross-core invocation between the NAPI and SoftIRQ layers, and makes the NAPI polling mechanism more efficient. In contrast, load balancing employs many cores but at low load they are all underutilized. These cores are likely to enter power-saving *C-states*, resulting in wakeup delays of 50–100 μ s the next time work is assigned to them. Furthermore, the continual arrival of packets on all cores reduces the effectiveness of power-saving mechanisms.

Ideally, the load balancing configuration should change dynamically with load, but there does not appear to be a way to do this in Linux. Thus, Homa/Linux is optimized for high loads. As a result, P99 latency for short messages is actually worse at low load than high load (see Section 5.4). However, Homa/Linux includes one optimization for low load. The algorithm for choosing a SoftIRQ core checks to see if the current batch contains only a single packet (an indicator of low load). If so, the NAPI core is also used for SoftIRQ. This reduces round-trip latency by 3–4 μ s when the system is underloaded.

4.3 Real-time processing: the pacer

As discussed in Section 2, Homa/Linux must limit the length of the NIC's internal transmit queue to enforce SRPT during output: if a large queue builds up in the NIC, then it will delay small messages. When the NIC queue length exceeds a threshold, Homa/Linux no longer transmits packets immediately; their messages are added to a queue and a *pacer* thread is awakened. The pacer thread manages the queue, passing packets to the NIC in SRPT order as NIC queue length permits.

The NIC queue length is not directly observable, so Homa/Linux maintains `nic_empty_time`, an estimate of the time when all queued packets will have been transmitted. As each transmitted packet is passed to the IP stack, this variable is updated based on the packet length and link speed. A system parameter controls how far into the future `nic_empty_time` is allowed to get; the current value is 2 μ s.

The pacer operates under severe real-time constraints: to keep the NIC queue short while fully utilizing the uplink, it must queue new packets at a time granularity of 1–2 μ s. There is no sleep/wakeup mechanism in Linux that can operate at this timescale, so the pacer thread must poll the processor cycle counter to wait for the next transmission time. As a result, the pacer consumes most of a core under heavy output load.

Even with a dedicated core, the pacer can fall behind. In the original design, once the pacer queue became nonempty, all output packets passed through the pacer. Unfortunately, a single thread cannot push small packets through the IP stack fast enough to drive the network at full speed. In addition, the scheduler occasionally deschedules the pacer; this can produce gaps of several milliseconds with no packets transmitted.

Homa/Linux includes three additional mechanisms to ensure full usage of the uplink. First, packets smaller than a threshold (currently 1000 bytes) bypass the pacer mechanism: they are passed to the NIC immediately without consulting or updating `nic_empty_time` (short packets transmit so quickly that it isn't possible to queue them faster than the NIC sends them, so the pacer is superfluous). Second, other cores help push packets through the network stack when the pacer falls behind. Before queuing a message for the pacer, Homa/Linux checks `nic_empty_time`; if it has dropped below the threshold for sending more packets, it indicates that the pacer isn't keeping the uplink fully utilized, so packets are transmitted directly, even if the pacer queue is occupied. Third, the pacer is invoked explicitly by the SoftIRQ layer after processing each batch of Homa packets; if the pacer thread has fallen behind, this invocation will queue more packets (but it returns without polling).

4.4 Grants

The goal of the grant mechanism is to maintain RTTbytes of outstanding grants (data granted but not yet received) for each *active message*. The number of active messages is limited by the degree of overcommitment; only the highest priority messages (according to SRPT) are active. In addition, Homa/Linux will not grant to more than one message from a given peer at a time, since the peer will only transmit the shortest one. To implement this, Homa/Linux maintains a global 2-level priority queue of incoming messages, consisting of a list of messages from each peer, plus a list of all peers with non-empty lists. Each is sorted in increasing order of the number of bytes not yet granted; the active messages consist of the first message from each of the first few peer lists.

Sending grants is not triggered by a clock, but rather by packet arrivals: after the SoftIRQ layer processes each batch of incoming packets, it checks to see if any active messages need additional grants. Packet arrivals may also change the structure of the grant queues (a new message may appear or an existing message may become fully granted).

The original design of Homa called for one grant packet to be sent for each scheduled data packet. However, this approach results in high overheads. Furthermore, the use of TSO means that packets are transmitted in groups, so there is no benefit in sending grants at per-packet granularity. Thus, Homa/Linux provides a parameter that specifies a minimum increment for grants; it is currently set to 10000 bytes, which is the same as the size of Homa's TSO packets.

4.5 Other implementation issues

Locking. The Linux networking stack is designed around per-socket locks. This approach works well for TCP because each flow is associated with its own socket; thus different flows can be processed concurrently without lock conflicts. However, a Homa application typically only has one socket, which is used for all messages. Homa initially used socket-level locking, but this resulted in severe contention for socket locks.

Homa was eventually refactored to use RPC-level locks as the primary synchronization mechanism. However, per-RPC locks created additional complications. For example, when the first packet arrives for an RPC, an entry must be created in a hash table of RPCs associated with the socket; future packets must use the existing RPC structure. However, multiple "first" packets for an RPC might be processed concurrently on different cores; the natural way to synchronize them is to use the socket's lock. To process packets without acquiring the socket lock, Homa/Linux associates a lock with each bucket in the socket's hash table; this lock covers all RPCs in that bucket. Bucket locks synchronize the lookup of an existing RPC with the creation of a new one, while allowing RPCs in other buckets to be processed concurrently.

Another issue with locking is the potential for deadlock. There are several places in Homa/Linux where multiple locks must be held. RPC locks are normally acquired before any others, but there are a few places where an RPC lock needs to be acquired while holding a different lock; this risks deadlock. Code had to be reorganized on a case-by-case basis to prevent deadlock. For example, in some situations the RPC lock can be acquired conditionally; if it is not available, then the operation can be deferred until later.

Combining FIFO with SRPT. Homa's SRPT priority mechanism is ideal for reducing small-message tail latency, and it also works well for most large messages because of its run-to-completion nature. However, under high load, a few of the largest messages may suffer very high tail latency. To mitigate this problem, Homa/Linux directs a small configurable fraction of the total network bandwidth to the *oldest* message instead of using SRPT; this occurs both when issuing grants for incoming messages and in the pacer for outgoing messages. The current fraction is 5%, which eliminates most of the penalty for the largest messages without affecting tail latency for short messages. This improves tail latency for the largest messages by about 2x in pathological cases.

Reaping RPCs. Any long-running operation creates a threat to tail latency because it may delay other work. One example is RPC reaping, which frees the resources for an RPC after it completes. For clients, this is just before returning from `homa_recv`; for servers, it is after the response has been sent. Reaping can take tens of microseconds for large RPCs, most of which is spent freeing packet buffers. Reaping was originally done immediately when RPCs were freed, but it had a noticeable impact on tail latency. On servers, for example, reaping could occur in the SoftIRQ layer while handling an incoming packet, causing unpredictable delays for subsequent packets.

To reduce the impact of reaping on tail latency, Homa/Linux now defers reaping so that it does not occur when an RPC is freed. Instead, reaping occurs in `homa_recv` while waiting for incoming messages: large messages are reaped incrementally in chunks of a few packet buffers, checking for incoming messages after each chunk. This approach

hides the cost of reaping unless the system is so loaded that `homa_recv` never waits. If the pool of unreaped messages grows too large, then `homa_recv` will stop and reap despite the waiting messages; this situation is rare in practice.

Receive polling. If a thread blocks in `homa_recv`, it takes about 2.5 μ s to wake it on message arrival; this contributes significantly to latency. To avoid this cost, Homa polls briefly in `homa_recv` before blocking the thread. This saves about 2 μ s if a message arrives during the polling interval. The interval is a system parameter, currently 50 μ s. Polling is useful primarily when the system is lightly loaded; it has little impact on the tail latency measurements in Section 5.

Timer thread. Homa contains a dedicated in-kernel thread that wakes up at 1 ms intervals, checks for overdue packets, requests retransmissions, and eventually declares a peer dead if it fails to respond. Lost packets are rare, so slow response is usually due to overload on the peer; to minimize the extra load from retransmission requests, the timer thread will only request retransmission for a single RPC at a time for each peer (the oldest one). If a peer is declared dead, then all RPCs to/from that peer are aborted.

Computing unscheduled priorities. Each Homa host must send information to its peers about the priorities to use for unscheduled packets. Priorities are computed by a user-level daemon, `homa_prio`, which runs regularly (currently every 500 ms) and collects information from Homa/Linux about the size distribution for recently received messages. It then decides how many priorities to use for unscheduled packets and computes cutoff values (the largest message size for each priority level) as described in Section 2. If the cutoffs have changed significantly, `homa_prio` passes them to Homa/Linux using the `sysctl` mechanism. Homa/Linux does not immediately notify all its peers; it waits until the next message from each peer, and then sends the new cutoffs.

Long-term state. As mentioned previously, Homa stores no long-term connection information. It does, however, keep long-term state for each peer that it has communicated with. A peer’s state is about 200 bytes, of which almost half consists of cached routing information. The remainder includes information about unscheduled priorities for that peer and information for detecting timeouts and managing grants. This is far less than the 2000 bytes that TCP stores for each open socket. Peer state is created on demand and never discarded.

Configuration parameters. One disadvantage of Homa/Linux is that it has about 30 configuration parameters. Many were added solely for evaluating the implementation and need not be considered in practice. For many others the exact value has little impact on system performance. About 5–10 parameters can have a significant impact on performance; for them the best value depends on hardware characteristics such as network speed, CPU speed, and number of cores. I believe that it is possible to compute their values automatically by running benchmarks, but I leave this to future work. The only configuration parameter

CPU: E5-2640v4 (10 cores, 2.4 GHz)
RAM: 4x 16 GB DDR4-2400 DIMMs
Disk: Intel DC S3520 SSD (480 GB 6G SATA)
NIC: Mellanox ConnectX-4 25 Gbps
Switch: Mellanox 2410

Table 1: CloudLab [10] x1170 hardware configuration used for benchmarking. All nodes ran Linux 5.4.80. Hyperthreads were enabled (2 hyperthreads per core). TSO and RSS were enabled for all protocols, with separate transmit/receive channels for each hyperthread. C-States were enabled, Meltdown mitigations were disabled, and interrupt moderation was disabled. All 40 nodes were connected to a single switch.

	Homa	TCP	DCTCP
100B latency (μ s)	15.1	23.4	24.1
500KB throughput (Gbps)	10.0	20.3	20.5
Client throughput (Gbps)	23.8	23.9	21.4
Server throughput (Gbps)	23.7	23.6	22.4
Client RPC rate (Mops/sec)	1.6	1.0	1.0
Server RPC rate (Mops/sec)	1.6	1.0	1.0

Table 2: Basic Homa and TCP performance. The top two lines used a single client thread issuing back-to-back requests to a single server. Latency was measured end-to-end at application level with 100-byte requests and responses; throughput was measured with 500 KB requests and responses. For the remaining measurements each client had multiple threads; each thread issued multiple concurrent RPCs. Client performance was measured with a single client node spreading requests across 9 server nodes; server performance was measured with 9 client nodes all issuing requests to a single server node. Throughput was measured with 500 KB requests and responses and counts only message payloads; RPC rate was measured with 100-byte requests and responses. Each number represents the best average across five 5-second runs.

for which the best value might vary from application to application is the polling interval; this should probably be made an argument of the `homa_recv` kernel call.

5 Performance Evaluation

This section evaluates Homa/Linux’s performance, comparing it with the Linux implementations of TCP and DCTCP. The most important metric is tail latency for short messages under high load, but the benchmarks also measure performance for large messages and lower loads. This section also evaluates concerns that have been raised in recent papers about Homa’s use of priorities and network buffers.

The benchmarks ran on a 40-node cluster described in Table 1. Each server had 10 cores with two-way hyperthreading enabled. Unless otherwise indicated below, the term “core” refers to a single hyperthread. Unless otherwise stated, all measurements used a maximum packet size (MTU) of 3000 bytes, which produced better results for all protocols than the traditional 1500 bytes. For DCTCP the ECN marking threshold was 70 KB.

5.1 Basic latency and throughput

Table 2 shows latency and throughput for Homa/Linux and TCP under best-case conditions. Homa/Linux round-trip-times for short messages are about one-third lower than those of TCP or DCTCP (15.1 μ s vs. 23.4/24.1 μ s). This difference is primarily due to Homa’s use of polling (4 μ s) and its optimization of SoftIRQ core selection (3–4 μ s). In addition, Homa’s single-socket-per-thread approach eliminated

Name	Mean	Description
W2	433	Search application at Google [33].
W3	2423	Aggregated workload from all applications running in a Google datacenter [33].
W4	60175	Hadoop cluster at Facebook [32].
W5	385315	Web search workload used for DCTCP [1].

Table 3: The message size distributions used for benchmarks. The workloads were taken from [25], except that messages larger than 1 MB in W4 and W5 were truncated to 1 MB (the largest size permitted under Homa/Linux). The workloads are ordered by average message size (“Mean”): W2 is most skewed towards small messages and W5 is most heavy-tailed.

the need for `epoll` system calls, which saves 1 μ s. Section 6 shows that latencies in real applications are considerably higher than this for both Homa/Linux and TCP. For comparison, the lowest achievable round-trip latency for this hardware (using kernel bypass) is 3.7 μ s [19].

Homa’s throughput is only about half that of TCP or DCTCP when a single client sends large RPCs back-to-back to an unloaded server (10 Gbps vs. 20 Gbps). This is because Homa’s message-based interface reduces opportunities for pipelining. In particular, Homa/Linux cannot transfer any part of a message to a waiting application until the entire message has arrived, whereas TCP can overlap network transmission and copying to user space. When multiple RPCs are active simultaneously, Homa’s throughput is equivalent to TCP’s, while DCTCP’s throughput is slightly lower.

Table 2 also shows the maximum small message request rate. Homa’s throughput is 60% above TCP or DCTCP. One reason is Homa’s ability to batch received packets more effectively than TCP, as described in Section 4.1. Homa generated average batches of 2–3 packets at the NAPI level, whereas TCP did not batch packets at all for this benchmark.

5.2 Cluster benchmarks

Most of the remaining evaluation is based on a cluster benchmark that uses all 40 nodes. Each node operates simultaneously as both client and server, with multiple client and server threads chosen for each protocol to maximize its performance. Each node has multiple independent Homa server sockets or TCP listen sockets. Clients send request messages to servers chosen at random, and servers return response messages of the same size as the requests. Message sizes are chosen at random to match one of four workload distributions, W2–W5, described in Table 3. These distributions are the same as those used in Montazeri et al. except that W1 is omitted because of space limitations (W1’s behavior is almost identical to W2). The timing of new requests is based on a Poisson arrival function that produces a particular average throughput.

Figure 3 compares Homa with TCP and DCTCP for each of the four workloads under high network loads. The figure uses *slowdown* as a measure of latency, which allows comparisons between messages with different lengths. The slowdown for a given RPC consists of the end-to-end round-trip time (RTT) observed by the client application divided by the RTT for RPCs of the same length measured with Homa under the ideal conditions of Table 2; smaller slowdowns are better.

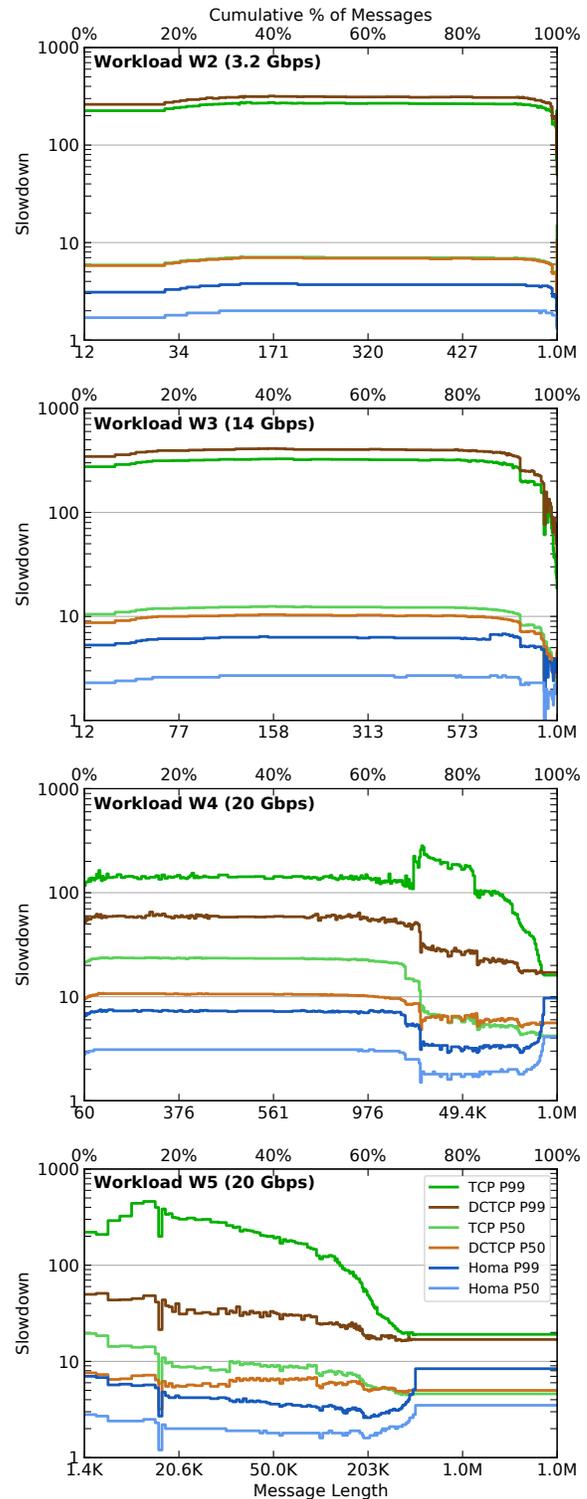

Figure 3: Median and 99th-percentile slowdown as a function of message size for workloads W2–W5. Each x-axis is linear in number of RPCs (i.e. it reflects the CDF of message length for that workload). The network load for each workload (e.g. 20 Gbps for W4 and W5) was chosen so that the protocols operated at 80–90% of their maximum sustainable rates; load is measured in units of message payload bytes sent by each host (an equal amount was also received).

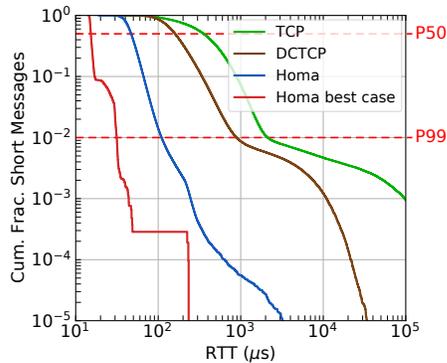

Figure 4: Complementary CDF of round-trip latency for the shortest 10% of RPCs for W4 (messages with 315 bytes or fewer) in Figure 3. A point (x, y) indicates that a fraction y of RPCs had round-trip times longer than x . “Homa best case” was measured under the conditions of Table 2.

Homa’s latencies are significantly lower than both TCP and DCTCP. For example, Homa’s P99 latencies for short messages are 19–72x lower than those for TCP and 7–83x lower than DCTCP. Homa’s P50 latencies for short messages are 3.5–7.5x lower than TCP and 2.7–3.8x lower than DCTCP. Homa’s P99 slowdown is actually lower than P50 slowdown for TCP and DCTCP, except for the the largest messages in W4 and W5. DCTCP generally outperforms TCP, as expected.

W2 is different from the other workloads in that network congestion is not an issue: almost all messages are short, so none of the protocols can support more than about 40% network utilization. For this workload performance is limited primarily by software overheads; Homa still provides much lower latency than either TCP or DCTCP. An analysis of TCP’s P99 behavior showed that it is caused by scheduler anomalies where two threads end up assigned to the same core, even though there are fewer application threads than cores. One of them eventually migrates to a different core, but by the time it resumes execution, many milliseconds have been lost. Anomalies like this did not occur for Homa.

One potential concern with Homa’s SRPT policy is its impact on large messages. Figure 3 shows that this is not a problem in practice. Slowdowns for workloads W4 and W5 do increase for large message sizes, but Homa still beats both TCP and DCTCP on P50 and P99 latency. There is no message size in any workload where TCP or DCTCP outperformed Homa.

Figure 4 shows more detail on the round-trip latency for short messages in W4. Homa’s latencies are better than TCP and DCTCP at every percentile, typically by at least an order of magnitude.

Homa’s slowdown in Figure 4 is entirely due to software overheads: Homa has eliminated network congestion as a significant factor. To verify this, I used a timetracing package to extract precise end-to-end traces of short RPCs with latencies near the 99th percentile. Latency for these RPCs was primarily due to hot spots in load balancing: an application thread cannot execute to handle a short message because its core is

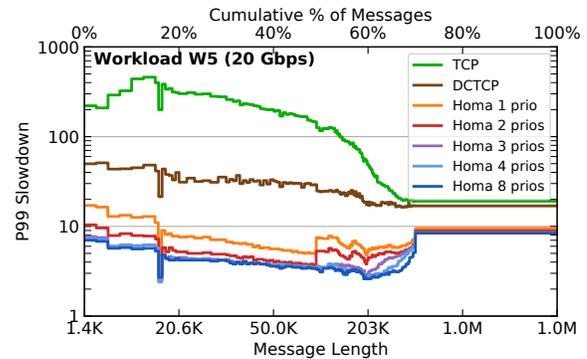

Figure 5: The impact of the number of available priority levels on Homa’s P99 slowdown for workload W5 (other workloads are omitted because of space limitations; they are less sensitive to the number of priorities than W5). TCP and DCTCP are shown for comparison.

occupied by NAPI processing for unrelated large messages. These NAPI bursts can last 100 μ s or more.

In contrast, timetraces for TCP RPCs near P99 showed different causes of tail latency. Roughly two-thirds of the traces had head-of-line blocking where a short message was stuck behind a long one in the same stream. In the remaining traces the extra time occurred after a packet was accepted by the source NIC and before an interrupt occurred on the destination, suggesting buffer buildup in the NIC or at the switch’s egress port. This analysis shows that the P99 latency difference between TCP/DCTCP and Homa is because of protocol features, as opposed to quality of the implementations.

5.3 Number of priorities

One of the concerns that has been raised about Homa is its use of switch priorities (e.g., [21]): priority queues are a limited resource, and in some datacenters they are already allocated to applications with critical QoS needs. Figure 5 shows that Homa/Linux needs only a few levels to achieve maximum performance: it does well with 2 priorities, and additional levels benefit only a small range of message sizes. Even with only a single priority level, Homa’s P99 latency is still much better than DCTCP or TCP.

5.4 Reduced load

The measurements in Section 5.2 were made under high load (80–90% of the maximum that the protocols and network can sustain). Figure 6 shows slowdown for Homa and DCTCP when the load is reduced by a factor of 2x or 10x. Because of space limitations, measurements are shown only for W4, and only for Homa and DCTCP (other workloads are similar).

Figure 6 shows that Homa is more stable than DCTCP. Homa’s latency for short messages varies by less than 2x across a 10x load change, whereas DCTCP’s latency varies by 7x. Homa’s P99 short-message latency at the highest load is 40% lower than DCTCP’s P99 latency at a 10x reduced load.

Homa displays a performance inversion in Figure 6. Once the load drops below 50% of maximum, short-message latency begins to increase; Homa latencies at the lowest load are about 25% *higher* than those at the highest load. The inversion is due to C-states. At low loads, cores may be idle for

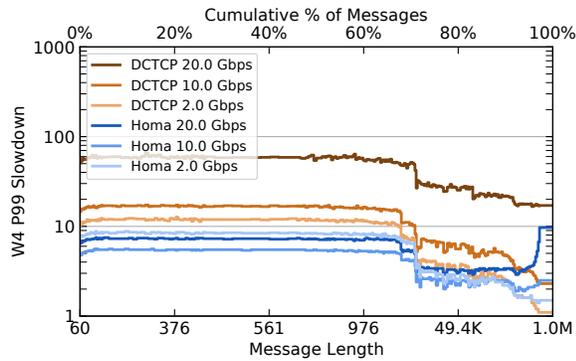

Figure 6: P99 slowdown as a function of message size for W4 under varying loads.

significant periods, causing them to enter C-states; it takes 50–100 μ s to awaken them when packets arrive. I confirmed this behavior by running the benchmark with C-states disabled: in this case, Homa latency continues to improve with lower loads.

Figure 6 suggests that Homa’s automatic priority allocation mechanism may outperform the manual approaches currently used in datacenters. Consider an application using DCTCP whose workload matches W4, and suppose it has exclusive use of the highest network priority. It will then behave roughly as if it had a private network, so its performance will match the DCTCP curve in Figure 6 corresponding to the load generated by that application. Now suppose that, instead of manually allocating QoS levels, all applications switch to Homa, and Homa uses all the priority levels to support them without preference. The performance will now match the Homa curve in Figure 6 corresponding to the combined load of all the applications. There is almost no overlap in these curves: shared Homa provides better latency than differentiated DCTCP for all but the largest 20% of messages. If those particular message sizes are not crucial for the application’s performance, it would be better off in a shared environment under Homa, even though Homa offers no particular QoS support. The shared approach would also eliminate the administrative burden of assigning and managing QoS levels.

5.5 Buffer usage

Homa uses buffers relatively economically compared to TCP, but its performance will degrade if buffer space is exhausted and packets are dropped. Hai et al. measured Homa with switch buffers limited to 200 KB per port [14]. They found that this resulted in very poor Homa performance due to dropped packets and the subsequent timeouts and retransmissions. I analyzed buffer usage in our cluster to get a better understanding of this issue, and found that Homa fits easily in the buffer space available in our 25 Gbps environment.

Hai et al. assumed a fixed-size buffer for each port. However, many modern switches have dynamic buffer pools that can be shared between ports. For example, our switches have 16 MB of buffer space, of which 13 MB can be dynamically shared among 40 ports.

	W2	W3	W4	W5	W5-6K
homa_send	1.35	1.38	0.47	0.45	0.38
homa_recv	2.11	2.54	1.29	1.32	1.22
homa_reply	1.60	1.69	0.56	0.50	0.44
NAPI	1.29	1.76	1.18	1.37	1.01
SoftIRQ	1.31	1.58	0.90	0.87	0.82
Pacer	0.02	0.34	0.71	0.70	0.66
Timer	0.01	0.01	0.01	0.01	0.01
Total	7.69	9.29	5.11	5.03	4.53
Polling	7.30	6.25	1.05	0.18	0.30

Table 4: Total core usage for the components of Homa in the benchmarks from Figure 3; 1.0 corresponds to 100% usage of one hyperthread (work is actually spread across many cores). Polling time is listed separately, and is not included in `homa_recv`. The times for system calls do not include time to enter and leave the kernel. “W5-6K” shows W5 with the MTU increased from 3000 to 6000 bytes.

Using statistics maintained by the switch, I found that Homa’s maximum buffer occupancy across all ports ranged from 246 KB for W2 to 8.5 MB for W5, well within the pool’s 13 MB capacity. To confirm the number for W5, I reduced the pool size to 9 MB and reran the benchmark: its performance was unaffected and the switch recorded no packet drops. I then further reduced the pool size to 7 and then 6 MB. At 7 MB there was still no performance degradation, but Homa dropped 500–1000 packets per second per port under the W5 workload. With 6 MB of buffer space, Homa dropped about 90,000 packets per second per port under W5 (a rate of 0.13%) and performance degraded severely. For comparison, TCP performance dropped noticeably when buffer space was reduced to 10 MB and severely at 6 MB; DCTCP experienced no degradation until buffer space dropped below 2 MB.

Homa’s maximum buffer usage amounts to about 220 KB per port, which is only slightly higher than the value that produced poor results for Hai et al. It seems likely that the dynamic buffer pool explains the difference in our results. Assuming that buffer usage scales with link speed, buffer requirements (and availability) can be characterized in units of Kbytes of buffer space per Gbps of aggregate switch bandwidth. Homa’s maximum usage was 8.5 KB/Gbps, though it performed well with only 7 KB/Gbps. Looking forward to 100 Gbps networks, Broadcom’s Tomahawk 3 switching chip [35] provides 7.5 KB/Gbps of buffer space, which appears to be adequate for Homa. I believe that Homa’s buffer usage can be reduced, but I leave this to future work.

6 Software Overheads

As discussed in the preceding section, Homa/Linux eliminates congestion as a significant performance factor. Tail latency is now limited by software overheads, not network congestion. New congestion control schemes are unlikely to be impactful unless they also reduce software overheads (and simulation results that omit those overheads may be misleading). Significant gains may be had if overheads can be reduced: for example, the RAMCloud implementation of Homa [25] has much lower software overheads than Homa/Linux; as a result, it provides 8x lower P99 latency for short messages in W4

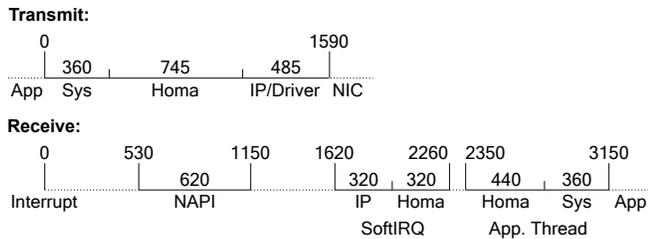

Figure 7: Timelines (in ns) for sending and receiving short messages under the best-case conditions of Table 2; the receiving thread is polling in `homa_recv` when the message arrives (an additional 2000 ns are incurred if the thread is sleeping). All times are in ns. “Sys” refers to Linux code for entering and leaving system calls.

(unfortunately, the RAMCloud implementation is impractical, as discussed below). This section provides more data on software overheads.

As discussed previously, software overheads (in particular, hot spots due to conflicts between the thread scheduler and network load balancers) are the primary source of tail latency for Homa/Linux. In addition, software overheads limit throughput and place excessive demands on cores for packet processing. They particularly impact throughput for short messages: the 1.6 Mops/sec maximum request rate reported for servers in Table 2 consumes resources equal to 18 of the machine’s 20 cores, even though no meaningful work is done in servicing the requests. Table 4 shows core utilization for each of the four workloads; W2 and W3, which have the smallest message sizes, consume almost all of the cores, and yet they are unable to fully utilize a 25 Gbps network. W4 and W5 process larger packets, so they use fewer cores. The pacer thread consumes about 0.7 core for W4 and W5, which have many large messages. Extrapolating from Table 4, Homa/Linux will require at least 18 cores (excluding polling) to drive a 100 Gbps network at 80% utilization.

One possible way to reduce software overhead is to increase the MTU. However, Table 4 shows only small benefits: doubling the MTU from 3000 to 6000 bytes reduces core utilization for W5 only 11%, and workloads with smaller messages benefit even less.

Figure 7 breaks down the best-case latency for sending and receiving short messages. The total round-trip software overhead is about 9.5 μ s, consisting of 1.6 μ s on each node to send a message and about 3.2 μ s on each node to receive one. This is notably higher than the network time (from NIC queue to interrupt), which is about 5.6 μ s per round-trip. Figure 7 and Table 4 show that software overheads are distributed across many components; there is no single culprit to optimize.

Unfortunately, Figure 7 significantly understates the latency for real workloads. Software overheads increase by 2–3x when load balancing is used. This can be seen in the upper left corner of Figure 4. The “Homa best case” RTT is about 15 μ s; in this measurement, all protocol processing occurs on a single core on each machine. However, in the W4 workload, where protocol processing is distributed across cores, the median RTT for short requests is 3x higher (about 47 μ s); only 1% of requests complete in under 30 μ s. An analysis of de-

tailed timetraces showed that each stage of processing from Figure 7 slows down by a factor of 2–3x (presumably due to cache coherency traffic?); again, there is no single culprit.

7 The Future of Transport Protocols

The preceding sections showed that transport protocols implemented in kernel software carry a painfully high cost in terms of both application latency and core usage. Although some improvements may be possible, such as better thread schedulers that reduce hot spots from load balancing, fundamental challenges will remain. This section discusses the possibility of moving transport protocols out of the kernel.

7.1 Moving transport protocols to user space

Several recent projects have explored moving protocol processing to user space, including MICA [22], RAMCloud [29], IX [5], ZygOS [31], Shenango [27], eRPC [19], and Snap [23]. At first glance, these systems appear to reduce software overheads significantly. For example, Shenango and RAMCloud can serve about 1 M requests/sec/core and eRPC can serve 10 M requests/sec/core, vs. just 0.1 M requests/sec/core for Homa/Linux. eRPC offers best-case latency of 3.7 μ s, vs. 15.1 μ s for Homa/Linux, and the RAMCloud implementation of Homa provides P99 latency for W4 less than 15 μ s, vs. about 100 μ s for Homa/Linux.

However, most of these systems have significant simplifications and/or restrictions, such as the following:

- They measure under unrealistic conditions like those in Table 2.
- They don’t do load balancing, or do it in a hand-optimized fashion that eliminates hot spots and the 2–3x load-balancing overhead discussed above.
- The measurement workloads contain only short or only long messages (combined workloads are both more realistic and more challenging).
- They don’t consider congestion control.
- They assume that every application can implement the protocol independently (see below).

Many of the overheads experienced by Homa/Linux cannot be eliminated; for example, at least one core will still be consumed polling the NIC and receiving packets, and if output rate limiting is needed, another core will be consumed for that.

Of the user-space systems listed above, only Snap provides a full-featured production implementation. However, it reduces software overheads by only about 2x compared to Homa/Linux (Snap requires 7–14 cores to drive a 100 Gbps network at 80% load bidirectional, vs. 18 for Homa/Linux; this is still a steep price to pay). Snap appears to incur load balancing overheads similar to those for Homa/Linux. A single Snap core without load balancing can drive a 100 Gbps network at 80% load in one direction, but when load balancing is enabled (as in the numbers for 7–14 cores above) throughput/core drops by 3.5–7x. Furthermore, Snap reported P99 latencies for short messages of 300–400 μ s under high network loads, which is 3–4x higher than Homa/Linux. This suggests

that user-space implementations will not be a panacea for the problem of high software overheads.

One of the challenges with user-space protocol implementations is that they perform best when every application can implement the protocol independently. However, not all protocols fit this model. For example, Homa requires global state for congestion control (for grant management and the pacer). If global state is required, then the protocol must be implemented in a shared service and packets must pass through that service on their way to and from the network. This introduces extra core/thread crossings, adding significant overhead. Snap uses this approach, which could explain why its overhead is higher than many other user-level protocol implementations.

7.2 Moving transport protocols to the NIC

The challenges with software transport protocols will only get worse in the future, since network speeds are increasing while CPU speeds are static. We are approaching a point where it no longer makes sense to implement transport protocols in software. The alternative is to move them entirely to the NIC; applications would communicate directly with the NIC using kernel bypass. Packets would no longer be visible to host software: all communication with the NIC would be in terms of messages. In addition, the NIC would implement intelligent load balancing, such as distributing incoming requests across available threads in a service, so that packets do not need to pass through an additional core just for load balancing.

Moving the transport protocol to the NIC would reduce end-to-end application latency by at least 5x, increase small-message throughput by 5–10x, and use silicon real estate more efficiently, freeing cores currently used for inefficient protocol processing so they can run application code instead. Reducing end-to-end latency would also reduce RTTbytes, cutting buffer consumption in the switches. This transition could be as impactful for system performance as the transition from programmed I/O to direct memory access in the 1960's.

Designing such a NIC will be challenging; it will require a new architecture that combines a line-rate packet processing pipeline with enough programmability to allow a variety of transport features and to support easy transport maintenance and evolution. The NIC will also need to support network virtualization features commonly implemented in software today [30, 9]. There exist systems that provide some of the required features, but none is fully satisfactory. For example:

- RDMA NICs provide kernel bypass and low latency, but their mechanisms for congestion control and load balancing are inadequate. In addition, existing NICs are not open or programmable.
- Today's "smart NICs" have inadequate performance and/or programmability. Smart NICs come in two flavors. The first is implemented with many general-purpose cores. These NICs still implement transport protocols in software, with all the performance problems discussed above. The second flavor is based on FPGAs; they can potentially provide adequate performance, but are difficult to program.

- New packet processing pipelines such as P4 [6, 7] operate at line rate and are programmable, but they do not currently have enough power to implement transport protocols. As one example, P4 does not provide long-lived state that is required for transport protocols.

One promising direction of research is to extend P4 with additional mechanisms to meet the needs of transport protocols [18]; this work is still embryonic.

7.3 The future of TCP

TCP has a long and illustrious history, and it has found use across an extraordinary range of technologies and environments. However, datacenters did not exist when TCP was designed, and virtually every aspect of the TCP design is wrong for the datacenter:

- Its connections create high space and time overheads.
- Its stream orientation is awkward for applications and causes high tail latency due to head-of-line blocking.
- Its fair scheduling increases tail latency for all message sizes.
- Its sender-driven congestion control ensures buffer occupancy at high loads, which drives up tail latency.
- It doesn't take advantage of in-network priority queues.
- It requires in-order delivery, restricting opportunities for load balancing both in network hardware and host software.

Furthermore, TCP's high implementation complexity will make it difficult to implement in hardware. Thus, it is difficult to imagine a path to high performance datacenter networking that is based on TCP.

8 Related Work

The last decade has seen many proposals to improve TCP performance and/or solve the congestion control problem for datacenters. Examples include DCTCP [1], D³ [37], HULL [2], D²TCP [36], PDQ [17], pFabric [3], PIAS [4], QJUMP [13], pHost [11], Karuna [8], and NDP [15]. Of these, DCTCP appears to be the only one with a readily-available Linux implementation that can be compared with Homa/Linux.

Homa's congestion control mechanism is effective against congestion at the network edge, but it does not address congestion in the core. Several other recent projects have addressed core congestion, including TIMELY [24], HPCC [21], and Swift [20]. Swift and Homa could probably be synergistically combined, with Swift dynamically adjusting RTTbytes to manage congestion in the core while Homa eliminates it at the edge. At the same time, it seems possible that core congestion is due primarily to TCP's requirement of flow-consistent routing, and that a datacenter using Homa with packet spraying would not experience significant core congestion; this would be an interesting experiment for future work.

Aeolus [14] proposed modifications to Homa to improve performance when buffer space is exhausted. However, measurements in Section 5.5 indicate that buffer exhaustion is unlikely to occur in modern switches with shared buffer pools, so the Aeolus modifications are not necessary.

As mentioned in Section 6, several recent projects have developed network transports outside the kernel in order to avoid the overheads of an in-kernel transport. Examples include MICA [22], RAMCloud [29], IX [5], ZygOS [31], Shenango [26, 27], eRPC [19], and Snap [23].

9 Conclusion

This paper has demonstrated two things. First, it has shown that the Homa transport protocol can be implemented in a practical setting that allows it to be used by a variety of applications. Homa/Linux retains the benefits of Homa's congestion-control mechanism and outperforms TCP and DCTCP by a wide margin, offering order-of-magnitude lower tail latencies across a range of workloads and message sizes.

Second, this paper has shown that the battle for networking performance is shifting from network protocols to software overheads. Increasing network speeds make it ever more difficult to do protocol processing in software, and overheads increase as more cores are harnessed. If these overheads can be eliminated, for example with new NIC architectures, another factor of 5–10x in networking performance is possible.

10 Acknowledgments

This work was supported by Cisco, Fujitsu, Google, Huawei, NEC, and VMware. Bare-metal computing resources were provided by CloudLab [10]. Collin Lee, Yilong Li, Amy Ousterhout, and Seo Jin Park provided helpful comments on drafts of this paper. The paper also benefited from comments and suggestions from Michio Honda, the paper's ATC shepherd, and anonymous reviewers, as well as copy editing by Geoff Kuenning.

11 Appendix

This appendix provides additional details on a few aspects of the Homa/Linux implementation.

11.1 GRO packet batching

As discussed in Section 4.1, Homa/Linux collects incoming packets into batches for SoftIRQ processing without regard to message structure. Unfortunately, the Linux infrastructure segregates incoming packets using a hash of packet header fields. When a new packet arrives, Linux uses its hash to find a list of packets being held for batching (if any) that match that hash. Then it passes the new packet and the held list to a transport-specific function. The transport-specific function can batch the packet with an existing packet on the list (by incorporating it into a sublist within the existing packet). If the transport-specific function chooses not to batch the new packet with an existing one, then Linux adds the new packet to the list as a "root" for future batching.

This default mechanism prevents transports from batching packets that hash to different lists. However, the transport-specific function has a third option, which is to indicate that it has completely processed the packet, so Linux should not add it to the list or take any other actions. Homa/Linux takes

advantage of this feature. Homa/Linux keeps track of a distinguished held list for each core (the one corresponding to the first packet received by that core). When packets arrive for any other held list, Homa/Linux ignores that list, merges the packet with the first Homa packet on the distinguished list instead, and indicates to Linux that the packet has been fully processed. As a result, all incoming Homa packets are merged together into a single batch. When the batch is transmitted to SoftIRQ, the distinguished list is reset.

11.2 skbuff management

Homa/Linux uses regular Linux skbuffs for packet buffering. It increments the reference count on transmitted skbuffs in order to retain them until they have been acknowledged. The original skbuff cannot be retransmitted because transmission is not idempotent; for example, lower-level protocol headers get prepended as the buffer traverses the IP stack. Thus, if retransmission is required, Homa/Linux copies the skbuff's data into a new skbuff.

Homa/Linux keeps the skbuffs for an incoming message in a list sorted by offset in the message. New packets are inserted into the list starting at the back (highest offset). With this approach, packet insertion will not require traversing many list elements unless the packet has been delayed a long time.

11.3 Synchronization details

Homa/Linux's approach to socket locking allows it to avoid the awkward mechanism used elsewhere in Linux for locking sockets in SoftIRQ handlers (a SoftIRQ handler could have interrupted a background thread that holds the socket lock needed by SoftIRQ, so SoftIRQ cannot wait for socket locks; when it finds a locked socket, it defers packet processing until the thread releases the lock). Instead, Homa/Linux uses spinlocks for sockets, with interrupts disabled. This prevents an application thread from being interrupted while holding a socket lock.

Homa/Linux takes advantage of the Linux RCU mechanism to prevent sockets from being deleted while operations are underway on them. This eliminates the need to acquire socket locks in some situations, and is particularly useful in situations where it would have been necessary to acquire the socket lock before acquiring RPC locks (this would violate ordering constraints necessary to prevent deadlock).

Ayudante: A Deep Reinforcement Learning Approach to Assist Persistent Memory Programming

Hanxian Huang Zixuan Wang Juno Kim Steven Swanson Jishen Zhao
University of California, San Diego

Abstract

Nonvolatile random-access memories (NVRAMs) are envisioned as a new tier of memory in future server systems. They enable a promising persistent memory (PM) technique, with comparable performance of DRAM and the persistence property of storage. However, programming PM imposes non-trivial labor effort on writing code to adopt new PM-aware libraries and APIs. In addition, non-expert PM code can be error-prone. In order to ease the burden of PM programmers, we propose *Ayudante*¹, a deep reinforcement learning (RL)-based PM programming assistant framework consisting of two key components: a deep RL-based PM code generator and a code refining pipeline. Given a piece of C, C++, or Java source code developed for conventional volatile memory systems, our code generator automatically generates the corresponding PM code and checks its data persistence. The code refining pipeline parses the generated code to provide a report for further program testing and performance optimization. Our evaluation on an Intel server equipped with Optane DC PM demonstrates that both microbenchmark programs and a key-value store application generated by *Ayudante* pass PMDK checkers. Performance evaluation on the microbenchmarks shows that the generated code achieves comparable speedup and memory access performance as PMDK code examples.

1 Introduction

Enabled by nonvolatile random-access memory (NVRAM) technologies, such as Intel Optane DIMM [33], persistent memory (PM) offers storage-like data persistence through a fast load/store memory interface [5, 63]. PM is envisioned to be a new tier of memory in future servers with promising benefits, such as fast persistent data access and large capacity.

However, the PM technique also introduces substantial challenges on programming. First, currently the burden of PM programming is placed on system and application programmers: they need to implement new PM programs or rewrite

legacy code using PM programming libraries with a variety of programming interfaces and APIs [10, 16, 17, 22, 27, 31, 73]. Despite the promising development of libraries, implementing PM programs requires non-trivial labor efforts on adopting new libraries, debugging, and performance tuning. Second, the storage-inherited crash consistency property demands rigorous data consistency of the stand-alone memory system [44, 54] to recover data across system crashes; fully exploiting NVRAM's raw memory performance [15, 34, 76, 77, 80] requires programs to minimize the performance overhead of crash consistency mechanisms. As such, programmers need to understand the durability specifications and ordering guarantees of each PM library in order to provide sufficient persistence guarantee, while avoiding the performance overhead of adding unnecessary persistence mechanisms. Third, because various PM libraries provide different programming semantics, programmers need to manually transform the semantics, when switching from one PM library to another. As a result, PM programming is a tedious and time-consuming task even for the expert PM programmers, while imposing a painful learning period for non-experts. Moreover, the challenges significantly prolong the software development process and hold back the wide adoption of the PM technique.

In order to address these challenges, we propose *Ayudante*, a deep reinforcement learning (RL)-based PM programming framework to assist PM programming by transforming volatile memory-based code into corresponding PM code with minimal programmer interference. *Ayudante* consists of two key components as illustrated in Figure 1. First, *Ayudante* employs a deep RL-based code generator to automatically translate volatile memory-based C, C++, or Java code into corresponding PM code, by inserting PM library functions and instructions. Second, we design a code refining pipeline to parse the generated code to provide a report for programmers to further test, debug, and tune the performance of the code after the inference of our RL model. *Ayudante* intends to save the time and energy of programmers on implementing PM code from scratch. As such, *Ayudante* allows programmers to focus on leveraging or implementing volatile

¹Ayudante source code: [1]

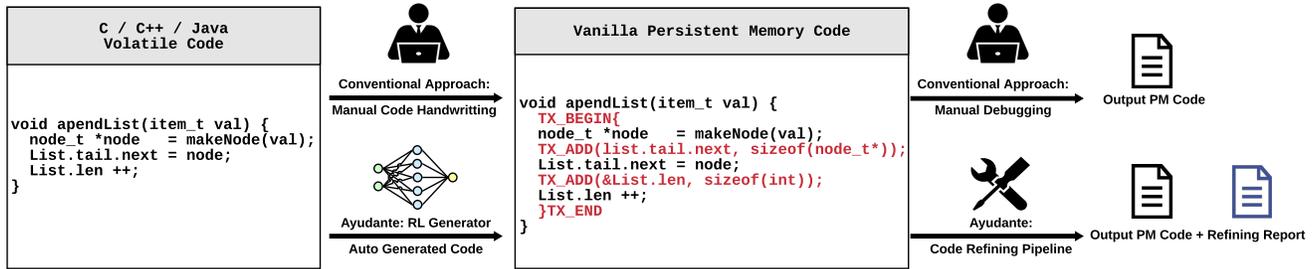

Figure 1: Ayudante framework overview. The framework takes conventional C, C++, or Java source code for volatile memory as an input and generates the corresponding PM code. Ayudante leverages a RL-based method to automatically translate the volatile version of source code to a nonvolatile version by inserting proper PM library annotations. In addition, Ayudante generates a code refining report to help reduce bugs and improve run-time performance.

memory-based code on traditional programming semantics that they are familiar with.

Due to the similarity to neural machine translation (NMT) problems in natural language processing (NLP), program translation is recently demonstrated to have promising results by adapting NMT techniques, such as sequence-to-sequence models [35, 79], word embedding [9, 12, 56], and tree-to-tree LSTM encoder-decoder on abstract syntax tree (AST) [11, 14]. However, the existing machine learning (ML)-based program translation methods focused on simple programs and data structures; the models fall short of handling sophisticated program syntax, data structures, and consistency reasoning, which yield large and complex search spaces [11, 14]. To this challenge, we integrate our RL model with Monte-Carlo tree search and carefully design our neural network architectures to improve generation efficiency. Furthermore, we adopt transfer learning to train the model for Java code generation based on the model trained for C and C++ languages to reduce training time. In summary, this paper makes the following contributions:

- We propose *Ayudante*, the first deep RL-based PM programming assistant framework, which automatically transforms volatile memory code to PM code. Our RL model mimics the behavior of expert PM programmers navigating through the input source code to add proper PM functions and instructions. We augment the RL model with Monte-Carlo tree search strategy to achieve efficient generation.
- We leverage a novel transfer learning model to transfer the PM programming semantics from the existing libraries of one programming language to another. In particular, this paper shows an example of transferring the knowledge of PM programming semantics from C/C++ to Java, saving training time for Java-based PM code generator. This approach sheds light on adapting PM code generation in various languages at low extra effort.
- We evaluate Ayudante with microbenchmarks incorporating various data structures and a key-value store application. Our results show that all the generated PM code passes PMDK checkers, with comparable performance on an Intel

Optane DC PM server as code handwritten by experts.

- Ayudante assists novice PM programmers by reducing their time and energy spent on learning new PM libraries, automating the modifications on legacy code, and facilitating bug detection and performance tuning.

2 Background and Motivation

We motivate our Ayudante framework by PM programming challenges and opportunities in deep RL.

2.1 PM Programming Common Practice

PM systems introduce a new set of programming semantics that diverges from the conventional storage systems programming. Instead of extensively relying on slow system calls to access the persistent data, programmers now directly communicate with the byte-addressable nonvolatile main memory (NVMM) using load and store instructions. As PM combines the traits of both memory and storage, PM system requires crash consistency without hurting the memory-like access performance. One common practice of PM programming is to first use a PM-aware filesystem [20, 78] to manage a large memory region in NVMM. An application can then use a direct access (DAX) `mmap()` system call provided by the filesystem to map a nonvolatile memory region into its address space. From there, the application can directly access the NVMM. This programming model is portable and achieves high performance by reducing costly system calls that are on the critical paths [34, 80].

The PM programming model avoids directly using filesystem system calls for data accesses, making it difficult to use the conventional storage system’s crash consistency and failure recovery mechanisms that extensively use system calls. As a result, PM programs need to maintain crash consistency and develop recovery mechanisms by themselves, rather than simply relying on the underlying filesystems. It is the programmers’ responsibility to provide the crash consistency along with a proper recovery mechanism. Because PM programs rely on load and store instructions to access PM, a single mis-ordered store instruction or a missing cacheline

flush and write-back may make it impossible to recover to a consistent state after a system crash. As such, PM programs need to adopt (i) cacheline flush or write back instructions to ensure that data arrives at NVMM [20] and (ii) proper memory fence instructions to maintain the correct memory ordering [20]. To simplify the crash consistency guarantee in programming, many PM libraries [17, 22, 74] support fine-grained logging of the data structure updates, checkpointing [78], shadow paging [32], or checksum [40, 62] as the most common approaches to enforce failure atomicity to guarantee the recovery of data.

2.2 Challenges of PM Programming

Despite the promising performance and portability, the PM programming model imposes substantial challenges to software programmers on ensuring crash consistency and failure recovery, debugging, and performance optimization.

Labor Efforts of Adopting PM Libraries. Each PM library, such as PMDK [17], Atlas [10], go-pmem [22], and Corundum [31], typically defines its own failure model and provides a set of new programming semantics to hide the instruction level details. Although the high-level programming semantics ease the programming burden, it is still laborious and error-prone to use those libraries as shown in Figure 3. In order for programmers to correctly use those libraries, they must learn the APIs and integrate them into the legacy code after fully understanding their own programming models.

We investigate code modification efforts of various PM programs as shown in Figure 2. It requires the change of 1547 lines of code (LOC) in order to transfer a volatile version of Memcached [28] into PM version [48] using PMDK library [17], which is 14% of the Memcached source code. Figure 2 also shows that other widely used data structures supported by PMDK require at least 15% LOC changes. It is invasive to perform such intensive modifications to a code base that is already complex and highly optimized for volatile memory operations.

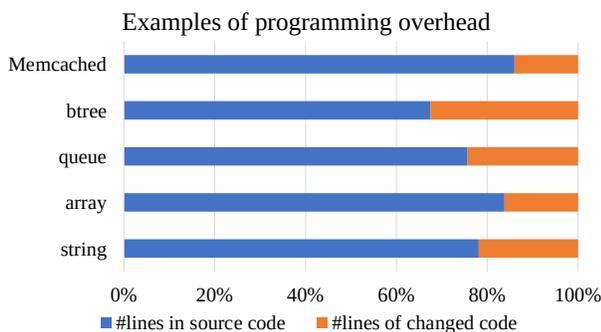

Figure 2: Proportion of lines of changed code to adopt a PM library, with PMDK microbenchmarks and a Memcached application.

Error-prone Non-expert Code and Debugging. Despite the high-level programming semantics provided by PM libraries,

writing a PM code can be error prone as shown by previous studies [44, 45, 54]. It is typically programmer’s responsibility to test and debug PM programs. Many crash consistency related bugs in PM code are hard to identify, as they may not interfere with program execution until the recovery stage after a system crash. Figure 3 shows such an example, where a programmer forgets to add a snapshot API offered by a PM library. The example executes normally but the program recovers to an undefined, non-consistent state undetected. Such bugs are not intuitive, and therefore extremely difficult to debug. Recent development of PM debugging tools leads to promising results [44, 45, 54]. However, the tools still rely on programmer’s experience and knowledge on PM to annotate or navigate through the programs find bugs, making it hard to use by non-expert programmers.

```

1 int Queue::enqueue(...) {
2     ...
3     TX_BEGIN(pop) {
4         TX_ADD_DIRECT(&queue->back);
5         queue->back += 1;
6         TOID(struct entry) entry =
7             TX_ALLOC(struct entry, sizeof(struct entry) + len);
8         D_RW(entry)->len = len;
9         memcpy(D_RW(entry)->data, data, len);
10        // the following snapshot code is missing:
11        // TX_ADD_DIRECT(&queue->entries[pos]);
12        queue->entries[pos] = entry;
13    } TX_ONABORT {
14        ret = -1;
15    } TX_END
16 }

```

Figure 3: A buggy example of enqueue implementation using PMDK. The programmer forgets to add a snapshot function, and therefore violates the crash consistency requirement.

Performance Tuning. PM programming requires the cacheline flushes and fences to ensure that data updates arrive at NVMM in a consistent manner [13, 85]. These instructions introduce performance degradation by defeating the processor’s hardware performance optimization mechanisms, including caching and out-of-order execution. Although it is generally acceptable to sacrifice certain levels of run-time performance to maintain data persistence, unnecessary cacheline flushes and fences will significantly hurt system performance, rendering undesirable deployment performance of PM in production environments. Therefore, it is essential to avoid using unnecessary cacheline flushes and fences. Furthermore, various PM libraries relax the crash consistency guarantee at different degrees for performance optimization. It is the programmers’ responsibility to cherry-pick the optimal library for their application which in turn requires a vast amount of experience and prior knowledge.

2.3 Deep RL for PM Programming

We identify deep RL as a promising technique to perform automatic PM code generation, due to its powerful learning capability in tasks with a limited amount of available training

data [21, 29]. RL [69, 70] is a category of ML techniques that tackles the decision making problems. Deep RL [21, 29, 50, 51] augments deep neural networks with RL to enable automatic feature engineering and end-to-end learning [21]. We observed that deep RL is a better solution than RL for problems with higher dimensional complexity as it does not rely on domain knowledge. Due to these promising features, deep RL is widely used in games [51, 53, 68], robotics [36, 38, 60], and natural language processing [65, 75].

No end-to-end frameworks currently exist to automatically translate a piece of volatile memory code into PM code and perform crash consistency checking. State-of-the-art PM libraries [17, 22, 27, 31, 42, 47] and debugging tools [44, 45, 54] require programmers to annotate the code. Jaaru [24] does not require programmer’s annotation but it relies on the program crash to detect bugs. It is also impractical to enumerate all the possible changes of each line of the code, while passing the checks of compilers and debugging tools. To address these issues, it is critical to automate PM code transformation, while achieving a high PM checker passing rate at a low transformation cost.

Fortunately, translating a volatile memory code into PM code can be formulated as a decision problem for sequential code editing, which is considered as solvable by deep RL. Moreover, augmented with Monte-Carlo tree search [8, 18] – a type of look-ahead search for decision making – deep RL is able to search the decision results more efficiently and effectively. Previous automatic code generation and translation studies focus on translation between different programming languages [41] and addressing debugging syntax errors [26]. To our knowledge, this paper is the first to formulate a ML-based PM program translation problem.

3 Ayudante Design

To embrace the opportunities and address the challenges described above, we propose Ayudante, a deep RL-based programming assistant framework as illustrated in Figure 1.

3.1 Ayudante Framework Overview

Ayudante consists of two key components: a deep RL-based code generator and a code refining pipeline. Our code generator takes conventional source code developed for volatile memory systems as the input and generates a vanilla PM code through a RL model. We design our RL model to mimic programmer’s behavior on inserting PMDK library annotations into the volatile version of code. In order to reduce the training time and effort, we first train our model for C/C++ code by RL, and then employ transfer learning to adapt our model to Java programs. We show that our model is generalizable to various PM programs in our test set on the open source Leetcode solution programs (Section 5). Our code refining pipeline integrates multiple PM checking and debugging tools to generate a report of syntax bugs (if any) and suggestions on run-time performance optimization. The report allows programmers to further improve and test the

code.

Ayudante offers the following promising automated characteristics in assisting PM programming:

- **Efficient PM code generation** through a deep RL model augmented with Monte-Carlo tree search, which efficiently searches the correct code edits with significantly smaller search space.
- **Reduced bugs** through a deep RL model pre-trained to avoid bugs detected by checkers in the training environment.
- **Code refining reports and improved performance** through a code refining pipeline for programmers to further inspect the possible improvements to the generated programs if necessary.

3.2 Deep RL-based Code Generator

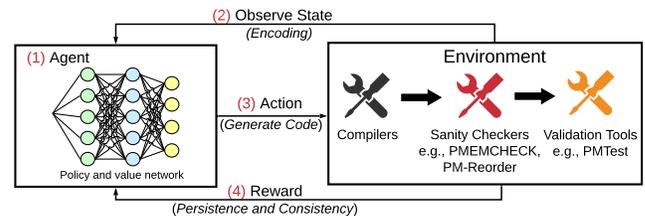

Figure 4: Ayudante’s deep RL model consists of an agent and an environment. During model training, the agent repeatedly generates and sends actions to the environment based on the rewards and states it receives.

We design a deep RL network that generates the PM code. The trained network mimics the programmer’s behavior; it navigates through the input source programs and adds proper code in the corresponding locations. Figure 4 shows Ayudante’s deep RL model, which consists of (a) an agent with a *policy and value network* and (b) an *environment*. The policy and value network responds to a state (the encoded input source code) and outputs an action (which navigates through source code and inserts PM library functions). The environment applies the action to the last code state to generate a new code state, and tests it by a set of PM code checkers to return a reward to the agent. Details of integrating various PM checkers in the environment are discussed in Section 4.4.

The model is trained on a volatile version of PMDK example code [17] (by removing PM annotations). During training, the policy and value network is updated for a better action policy according to the reward function. After training offline, the RL generator performs online inference to generate the best actions and output a PM code according to the pre-trained policy and value network. We test on the data structures from open-source Leetcode solution code [6, 61, 83]. In the following, we describe the details of our RL and transfer learning models. Section 4 will discuss detailed implementation of training and inference of our models and the datasets used for training and testing.

3.2.1 Agent, State, Action, and Reward

As shown in Figure 4, our RL model consists of four major components: agent, state, action, and reward.

Agent. An agent is an executor of actions on a state. In our model, a state is a representation of source code, while an action is navigating through source code or inserting one PM library API function to source code. The agent repeatedly obtains a new state from the environment, executes actions on the state, and re-compiles the modified code if necessary, until the model outputs a complete PM code that passes the checkers in the environment.

State. A state is a pair of *string* and *position*. A string is a source code in plain text, while a position represents the current position in the code to take an action at. To preprocess the input and make the source code recognizable by the RL model, we perform an *encoding* operation, which transforms the source code into a sequence of *tokens* to feed into the RL model. The encoding using an Encoder-Decoder long short-term memory (LSTM) autoencoder [30] to fit sequence data. Once the autoencoder fits, the encoder in the model is used to encode or compress sequence data as a feature vector input to the RL model. Each encoded token represents either the program text or a program location for an API insertion. The string is initialized in a tokenized form of the input source code. The program location token is initialized to the first token in the program. We encode the program text, augmented with the program location using an LSTM network [30] and feed the state into the policy and value network. When taking an action, the modification is executed on the original program by the environment before compilation and testing.

Action. Our RL model has two types of actions: (1) navigation, which jumps to a new program location and (2) edit, which modifies the string (i.e. modifies the source code). The two actions are non-overlapping: navigation action does not update the code, while edit action only adds a PM library API function to the current program location without changing the location. We define two navigation actions, move-down and move-out. Move-down sets the program location to the next token. Move-out moves the program location to the current curly braces. A combination of these two navigation actions allows the model to enumerate all possible insertion locations of PM library APIs.

The edit action utilizes the possible library API annotations, which we manually select from PMDK [17]. The edit action either annotates one line of code or wraps a block of source code into a pair of annotations (e.g., wrapping with `TX_BEGIN` and `TX_END`). We do not consider deletion of previous API annotations, because it is identical to do nothing in the deleted locations. The invalid edit action that causes syntax errors or bugs will be rejected by the environment and punished by the reward function.

Reward. In a typical RL model, a reward is used to measure the consequences of the actions and feedback to the agent

to generate better actions. In our training process, the agent performs a set of navigation and edit actions to the program, and receives either the maximum reward if the generated code passed all the PM checkers in the environment, or a small reward formulated as follows, which consists of three penalties – step, modification, and code error reported by checkers, respectively:

$$r_t = \phi_1 \cdot \ln S + \phi_2 \cdot \ln M + \sum_{i=1}^n \rho_i \cdot E_i \quad (1)$$

The step penalty is defined by a penalty factor ϕ_1 and a step number S . A step refers to an iteration of taking a new action and feedback the corresponding reward. In each step, the agent is penalized with a very small step penalty (with a small ϕ_1) to motivate the agent to take fewer steps.

The modification penalty is defined by a factor ϕ_2 and a modification number M . ϕ_2 penalizes unnecessary edits and encourages the RL generator to complete the PM code with fewer modifications.

The code error penalty is defined as a summation of penalties given by multiple testing tools. For tool i , ρ_i represents the impact factor of the tool (i.e. how important the tool is), while E_i is the number of errors reported by the tool. The code error penalty penalizes those actions that introduce bugs and encourages the RL model to learn to avoid the bugs detectable by the checkers in the environment. The ρ_i can be tuned to give more attention to testing tool i , so as to reduce the corresponding bugs detectable by this tool in the ultimately generated code. In our model, the number of errors E_i is a few magnitudes lower than the number of steps S . Therefore, we use $\ln S$ in the reward instead of S to balance the penalties. The same reason applies to $\ln M$.

3.2.2 An Example of RL-based Code Generation

Figure 5 shows an example PM code generated by our RL model. To generate such code in inference, our trained model takes an input of a pure C code (in black color in Figure 5) that is never seen during training. Our model encodes the code into tokens, then performs actions on the tokens as marked by arrows in Figure 5. At each step t , the agent of the model (i) retrieves a state $s_t \in S$ from the environment and (ii) selects an action a_t from all candidate actions with the maximum conditional probability value generated by the policy and value network. In Figure 5, the agent first chooses navigation actions for step ① and ②, then an edit action for step ③. At this point, as the agent changes the state (the source code), the environment executes the edit action to generate a new state s_{t+1} and a corresponding scalar reward r_t . Similarly, the agent performs edit actions at steps ⑦ and ⑩, and therefore generates a complete PM code. The generated code is further verified by the environment using a pipeline of multiple PM testing tools shown in Figure 4. In this example, the generated code passes all the tests. The code refining pipeline

(Section 3.3) will automatically generate code refining suggestions if it identifies bugs or performance degradation that requires programmer’s attention.

```

1  int64_t Queue::pop(){
2  int64_t ret = 0;
3  auto pool = pmem::obj::pool_by_vptr(this);
4  obj::transaction::run(pool, [this, &ret] {
5      if (head == nullptr)
6          throw std::runtime_error("Empty queue");
7      ret = head->value;
8      auto n = head->next;
9      obj::delete_persistent<Node>(head);
10     head = n;
11     if (head == nullptr) tail = nullptr;
12 });
13 return ret;
14 }

```

Figure 5: An example of a sequence of actions taken by the trained agent to generate PM code based on its volatile memory version.

3.2.3 Policy and Value Network

The *policy and value network* (Figure 4) determines which action to take based on an action-value function. In Ayudante, we use deep Q-learning [50, 72], a representative and widely adopted policy and value network. Q-learning is model-free and generalized not to depend on any specific RL models. In Q-learning, the function Q calculates an expected reward given a set of states and actions, which includes the reward of future subsequent actions. In Ayudante, we use deep Q-learning to combine Q-learning with a deep neural network to form a better end-to-end generator. The function Q is defined as:

$$Q(s_t, a_t) = (1 - \alpha)Q(s_t, a_t) + \alpha(r_t + \gamma \cdot \max_a Q(s_{t+1}, a)) \quad (2)$$

where t represents a time step that requires an action to be taken; s_t is a sequence of actions; a_t is the action; r_t is the reward. The decay rate is $0 \leq \alpha \leq 1$. The discount factor is $0 \leq \gamma \leq 1$. We apply such a Q function to our Deep Q Network, working as an iterative decision making algorithm outlined in Algorithm 1. The objective of deep Q-learning is to minimize $(Y - Q(\phi, a; \theta))^2$ based on sequences of actions and observations $s_t = x_1, a_1, x_2, a_2, \dots, a_{t-1}, x_t$. Here, Y represents the expected reward, while $Q(\phi; a; \theta)$ is the reward calculated from the Q function, with trainable weight parameters θ . The Q function works on fixed-length representation of code modification histories collected by function ϕ . M is the maximum number of epochs and T is the number of iteration to modify the code used to simulate the descent process, which are user-defined parameters. This process will also generate the training datasets of Q-learning, stored in a replay memory \mathcal{D} , with a maximum capacity N . When \mathcal{D} is inquired for a minibatch of transitions, it will return Y_j and $Q(\phi, a_j; \theta)$.

Algorithm 1 The policy and value network function.

- 1: Initialize replay memory \mathcal{D} to capacity N and random initialize θ
- 2: **for** epoch from 1 to M **do**
- 3: Initialize sequence $s_1 = \{x_1\}$ and $\phi_1 = \phi(s_1)$
- 4: **for** t from 1 to T **do**
- 5: With probability $< \epsilon$ select a random action a_t
- 6: Otherwise select $a_t = \max_a Q^*(\phi(s_t), a; \theta)$
- 7: Execute action a_t : navigate or insert an API
- 8: Get reward r_t , and next state x_{t+1}
- 9: Set $s_{t+1} = s_t, a_t, x_{t+1}$ and $\phi_{t+1} = \phi(s_{t+1})$
- 10: Store transition $(\phi_t, a_t, r_t, \phi_{t+1})$ in \mathcal{D}
- 11: Sample a minibatch of transitions $(\phi_t, a_t, r_t, \phi_{t+1})$ from \mathcal{D}
- 12: Set $Y_j = r_j + \gamma \max_{a'} Q(\phi_{j+1}, a'; \theta)$ for a non-terminal ϕ_{j+1} or $Y_j = r_j$ for a terminal ϕ_{j+1}
- 13: Minimize Loss $(Y_j - Q(\phi_j, a_j; \theta))^2$
- 14: **end for**
- 15: **end for**

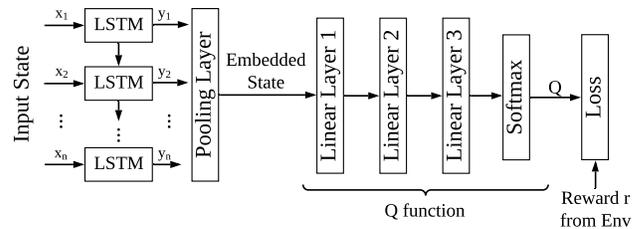

Figure 6: Neural architecture of the policy and value network.

Figure 6 shows the neural network architecture of our policy and value network. We first embed the input source code with LSTM and a pooling layer. Then, we pass the embedded state to three fully-connected layers. The Softmax function will output the Q value; the action will be selected either by maximizing the reward or with a small probability to play a random action. Finally, we calculate the loss function by the real reward r and the Q value, and update the trainable parameters θ in the Q function. Here we adopt two sets of parameters (θ and θ') in the same shape. One is for selecting an action and another one is for evaluating an action. They are updated alternatively.

3.2.4 Monte-Carlo Tree Search

Searching for correct edits is non-trivial due to two key challenges – exponentially large search space and unnecessary decision search. First, with the increase of lines of code in programs and the number of actions, the search space grows exponentially. This leads to exponential search time using uninformed search algorithms such as enumerative search [3, 4]. Second, a correct decision search requires both localize and make precise edits to generate a PM code as illustrated in

Figure 5. An invalid edit that introduces bugs leads to unnecessary decision search, if the model is unaware of such bugs and proceeds to search for new actions. To tackle the first challenge, we adopt an efficient search strategy Monte-Carlo Tree Search (MCTS) [67], which is highly efficient and effective in searching exponentially increased states. To address the second challenge, we combine the policy and value network (Section 3.2.3) with MCTS to guide selection towards potentially good states and efficiently evaluate the payout.

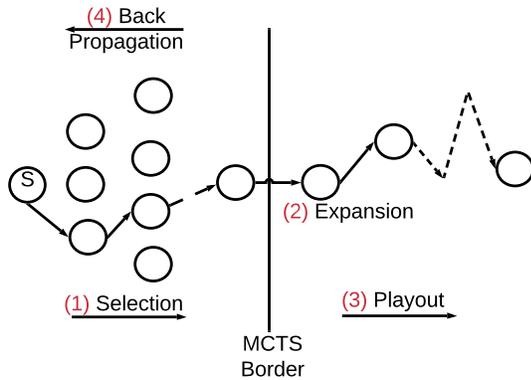

Figure 7: Overview of a simulation of Monte-Carlo tree search.

As shown in Figure 7, one round (or “simulation”) of MCTS consists of four phases. (1) **Selection** starts from the root node and selects the successive child nodes until reaching a leaf node. Here, the root node represents the current state, while a leaf node is a potential child node with at least one unexplored child (i.e., not covered by previous search). We employ a widely-used Upper Confidence Trees (UCT)-based strategy [37] to select the node with the maximum value V

$$V = q_i + c \sqrt{\frac{\ln N_i}{n_i}} \quad (3)$$

where q_i is the current action-value estimate after the i -th move; n_i is the number of simulations for the node considered after the i -th move; N_i is the total number of simulations after the i -th move run by the parent node of the one considered. c is the exploration parameter that is theoretically equal to $\sqrt{2}$; in practice, it is typically chosen empirically. The first term is high for a move that gets a high successful edits rate. The second term is high for a move with few simulations. Therefore, a large V value will lead the search to a better final solution. (2) **Expansion** unless reaches a goal state, create one or more valid child nodes. (3) **Playout** instead of evaluating the position after running a full simulation and sampling the moves until reaching a goal state in the vanilla MCTS, we approximate the value of the position by the deep Q-learning network. (4) **Back-propagation** utilizes the result from playout to update node information in reverse order.

3.2.5 Transfer Generating Knowledge of C/C++ to Java

To fully leverage the code translation knowledge learned from the RL generators for C and C++, we train a Java generator model by employing transfer learning [64]. Transfer learning is an effective technique to take features learned from one domain and leverage them in a new domain with certain similarity, to save training time and achieve higher inference accuracy on the new domain. The most commonly used transfer learning technique is fine-tuning [82], which freezes (sets as un-trainable) some layers of a pre-trained model and train the other trainable layers on a new dataset to turn the old features into predictions on the new dataset. However, the fine-tuning is a destructive process, because the new training will directly discard the previously learned function and lose the pre-trained knowledge on generating C/C++ code.

To address this issue, we employ a progressive network technique [64]. Progressive network also leverages the pre-trained models, whereas utilizing the output rather than the pre-trained parameters. Doing so overcomes the problem of discarding the prior knowledge in further training. Given a pre-trained RL generator G_j , with hidden activations $h^{(1)j} \in R^{n_i}$ from layer i , where n_i is the number of units at layer i , the progressive network utilizes a single hidden layer multi-layer perception σ to adjust different scales of various hidden layer inputs and adapt the hidden input to the new model by

$$h_i^k = \sigma(W_i^{(k)} h_{(i-1)}^k + U_i^{(k:j)} \sigma(V_i^{(k:j)} \alpha_{i-1}^{(<k)} h_{i-1}^{(<k)})) \quad (4)$$

where the $h_i^{(k)}$ is the hidden activations for layer i in task k , $W_i^{(k)}$ is the weight parameters for layer i in task k , $U_i^{(k:j)}$ are the lateral connections (a $n_i \times m_j$ matrix) from layer $i-1$ of task j to layer i of task k , $V_i^{(k:j)}$ is the projection matrix to be trained, and α is a learned scalar initialized to a small random value. The progressive network fully exploits the hidden knowledge represented by the hidden activation in multiple similar tasks in sequence.

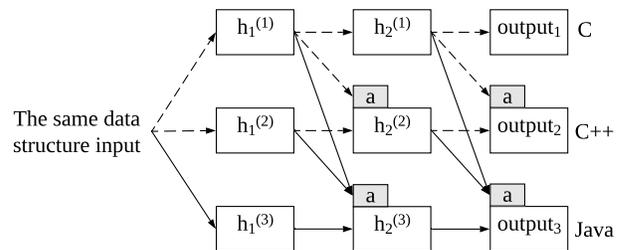

Figure 8: The workflow of the progressive network to transfer from generating C and C++ code to generating Java code, where a refers to the adaptor function shown by Equation 4.

By adopting fine-tuning and progressive networking, we take advantage of the generators for C and C++ which are well-pretrained on a sufficient training dataset and show the

potential of assisting writing PM code for other programming languages.

3.3 Code Refining Pipeline

Previous ML-based code generators pay much attention to improving the inference accuracy. Yet, even on well-investigated translation tasks (*e.g.*, CoffeeScript-JavaScript Task [14] and FOR/LAMBDA translation task [19]) on popular programming language (*e.g.*, C/C++/JAVA/Python), state-of-the-art deep learning models only achieve up to 70% ~ 90% inference accuracy [14, 19]. Due to the inherent fuzzy and approximate nature of deep learning, it is impossible to achieve 100% accuracy for all generated programs only by an ML model, let alone many complicated bugs that require programmer’s domain knowledge to detect and fix.

To address the limitations of ML-based method, we design a code refining pipeline to search for bugs that may remain in the code generated by the RL model. As shown in Figure 4, we incorporate a set of code refining tools in three levels: (1) *compilers* check on the syntax and library API usage bugs; (2) *sanity checkers*, including PMEMCHECK and PM-Reorder [17], check on the consistency and reordering bugs; (3) *validation tools*, including PMTest [45], XFDetector [44], and AGAMOTTO [54], perform a deep bug search in terms of crash consistency and failure recovery. We organize these tools as a pipeline to ensure that high-level bugs (*e.g.*, syntax bugs) are identified as early as possible before starting the time-consuming deep bug search. The output of the code refining pipeline is a code refining suggestion report for programmers to further manually inspect the code.

Figure 9 shows an example output of our code refining pipeline. In this example, the vanilla generated code is called `node_construct` followed by a `pmemobj_persist`. Our code refining pipeline identifies that `node_construct` already persists the tree node data. Therefore, there is no need to persist it again. This optimization suggestion is reported to the programmer, who decides to remove the redundant persistence API call, leading to the improved code.

```

Vanilla generated code
int node_construct() {
// set up btree node
...
pmemobj_persist(pop, node,
a->size);
// persist data
}

void btree_insert() {
// set up btree structure
...
POBJ_ALLOC(..., node_construct);
pmemobj_persist(pop, dst, args.size);
// duplicated persistence
}

Improved code
int node_construct() {
// set up btree node
...
pmemobj_persist(pop, node,
a->size);
// persist data
}

void btree_insert() {
// set up btree structure
...
POBJ_ALLOC(..., node_construct);
}

```

Figure 9: A piece of B-Tree code improved by the code refining pipeline.

4 Implementation

4.1 Training and Testing Dataset

We are the first to develop both training and testing datasets for ML-based PM code translation problems. We preprocess the datasets by including header files, creating the pool file (memory-mapped file) and initializing the root object for further read and write operations.

Training Set. We use the dataset from the PMDK library [17] with 18 C code examples, 14 C++ programs, and two Java programs. Because the PMDK example code is the nonvolatile version expert code, we obtain a volatile version of each program by manually discard the PMDK APIs in the code.

Testing Set. To show the generalization ability of our model, we test it with code never seen by the model and measure how well the model generates for such new code in the inference process. Our testing dataset consists of volatile code of 48 C programs, 42 C++ programs, and 13 Java programs obtained from the open-source Leetcode solution [6, 61, 83]. These programs perform similar functionality as PMDK example programs on various data structures widely used in persistent memory applications, including array, string, list, queue, btree, rbtree, hashmap, and combinations of multiple data structures.

4.2 Training Configuration

Deep RL Implementation. We implement the RL generator in PyTorch [58]. We identify the suitable hyper-parameters of the RL generators and update the weight parameters in the policy and value network in the training process. In particular, the LSTM encoder in our model has two recurrent layers, each with 128 cells. The *string* has on average 112 tokens, which are embedded into 48-dimensional vectors. The LSTM encoder for state embedding and the policy network are trained together in an end-to-end manner. We set the decay rate $\alpha = \frac{K}{K+T}$ to achieve the temporal decay, with $K = 10$ and T as the epoch number. We set the discount rate γ as 0.95. For the reward function, when using different checkers, the relative relationship between step, modification, and code error penalties can be different. In our model, we set step penalty factor ϕ_1 as -0.01 and modification penalty factor ϕ_2 as -0.005 . For the impact factor of each tool in the code error penalty, we set $\rho_1 = -0.1$ and $\rho_2 = -0.06$ and $\rho_3 = -0.065$ for PMEMCHECK, PM-Reorder and PMTest respectively. We set the maximum reward as 1. We train the RL generator on two Nvidia GeForce GTX 2080 Ti GPUs with 11 GB Memory for 60 epochs.

Transfer Learning Implementation. The progressive network is also implemented in PyTorch [58], and trained on two NVIDIA GeForce GTX 2080 Ti GPUs with 11GB Memory for 30 epochs. We use a dynamic learning rate scheduler in PyTorch with an initialization of 0.001 for progressive networks.

4.3 PMDK APIs

PMDK [17] is a collection of libraries developed for PM programming. These libraries build on the DAX feature that allows applications to directly load and store to PM by memory-mapping files on a PM-aware file system. We employ the *libpmobj* library, which provides a transactional object store, memory allocation, and transactions with atomicity, consistency, isolation, and durability for PM systems. We pick 21 library functions (such as `pmobj_persist`, `pmobj_create`, `pmobj_open`) and 78 macros (such as `TOID`, `POBJ_ALLOC`, `D_RW`, `D_RO`, `POBJ_ROOT`). For C++ code, we employ *libpmobj-cpp*, a C++ binding for *libpmobj*, which is more approachable than the low-level C bindings. For Java code, we use persistent collections for Java based on the *libpmobj* library.

4.4 Checkers

We use checkers in both the *environment* of our RL model and the code refining pipeline. As illustrated in Figure 4, the checkers are organized into three levels. First, we use compilers (such as `gcc`) to detect syntax errors. Second, we use sanity checkers, such as `PMEMCHECK` and `PM-Reorder`, to detect consistency and reordering bugs. Finally, we use high-level validation tools, such as `PMTest` [45], `XFDetector` [44], and `AGAMOTTO` [54], to further capture durability and ordering violations in PM operations, cross-failure bugs [44], and redundant cache line flushes and fences [54].

As demonstrated in Section 5.1, the more checkers used, the higher the PM checker passing rate and robustness. However, increasing the number and complexity of checkers also leads to a much longer training time. Therefore, we only use `PMTest` [45] in the *environment* in RL model training. The code refining pipeline adopts all three aforementioned high-level validation tools one after another to validate a program generated by our RL model. As these are independent of each other, the order of running the tools does not matter. In the following, we discuss the implementation details of integrating various checkers in *Ayudante*.

Compilers. We adopt `gcc` version 7.5.0. as the compiler in this paper.

PMEMCHECK. `PMEMCHECK` is a persistent memory analysis tool that employs the dynamic memory analysis tool `Valgrind` [55], to track all stores made to persistent memory and inform programmers of possible memory violations. Other than checking and reporting the non-persistent stores, `PMEMCHECK` also provides other options to look out for memory overwrites, redundant flushes, and provides transaction checking such as check stores that are made outside of transactions or regions that overlapped by different transactions. Here we mainly feedback the error number from the error summary reported by `PMEMCHECK` to the reward in the model.

PM-Reorder. `PM-Reorder` is another tool for persistence correctness checking. It will traverse the sequences of stores

between flush-fence barriers made by the application, and replays these memory operations many times in different combinations, to simulate the various possible ways the stores to the NVDIMM could be ordered by the system. Given an exhaustive consistency checking function, this process will uncover potential application bugs that otherwise could have been encountered only under specific system failures. It provides various optional checking orders, such as *ReorderFull* to check all possible store permutations, *ReorderPartial* to check 3 random order sequences, *ReorderAccumulative* to check a growing subset of the original sequence. Here we mainly use *ReorderPartial* to achieve consistency checking while keeping training efficiency. `PM-Reorder` requires users to provide a user-defined consistency checker, which is a function that defines conditions necessary to fulfill the consistency assumptions in source code and returns a binary value (0 represents consistent and 1 represents inconsistent). With each value in a data structure, *Ayudante* provides a default consistency checker, which determines whether each value field is properly assigned compared to the number that we store in the value field [59]. For example, if the main function sets nodes 0, 1, and 2 of a list as 100, 200, and 300, *Ayudante* will provide a consistency checker that traverses these three nodes to evaluate whether their corresponding values are correctly assigned or not. Here we mainly leverage the inconsistency number reported by `PM-Reorder`.

PMTest. `PMTest` is a fast and flexible crash consistency detecting tool, which reports violations in durability and ordering of PM operations, such as whether a persistent object has been persisted, ordering between persistent updates, and unnecessary writebacks or duplicated logs. With C/C++ source code, *Ayudante* automatically generates annotations using the C/C++-compatible software interface offered by `PMTest`, including (i) wrapping the entire code with `PMTest_START` and `PMTest_END` functions and (ii) using `TX_CHECKER_START` and `TX_CHECKER_END` to define the boundary of each transaction as required by the `PMTest` high-level checkers. These annotations will be removed after testing the generated code. We use the high-level checkers to validate three items: (1) the completion of a transaction, (2) the updates of persistent objects in the transaction are recorded in the undo log before modification, and (3) the code is free of unnecessary writebacks or redundant logs that constitute performance bugs. An issue with (1) or (2) will be reported as a `FAIL`, while issues with (3) are identified as `WARNINGS`. During the training process, we use the number of `FAILS` from `PMTest` as feedback to the neural network. In the refining pipeline, we use the `WARNING` information to suggest code refining on removing the redundant writebacks and logs.

XFDetector. `XFDetector` detects cross-failure bugs by automatically injecting failures into a pre-failure execution; it also checks cross-failure races and semantic bugs in the post-failure continuation. With C/C++ source code, *Ayudante* generates the annotations by wrapping the

Table 1: Intel server system configuration.

CPU	Intel Cascade Lake engineering sample 24 Cores per socket, 2.2 GHz 2 sockets, HyperThreading off
L1 Cache	32KB 8-way I\$, 32KB 8-way D\$, private
L2 Cache	1MB, 16-way, private
L3 Cache	33MB, 11-way, shared

DRAM	DDR4, 32GB, 2666MHz, 2 sockets, 6 channels per socket
NVRAM	Intel Optane DIMM, 256 GB, 2666 MHz 2 sockets, 6 channels per socket
Kernel	Linux 5.1
Software	GCC 7.1, PMDK 1.7

code with `RoIBegin(1, PRE_FAILURE|POST_FAILURE)` and `RoIEnd(1, PRE_FAILURE|POST_FAILURE)` functions offered by XFDetector’s C/C++-compatible interface to define the region-of-interest (RoI); such annotations will be removed after code testing.

AGAMOTTO. AGAMOTTO detects persistency bugs using two universal persistency bug oracles based on the common patterns of PM misuse of C++ code: it identifies (i) modifications to PM cache lines that are not flushed or fenced; (ii) duplicated flushes of the same cache line or unnecessary fences. AGAMOTTO symbolically executes PM workloads to identify bugs without requiring annotations.

5 Evaluation

Experimental Setup. Table 1 shows configuration of the Intel server adopted in our experiments. We configure the Optane DIMMs in App Direct interleaved mode [33] and employ ext4 filesystem in DAX mode. We disable hyper threading and boost the CPUs to a fixed frequency to maintain a stable performance. We run each program 10 times and report the geometric mean.

5.1 PM Checker Passing Rate in Inference

We employ PM checker passing rate (CPR) defined in Equation 5 – the percentage of generated code that passes all the PM checkers – to measure the generalization ability of the trained model.

$$CPR = \frac{\#PassCheckers}{\#Generated} \quad (5)$$

In our experiments, we use PMEMCHECK as the checker to verify the PM CPR in inference. We train three versions of RL generators with various checker combinations in the environment, including (1) PMEMCHECK; (2) PMEMCHECK and PM-Reorder; (3) PMEMCHECK, PM-Reorder, and PMTest. separately and Table 2 shows the CPR in inference tested on microbenchmarks, a key-value store application, and Leetcode solution set. Our results show that all the

generated code of RL generator with checker combinations (2) and (3) passes the checkers with the key-value store workload testing and microbenchmarks incorporating array, string, list, queue, btree, rbtree, and hashmap data structures. Our experiments also show that Ayudante can handle programs with multiple data structures. For example, the Leetcode solution for merging k -sorted lists [7] adopts both `list` and `queue` data structures; the generated code makes both data structures persistent and passes the PMEMCHECK checker. Moreover, we observe that the more checkers used to feedback the reward, the higher CPR is achieved in inference. This is because checkers will complement each other to penalize different types of bugs and encourage more precise edits on the source code to avoid the bugs. Note that none of the existing ML-based models can achieve 100% inference accuracy due to the inherent approximate nature of ML. However, our method improves the CPR in inference by effectively taking advantage of different checkers in the training process and the refining pipeline to further report the testing and show improvement suggestions.

Table 2: The PM CPR in inference and the average percentage lines of code (LOC) changes, compared among using various checkers in the environment during training process of deep RL-based code generator.

Testing Set	Checkers in Environment	CPR	LOC
Microbenchmarks and KV store application	PMEMCHECK	87.5%	12.3%
	PMEMCHECK & PM-Reorder	100%	13.4%
	PMEMCHECK & PM-Reorder & PMTest	100%	13.8%
Leetcode solution	PMEMCHECK	60.2%	12.5%
	PMEMCHECK & PM-Reorder	62.1%	13.1%
	PMEMCHECK & PM-Reorder & PMTest	78.7%	13.4%

5.2 Execution Performance

We also evaluate the execution performance of the generated code under various input sizes by running the programs on an Intel Optane DIMM server configured as Table 1. We show the memory bandwidth performance in Figure 10a and Figure 10 on `lists`, `array`, `queue`, and `btree` microbenchmarks. As shown in Figure 10a, the generated code achieves a similar bandwidth compared with expert code provided by PMDK code examples. We also employ `perf` [25] to profile the last level cache load, store, and data TLB (dTLB) load events. As shown in Figure 10, the generated code has a cache and TLB performance comparable to PMDK. Although `lists` has a higher number of (30%) LLC store events due to unnecessary persistence API calls, it does not significantly affect the overall program execution performance.

We further evaluate the scalability of generated code by investigating the performance with different input sizes. Figure 11 shows that the bandwidth of the generated code is comparable to PMDK examples. Therefore, our code generator

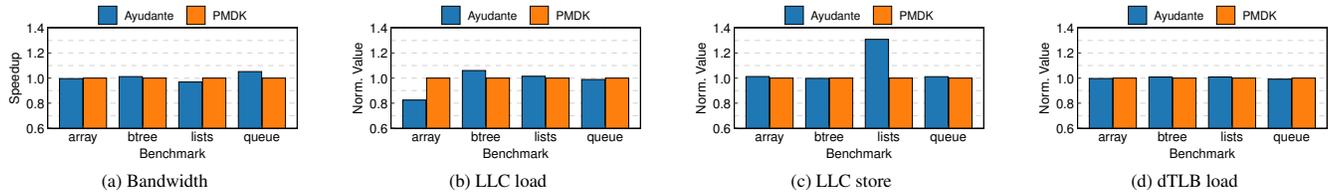

Figure 10: Performance evaluation of code generated by Ayudante, on bandwidth, LLC load, LLC store, and dTLB load on Intel server with Optane DC PM. The bandwidth is calculated based on the modified data structure size. Numbers are normalized to corresponding PMDK microbenchmark performance.

is highly stable and reliable in generating high-performance PM code.

5.3 Bug Avoidance and Reduction

Ayudante employs two mechanisms to avoid and reduce both syntax and performance bugs.

Avoidance. During the training process, we utilize the checkers to penalize our model from buggy edits to avoid bugs in the generated code. We use PMEMCHECK to penalize non-persistent stores and misused transactions. We adopt PMReorder to penalize in-consistency stores. We employ PMTest to penalize non-persistent objects, wrong ordering, and redundant logs. As an example in practice, we observe 17 non-persistent errors in an intermediate code state during the training process; after training, all the bugs are eliminated after step-by-step searches and edits. This also demonstrates that the RL generator is able to help to debug.

Reduction. Beyond the sanity checks using PMEMCHECK and PMReorder, we also design a code refining pipeline to further perform deep bug search and code refining suggestions generation. An example is shown in Section 3.3 to demonstrate the results of the code refining pipeline.

5.4 Labor Effort Reduction

We evaluate the reduction of programming labor effort with average lines of code (LOC) changed as shown in Table 2. In our experiments, the percentage of LOC changes is typically 12% ~ 15%, which significantly reduces the labor effort on developing PM applications. We test the LOC of three different versions of models by adopting different numbers of checkers. Intuitively, more checkers leads to more robust generated code, hence more APIs inserted to guarantee consistency; this results in more LOC changes. However, the difference of the total LOC is small among different versions of models, while our models bring significant CPR improvement as demonstrated in Table 2.

6 Discussion

Limitations of ML-based Approaches. Due to limitations of ML as discussed in Section 3.3, it is impossible for an ML model to achieve 100% inference accuracy with all programs due to the inherent fuzzy nature of ML [11, 14, 19]. In fact, inference accuracy improvement remains a critical challenge in ML community [23, 49]. To address the accuracy limitation,

Ayudante’s code refining pipeline effectively reduces user efforts on debugging and optimizing the generated programs.

Limitations of PM Checkers. Ayudante relies on PM checkers during model training to provide rewards and in the code refining pipeline to provide code optimization suggestions. Therefore, the capability of PM checkers is critical to the quality of code generated by Ayudante. So far, none of the existing PM checkers detects all PM bugs or programming issues. Ayudante addresses the issue by adopting a three-level checking process, which incorporates multiple PM checkers, to generate the rewards during RL model training (Section 4.4); different checkers complement each other during training. As demonstrated in Table 2, the more checkers used, the higher the PM checker passing rate and robustness. Furthermore, our code refining pipeline adopts multiple high-level validation tools, such as XFDetector [44], and AGAMOTTO [54], to further detect bugs that are not captured in training. Once more comprehensive PM checkers are developed by the community, we can retrain our model by replacing the current PM checkers to further improve PM code generation and refinement.

7 Related Work

To our knowledge, this is the first paper to design an ML-based automatic PM program assistant. This section discusses related works.

PM Programming Tools. Prior works focused on developing PM debugging and testing tools [44, 45, 54], programming libraries and APIs [10, 17, 22, 31, 74]. The tools are helpful for PM programming. However, these tools require users to manually write PM code from the scratch, which is challenging for non-expert programmers and tedious and time-consuming work for expert programmers as discussed in Section 2. Recent works also explored user-friendly libraries and high-level programming semantics for converting the data structures developed for volatile memory into PM programs [27, 42, 47]. Concurrent work TIPS [39] goes further and provides a systematic framework to convert DRAM-based indexes for the NVMM with plug-in APIs to plug-in a volatile index and facade APIs to access the plugged-in index. However, Ayudante focuses on automatically generate PM code by inserting library API functions in the source code. As such, Ayudante is orthogonal to these libraries and programming semantics;

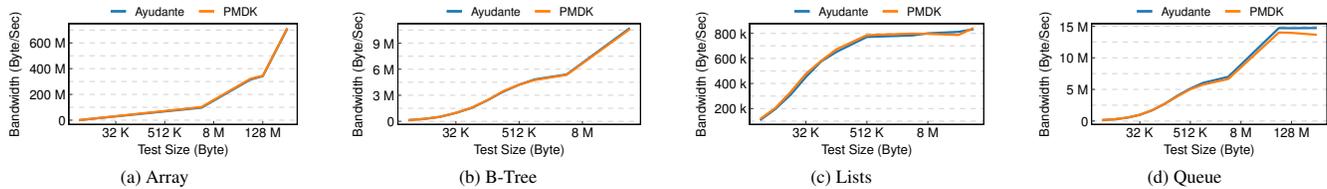

Figure 11: Bandwidth comparison between Ayudante generated code and PMDK microbenchmarks on the Intel server.

the model can also be trained based on such libraries as a substitute or complementary of PMDK.

Conventional Code Translation. Code translation problem on popular and familiar programming language, *e.g.*, C/C++/Java/C#/Python/Go, has been well investigated [2, 43, 46, 57, 71]. Previous tasks focus on adding annotation and source-to-source code translation can be categorized as 3 main folds: (1) Adding specific annotations to achieve certain constraints. An example is parallelization annotation, annotating to a program with proper statements that are required by parallel computing libraries and make the source program can run on parallel hardware, *e.g.*, OpenCL [71], CUDA [57] and OpenMP [43]. (2) translate between different types of source code. Such as source-to-source compilers LLVM [46] to translate between C and C++ by first compiling source code to LLVM bitcode then decompiling the bitcode to the target language. (3) translate code between different versions of one programming language. For example, python’s 2to3 tool [2] translates from python version 2 to version 3 by parsing the program to abstract syntax tree then translate it. Though transcompilers are preferred among the software developers for its definite transformation process, it suffers from tremendous developing labor efforts and is error-prone.

ML-based Program Generation. To model the edits to transform code into a target code, one needs to learn the conditional probability distribution of the target code version given the source code. A good probabilistic model will assign higher probabilities to plausible target versions and lower probabilities to less plausible ones. Neural Machine Translation models (NMT) are a promising approach to realize such code edit models and use distributed vector representations of words as the basic unit to compose representations for more complex language elements, such as sentences and paragraphs, *e.g.*, the sequence-to-sequence (Seq2Seq) models [35, 79] and word embedding [9, 12, 56]. However, code edits also contain structural changes, which requires the model is syntax-aware. To overcome the rigid syntax constraints in programming language, recent studies leverage tree-to-tree LSTM encoder-decoder on abstract syntax tree for program statements translation [11, 14]. However, these work are either rule-based that requires additional knowledge of the programming languages, such as grammar [11, 52, 66, 81, 84], or applying a model to implicitly learn the translation policies [14, 81] that require enough training dataset to achieve the high inference performance, which is challenging to apply to a new task without

training dataset.

8 Conclusions

We propose Ayudante, a deep reinforcement learning based framework to assist persistent memory programming. Ayudante provides a deep RL-based PM code generator that mimics programmers behavior to add proper PM library APIs to the volatile memory-based code. Ayudante also provides a code refining pipeline that reports code improvement suggestions to the programmers, to help reduce bugs and improve run-time performance. Ayudante utilize a novel transfer learning to transfer PM programming semantics from C/C++ to other languages like Java. We evaluate Ayudante with microbenchmarks of various data structures which pass all code refining pipeline checkers and achieve comparable performance to expert-handwritten code. Ayudante significantly reduce the burden of PM programming, and shed light on machine auto programming for PM and other domains.

TIPS: Making Volatile Index Structures Persistent with DRAM-NVMM Tiering

R. Madhava Krishnan Wook-Hee Kim Xinwei Fu Sumit Kumar Monga
Hee Won Lee* Minsung Jang† Ajit Mathew‡ Changwoo Min
Virginia Tech Samsung Electronics* Peraton Labs†

Abstract

We propose TIPS— a framework to systematically make volatile indexes persistent. TIPS neither places restrictions on the concurrency model nor requires in-depth knowledge of the volatile index. TIPS relies on novel *DRAM-NVMM tiering* to support an index-agnostic conversion, durable linearizability and its concurrency model called the *tiered concurrency* to achieve a good performance, scalability. TIPS proposes a hybrid low overhead logging technique called the *UNO logging* to guarantee crash consistency and to handle persistent memory leaks across crashes. We converted seven volatile indexes with different concurrency models and the Redis key-value store application using TIPS and evaluated them using YCSB. Our evaluations show that TIPS-enabled indexes outperform the state-of-the-art index conversion techniques PRONTO, NVTraverse, RECIPE, and the NVMM-optimized B+Tree indexes (BzTree, FastFair), Hash indexes (CCEH and Level Hash) and Trie (WOART) indexes by 3-10× while supporting strong consistency and index-agnostic conversion.

1 Introduction

Indexes are a fundamental building block in many storage systems, and it is critical to achieving high performance and reliability [34, 47]. With the advent of Non-Volatile Main Memory (NVMM), such as Intel Optane DC Persistent Memory [10, 52], there have been a numerous number of research efforts targeted towards developing NVMM-optimized indexes [5, 11, 13, 26, 30, 36, 42–44, 53–56, 58, 59, 63, 65, 66]. Such index designs mainly focus on reducing the crash consistency overhead by primarily relying on index-specific optimizations to improve the overall performance.

However, maturing and hardening an index requires a lot of time and effort. For example, recently proposed NVMM indexes have critical limitations, such as (1) weaker consistency guarantee [23, 37], (2) not handling memory leaks in the wake of a crash [11, 26, 36, 53, 66], (3) limited concurrent access [13, 27, 36], and (4) not supporting variable-length keys [13, 26, 55, 65]. Most of these missing features are critical in real-world systems and it delimits the adoption of these indexes to the real-world applications without further maturing.

Alternatively, there are decades of research on in-memory DRAM indexes [16, 39, 45, 47, 60] which are well optimized, engineered and used in many real-world applications such as

in-memory key-value stores and databases [18, 19, 32, 57]. If we can leverage these in-memory DRAM indexes for NVMM, it not only gives a large pool of well-engineered indexes but it will also pave way for the real-world applications built on top of these indexes to use and adopt NVMM. The challenges in building an NVMM-optimized index has lead to a spike in the interest to port legacy DRAM applications, particularly in-memory key-value stores [1–4, 6, 7, 46, 49]. However, prior works [6, 46, 49] report that manual porting is complex, and error-prone requiring a lot of engineering effort. So we believe that *it is important to provide a systematic way to convert DRAM-based indexes for the NVMM.*

A few recent studies have proposed techniques [50, 62] or guidelines [15, 21, 23, 37] to convert volatile indexes to NVMM. Unfortunately, these techniques have some critical limitations such as (1) limited applicability due to restrictions on the concurrency control (*e.g.*, supporting only lock-free indexes) [15, 21, 23, 37, 50], (2) supporting a weaker consistency guarantee (*i.e.*, buffered durable linearizability) [23, 37, 62], (3) requiring in-depth index-specific knowledge [15, 21, 23, 37], (4) high performance and storage overhead due to their crash consistency mechanism [23, 50, 62], and (5) not addressing persistent memory leaks [15, 21, 23, 37, 62]. We further discuss the limitations of these techniques in §2.

To address these problems, we propose TIPS— an index-agnostic framework to systematically make a volatile DRAM index persistent, while supporting (1) wider applicability by not placing any restrictions on the concurrency model of an index, (2) strong consistency model (*i.e.*, durable linearizability), (3) index-agnostic conversion without requiring in-depth knowledge on a DRAM index, (4) low overhead crash consistency mechanism, (5) safe persistent memory management (*e.g.*, no persistent memory leak), and in addition to achieving (6) high performance and good multicore scalability. This paper makes the following contributions:

- We propose a novel *DRAM-NVMM data tiering approach* and its concurrency model called the *tiered concurrency* to achieve good performance, scalability, and applicability.
- We propose a low overhead hybrid logging technique called the *UNO logging* to guarantee crash consistency, to prevent memory leaks and to guarantee durable linearizability.
- We propose the TIPS *framework* based on these approaches. TIPS provides index-agnostic conversion and does not place any restrictions on the concurrency model or require in-depth knowledge of the volatile index being converted.

*†The authors contributed to this work while they were at AT&T Labs Research. ‡The author is currently in Amazon.

- We converted seven volatile indexes with different concurrency models, a real-world key-value store Redis and evaluated them using YCSB [14]. Our evaluation shows that TIPS outperforms the state-of-the-art index conversion techniques and the NVMM-optimized indexes by 3-10× across the different YCSB workloads.

2 Background and Motivation

We discuss the limitations of existing conversion techniques and their implications below:

(1) Restrictions on Concurrency Control. All prior techniques have limited applicability; *i.e.*, they are designed to support only a specific concurrency model. For example, NVTraverse [21] and link-and-persist [15] are designed for lock-free indexes while MOD [23] is designed for purely functional data structures. PRONTO [50] is applicable only to the globally blocking indexes (*e.g.*, protected by a global mutex) while RECIPE [37] guidelines apply only to the indexes that support lock-free or fine-grained locking.

(2) Supporting Weak Consistency. Another limitation is that most techniques [23, 37, 62] support only a weaker consistency; A linearizable DRAM index converted using these techniques will support only a weaker consistency model, Buffered Durable Linearizability (BDL) [29]. Linearizability has been the standard consistency model in DRAM indexes for almost three decades [25]. Its NVMM counterpart is Durable Linearizability (DL) [29], and it plays a critical role in ensuring the correctness and consistency of the NVMM index and data. Indexes with a BDL guarantee can experience a large amount of data loss in the wake of a crash. Moreover, it increases the programming complexity as the developers are burdened with reasoning about the data consistency. This makes the conversion process complex and more error-prone; for instance, many fundamental and non-trivial crash consistency bugs have been found in the RECIPE indexes [21, 22].

(3) Requiring In-depth Knowledge. Many techniques [15, 21, 23, 37] require in-depth knowledge of the volatile index and expertise in NVMM programming to apply their guidelines correctly. Such efforts are non-trivial as even missing a single sfence or a clwb may render an index irrecoverable.

(4) High Storage and Performance Overhead. Many techniques suffer from high storage and performance overhead [23, 50, 62] mainly due to their crash consistency mechanism. For example, PMThreads [62] requires two full replicas (one each on DRAM and NVMM) of the original data. MOD [23] uses Copy-on-Write (CoW) to guarantee crash consistency. Such a high storage overhead might be acceptable for primitive data structures (*e.g.*, stack, vector). However, it can be detrimental for indexes and real-world key-value stores designed to handle a large volume of data. Although PRONTO [50] uses operational logging for crash consistency and employs a dedicated background thread for every writer to perform the logging, it still incurs a high overhead due to

the synchronous waiting between the writers and background threads. We further empirically analyze these overheads in §7.

(5) Persistent Memory Leaks. Another critical but a largely understated problem is the persistent memory leaks. While the prior conversion techniques and the NVMM-optimized indexes focus on providing crash consistency, they completely ignore the memory leak problem. Although NVMM allocators can guarantee failure atomicity for allocation/free even the mature allocator such as the PMDK [28] does not provide an efficient solution to identify and fix the memory leak [17]. Hence it is critical to address this within the TIPS framework.

3 Overview of TIPS

We first discuss our design goals followed by the design overview. We assume that an index being converted has key-value store style operations such as insert, delete, update, lookup, and scan. Throughout this paper, we address insert, delete and update as writes, and lookup and scan as reads. The term *plugged-in index* denotes a user-defined volatile index on NVMM that is plugged into TIPS framework. We assume that locks can be reinitialized after crash recovery.

3.1 Design Goals

G₁ Support Various Concurrency Models. We aim not to place restrictions on the concurrency model of the volatile indexes. With TIPS, we support the conversion of indexes that use a global lock (*e.g.*, Mutex), lock-free (*e.g.*, CAS), and fine-grained locking (*e.g.*, ROWEX [39]).

G₂ Support Durable Linearizability (DL). The challenge to guarantee DL in TIPS is to achieve it without compromising the performance, scalability, and index-agnostic conversion.

G₃ Support Index-agnostic Conversion. We aim to support near black-box, index-agnostic conversion to circumvent the need for in-depth knowledge on the volatile index and NVMM programming. This will make the conversion process simple, intuitive, and less error-prone. We aim to achieve this by internally handling the complications of NVMM programming such as guaranteeing crash consistency and preventing persistent memory leak within TIPS and also providing an uniform programming interface to assist the conversion.

G₄ Design a Low Overhead Crash Consistency mechanism. TIPS can not rely on index-specific optimizations for crash consistency to support an index-agnostic conversion. The crash consistency mechanism should incur low overhead to achieve high performance and scalability. A crash consistency mechanism also should prevent persistent memory leaks by reclaiming the unreachable objects upon recovery.

G₅ Achieve High Performance and Scalability. Ideally, we aim to perform and scale on par with NVMM-optimized indexes. Also, we strive to retain the original characteristics of the plugged-in index; for example, if the volatile index is designed for cacheline efficiency or optimized for scalability, we aim to retain and leverage such characteristics to improve

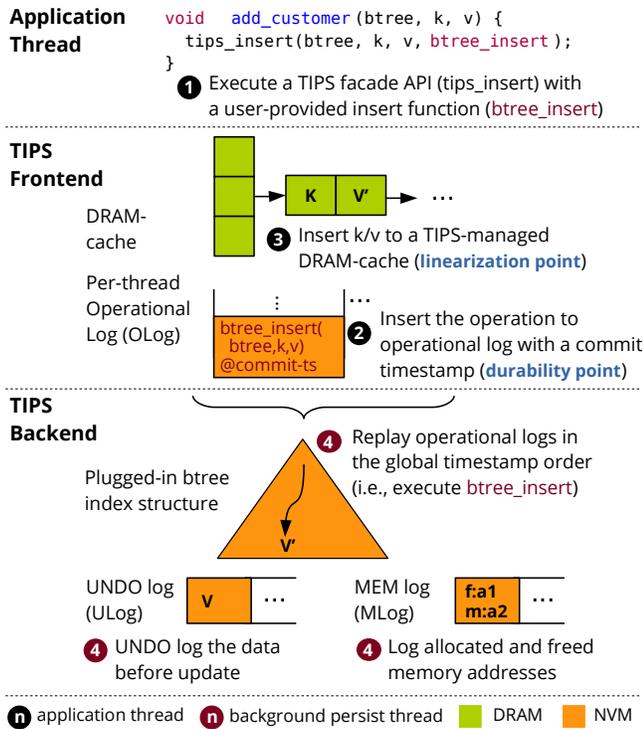

Figure 1: Illustrative example of inserting a key-value pair in TIPS.

the overall performance and scalability of a TIPS index.

3.2 Design Overview

3.2.1 High-Level Idea of TIPS

Figure 1 presents the TIPS architecture and illustrates how a write operation is handled in the TIPS framework. TIPS frontend consists of a hash table on DRAM (DRAM-cache) and an operational log (OLog) on NVMM. TIPS backend consists of the plugged-in index – the user-provided volatile index – a background thread (persist-thread), UNDO log (ULog), and MEM log (MLog). When a write is issued (①), TIPS first commits it to the per-thread OLog for guaranteeing durability (② - durability point) and then inserts a new key-value pair entry (or a tombstone for deletion) in the DRAM-cache to make the write visible (③ - linearization point). Then the persist-thread in the TIPS backend (④) replays the same write in the background to update the plugged-in index. To guarantee crash consistent update to the plugged-in index, TIPS uses ULog to store the unmodified data for recovery. Once the plugged-in index is updated, the corresponding key-value entry in the DRAM-cache will be reclaimed later.

Alternatively, a lookup operation first looks for the target key in DRAM-cache and it goes to the plugged-in index only if the target key is not present in DRAM-cache. With this high-level idea, we next present the design overview of TIPS and also explain how it contributes towards achieving our design goals discussed in §3.1.

3.2.2 DRAM-NVMM Tiering (G_1, G_2, G_3, G_5)

At its core, TIPS adopts a novel DRAM-NVMM data tiering approach. As illustrated in Figure 1, two critical components that enable the DRAM-NVMM tiering are DRAM-cache in the TIPS frontend and plugged-in index in the TIPS backend. Although prior NVMM-optimized B+tree index designs [42, 55] and conversion techniques [50, 62] have proposed to use both NVMM and DRAM, our approach is fundamentally different. For example, PRONTO [50] builds the index on DRAM and logs the index operations on the NVMM to guarantee durability. Such a tiering design limits PRONTO indexes from scaling beyond the DRAM capacity. Instead, in TIPS, we propose tiering of the data (i.e., key-value pairs) while keeping the plugged-in index intact on the NVMM.

Benefits. (1) Tiering the data between DRAM-NVMM makes our approach *generally applicable* to any index. This enables all the TIPS indexes to take advantage of the faster DRAM. (2) Unlike PRONTO, TIPS can achieve a better capacity scaling by keeping the plugged-in index on the NVMM. (3) The writes are made visible through DRAM-cache (③ in Figure 1); this enables TIPS to guarantee DL agnostic of the plugged-in index. (4) On top of DRAM-NVMM tiering, we build the *plug-in programming model* to enable index-agnostic conversion (§3.2.6). (5) Tiering the data enables a new concurrency model called the *tiered concurrency*, which is key to achieving high performance and scalability.

3.2.3 Tiered Concurrency for Scaling Frontend (G_1, G_5)

Having TIPS frontend and backend enables two different levels of concurrency: (1) concurrency model of the DRAM-cache and (2) concurrency model of the plugged-in index. We call this a *tiered concurrency model*. TIPS frontend allows parallel readers and parallel disjoint writers as DRAM-cache is a concurrent hash table and OLog is per-thread. In the critical path, all requests succeeding in the TIPS frontend (all writes and read hits) will follow the concurrency model of DRAM-cache, and the operations that go to the TIPS backend (read misses and scan) will follow the concurrency model of a plugged-in index. Also, the background writes (④ in Figure 1) to the plugged-in index is done off the critical path adhering to concurrency model of the plugged-in index.

In a nutshell, to achieve write scalability TIPS restricts writes to the faster frontend (DRAM-cache and per-thread OLog) and for read scalability, it relies on both the DRAM-cache and the concurrency model of the plugged-in index. Range scans always go to the plugged-in index as it requires full key-value data (see details in §4.1.6). Relying on the plugged-in index for read/scan helps TIPS to reduce the DRAM footprint as it does not need to cache the entire dataset in DRAM-cache. Instead, it can reclaim the keys once the plugged-in index is updated.

Benefits. (1) Even if the plugged-in index supports only blocking concurrency (e.g., mutex), it can still leverage the

```

1 /* TIPS facade API to use a TIPS-enabled index */
2 bool tips_insert(void *ds, key_t k, value_t v, fn_insert_t *f);
3 bool tips_update(void *ds, key_t k, value_t v, fn_update_t *f);
4 bool tips_delete(void *ds, key_t k, fn_delete_t *f);
5 value_t *tips_lookup(void *ds, key_t k, fn_lookup_t *f);
6 value_t *tips_scan(void *ds, key_t start_key, int range,
7                   fn_scan_t *f);
8
9 /* TIPS plug-in API to implement a TIPS-enabled index */
10 bool tips_u_log_add(void *addr, size_t size);
11 void *tips_alloc(size_t size);
12 void tips_free(void *addr);

```

Figure 2: TIPS facade APIs to access a TIPS-enabled index, and plug-in APIs for plugging-in a volatile index to TIPS.

DRAM-cache to process all the writes and read hits concurrently to achieve good performance. (2) Unlike the previous techniques [15, 21, 37, 50], it does not place any restrictions on the concurrency model of the volatile indexes and hence any volatile index can be plugged-in to the TIPS framework.

3.2.4 Adaptive Scaling for Backend Scalability (G_5)

The backend writes are slower than the frontend as it writes to the NVMM. This can cause an imbalance in the system; to prevent this, we propose adaptive scaling of background writers (workers) for scaling the TIPS backend. With adaptive scaling, TIPS continuously monitors both the frontend and backend write throughput, and when there is an imbalance it scales up the worker count to catch up with the faster frontend and vice versa. While scaling up, TIPS identifies the best worker count based on the write scalability of the plugged-in index and it caps the scale-up at that count to get maximum performance. Also, the real-world workloads are rarely 100% writes, so the time between writes and the adaptive scaling can help the backend writers to catch up with a faster frontend.

Benefits. (1) It effectively utilizes the write concurrency of the plugged-in index. (2) Unlike PRONTO [50] which demands a dedicated worker for every foreground writer, TIPS can dynamically adjust the worker count based on nature of the workload and the plugged-in index.

3.2.5 UNO Logging for Crash Consistency (G_4)

To achieve a low overhead index-agnostic crash consistency, we propose the *UNO logging protocol*, which makes a hybrid and synergistic use of traditional UNDO logging and Operational logging. In TIPS, we use operational logging (OLog) to guarantee immediate durability and UNDO logging (ULog) to ensure failure-atomicity while updating the plugged-in index. The unique aspect of *UNO* logging lies in how we leverage the OLog to reduce the notorious UNDO logging overhead and also reduce the number of p-barrier (c1wbs followed by sfence) by batching the recurring updates to the same cache line and consequently achieve a low overhead crash consistency. Furthermore, MEM Log (MLog) internally logs all the allocated and freed addresses and TIPS uses this information to identify and free all the unreachable memory upon recovery to prevent memory leaks and defers the actual memory free operations until OLog entries are

```

1 void hash_insert(hash_t *hash, key_t key, val_t value) {
2     node_t **pprev_next, *node, *new_node;
3     int bucket_idx;
4     pthread_rwlock_wrlock(&hash->lock);
5     // Find a node in a collision list
6     // Case 1: update an existing key
7     if (node->key == key) {
8         // Before modifying the value, backup the old value
9 +     tips_u_log_add(&node->value, sizeof(node->value));
10        node->value = value; // then update the value
11        goto unlock_out;
12    }
13    // Case 2: add a new key
14    // Allocate a new node using tips_alloc
15 +    new_node = tips_alloc(sizeof(*new_node));
16    new_node->key = key; new_node->value = value;
17    new_node->next = node;
18    // Backup the prev node before modifying it
19 +    tips_u_log_add(pprev_next, sizeof(*pprev_next));
20    *pprev_next = new_node; // then update then the node
21    unlock_out:
22    pthread_rwlock_unlock(&hash->lock);
23 }

```

Figure 3: Code snippet of a TIPS-enabled hash table insert. Only three lines are modified in the original code; Lines 9, 19 for UNDO logging and Line 15 for persistent memory allocation.

consumed to prevent double-free bugs.

Benefits. (1) Using OLog requires only *two p-barriers* in the critical path for all write operations; *one p-barrier* to persist a OLog record and *one* more to persist the tail pointer (§4.1.5). This makes the durability guarantee cheap and consequently a better performance (§7.2, §7.4). (2) TIPS alleviates the UNDO logging overhead by leveraging the OLog information to selectively log only the memory required for correct recovery besides the merit that UNDO logging in TIPS is performed by the background workers (§4.3.2). (3) With MLog TIPS handles the persistent memory leaks with its framework instead of delegating it to the users.

3.2.6 Plug-In Programming Model for Index-agnostic Conversion (G_2)

The plug-in programming model provides two sets of APIs as shown in Figure 2: (1) plug-in APIs to plug-in a volatile index to the TIPS framework and (2) facade APIs to access the plugged-in index. The facade APIs internally manage the OLog and DRAM-cache without requiring any user intervention (steps ①, ②, ③ in Figure 1). With the facade APIs, the plugged-in index implementation should be passed as a function pointer *f* which is used by TIPS to update the plugged-in index. To guarantee crash consistent updates to the plugged-in index, the developers must modify their index implementation using TIPS plug-in APIs. The modifications are simple, as shown in Figure 3: (1) replacing the volatile memory allocation (and free) with `tips_alloc` (and `tips_free`) and (2) adding `tips_u_log_add` before modifying/writing to an NVMM address. TIPS will execute this modified code (e.g., `hash_insert` in Figure 3) during the background reply.

By replacing the `malloc` with `tips_alloc`, the plugged-in index will now be allocated on the NVMM, and `tips_alloc` will also capture all the newly allocated address in the MLog to prevent persistent memory leaks. The developer

added `tips_u_log_add` would ensure crash consistency while updating the plugged-in index, and TIPS internally optimizes the UNDO logging (§4.3.2) for better write coalescing and performance. Moreover, a developer is not required insert p-barriers to the volatile codebase manually. Instead, they just need to annotate the stores to NVMM with `tips_u_log_add`. Thus, LoC changes in the plugged-in indexes are minimal, as shown in Table 2. While the developers still have to add the `tips_u_log_add` manually, they need not handle the persistence/visibility order as in the case of manually inserting p-barriers, and this makes the conversion easy and less error-prone. Note that updates to the newly allocated addresses (in Memlog) and existing addresses (in ULog) are batched and persisted internally by TIPS before reclaiming the respective logs. More details on this in §4.3.

4 Design of TIPS

We first describe the TIPS frontend design in §4.1, followed by the TIPS backend design in §4.2.

4.1 TIPS Frontend Design

4.1.1 DRAM-cache

The DRAM-cache is a concurrent open chaining hash table. Concurrent writers working on the different buckets are allowed to proceed in parallel while the ones working on the same bucket are synchronized using a spinlock. Readers do not need any synchronization (*i.e.*, lock-free reads) as all writes to DRAM-cache are performed via a single atomic store. DRAM-cache also employs a RCU-style epoch based reclamation scheme for garbage collection. We choose open chaining hash table to guarantee $O(1)$ writes and avoid expensive rehashing in the critical path. We discuss the configurations for chain length and bucket size in §6 and §7.

4.1.2 Handling Write Operations

All write operations are first committed to the OLog to guarantee durability, and then a new entry is created and added to the DRAM-cache to make the writes visible. For delete, the entry also carries a tombstone mark for the readers to identify that it has been deleted logically. To make writes faster, the entries are always added at the head of a bucket. We explain how TIPS guarantees Durable Linearizability (DL) in §5.

4.1.3 Handling Lookup Operation

Readers first traverse the DRAM-cache bucket looking for the target key. As the collision chain is sorted by the arrival order of write requests, the readers can stop at the first match instead of traversing the entire chain. If the key is not present, then TIPS internally redirects the readers to the plugged-in index using the function pointer provided in the `tips_lookup` call. Scan operations require traversing the plugged-in index and the OLog to return a consistent result. We further describe it in §4.1.6 after introducing the OLog design.

4.1.4 Safe Reclamation

Since all writes happen in the DRAM-cache, the collision chain can proliferate and result in a high chain traversal overhead. To address this, we employ a background garbage collector thread called the gc-thread. When the chain length of a bucket exceeds the preset threshold, the gc-thread is triggered, which then visits the respective bucket and safely reclaims the entries. To ensure safe reclamation of entries *i.e.*, without impacting the concurrent readers, TIPS employs an epoch-based reclamation scheme, which is widely used in lock-free and RCU-based data structures [20, 24, 48, 61]. TIPS manages two types of epochs: (1) local epoch, which is the global epoch value when readers enter the critical section, and (2) global epoch, which is advanced when all active readers in the current epoch exit the critical section.

The gc-thread first logically reclaims entries by unlinking them from the collision chain and storing them in the free-list. The reclaimed entry then becomes invisible to new readers. Note that the gc-thread logically reclaims the entries that are successfully replayed, so upon a read miss, readers can still retrieve the reclaimed entries from the plugged-in index. To determine if there are any outstanding readers on the logically reclaimed entries, the gc-thread checks the local epoch of all the active readers. If the local epoch is the same as the global epoch, *i.e.*, no outstanding readers from the previous epoch exist; then the gc-thread physically frees the entries in the free-list that are logically reclaimed two epochs ago. Note that the gc-thread atomically modifies the collision chain, so the readers and writers are free to enter the critical section without waiting for reclamation to finish.

4.1.5 Operational Log (OLog)

OLog guarantees durability to the write operations executed on the DRAM-cache. An OLog record consists of the operation type (insert, delete or update), the respective function pointer to the plugged-in index logic, key, value, and a global timestamp (`commit-ts`) to denote the commit order of an operation. OLog is a circular buffer where new entries are always added at the tail. The atomicity for an OLog write is guaranteed by its tail pointer update. Once an OLog record is written and persisted, the tail pointer is atomically updated to point to the new record, followed by persisting the tail pointer.

4.1.6 Handling the Scan Operations

Algorithm. The scan operation in TIPS is always directed to the plugged-in index, as it requires a full range of keys and values. However, the plugged-in index is not guaranteed to be up-to-date since the persist-thread might still be propagating some of the updates that might potentially fall within the scan range. So, after scanning the plugged-in index, TIPS traverses the OLogs looking for any potential keys that might fall within the scan range. Upon finding any, the scan buffer is adjusted to incorporate not yet propagated operations.

Traversing OLog. To minimize the OLog traversal over-

head, we leverage the commit timestamp of each OLog record (`commit-ts`) and the timestamp when a scan operation starts (`scan-ts`). While traversing the OLog, the scan thread compares its `scan-ts` with the `commit-ts`. If the `commit-ts` \leq `scan-ts`, then the scan thread reads the key information in the OLog record and checks if it falls within the scan range. It is safe to ignore OLog records with `commit-ts` $>$ `scan-ts` because these are in the future with respect to the scan thread, so it can stop traversing the OLog. Refer to §5 for correctness. Traversing the OLog is fast and adds only a negligible overhead for three reasons: (1) We partially traverse not-yet-propagated OLog entries stopping at the first future entry. (2) As the persist-thread continuously propagates the updates, there will not be much backlog in the OLog. (3) Finally, the scanning of OLog is a sequential read operation on the NVMM, which is almost as fast as reading from the DRAM [64]. We verify this empirically in §7.3.

4.2 TIPS Backend Design

The primary role of the TIPS backend is to combine and replay the per-thread OLog on the plugged-in index. To guarantee correct replay order, the persist-thread combines the per-thread OLog entries, and then it spawns the required number of background workers, which replays the combined entries to the plugged-in index. The persist-thread decides the required worker count on-fly using the adaptive scaling algorithm. The following subsections explain each of these steps in detail.

4.2.1 Adaptive Scaling of Background Workers

TIPS automatically adjusts the number of workers at every epoch based on the write scalability of the plugged-in index and the nature of the workload. One epoch (e) is defined as one iteration of combining and replying the OLog entries. We denote W_{e+1} as the worker count for the next epoch $e + 1$.

At every epoch e , TIPS calculates the foreground throughput (F_e), which is the number of OLog entries produced by application threads during the epoch, and the background throughput, which is the number of OLog entries consumed by the worker threads during the epoch. TIPS calculates the processing rate R_e , which is F_e/B_e . It aims to maintain R_e close to 1 by adjusting the number of workers (W_{e+1}).

If $R_e > 1$, the foreground writers are filling up the OLog at a faster pace, and if this situation persists, it will lead to blocking of writers as the workers are slow in clearing up the OLogs. So TIPS will increase W_{e+1} by a predefined step Δ aiming to improve the B_e and keep up with F_e .

If $R_e < 0.5$, workers are clearing up the OLogs faster than foreground writers fill them up. Employing excess number of workers is a waste of CPU, so TIPS decreases W_{e+1} by Δ .

Finally, if $1 < R_e < 0.5$, TIPS considers that the workers are on par with foreground writers and hence maintains the same number of workers (*i.e.*, $W_{e+1} = W_e$).

TIPS maintains a user-configurable upper bound (W^{up}) and a lower bound (W^{low}) to cap the number of workers (W_e)

while scaling up and down respectively. In addition, while scaling up, TIPS memorizes the best performing worker count (W^{max}); so that if W_e reaches the upper bound TIPS can fall back to W^{max} and continue until scaling down is needed.

By default, TIPS sets W^{low} to 0 and W^{up} to the number of physical cores. TIPS uses a smaller Δ when the worker count is small (*i.e.*, $\Delta = 1$ when $W_e < 4$) and uses a bigger Δ when the worker count is large (*i.e.*, $\Delta = 4$ when $W_e \geq 4$).

4.2.2 Concurrent Replay of OLog Entries

After deciding the number of workers, persist-thread combines the per-thread OLog entries and adds them to the per-worker queue. To avoid copy overhead, TIPS maintains only a pointer to the OLog record in per-worker queue.

There are two key invariants that must be maintained in the combining process: (1) Since the OLog records are replayed concurrently, it is essential to maintain the correct ordering, especially for non-commutative operations (*e.g.*, `insert(k1, v)` and `delete(k1)`). For commutative operations (*e.g.*, `insert(k2, v)` and `delete(k3)`), the replay can be done in any order without violating the correctness. (2) The OLog can not be reclaimed until all the entries in the per-worker queues are consumed. For (1), TIPS uses hashing to ensure that all the non-commutative operations will be placed in the same worker-queue. After combining, persist-thread spawns W_e workers. Then each worker sorts the entries in the timestamp (`commit-ts`) order and replays them to the plugged-in index. This ensures that non-commutative operations are always executed by the same worker in their exact order of arrival. For (2), persist-thread waits until the end of the current epoch to safely reclaim the OLog (see the details in §4.3.3).

4.3 UNO Logging

In this section, we describe the design of ULog and MLog. Similar to OLog, the atomicity of ULog and MLog writes is guaranteed by atomic tail pointer update. Both ULog and MLog are protected using a global Readers-Writer lock.

4.3.1 Memory Log (MLog)

What to log? All the newly allocated and freed addresses are recorded in the MLog along with a tag to denote if the address is allocated or freed. Also, each allocated address carries a timestamp (`alloc-ts`) to denote the time at which the particular address is allocated. TIPS memory allocation APIs internally use PMDK allocator. PMDK not only guarantees failure atomicity for memory allocation and free but also atomic persistence of a variable that stores the NVMM heap address [28]; TIPS passes an address in MLog to the PMDK memory allocation API that guarantees the address pointing to the allocated memory is persisted when returning from the API. Similarly, PMDK memory free guarantees atomic persistence for an address that is set to NULL. During recovery, all the non-NULL addresses with the “allocated” tag in MLog are deemed to be non-reachable. Such addresses are freed to avoid memory leaks as the insert operations that created these

addresses will be re-executed again from the OLog. Similarly, it is possible to re-execute the same OLog entry more than once; This can cause a double-free bug if a crash happens amidst a delete operation. To avoid this, TIPS logically removes the address from the plugged-in index, stores it in the MLog, and defers the actual memory free until the subsequent OLog reclamation. Because after reclaiming the OLog, the delete operation can not be re-executed again.

A running example. Suppose that inserting (or deleting) a key triggers split (or merge) on the leaf node A in a B+ tree, and a new leaf node A' is allocated (or the existing A freed). Say a crash happens before the completion of split (or merge) but after allocating A' (or freeing A). During the recovery, TIPS will re-execute the same insert (or delete) from the OLog, and it once again allocates a new leaf node A" (or free A again). This scenario leads to a persistent memory-leak of A' (or double-free of A). With the MLog, TIPS can reclaim the previously allocated node A' (or restore node A) during recovery to avoid persistent memory leak (or double-free).

4.3.2 UNDO Log (ULog)

What to log? ULog is used by the worker threads to guarantee failure-atomic updates to the plugged-in index. Generally, all the addresses that are being modified are required to be logged in the ULog. Instead, in TIPS, we leverage the OLog information to selectively log only the addresses that are needed for correct recovery. To decide whether to log a given address, the workers rely on two timestamp information: 1) the time at which the requested address is allocated (`alloc-ts`) and 2) the time of last OLog reclamation (`reclaim-ts`). If the requested address has its `alloc-ts` > `reclaim-ts` (*i.e.*, the address is allocated after the last OLog reclamation), then the operation to recreate the contents of this address is guaranteed to be present in the OLog. Hence the workers skip the UNDO logging. Otherwise, the workers first check if the requested address is already logged due to any previous write request. If so, the workers will skip the UNDO logging; else, they record the contents of the requested address in the ULog. The persist-thread defers the persistence of addresses in the ULog until the subsequent ULog reclamation. Thus, recurring updates to the same address can be batched and persisted at the start of every ULog reclamation.

A running example. Say a B+ tree node A is being modified 500 times between two ULog reclamations. Then a worker will log A in the ULog at the time of its first modification and reuse the same record until the next ULog reclamation. After the 500th update, say a ULog reclamation is triggered; the persist-thread before reclaiming the ULog will persist A with its latest update. If a crash happens before persisting A, during the recovery, TIPS correctly spots and reverts node A to the state before its first modification from the ULog. Then it re-executes all the 500 updates from the OLog to bring A to its latest state before the failure.

4.3.3 UNO Logging Reclamation

Log reclamation is triggered when any of OLog or ULog reaches their preset capacity threshold. The persist-thread always reclaims all the logs together even if only one of them reaches its capacity threshold. That is because, in TIPS, the information required for a correct recovery is distributed across all three logs. The reclamation yields for two cases; it waits until the (1) current epoch of background replay to end, and (2) pending scans to finish traversing the OLog. The UNO logging reclamation consists of the following two steps:

Step 1. Flush the addresses in the ULog and MLog. First, all the addresses in the ULog and MLog are persisted by calling `p-barrier`. This guarantees that all the writes that occurred since the last UNO reclamation are persisted.

Step 2. Reclaim the logs. Replayed OLog entries and persisted ULog entries in Step 1 are obsolete; they can be safely reclaimed to free up space for the incoming writes. Since the OLog has been reclaimed; we no longer required to keep track of the allocated and freed addresses; so the logically reclaimed addresses stored in the MLog are physically freed and then the MLog space can also be safely reclaimed.

Crash safety of reclamation. The reclamation procedure is crash-safe. The crash safety is guaranteed by *atomically setting the `flush_done` flag after the completion of Step 1*. Upon a crash, the recovery procedure first checks the `flush_done` flag. If the flag is set, it means that Step 1 has been completed successfully before the crash occurred and this guarantees that all the updates to the plugged-in index are persisted. Hence the recovery simply reclaims the remaining logs (Step 2) and terminates. If the flag is unset, then a standard recovery procedure described in the following section is followed.

4.4 Recovery

TIPS flushes all the logs and sets the tail pointer of the UNO log to NULL upon a safe termination. Therefore, if the tail is non-NULL upon a TIPS restart, it triggers the recovery procedure. If `flush_done` is set, recovery proceeds as described in the previous section. Otherwise, the recovery consists of three steps; (1) replay ULog to set the index to the exact consistent state that existed at the last UNO reclamation; (2) free all the newly allocated addresses (before the crash) from the MLog to prevent persistent memory leaks; (3) replay the OLog to get to the last successfully committed update before the crash. Note that the logs are replayed only up to their tail pointers to avoid executing any partial writes during the recovery.

If a crash occurs during the ULog replay (Step 1) or MLog free (Step 2), TIPS can continue from where it left off. This is because the changes to the plugged-in index due to ULog replay are immediately persisted. Also, freeing MLog after ULog replay does not affect the persistent state of the index. As described in §4.3.1, freeing MLog entries is guaranteed with atomic persistence to NULL, making this step failure-safe. On the other hand, if there is a crash while executing OLog

entries (Step 3), TIPS treats it similar to the failure during normal execution; *i.e.*, after rebooting, TIPS re-executes all the three steps. Because replaying OLog during recovery is treated similar to replaying the OLog in the background during normal execution. Note that re-executing OLogs after the ULog and MLog replay is idempotent, so it does not affect the consistency of the plugged-in index.

5 Correctness of TIPS

Theorem 1. TIPS guarantees Durable Linearizability (DL).

Proof. To guarantee DL, TIPS must satisfy three main invariants: (1) Effect of a committed operation can not be undone in the face of a crash. For all the non-commutative operations (*e.g.*, `insert(k1,v)`, `delete(k1)`), (2) the order of commit (*i.e.*, OLog write), and visibility (*i.e.*, DRAM-cache write) must always be maintained; and (3) also the background replay must be performed in the linearization order—in the same order as the operations are made visible in the TIPS frontend.

For (1), the effect of a write operation is visible only after updating the DRAM-cache entry, which is strictly done after persisting the OLog record. This guarantees that the readers will never observe the effects of non-durable write. For (2), the commit and the visibility order for non-commutative operations are synchronized using the per-bucket spinlock in the DRAM-cache as such operations is always guaranteed to happen on the same DRAM-cache bucket. A writer acquires the lock and commits its operation in the OLog with a timestamp (`commit-ts`). Then it adds the entry in the DRAM-cache and releases the lock, which guarantees that the order of commit and visibility is always the same for non-commutative operations. For (3), as described in §4.2.2, TIPS uses hashing to ensure non-commutative operations always go to the same worker queue. Then the worker sorts its queue in the `commit-ts` order and updates the plugged-in index to maintain the linearization order. For commuting operations, maintaining the linearization order is not required as they work on disjoint keys, so the effect of such operations will be the same regardless of the order in which they are executed.

By guaranteeing DL, TIPS eliminates the possibility of non-trivial crash consistency bugs as found in the previous work RECIPE [37]. Particularly, TIPS avoids the dirty read bugs as unpersisted writes are never visible to readers as guaranteed by (1). Even if certain reads are served from the DRAM-cache and say a crash happens, the OLog reply during the recovery will ensure that the plugged-in index is up to date with all the committed writes that happened before the crash. This ensures that all the pre-crash reads are still valid as they can be retrieved from the plugged-in index. □

Theorem 2. TIPS guarantees DL for scan operations.

Proof. A scan operation in TIPS traverses both the plugged-in index and the OLog, and then it merges the results. The DL guarantee can be violated if (1) the scan thread reads a

partially written OLog entry and (2) if it reads the unpersisted tail pointer. Both these cases can result in loss of data if a crash happens because of reading non-durable data. To avoid (1), the scan thread traverses the OLog from head to tail and this will hide any ongoing OLog writes as the failure atomicity of an OLog write is guaranteed by atomically updating the tail pointer (§4.1.5). To avoid (2), the scan thread before starting its traversal, checks if the tail pointer is persisted. If yes, it starts traversing; else, it backs off and retries. □

6 TIPS Implementation

TIPS is written in C, and the core library is about 5000 LoC. We use the hardware clock (`rdtscp` in x86 architecture) for scalable timestamp allocation. To address the clock skew between the CPU cores, we use ORDO [31] as done in many other previous works [33, 35]. Note that ORDO does not require any hardware extensions. We set the maximum DRAM-cache chain length to 5 beyond which the `gc`-thread starts reclaiming the applied entries in the chain. We chose this number after carefully considering the DRAM/NVMM random read performance ratio; random read latency in NVMM is about $5\times$ slower than DRAM [64] so that traversing more than 5 nodes in the collision chain do not pay off.

7 Evaluation

We evaluate TIPS by answering the following questions: (1) How do TIPS perform against prior conversion techniques (§7.2)? (2) How do the TIPS-indexes perform against prior NVMM-optimized indexes (§7.3)? (3) How do the TIPS-indexes scale for different workloads (§7.4)? (4) What is the sensitivity for DRAM-cache and UNO logging size (§7.5)? (5) How does TIPS impact real-world application (§7.6)?

Evaluation Platform. We use a system with Intel Optane DC Persistent Memory (DCPMM). It has two sockets with Intel Xeon Gold 5218 CPU with 16 cores per socket, 512GB of NVMM (4×128 GB) and 64 GB of DRAM (4×16 GB). We used GCC 8.3.1 with `-O3` flag to compile benchmarks and ran all our experiments on Linux kernel 4.18.16.

Configuration. We used YCSB [14]—a standard key-value store benchmark (Table 1) for all our evaluations. We used `index-microbench` [60] to generate the YCSB workloads. We ran the benchmarks for 32 million keys; we first populate an index with 32M keys and then run the workloads, which performs 32M operations. We use random integer and string keys with uniform distribution. We also evaluate the TIPS for large datasets and Zipfian distribution in §7.4. We preset the size of our per-thread OLog and the global ULog to 32MB each, the DRAM-cache to cache 25% of the total number of keys (300 MB) and the upper bound for the number of workers (W^{up}) to 32 (*i.e.*, half of the available CPUs). We present the sensitivity analysis for these configurations in §7.5. To ensure a fair comparison, we carefully chose the indexes as the existing conversion techniques are specific to certain concurrency

models. We also ported all the indexes to use the PMDK memory allocator. Porting all the RECIPE [37] and NVTraverse [21] indexes with PMDK allocator incurred about 1800 LoC. For all our evaluations (unless mentioned specifically), we use 32 threads to match the maximum physical CPU cores (without hyperthreads) available on our platform and present the scalability results for all the TIPS-indexes in §7.4.

7.1 Converting Volatile Index using TIPS

Converting an index using TIPS is simple (§3.2.6), and it requires only minimal LoC changes as shown in Table 2. For all the indexes, we replace the memory allocation (and free) with `tips_alloc` (and `tips_free`). Below we discuss how we annotated the NVMM stores with `tips_uolog_add`.

Index with Single Pointer Updates. Indexes for which write operations involve updating only a single pointer such as a Hash Table (HT), BST, and CLHT requires a `tips_uolog_add` before updating the HT/BST/CLHT node in the insert and delete logic, similar to the example shown in Figure 3. The lock-free indexes (LFHT/LFBST) use atomic Compare and Swap (CAS) and we added a `tips_uolog_add` before the CAS logic such that `tips_uolog_add` will be called again upon a CAS retry. Note that repeated UNDO logging will neither impact the correctness nor the performance as TIPS performs UNDO logging for an address only at the time of its first modification (§4.3.2). All such conversions require only 5-8 lines of change to the existing volatile codebase (Table 2).

Index with Multi-Pointer Updates. For the indexes like the B+tree or ART `tips_uolog_add` is added to backup the B+Tree/ART node before the triggering node split/merge operation. Also, `tips_uolog_add` is added before modifying the B+Tree/ART node in the normal case insert and delete logic. Totally it required only 11 and 9 LoC changes in the B+tree and ART codebase respectively. Note that none of the indexes require any modification in their read and scan logic.

Comparison with other Conversion Techniques. PRONTO [50] requires developers to manually add `op_begin()` and `op_commit()`. With NVTraverse [21] developers must first modify the index implementation to a "traversal" index and then manually add the `ensureReachable` and `makePersistent` APIs. Similar to the `tips_uolog_add` (§3.2.6), the aforementioned APIs will internally issue p-barrier without requiring any user intervention. Additionally, unlike PRONTO and NVTraverse, TIPS can be used on indexes supporting different concurrency models. Like TIPS, both PRONTO and NVTraverse formally prove that their conversion yields correct persistent algorithm by guaranteeing DL. As also reported in the NVTraverse paper,

YCSB Workload	Read-Write-Scan %	Workload Nature
A	50-50-0	Write Intensive
B	95-5-0	Read Intensive
C	100-0-0	Read Only
D	95-5-0	Read Latest
E	0-5-95	Short Range Scan

Table 1: Characteristics of YCSB workloads.

Indexes	Concurrency Control	LoC
Hash table (HT)	Readers-writer lock	5/211
Lock-Free HT (LFHT) [51]	Non-blocking reads and writes	5/199
Binary Search Tree (BST)	Readers-writer lock	5/203
Lock-Free BST (LFBST) [12]	Non-blocking reads and writes	5/194
B+tree	Readers-Writer lock	8/711
Adaptive Radix Tree (ART) [40]	Non-blocking reads/blocking writes	9/1.5K
Cache-line Hash Table (CLHT) [16]	Non-blocking reads/blocking writes	8/2.8K
Redis [8]	Blocking reads and writes	18/10K

Table 2: Lines of code (LoC) to convert volatile indexes using TIPS.

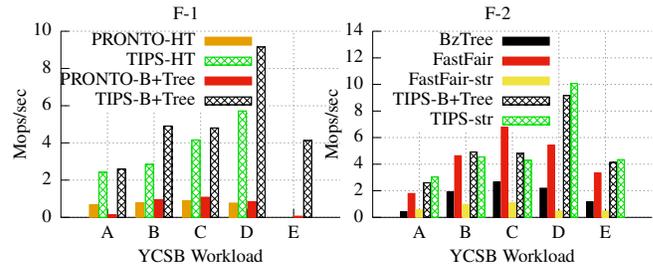

Figure 4: Performance comparison of TIPS against PRONTO for Hash Table (HT) and B+Tree (F-1) and TIPS-B+Tree against the NVMM-optimized B+Tree indexes— FastFair and BzTree (F-2).

RECIPE [37] can not always guarantee a correct conversion, even for the indexes that fall under their prescribed condition.

Moreover, RECIPE does not formalize the guarantees of their conversions and does not discuss the implications of guaranteeing BDL. Their updated ArXiv version [38] prescribes to selectively add p-barrier to specific loads to guarantee DL. But it is left to the developers to figure out the loads that needs to be correctly flushed; this further complicates the conversion. Alternatively, TIPS requires only minimal and simple modifications in the volatile codebase. We also formally describe how our conversion guarantees DL and yields a correct persistent algorithm for all our conversions.

7.2 TIPS vs. Other Conversion Techniques

TIPS vs. PRONTO [50]. PRONTO is the state-of-the-art technique to convert globally blocking indexes with DL guarantee. As shown in Figure 4 (F1), both TIPS-HT and TIPS-B+Tree outperform the PRONTO counterparts by 20× across all workloads. Although both TIPS (TIPS-HT, TIPS-B+Tree) and PRONTO use RW lock for concurrency, TIPS can process the reads and writes concurrently in the DRAM-cache, and hence it shows a better performance. Also, PRONTO's overhead mainly comes from the synchronous waiting of writers for its background thread to complete the logging. Our performance profiling on the PRONTO-HT reveals that about 25% of the execution time is spent on synchronous waiting. In TIPS, there is no such synchronous waiting as it does not have any separate logging threads. Instead, writers will perform logging in their private OLog. Another source of overhead is the blocking during snapshots, which accounts for 8% of the execution time. Moreover, PRONTO builds its index on DRAM, so it can not scale beyond the DRAM capacity while TIPS can scale up to the NVMM capacity. This is a critical design benefit because legacy applications adopt NVMM not

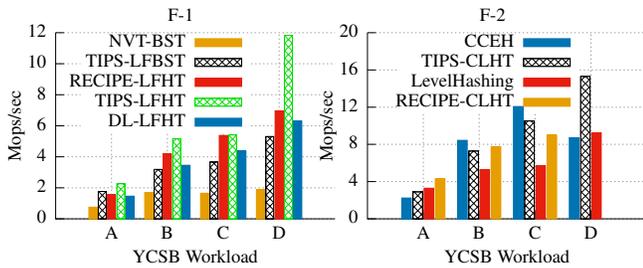

Figure 5: Performance comparison of TIPS with NVTraverse (F-1), RECIPE (F-1, F-2) and TIPS-CLHT with NVMM-optimized hash indexes—CCEH and LevelHashing (F-2).

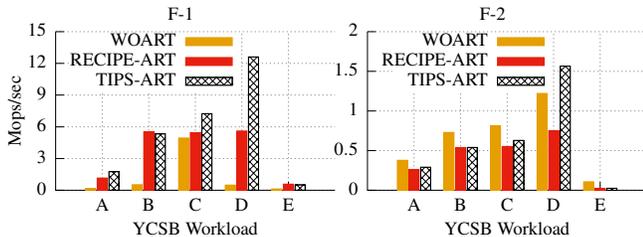

Figure 6: Performance comparison of TIPS-ART with RECIPE-ART and WOART for 32 threads (F-1) and 1 thread (F-2).

just for durability but also for its large in-memory capacity.

TIPS vs. NVTraverse [21]. NVTraverse is the state-of-the-art technique to convert lock-free indexes with DL guarantee. As shown in Figure 5 (F-1), TIPS-LFBST outperforms NVT-BST by up to $3\times$ across all workloads. Further analysis revealed that on average, each read and write in NVT-BST incurs 6 and 17 p-barriers, respectively, in the critical path. While TIPS-LFBST incurs only 2 p-barriers for each write in the critical path and reads never require p-barrier, thanks to the UNO logging and the DRAM-cache. Moreover, TIPS serves up to 25% of read requests from the DRAM-cache. So the readers do not need to traverse the BST on the NVMM for 25% of its read requests and hence a better performance.

TIPS vs. RECIPE [37]. Comparing TIPS and RECIPE in terms of performance is not an apple-to-apple comparison as RECIPE supports only a weaker consistency (*i.e.*, BDL). Besides performance, we also stress how hard it is to achieve DL without trading off performance. Figure 5 and Figure 6 compare the performance of TIPS and RECIPE for LFHT, ART [39], and CLHT [16], respectively. TIPS indexes perform similar or better than RECIPE indexes across all workloads except for CLHT in workload A. This is because writes to CLHT incurs only one cacheline modification and one p-barrier in RECIPE. While in TIPS-CLHT, it incurs two p-barriers to commit the OLog. Nonetheless, TIPS-CLHT supports DL, and it performs mostly similar to NVMM-optimized hash indexes CCEH [53] and LevelHashing [66]. An easy way to guarantee DL, as proposed by Izraelevitz *et al.* [29] is to add a p-barrier for every reads and writes. We followed it to make a DL version of the RECIPE hash table (DL-LFHT in Figure 5). Such a conversion leads up to $1.4\times$ drop in performance. One can also perform index-specific optimizations like the NVTraverse to guarantee DL. However, it requires

expertise in NVMM programming and in-depth knowledge of the volatile index. Conversely, TIPS achieves DL with good performance and, notably, in an index-agnostic way.

7.3 TIPS vs. NVMM-optimized Indexes

TIPS-B+tree. Figure 4 (F-2) shows the performance of TIPS-B+tree against FastFair [26], and BzTree [11]. TIPS outperforms BzTree by up to $3\times$ across all workloads; BzTree uses CoW and PMwCAS [59] to support crash consistency, and this generates a lot of NVMM write traffic. Unlike BzTree, TIPS-B+tree supports low overhead crash consistency using UNO logging and hence a better performance. TIPS performs similar or better than FastFair except for workload C. FastFair, with its smaller fanout (16), provides good point query performance, and TIPS-B+tree with a larger fanout (128) provides a good range query performance than FastFair. For string keys, FastFair (FastFair-str) performs up to $5\times$ slower than TIPS (TIPS-str) as it loses its cache efficiency due to additional pointer chasing to retrieve string keys. Note that TIPS stores pointer to its keys for both string and integer keys; therefore no significant performance drop is observed.

TIPS-ART. In Figure 6, we present the performance of TIPS-ART and WOART [36]—volatile ART variant designed for NVMM. WOART is single-threaded, and hence we used a global lock for concurrency as done in previous work [37, 38]. WOART performs up to $40\times$ slower than TIPS-ART across different workloads due to its poor concurrency model. For a single thread, TIPS-ART performs similar to WOART except for workload E. For workload E, the performance of TIPS-ART and RECIPE-ART are almost identical; this proves our claim in §4.1.6 that the additional OLog traversal in scan operations imposes negligible overhead. Our performance profiling revealed that only 2-3% of the time is spent on traversing OLog regardless of thread count.

7.4 Analysis on TIPS Design

Write Scalability. Figure 7 shows the scalability of the TIPS indexes. For write-intensive workload A, all TIPS indexes show good performance and scalability; for TIPS-B+Tree a sharp increase is observed after 16 threads. Because (1) for lower thread counts, the aggregate OLog size is less (OLog is per-thread). Moreover, as TIPS-B+Tree uses global RW lock TIPS backend writes are slower than the concurrent frontend writes, and consequently, foreground writers are blocked due to the lack of OLog space. (2) For higher thread counts, foreground blocking time is significantly reduced with a larger aggregate OLog size. Although the TIPS-HT uses RW lock, it is per-bucket and hence a better level of concurrency than the TIPS-B+tree. This enables TIPS backend to reply the OLog concurrently and hence a better performance for TIPS-HT. Still, for 16 threads, TIPS-B+tree outperforms PRONTO-B+Tree which also uses global RW lock by up to $3\times$.

Read Scalability. All TIPS indexes show good scalability for read-intensive workloads. Indexes supporting concurrent

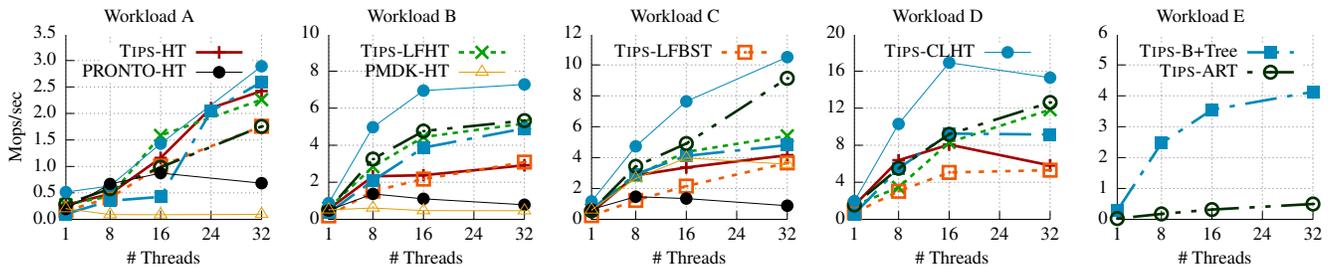

Figure 7: Scalability of TIPS-HT (RW lock), TIPS-B+Tree (RW lock), TIPS-LFHT, TIPS-LFBST, TIPS-CLHT and TIPS-ART.

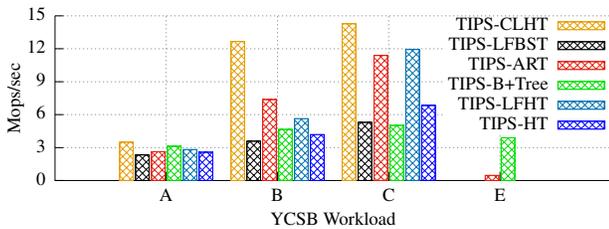

Figure 8: Performance of TIPS indexes for Zipfian workloads.

reads show good performance; for instance, TIPS-LFHT performs up to $1.2\times$ better than TIPS-HT (RW lock) in workload C. All indexes regardless of their concurrency model shows high performance for workload D. Because workload D follows read-latest distribution, latest writes are being repeatedly read. Fortunately, the latest writes are most likely to be present in the DRAM-cache; hence a higher read hit ratio and consequently better performance. Although we cache only 25% of the keys for all workloads, the read hit for workload D is about 70%, while for other workloads it is less than 25%.

Impact of UNO Logging. Both TIPS-HT and PMDK-HT (Figure 7) use RW lock, and they both use the UNDO logging to guarantee crash consistency while updating the hash table. However, despite the similarities, TIPS-HT significantly outperforms PMDK-HT. The main performance bottleneck in PMDK is the logging operations in the critical path. This is evident from Figure 7, PMDK-HT performs and scales on par with TIPS-HT for workload C (100% reads), but its performance plateaus even for a small fraction of writes (5%) in workload B. With UNO logging, UNDO logging is kept off the critical path and consequently making TIPS scale better.

Impact of Skewed Workloads. Figure 8 shows the performance of TIPS indexes for Zipfian distribution; all indexes shows up to $2\times$ better performance than the uniform distribution. Particularly for workload A, the chances of write coalescing in the ULog increases due to frequent updates to the same address. This reduces the number of UNDO logging performed, and further analysis revealed that the number of UNDO logging performed is reduced by 16% than that of uniform distribution. This further accelerates the background writes, and thus overall write performance is improved. For read-intensive workloads, repeated reading of hotkeys results in more DRAM-cache hits and eventually a better read performance. On average, the DRAM-cache hit ratio is increased by 5% for the Zipfian distribution. Overall, TIPS, in partic-

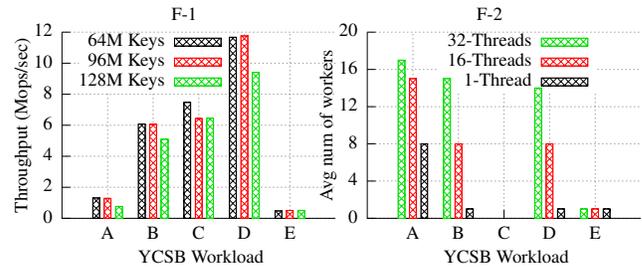

Figure 9: Studying the impact of large dataset (F-1) for 32 threads and adaptive scaling (F-2) for varying threads with TIPS-ART.

ular, UNO logging and DRAM-cache are well equipped to handle the skewed workloads. Note that we did not evaluate workload D as it supports read-latest distribution by default.

Impact of Large Dataset. Figure 9 (F-1) presents the performance of TIPS-ART for large datasets. While the performance for 64M and 96M keys is mostly the same across all the workloads, there is up to a 23% drop in performance for 128M keys. Particularly for workload C, the performance drop is also observed for 96M keys; for a larger dataset, the ART index grows bigger, and it results in increased pointer chasing to get to the leaf nodes, and hence there is a slight dip in the performance. Note that the RECIPE-ART also exhibits a performance drop of up to 16% across all workloads for 128M keys. Overall, this evaluation shows that TIPS as a system can handle much larger datasets effectively.

Impact of Adaptive Scaling. Figure 9 (F-2) shows the average number of background workers used for TIPS-ART. More workers are used for workload A as it is write-intensive, for all the other workloads workers count is relatively less as the write ratio is marginal. No workers are created for workload C as it is read-only. Workload E has the same write ratio (5%) as B and D, but TIPS employs only one worker for E. Because ART's scan is inherently slower, hence the foreground threads spend most of the time on the scan operation (*i.e.*, foreground writes are slow), this gives TIPS enough time propagate the updates. Thus our adaptive scaling can effectively adapt for the nature of workloads and the plugged-in index.

7.5 Sensitivity Analysis

Sensitivity to DRAM-cache Size. As shown in Figure 10, for read-intensive workloads, about $1.8\text{-}2.8\times$ performance increase is observed as % keys cached increases. This is because the read hit ratio increases as more keys are being

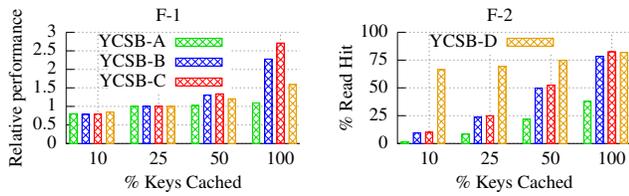

Figure 10: Performance sensitivity of TIPS-B+tree (F-1) and read hit % (F-2) for the varying DRAM-cache size. X-axis represents the % of keys cached in the DRAM-cache (default = 25%).

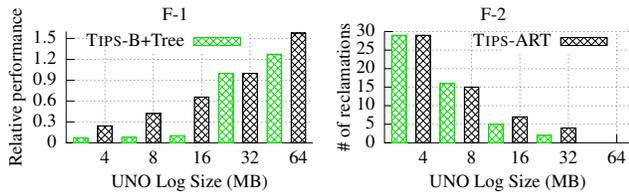

Figure 11: Performance sensitivity (F-1) and the number of log reclamations triggered (F-2) in TIPS-B+Tree and TIPS-ART for the varying UNO log size for Workload A (default = 32MB).

cached, enabling readers to complete their reads on the faster DRAM. Since workload A is write-intensive, it is less sensitive to DRAM-cache size. As more writes happen on the DRAM-cache, the applied keys are actively evicted, and it stores mostly the newly written keys. This poorly impacts the read hit ratio, and consequently, readers are forced to fall back to the B+tree on the NVMM.

Sensitivity to UNO Log Size. Figure 11 illustrates the performance of TIPS-ART, TIPS-B+tree for different UNO log sizes for the write-heavy workload A. As shown, there is a $4\times$ and $9\times$ performance drop for TIPS-ART and TIPS-B+tree with 32MB (default) and 4MB log size, respectively. This is because as the log size becomes smaller, the foreground writers are blocked for more time as TIPS-B+tree (RW lock) has a single-threaded backend. Whereas TIPS-ART supports concurrent backend and is relatively less affected by decreasing log size. Both TIPS-ART and TIPS-B+tree shows a $1.6\times$ performance increase for 64MB because the log size is big enough to completely buffer all writes, and zero reclamations are triggered for 64MB. Also, note that more than 3 reclamations are triggered for a default log size of 32MB. The impact of smaller log sizes is relatively marginal for read-heavy workloads. The performance change is negligible until 8MB, and about a 20% performance drop is observed for 4MB log size.

7.6 Real-world Application: Redis

We ported a popular DRAM key-value store, Redis [8], using TIPS (TIPS-Redis). We compare its performance with the vanilla Redis running on the DRAM (DRAM-Redis) and NVMM (NVMM-Redis), and also with Intel’s PMEM-Redis [7]. Note that NVMM-Redis does not ensure crash consistency and PMEM-Redis stores only the values in NVMM. Figure 12 shows the performance of Redis GET and SET operation evaluated using Redis-Benchmark [9]. We ran the benchmark for 32M keys (8-bytes) with a uniform random

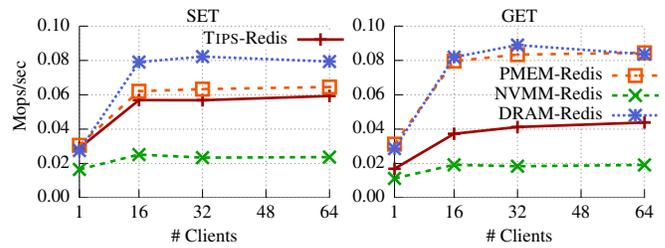

Figure 12: Performance comparison of TIPS-Redis with vanilla Redis running on DRAM and NVMM, and Intel’s PMEM-Redis.

distribution. For SET operations, TIPS-Redis consistently outperforms the NVMM-Redis by $2.5\times$, and it performs up to $1.5\times$ and $1.1\times$ slower than the DRAM-Redis and PMEM-Redis, respectively. For the GET operations, TIPS-Redis perform up to $2\times$ better than the NVMM-Redis and up to $2.2\times$ slower than the DRAM-Redis and PMEM-Redis. TIPS-Redis maintains all the data and the Redis core on the NVMM, so (1) it provides a larger in-memory capacity ($4\times$ in our experiment) and immediate durability. (2) Both PMEM-Redis and DRAM-Redis take about 100 seconds to restore data from disk every time a server instance is created. While TIPS-Redis takes less than 1 second to recover upon safe termination.

7.7 Recovery

We performed the recovery test on all the TIPS-indexes. We injected crash 200 times arbitrarily using SIGKILL, similar to previous work [37, 41]. We also tested a crash during the recovery procedure. All TIPS-indexes successfully recovered after every crash. The worst-case recovery time would be a crash happening when the OLog is full. To measure this time, we injected a crash just when the OLog becomes full. Recovery time ranges between 0.5 and 9 seconds depending on the number of OLogs and concurrency control of the index.

8 Conclusion

We propose TIPS, a framework to systematically make volatile indexes and in-memory key-value stores persistent. At its core, TIPS adopts a novel DRAM-NVMM tiering to support index-agnostic conversion and durable linearizability. With the tiered concurrency model, TIPS achieves good scalability, performance, and enhanced applicability. UNO logging protocol is critical to achieve low crash consistency overhead and prevent persistent memory leaks. In our evaluation, we showed that TIPS could be effectively applied to indexes with varying concurrency models and the TIPS-enabled indexes shows excellent performance against the state-of-the-art index conversion techniques and NVMM-optimized indexes.

Abstract

High-performance flash-based key-value stores in data-centers utilize large amounts of DRAM to cache hot data. However, motivated by the high cost and power consumption of DRAM, server designs with lower DRAM per compute ratios are becoming popular. These low-cost servers enable scale-out services by reducing server workload densities. This results in improvements to overall service reliability, leading to a decrease in the total cost of ownership (TCO) for scalable workloads. Nevertheless, for key-value stores with large memory footprints these reduced DRAM servers degrade performance due to an increase in both IO utilization and data access latency. In this scenario a standard practice to improve performance for sharded databases is to reduce the number of shards per machine, which degrades the TCO benefits of reduced DRAM low-cost servers. In this work, we explore a practical solution to improve performance and reduce costs of key-value stores running on DRAM constrained servers by using Storage Class Memories (SCM).

SCM in a DIMM form factor, although slower than DRAM, are sufficiently faster than flash when serving as a large extension to DRAM. In this paper, we use Intel® Optane™ PMem 100 Series SCMs (DCPMM) in AppDirect mode to extend the available memory of RocksDB, one of the largest key-value stores at Facebook. We first designed hybrid cache in RocksDB to harness both DRAM and SCM hierarchically. We then characterized the performance of the hybrid cache for 3 of the largest RocksDB use cases at Facebook (WhatsApp, Tectonic Metadata, and Laser). Our results demonstrate that we can achieve up to 80% improvement in throughput and 20% improvement in P95 latency over the existing small DRAM single-socket platform, while maintaining a 43-48% cost improvement over the large DRAM dual socket platform. To the best of our knowledge, this is the first study of the DCPMM platform in a commercial data center.

1 Introduction

High-performance storage servers at Facebook come in two flavors. The first, *2P server*, has two sockets of compute and a large DRAM capacity as shown in Figure 1a and provides

excellent performance at the expense of high power and cost. In contrast, *1P server* (Figure 1b), has one socket of compute and the DRAM-to-compute ratio is half of the *2P server*. The advantages of *1P server* are reduced cost, power, and increased rack density [1]. For services with a small DRAM footprint, *1P server* is the obvious choice. A large number of services in Facebook fit in this category.

However, a class of workloads that may not perform adequately on a reduced DRAM server and take advantage of the cost benefits of *1P server* at Facebook are flash-based key-value stores. Many of these workloads use RocksDB [2] as their underlying storage engine. RocksDB utilizes DRAM for caching frequently referenced data for faster access. A low DRAM to storage capacity ratio for these workloads will lead to high DRAM cache misses, resulting in increased flash IO pressure, longer data access latency, and reduced overall application throughput. Flash-based key-value stores in Facebook are organized into shards. An approach to improve the performance of each shard on DRAM constrained servers is to reduce the number of shards per server. However, this approach can lead to an increase in the total number of servers required, lower storage utilization per server, and dilutes the TCO benefits of the *1P server*. This leaves us with the difficult decision between *1P server*, which is cost-effective while sacrificing performance, or *2P server* with great performance at high cost and power. An alternative solution that we explore in this paper is utilizing recent Intel® Optane™ PMem 100 Series SCMs (DCPMM) [3] to efficiently expand the volatile memory capacity for *1P server* platforms. We use SCM to build new variants of the *1P server* platforms as shown in Figure 1c. In *1P server variants*, the memory capacity of *1P server* is extended by providing large SCM DIMMs alongside DRAM on the same DDR and bus attached to the CPU memory controller.

Storage Class Memory (SCM) is a technology with the properties of both DRAM and storage. SCMs in DIMM form factor have been studied extensively in the past because of their attractive benefits including byte-addressability, data persistence, cheaper cost/GB than DRAM, high density, and their relatively low power consumption. This led to abundant research focusing on the use cases of SCM as memory

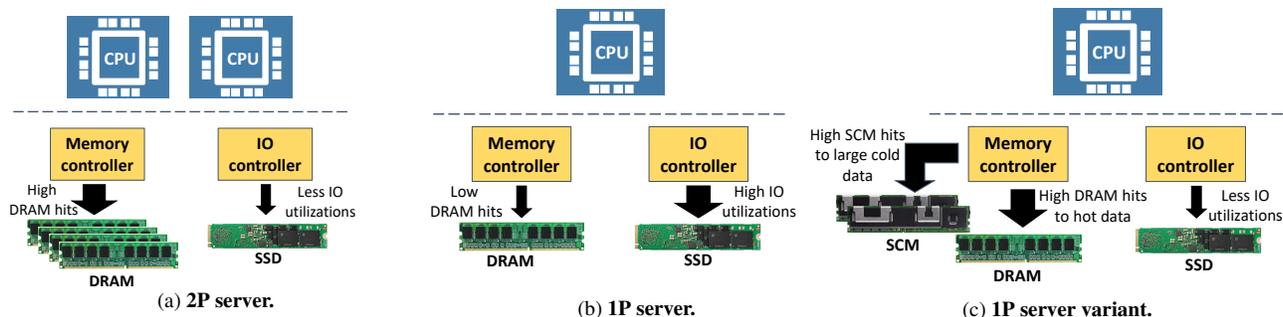

Figure 1: Server configurations with different DRAM sizes: (a) Server with 256GB memory, high hit rate to DRAM and low IO utilization (b) Server with reduced (64GB) memory, lower DRAM hit rate and increased in IO utilization and (c) Server with reduced memory and SCM added to the memory controller, high hit rate to DRAM & SCM due to optimized data placement, which decreases IO utilization.

Table 1: Example of memory characteristics of DRAM, SCM and flash per module taken from product specifications.

Characteristics	DRAM	SCM	Flash
Idle read latency (ns)	75	170	85,000
Read bandwidth (GB/s)	15	2.4	1.6
Power (mW / GB)	375	98	5.7
DRAM Relative Cost per GB	1	0.38	0.017
Granularity	byte addressable	byte addressable	block based
Device Capacity (GB)	32	128	2048

and persistent storage. The works range from optimizations with varying memory hierarchy configurations [4–8], novel programming models and libraries [9–11], and file system designs [12–14] to adopt this emerging technology. Past research was focused primarily on theoretical or simulated systems, but the recent release of DCPMM-enabled platforms from Intel motivates studies based on production-ready platforms [15–24]. The memory characteristics of DRAM, DCPMM, and flash are shown in Table 1. Even though DCPMM has higher access latency and lower bandwidth than DRAM it has a much larger density and lower cost, and its access latency is two orders of magnitude lower than flash. Currently, DCPMM modules come in 128GB, 256GB, and 512GB capacities, much larger than DRAM that typically ranges from 4GB to 32GB in a data-center environment. Hence we can get a tremendously larger density with DCPMM. If we efficiently (cost and performance) use this memory as an extension to DRAM, this would enable us to build dense, flexible, servers with large memory and storage, while using fewer DIMMs and lowering the total cost of ownership (TCO).

Although recent works demonstrated the characteristics of SCM [15, 18], the performance gain achieved in large commercial data-centers by utilizing SCM remains unanswered. There are open questions on how to efficiently configure DRAM and SCM to benefit large scale service deployments in terms of cost/performance. Discovering the use cases within a large scale deployment that profit from SCM has also been challenging. To address these challenges for RocksDB, we first profiled all flashed-based KV store deployments at Facebook to identify where SCM fits in our environment. These studies revealed that we have abundant

read-dominated workloads, which focused our design efforts on better read performance. This has also been established in previous work [25–27] where faster reads improved overall performance for workloads serving billions of reads every second. Then, we identified the largest memory consuming component of RocksDB, the block cache used for serving read requests, and redesigned it to implement a hybrid tiered cache that leverages the latency difference of DRAM and SCM. In the hybrid cache, DRAM serves as the first tier cache accommodating frequently accessed data for fastest read access, while SCM serves as a large second tier cache to store less frequently accessed data. Then, we implemented cache admission and memory allocation policies that manage the data transfer between DRAM and SCM. To evaluate the tiered cache implementations we characterize three large production RocksDB use cases at Facebook using the methods described in [28] and distilled the data into new benchmark profiles for db_bench [29]. Our results show that we can achieve 80% improvement to throughput, 20% improvement in P95 latency, and 43-48% reduction in cost for these workloads when we add SCM to existing server configurations. In summary, we make the following contributions:

- We characterized real production workloads, identified the most benefiting SCM use case in our environment, and developed new db_bench profiles for accurately benchmarking RocksDB performance improvement.
- We designed and implemented a new hybrid tiered cache module in RocksDB that can manage DRAM and SCM based caches hierarchically, based on the characteristics of these memories. We implemented three admission policies for handling data transfer between DRAM and SCM cache to efficiently utilize both memories. This implementation will enable any application that uses RocksDB as its KV Store back-end to be able to easily use DCPMM.
- We evaluated our cache implementations on a newly released DCPMM platform, using commercial data center workloads. We compared different DRAM/SCM size server configurations and determined the cost and per-

formance of each configuration compared to existing production platforms.

- We were able to match the performance of large DRAM footprint servers using small DRAM and additional SCM while decreasing the TCO of read dominated services in production environment.

The rest of the paper proceeds as follows. In Section 2 we provide a background of RocksDB, the DCPMM hardware platforms, and brief description of our workloads. Sections 3 and 4 explain the designs and implementation of the hybrid cache we developed. In Section 5 we explain the configurations of our systems and the experimental setup. Our experimental evaluations and results are provided in Section 6. We then discuss future directions and related works in Section 7 and Section 8 respectively, and conclude in Section 9.

2 Background

2.1 RocksDB architecture

A Key-value database is a storage mechanism that uses key-value pairs to store data where the key uniquely identifies values stored in the database. The high performance and scalability of key-value databases promote their widespread use in large data centers [2, 30–32]. RocksDB is a log-structured-merge [33] key-value store engine developed based on the implementation of LevelDB [30]. RocksDB is an industry standard for high performance key-value stores [34]. At Facebook RocksDB is used as the storage engine for several data storage services.

2.1.1 RocksDB components and memory usage

RocksDB stores key-value pairs in a Sorted String Table (SST) format. Adjacent key-value data in SST files are partitioned into data blocks. Other than the data block, each SST file contains Index and Filter blocks that help to facilitate efficient lookups in the database. SST files are organized in levels, for example, Level0 - LevelN, where each level comprises multiple SST files. Write operations in RocksDB first go to an in-memory write buffer residing in DRAM called the memtable. When the buffered data size in the memtable reaches a preset size limit RocksDB flushes recent writes to SST files in the lowest level (Level0). Similarly, when Level0 exhausts its size limit, its SST files are merged with SST files with overlapping key-values in the next level and so on. This process is called compaction. Data blocks, and optionally, index and filter blocks are cached (typically uncompressed) in an in-memory component called the Block Cache that serves read requests from RocksDB. The size of the Block Cache is managed by global RocksDB parameters. Reads from the database are attempted to be serviced first from the memtable, then next from the Block Cache(s) in DRAM, and finally from the SST files if the key is not found in memory. Further details about Rocksdb are found in [2]. The largest use of memory in RocksDB comes from the Block Cache, used for reads.

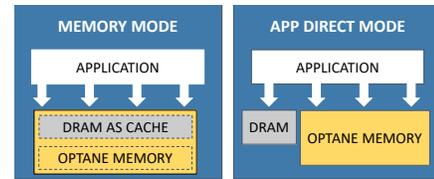

Figure 2: Intel® Optane™ memory operation modes overview.

Therefore, in this work we optimize the RocksDB using SCM as volatile memory for the Block Cache.

2.1.2 Benchmarking RocksDB

One of the main tools to benchmark RocksDB is `db_bench` [29]. `Db_bench` allows us to mock production RocksDB runs by providing features such as multiple databases, multiple readers, and different key-value distributions. Recent work [28] has shown how we can create realistic `db_bench` workloads from production workloads. To create evaluation benchmarks for SCM we followed the procedures given in [28, 35].

2.2 Intel® Optane™ DC Persistent Memory

Intel® Optane™ DC Persistent Memory based on 3D XPoint technology [36, 37], is the first commercially available non-volatile memory in the DIMM form factor and resides on the same DDR bus as DRAM [3]. DCPMM provides byte-addressable access granularity which differentiates it from similar technologies which were limited to larger block-based accesses. This creates new opportunities for low latency SCM usage in data centers as either a volatile memory extension to DRAM or as a low latency persistent storage media.

2.2.1 Operation mode overview

DCPMM can be configured to operate in one of two different modes: Memory Mode and App Direct Mode [38]. Illustrations of the modes are shown in Figure 2.

In **Memory Mode**, as shown in Figure 2, the DRAM capacity is hidden from applications and serves as a cache for the most frequently accessed addresses, while DCPMM capacity is exposed as a single large volatile memory region. Management of the DRAM cache and access to the DCPMM is handled exclusively by the CPU’s memory controller. In this mode applications have no control of where their memory allocations are physically placed (DRAM cache or DCPMM).

In **App Direct Mode**, DRAM and DCPMM will be configured as two distinct memories in the system and are exposed separately to the application and operating system. In this case, the application and OS have full control of read and write accesses to each media. In this mode, DCPMM can be configured as block-based storage with legacy file systems or can be directly accessed (via DAX) by applications using memory-mapped files.

2.3 Facebook RocksDB workloads

For our experiments and evaluation we chose the largest RocksDB use cases at Facebook, which demonstrate typical uses of key-value storage ranging from messaging services to

large storage for processing realtime data and metadata. Note than these are not the only workloads that benefit from our designs. The descriptions of the services are as follows:

WhatsApp: With over a billion active users, WhatsApp is one of the most popular messaging applications in the world [39]. WhatsApp utilizes ZippyDB as its remote data store. ZippyDB [40] is a distributed KV-store that implements Paxos on top of RocksDB to achieve data reliability and persistence.

Tectonic Metadata: The Tectonic Metadata databases are also stored in ZippyDB and are an integral part of the large blob storage service of Facebook that serves billions of photos, videos, documents, traces, heap dumps, and source code [41, 42]. Tectonic Metadata maintains the mappings between file names, data blocks and parity blocks, and the storage nodes that hold the actual blocks. These databases are distributed and fault-tolerant.

Laser: Laser is a high query throughput, low (millisecond) latency, peta-byte scale key-value storage service built on top of RocksDB [43]. Laser reads from any category of Facebook’s real-time data aggregation services [44] in real-time or from a Hadoop Distributed File System [45] table daily.

3 Hybrid cache design choices

3.1 The challenges of SCM deployment

The first challenge of introducing SCM in RocksDB is identifying which of its components to map to SCM. We chose the uncompressed block cache because it has the largest memory usage in our RocksDB workloads and because our studies reveal that a number of our production workloads, which are read-dominated, benefit from optimizing read operations by block cache extension. We also focused on the uncompressed block cache instead of the compressed ones, so that we can minimize CPU utilization increase when performing compression/decompression. This allowed us to increase the size of SCM (block cache) without requiring additional CPU resources. We also chose block cache over memtable because SCM provides better read bandwidth than writes, hence helping our read-demanding workloads. We then expanded the block cache size by utilizing SCM as volatile memory. We chose this approach because extending the memory capacity while reducing the size of DRAM and the cost of our servers is the primary goal. Although we can benefit from persisting block cache and memtable in SCM for fast cache warmup and fast write access, we left this for future work.

The next challenge is, how we should configure SCM to get the best performance. We have the options of using memory mode, that does not require software architecture changes or app-direct mode that necessitates modification in RocksDB but provides control of DRAM and SCM usage. Figure 3 demonstrates how memory-mode compares to our optimized app-direct mode. Optimized app-direct mode with various DRAM and SCM sizes, renders 20-60% throughput improvement and 14-49% lower latency compared with memory mode. This insight supports that our optimized implementation has

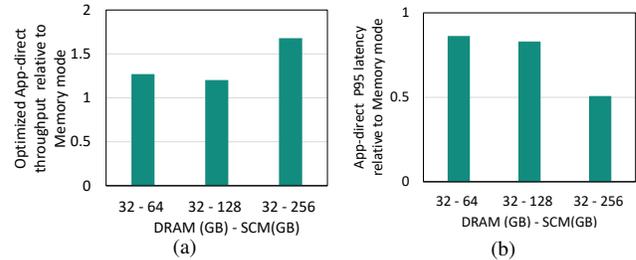

Figure 3: Throughput and latency comparison for memory mode and our optimized hybrid-cache in app-direct mode for WhatsApp.

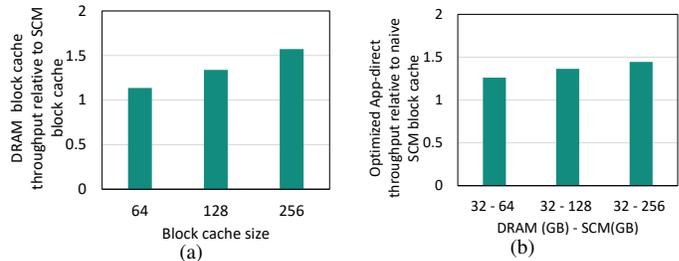

Figure 4: (a) Throughput of DRAM vs SCM based block cache. (b) Throughput of naive SCM vs optimized hybrid-cache for WhatsApp.

a better caching mechanism than memory mode, hence we focused our analysis on app-direct mode.

With app-direct we can manage the allocation of RocksDB’s components (memtable, data, filter, and index blocks) to DRAM or SCM. But since we know the data access latency of SCM is slower than DRAM (see Table 1), we have to consider its effect. We compared the throughput of allocating the block cache to DRAM or SCM in app-direct mode in vanilla RocksDB to understand the impact of the higher SCM access latency. As seen in Figure 4a, the slower SCM latency creates 13%-57% difference in throughput when we compare DRAM based block cache to a naive SCM block cache using app-direct mode. This result guided us to carefully utilize DRAM and SCM in our designs. In single-socket machines such as *IP servers*, we have one CPU and 32GB - 64GB DRAM capacity. Out of this DRAM, memtable, index, and filter blocks consume 10-15 GBs. The rest of DRAM and the additional SCM can be allocated for block cache. We compared the naive SCM block cache implementation (all block cache allocated to SCM using app-direct) to a smarter and optimized hybrid cache, where highly accessed data is allocated in DRAM and the least frequently access in SCM. The results in Figure 4b show with optimized app-direct we achieve up to 45% better throughput compared to a naive SCM block cache. From this, we can determine that implementing a hybrid cache compensates for the performance loss due to the higher SCM access latency. These results together with the high temporal locality of our workloads (as discussed below) motivated us to investigate a hybrid cache.

3.2 RocksDB workload characteristics

Below we scrutinize the characteristics of our largest RocksDB workloads that guided our hybrid cache design.

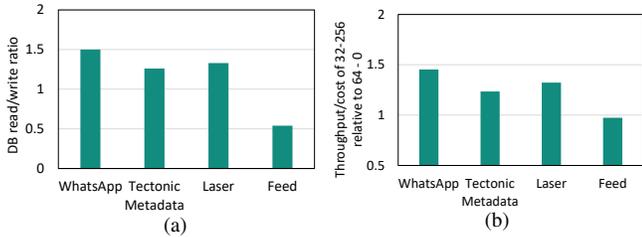

Figure 5: (a) Read to write ratio to DB. (b) Key-value throughput/-cost compare for large block cache friendly workloads and Feed with higher writes than reads.

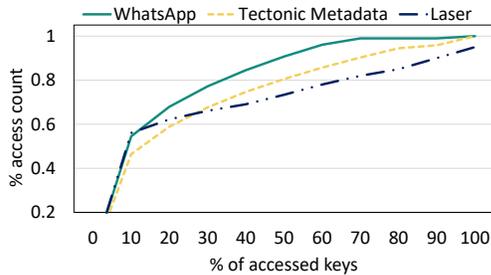

Figure 6: Key-value locality.

Reads and writes to DB: As we discussed earlier, prior work showed that optimizing reads provides large impact in commercial data center workloads [25–27]. Our studies also show that we have a large number of read-dominated workloads, therefore optimizing the block cache, used for storing data for fast read access, will benefit a number of our workloads. In RocksDB, when a key is updated in memtable it will be invalid in the block cache. Hence, if the workload has more write queries than reads, then the data in the cache will become stale. Note that write-dominated workloads won’t be affected by our hybrid cache designs because we did not reduce any DRAM buffer (memtable) in the write path. In our studies, we profiled deployed RocksDB workloads for 24 hours using an internal metrics collection tool to comprehend the read and write characteristics. Figure 5a shows the workloads described in Section 2.3 reads more bytes from the DB than it writes. To contrast, we evaluated one of our write-dominated workloads, Feed, also seen in Figure 5a. In Figure 5b, we calculated the throughput per cost of *IP server variants* with 32 GB DRAM and 256 GB SCM capacity normalized to throughput/cost of *IP server* with 64 GB DRAM capacity. The throughput/cost improvement of Feed for our largest DRAM-SCM system cannot offset the additional cost due of SCM. Hence, we focus on exporting read-dominated workloads to our hybrid systems.

Key-value temporal locality: Locality determines the cacheability of block data given a limited cache size. A hybrid cache with a small DRAM size will only benefit us if we have a high temporal locality in the workloads. In this case, significant access to the block cache will come from the DRAM cache, and SCM will hold the bulk of less frequently accessed blocks. We used RocksDB trace analyzer [35] to investigate up to 24 hours query statistics of workloads running on production *2P server* and evaluate locality as the distribution

of the total database access counts to the total keys accessed per database. Figure 6 shows that our workloads possess a power-law relationship [46] between the number of key-value pair access counts and the number of keys accessed. We can observe in the figure that 10% of the key-value pairs carry ~50% of the key-value accesses. This makes a hybrid cache design with small DRAM practical for deployment.

DB and cache sizes: The desirable DRAM and SCM cache sizes required to capture workload’s locality is proportional to the size of the DB. Workloads with high key-value locality and large DB sizes can achieve a high cache hit rate with limited cache sizes. But as the locality decreases for large DB sizes, the required cache sizes will grow. In the extreme case of random key-value accesses, all blocks will have similar heat, diluting the value of the DRAM cache and reducing overall hybrid cache performance asymptotically toward that of the SCM-only block cache. For small DBs, locality might not play a significant role because the majority of the DB accesses fit in a small cache. Such types of workloads will not be severely affected by DRAM size reduction, and choosing the *IP server variants* with large SCM capacity will be a waste of resources. In our studies, after looking at various workloads in production, we choose our hybrid DRAM-SCM cache configuration to accommodate several workloads with larger DB sizes (~2TB total KVstorage per server).

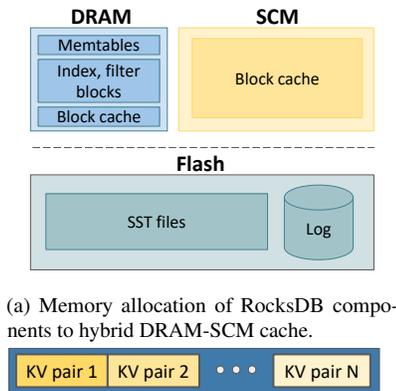

4 DRAM-SCM hybrid cache module

In our RocksDB deployment, we placed the memtables, index blocks, and filter blocks in DRAM. We then designed a new hybrid cache module that allocates the block cache in DRAM and SCM. The database SST files and logs are located in Flash. The overview of RocksDB components allocation in the memory system is shown in Figure 7a. Our goal in designing the new hybrid cache module is to utilize DRAM and SCM hierarchically based on their read access latency and bandwidth characteristics. In our design, we aim to place hot blocks in DRAM for the lowest latency data access, and colder blocks in SCM as a second tier. The dense SCM based hybrid block cache provides a larger effective capacity than practical with DRAM alone leading to higher cache hit rates. This dramatically decreases IO bandwidth requirements to the SST files on slower underlying flash media.

The block cache is an integral data structure that is completely managed by RocksDB. Similarly, in our implementations, the new hybrid cache module is fully managed by RocksDB. This module then is an interface between RocksDB and the DRAM and SCM block caches, and fully manages the caches’ operations. The overall architecture of the hybrid cache is shown in Figure 7c. The details of its internal components are as follows:

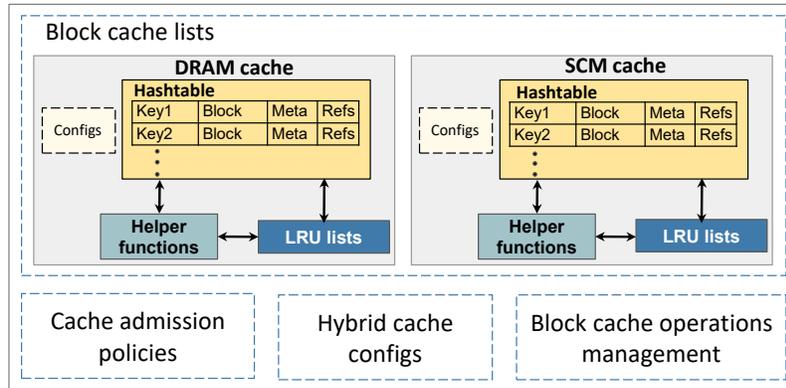

4.1 Block cache lists

The hybrid cache is a new top-level module in RocksDB that maintains a list of underlying block caches in different tiers.

(a) Memory allocation of RocksDB components to hybrid DRAM-SCM cache.

(b) Data block structure.

(c) Hybrid tier cache component and architecture.

Figure 7: RocksDB components and memory allocation.

The list of caches are extended from the existing RocksDB block cache with LRU replacement policy. Note that in our implementations we have DRAM and SCM cache, but the module can manage more than these two caches such as multiple DRAM and SCM caches in a complex hierarchy.

4.1.1 Block cache architecture and components

The internal structures of DRAM and SCM caches, which are both derived from the block cache, are shown in Figure 7c. The block cache storage is divided into cache entries and tracked in a **hashtable**. Each cache entry holds a key, data block, metadata such as key size, hash, current cache usage, and a reference count of the cache entry outside of the block cache. The data block is composed of multiple key-value pairs as shown in Figure 7b. Binary searches are performed to find a key-value pair in a data block. The data block size is configurable in RocksDB. In our case, the optimal size was 16KB. As the number of index blocks decreases we can increase the data block size. As a result, with 16KB we were able to reduce the number of index blocks making room for data blocks within our limited DRAM capacity. Every block cache has **configs** that are configured externally. This includes size, a threshold for moving data, a pointer to all other caches for data movement, and the memory allocator for the cache. The cache maintains an **LRU list** that tracks cache entries in order from most to least recently used. The **helper functions** are used for incrementing references, checking against the reference threshold, transferring blocks from one cache to another, checking size limits, and so on. For the components listed above we extended and modified RocksDB to support tiered structure, different kinds of admission policies and we designed new methodologies to enable data movement between different caches and to support memory allocation to different memory types.

4.1.2 Data access in the block cache

A block is accessed by a number of external components to the block cache, such as multiple reader clients of the RocksDB database. The number of external referencers is tracked by the reference count. Mapping to a block is created when it is

referenced externally, this will increment the reference count. Whereas when the referencer no longer needs a block, mapping is released, and the reference count is decremented. If a block has zero external references, it will be in the hashtable and tracked by the LRU list. If a block gets referenced again, then it will be removed from the LRU list. Note that in the LRU list, newly released blocks with no external references are on the top of the LRU list as the most recently used blocks, and when blocks are evicted, the bottom least recently used blocks are evicted first. The block cache is used for read-only data, hence it doesn't deal with any dirty data management. Therefore, when transferring data between DRAM and SCM we do not have to deal with dirty data.

4.2 Cache admission policies

Identifying and retaining blocks in DRAM/SCM based on their access frequencies requires proactive management of data transfer between DRAM, SCM, and flash. Hence, we developed the following block cache admission policies.

4.2.1 DRAM first admission policy

In this admission policy, new blocks read from flash are first inserted into the hashtable of the DRAM cache. The block cache data structures are size limited. Hence when the size of the blocks allocated in the DRAM cache exceeds the size limits, the oldest entries tracked by the DRAM LRU list are moved to the next tier cache (SCM cache) by the data mover function of the DRAM cache, using the SCM cache's memory allocator. On lookups, both the DRAM and SCM caches are searched until the cache block is found. If it is not found, it will initiate a flash read. Similar to the DRAM cache when the capacity of the SCM cache exceeds the limit, the oldest entries in the LRU list of the SCM cache are freed to accommodate new cache blocks evicted from the DRAM cache.

4.2.2 SCM first admission policy

In this admission policy, new blocks read from flash are first inserted in the hashtable of the SCM cache. Unlike the DRAM first admission policy, this policy has a configurable threshold for moving data from the SCM cache to the DRAM cache.

When the external references of cache entries in the SCM cache surpasses the reference threshold, blocks are considered to be hot and will be migrated to the DRAM cache for faster access. The data movement, in this case, is handled by the data mover function of the SCM cache. When the capacity of both the DRAM and SCM caches are full, the oldest LRU blocks are evicted from both caches. In the DRAM cache, LRU entries are moved back to the SCM cache, whereas in the SCM cache, the LRU entries are freed to accommodate new block insertions. On lookup, both the DRAM and SCM caches are searched until the cache block is found.

4.2.3 Bidirectional admission policy

In Bidirectional admission policy, similar to the DRAM first admission policy, new data blocks are inserted into the DRAM cache. As the capacity of DRAM and SCM cache reach the limit, the oldest LRU entries are evicted to SCM cache from the DRAM cache and are freed for the case of SCM cache. The difference between DRAM-first and Bidirectional cache is, after the oldest LRU entries are evicted from DRAM to SCM cache, if the external reference to an entry surpasses a preset threshold it is transferred back to the DRAM cache. This property allows us to re-capture fast access performance for blocks with inconsistent temporal access patterns.

In the hybrid cache, we can set the three of the admission policies or we can easily extend a new policy by configuring how to insert, lookup, and move data in the list of block caches. These configs are global parameters in the top-level hybrid cache and are used by the block cache operations manager and list of block caches. Optionally the thresholds for moving data in SCM first and Bidirectional policies can be set to change values based on the current usage of the caches. But in our experiments, we didn't see benefit with changing values. We also performed an analysis with different sizes of cache thresholds and we show the optimal threshold for SCM first and Bidirectional in our evaluations.

4.3 Hybrid cache configs

The hybrid cache configurations are set outside of the module by RocksDB, and include pointers to configs of all block caches, the number of block caches, ids, tier numbers of the caches, and admission policy to use. Configs are used during instantiation and at run time to manage database operations.

4.4 Block cache operation management

This unit redirects external RocksDB operations such as insert, lookup, update, and so on to the target block cache based on the admission policy. For example, it decides if an incoming insert request should go to the DRAM or SCM cache.

5 Systems setup and implementation

5.1 DRAM-SCM cache implementation

We configured Intel DCPMMs in App Direct mode using the IPMCTL [47] tool in our experiments. We used Linux Kernel

5.2 that brings support for a volatile use of DCPMM by configuring a hot-pluggable memory region called KMEM DAX. We then used NDCTL 6.7 [48], a utility for managing SCM in the Linux Kernel, to create namespaces in DCPMM in devdax mode. This mode provides direct access to DCPMM and is faster than filesystem-based access. We then used DAXCTL [48] utility for configuring DCPMM in system-ram mode so that DCPMM will be available in its own volatile memory NUMA node. To implement a hybrid DRAM-SCM cache we used memkind library [49], which enables partitioning of the heap between multiple kinds of memories such as DRAM and SCM in the application space. After the system is configured with DRAM and DCPMM memory types, we modified RocksDB block cache to take two types of memory allocators using memkind. We use MEM_KIND_DAX_KMEM kind for SCM cache and a regular memory allocator for DRAM. The overview of our implementation is shown in Figure 8.

Table 2: System setup: hardware specs and software configs.

Specification	System config
Application version	RocksDB 6.10
OS	CentOS-8
Linux kernel version	5.2.9
CPU model	Intel(R) Xeon(R) Gold 6252 @ 2.10GHz
Socket/Cores per socket	2/24
Threads total	96
L1/L2 cache	32 KB
L2/L3 cache	1 MB/35.75 MB
Memory controllers total	4
Channels per controller	3
Slots per channel	2
DRAM size	DDR4 192 GB (16 GB X 12 DIMM slots)
SCM size	DDR-T 1.5 TB (128 GB X 12 DIMM slots)
SSD model	Samsung 983 DCT M.2 NVMe SSD
SSD size/filesystem	2 TB / xfs

5.2 Evaluation hardware description

In our evaluations we used a Intel Wolf Pass [50] based system, utilizing 2 CPU sockets populated with Intel Cascade Lake processors [51]. Each CPU has 2 memory controllers with 3 channels each, and 2 DIMM slots per channel, for a total of 24 DIMM slots. DIMM slots were populated by default in a 2-2-2 configuration, with 12 total *16GB PC4-23400 ECC Registered DDR4 DRAM DIMMs* and 12 total *128GB Intel® Optane™ PMem 100 DIMMs*. This makes up a total of 192GB DRAM and 1.5TB of SCM per system. Backing storage for the RocksDB database was a *Samsung 983 DCT M.2 SSD*. The detailed specification is listed in Table 2.

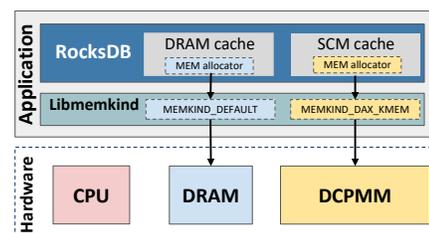

Figure 8: DRAM-SCM cache configuration with libmemkind.

Table 3: OCP Tioga Pass (2P server) and OCP Twin Lakes Platforms (1P server) details.

Specification	OCP Tioga Pass Config	OCP Twin Lakes Config
CPU model	Xeon(R) Gold 6138	Xeon(R) D-2191
Sockets/cores per socket	2/20	1/18
Threads total	80	36
Memory controllers total	4	2

DRAM size	DDR4 256 GB	DDR4 64 GB
SSD size	2 TB	2 TB

5.3 Facebook server designs

The Facebook platforms used for TCO analysis are the *2P server* platform based on the OCP Tioga Pass specification [52], and the *1P server* platform based on the OCP Twin Lakes specification [53]. In addition, we propose several *1P server* variants utilizing differing capacities of DRAM and SCM. The detailed specifications and relative costs of these platforms compared to the baseline *2P server* platform are listed in Table 3 and 4. Platform costs are calculated based on current OCP solution provider data [54,55] and DCPMM cost relative to DRAM provided in [56,57]. The relative cost of DRAM and DCPMM are predicted to maintain similar trends over time [56]. We calculated the cost by adding the cost of individual modules. For DRAM and SCM, we used 16GB and 128GB modules, respectively. In the TCO calculations although introducing SCM adds additional power cost, when we consider the overall power of the system including CPU, NIC, and SSD, the increase of power even for our largest 1P server becomes minimal. We have a power budget for a rack of servers with some power slack and the slight rise in power for SCM is sufficiently below our rack power budget.

Table 4: DRAM and SCM cache in server configuration and memory sizes used block cache in our experiments.

Configuration	2P serv.	1P serv.	64-128	32-128	32-256
DRAM size	256	64	64	32	32
SCM size	0	0	128	128	256
DRAM Block cache size	150	40	40	12	12
SCM Block cache size	0	0	100	100	200
Other Rocksdb components	10-15	10-15	10-15	10-15	10-15
Codebase	5	5	5	5	5
2P rel. cost	1	0.43	0.5	0.46	0.53

5.4 Cache and memory configurations

To experiment with SCM benefits when added to existing configurations we examined server configurations with different sizes of DRAM and SCM. The configurations we used are shown in Table 4. Our experiments verified that *1P server* has significant performance loss compared to *2P server*. The prominent questions here are how much benefit can we achieve by adding SCM to *1P servers*, and can we still maintain the TCO benefits of *1P server* platform. Hence

we used the *1P server* with 64 DRAM and no SCM as the baseline for our evaluations. We then evaluated how much performance we can gain by adding 128 GB SCM to the baseline. Since we are interested in DRAM constrained server configurations, we also evaluate the performance gain when we further reduce DRAM to 32 GB while adding 128 or 256 GB SCM. This gives us the four server configurations provided in Table 4. Although we experimented with 64GB of SCM, as seen in Section 3, to understand the performance of different SCM sizes, DCPMM is not available as a 64GB module, so we didn't consider it in the evaluation below. To run all of the server configurations, we limited the memory usage of the DRAM and SCM for the workloads to the sizes given in Table 4. We also use 1 CPU in our experiments because *1P servers* are single-socket machines. We aimed to maximize block cache allocation to evaluate our DRAM-SCM hybrid cache. To do this we studied the memory usage of other components in RocksDB when it runs in our production servers. We then subtracted these usages from total memory and assigned the rest of the memory for the Block cache. The block cache sizes we used in our evaluations are illustrated in Table 4.

5.5 Workload generation

To generate workloads, we first selected random sample hosts running WhatsApp, Tectonic Metadata, and Laser in production deployments to collect query statistics traces, being careful to select leaders for use cases relying on Paxos. Note that hosts running the same services manifest similar statistics. Then we followed the methodology in [28,35] to model the workloads. We also extended these methodologies [28,35] to scale workloads to match the production deployments. The *db_bench* workloads we developed mirror the following characteristics of production RocksDB workloads.

KV-pair locality: This is characterized by fitting real workload trace profiles to a probability cumulative function using power distributions in MATLAB [58] based on the power-law characteristics of the workloads (see Figure 6).

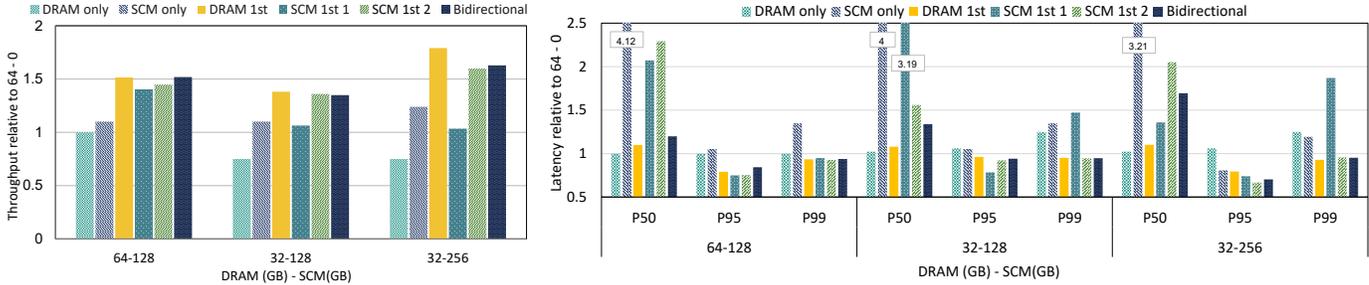

Value distribution: The granularity of value accessed is modeled using Pareto distribution from workload statistics in MATLAB [59].

Query composition: The percentage of get, put, and seek queries are incorporated in the *db_bench* profiles.

DB, key, and value sizes: We added the average values of the number of keys per database, key, and value size from collecting data from our production servers to create a realistic DB sizes in the *db_bench* profile.

QPS: The QPS in *db_bench* is modeled using sine distributions [60] based on trace collected in the production host.

Scaled db_bench profiles: After generating the workloads *db_bench* profile for a single database we scaled the workloads by running multiple RocksDB instances, simulating the number of production shards per workload on a single host. These shards share the same block cache. In RocksDB there exists multiple readers and writers to the database. To imitate

Figure 9: Throughput and application read latency comparison using only DRAM for block cache, using only SCM for block cache, and hybrid DRAM-SCM admission policies (DRAM first, SCM first, and Bidirectional) for WhatsApp using all server configurations in Table 4. (a) Throughput comparisons (db operations/sec) for admission policies. Here the baseline is 64-0 configs. (b) P50, P95, and P99 latencies for all admission policies and server configs compared to 64-0 server.

this property we run multiple threads reading and writing to the set of shards in the db_bench process.

6 Evaluation

6.1 Throughput and latency comparison for admission policies

In Figure 9 we compare the throughput achieved for 5 different categories: **DRAM Only**: The Block Cache is only allocated in DRAM. **SCM Only**: The Block Cache is only allocated in SCM using app-direct mode. **DRAM First**: The DRAM first policy discussed in Section 4. **SCM First 1 and 2**: The SCM first policy discussed in Section 4 with two threshold values. SCM 1st 1, with threshold value of 2 and SCM 1st 2 with the optimal threshold which is 6. **Bidirectional**: The Bidirectional policy discussed in Section 4 with the optimal threshold value which is 4.

In Figure 9a, we demonstrate the throughput differences of all admission policies for WhatsApp. The results show that using only SCM for block cache provides 15% throughput improvement for the 128 GB SCM configurations and 25% improvement for the 256GB SCM compared to the baseline (a server configuration with 64GB DRAM and no SCM). If we look at Figure 9b, because of latency differences between SCM and DRAM, getting data only from SCM worsens the P50 application read latencies. Therefore we conclude that while the default RocksDB SCM implementation may decrease flash IO utilization, it will have a net negative impact on Facebook application performance due to the 2X - 4X worse P50 latency observed. We can also see in the figure for all the server configurations DRAM first policy achieves the best performance. For 64 - 128 and 32 - 128 configurations, SCM first and Bidirectional get close in throughput benefit to DRAM first, but when there is a large block cache, like in the 32 - 256 configuration DRAM first attains the best result. This is because, in DRAM-first, data transfer between DRAM and SCM cache only occurs once, when DRAM cache evicts data to SCM. But in the case of SCM and Bidirectional policies, data transfer occurs when DRAM evicts data to SCM and when hot blocks are transferred from SCM to DRAM.

This creates more bandwidth consumption across the DDR bus resulting in performance degradation, especially for configurations with large block cache sizes. For larger DRAM capacities, SCM first 1, SCM first 2, and Bidirectional policies have comparable throughput because the large DRAM size reduces data evictions to SCM. But as DRAM is reduced (in 32 - 128), SCM 1st throughput falls quickly because it will move data from SCM to DRAM with a low activation threshold. When we increase DCPMM capacity in the 32 - 256 case, data transfer increases even for SCM 2 and Bidirectional policies, hence the DRAM first policy is the overall performance winner. If we look at read latencies shown in Figure 9b, the P50 latency remains similar for DRAM first compared to 64 - 0 configurations. The reason for this is that P50 latencies are primarily governed by DRAM accesses. The effect of data transfer from flash instead of SCM can be observed in the P95 and P99 latencies, where the DRAM First policy does significantly better than other policies and the default configuration with no SCM. Tectonic Metadata and Laser (not shown here) also attain the best performance with DRAM first policy.

6.2 Performance comparison of DRAM first policy for all workloads

Figure 10 shows the throughput and latency comparison of WhatsApp, Tectonic Metadata, and Laser for DRAM first admission policy (**the best admission policy for all workloads**) for all server configurations. As seen in the figure, our hybrid block cache implementation provides throughput improvement for all the workloads. As seen in Figure 10a, 10b, and 10c throughput is increased up to 50 - 80% compared to the baseline *IP server's* 64 - 0 due to the addition of SCM. The throughput increase is correlated to the total size of the block cache. Note that increasing the SCM or DRAM capacity further than 256GB will require either more DIMM slots or higher density DIMMs, with different price/performance/reliability considerations. The size of the database also impacts locality and the maximum throughput benefit, as discussed in 3.2. Because Tectonic Metadata has a larger DB size than WhatsApp or Laser the throughput benefit is expected to be smaller for each configuration. Looking at application level

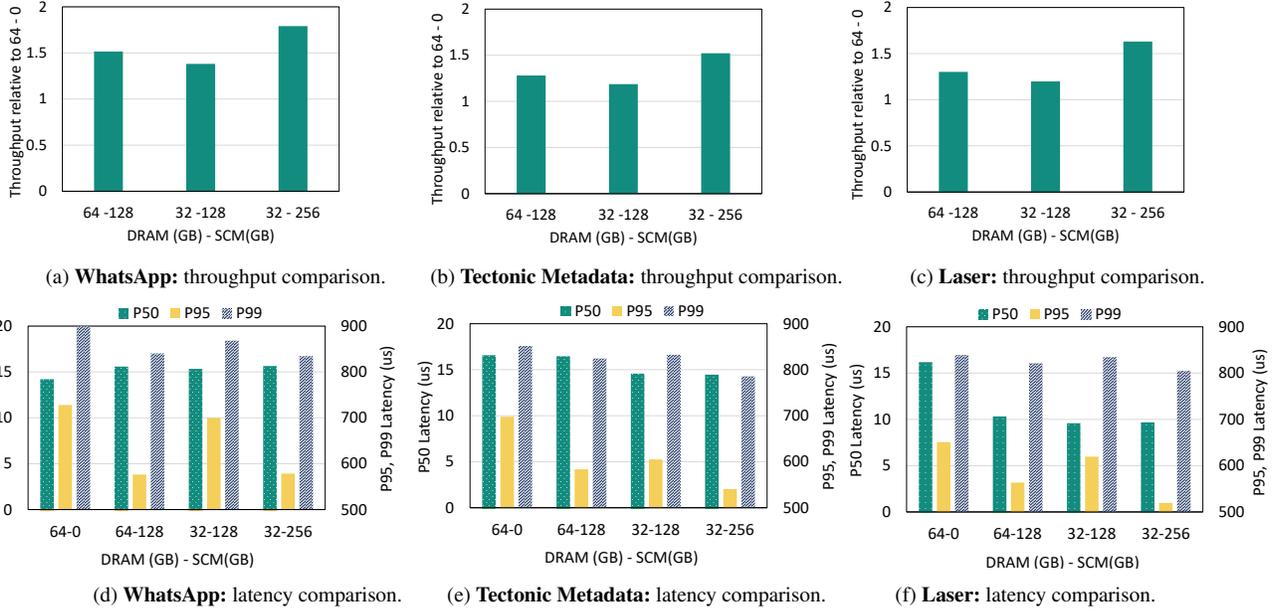

Figure 10: Throughput and application read latency comparison for WhatsApp, Tectonic Metadata and Laser for DRAM first admission policy using all server configurations shown in Table 4. (a,b, and c) Throughput comparisons (db operations/sec). Here the baseline is 64 - 0 configs. (d, e and f) absolute P50, P95, and P99 latencies for all workloads and server configs.

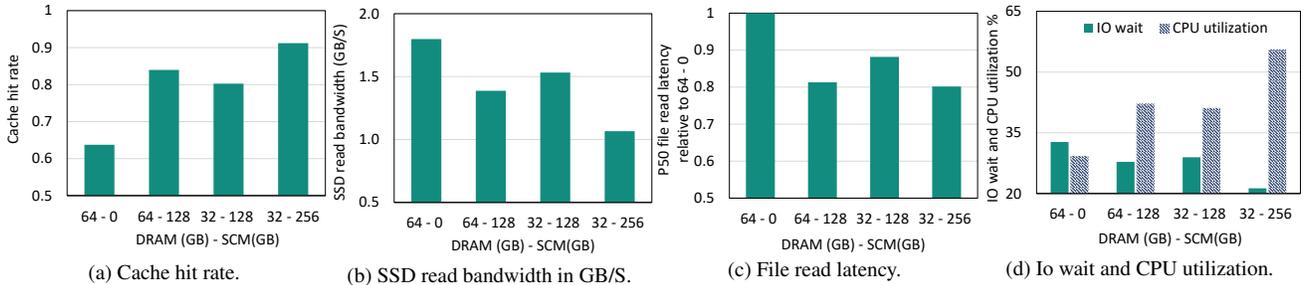

Figure 11: Cache utilization, IO read bandwidth, IO read latency, IO wait and CPU utilization of WhatsApp for DRAM 1st admission policy.

read latency in Figure 10d, 10e, and 10f, we observe that P50 latency is relatively stable for WhatsApp and Tectonic Metadata. While P50 latency does improve for Laser, the absolute magnitude of the improvement is less significant than the improvements to tail latency. P95 and P99 show an overall improvement of 20% and 10% respectively for all services. The P50 latencies primarily reflect situations where the data is obtained from DRAM. The benefit of SCM is reflected in P95 and P99 scenarios where in one case the data is in SCM, while the default case the data is in flash storage. Write latencies in all cases stay similar since we are only optimizing the block cache used for reads, while writes always go to the memtables residing in DRAM.

6.3 IO bandwidth, cache and CPU utilization

Figure 11 illustrates the cache hit rate, IO bandwidth, and latency improvement of DRAM first policy for WhatsApp. As seen in Figure 11a, the higher capacity of the block cache (sum of DRAM and SCM cache) leads to a higher cache hit rate. We show in Figure 11a, that for WhatsApp the hit

rate increases up to 30% and the increase is correlated to the cache size. Tectonic Metadata and Laser (not shown here) also follow a similar pattern of increasing hit rates.

Another important indicator explaining throughput gain is SSD bandwidth utilization. As the cache hit rate increases for the server configurations with SCM it translates to less demand for read access from the SSD, and therefore decreased IO read bandwidth. Figure 11b shows for WhatsApp adding SCM reduces SSD read bandwidth by up to 0.8 GB/s, or roughly 25% of the SSD's datasheet max read bandwidth. Figure 11c shows the file read latency improvement for all server configurations relative to 64 - 0. Decreased demand for read IO bandwidth improves the P50 latency by up to 20%. Latencies at higher percentiles stay the same because there are still scenarios where the IO queue will be saturated with reads, which drives worst-case latency. But for the majority of the requests, latencies are improved because of the decrease in IO bandwidth. The other workloads also show similar patterns. Figure 11d shows the CPU utilization for all server configurations. We observe that the CPU utilization increases

as the block cache size increases. This is due to the increase in CPU activity as we increase amount of data accessed with low IO wait latency from the cache. One thing to note is, even though CPU utilization increase for our new *IP server variants*, we can still safely service the workloads with 1 CPU even in the largest 256 SCM configuration.

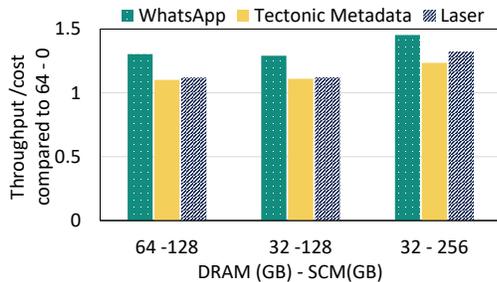

Figure 12: Throughput/cost of WhatsApp, Tectonic Metadata and Laser normalized to 64 - 0 IP servers throughput/cost.

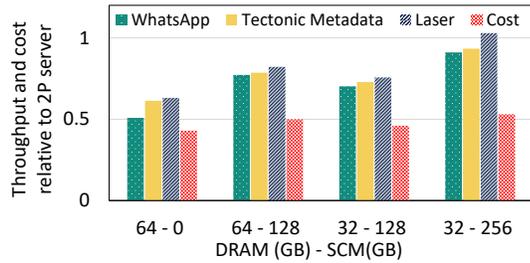

Figure 13: Throughput of IP and its variants compared to 2P servers.

6.4 Cost and performance

In the above sections, we aim to understand the performance achieved for different DRAM and SCM variations of the *IP server* configuration. The large capacity of SCM per DIMM slot enables us to dramatically increase the memory capacity of the platform without impacting the server motherboard design. As seen in Table 4 adding SCM increases the cost of a server. Figure 12 estimates the performance per cost compared to baseline *IP server* (64 - 0) configuration. We observe in the figure that the 32 - 256 configuration gives the best cost relative to performance across all workloads. In this configuration the 23% cost increase over the 64 - 0 baseline produces a 50% - 80% performance improvement. To a smaller degree the 64-128 and 32-128 configurations also provide performance-relative cost benefits over the standard *IP server*. Notable is the fact that the benefit across these two configurations is nearly identical due to the proportional difference in DRAM cost vs. performance increase. If future DRAM/SCM hardware designs provide additional flexibility across capacity pricing then we may discover new configurations which achieve even larger TCO benefits.

In Figure 13, we present a throughput comparison between the *2P server* and the various *IP server* configurations. The figure shows that increasing the amount of SCM brings throughput closer to parity with the *2P server* for a minimal

Table 5: Performance equivalent TCO relative to 2P.

Server types	2P server	1P server	1P (32 - 256)
Relative TCO	1.0	0.72 - 0.86	0.52 - 0.57

increase in relative cost. While the baseline *IP server* (64 - 0) configuration only achieves 50 - 60% of the performance of a *2P server*, the 32 - 256 *IP* variant raises relative performance to 93 - 102%. By dividing the relative cost of the platforms (Table 4) by their relative performance (Figure 13) for each workload we derive the performance-equivalent TCOs in Table 5. In the case of the 32 - 256 configuration, improving *IP* performance with SCM improves the relative TCO to 0.52 - 0.57 of the *2P server*. Therefore, we demonstrate that deploying SCM configurations of *IP servers* instead of *2P servers* results in an **overall cost savings of 43% - 48%** across some of the largest RocksDB workloads at Facebook. Note that although SCM adds more power per rack (5-10%) the performance gain allows us to deploy fewer racks, hence it's evidently a power win compared to the 64-0 server.

General takeaway: From this project, we have learned that SCM creates cost-effective solutions to increase performance in data centers. We have observed that based on the workload hotness/locality we can utilize DRAM and SCM to serve most workloads efficiently.

Even though the performance and cost of using SCMs are impressive for the chosen workloads, and the performance gain can be translated to other read-dominated workloads in our environment, a discussion on whether we should have a deployment of SCMs in Facebook at scale is outside the scope of this paper. We briefly discuss some additional challenges of mass-scale deployment:

Workloads: Section 3.2 talks about the class of applications that would benefit from SCM. We have also identified a number of write-heavy workloads at Facebook that would not benefit from SCMs.

Reliability: Since SCMs are not widely available in the market, the reliability of SCMs is a concern until they have been proven in mass deployments.

SKU diversification: Adding a new hardware configuration into the fleet requires consideration of other costs like maintaining a separate code path and creating a new validation and sustainability workflow. This complexity and cost will be added to the practical TCO of any new platform deployment.

7 Discussion and future work

In the previous section, we demonstrated that KV Stores based on RocksDB are examples of the potential advantages of SCM in a large data center. In the future, we want to experiment with extending the memory capacity of other large memory footprint workloads using SCM. Some candidate large scale workloads that will profit from large memory capacity are Memcached [61, 62] and graph cache [27]. Memcached is a distributed in-memory key-value store deployed in large data centers. Optimizing Memcached to utilize SCM will enable an extension of memory beyond the capacity of DRAM.

Graph cache is a distributed read optimized storage for social graphs that exploits memory for graph structure-aware caching. These workloads are read-dominated and have random memory accesses that can benefit from the high density and byte-addressable features of SCM. Although in this paper we did not leverage the persistent capability of SCM for RocksDB uncompressed block cache, in the future we want to study the benefits of fast persistent SCM for the memtable and SST files. We also want to explore with SCM is its performance via emerging connectivity technology such as Compute Express Link (CXL) [63]. The workloads we analyzed in this paper are more latency bound than memory bandwidth bound but, for high memory bandwidth-demanding services, sharing DRAM and SCM on the same bus will create interference. In such cases having dedicated SCM access via CXL will avoid contention, but at the same time will potentially increase data access latency, requiring careful design consideration.

8 Related work

Performance analysis and characterization in DCPMM:

Recent studies proved the potential of commercially available Intel® Optane™ memory for various application domains. [19, 64] has determined the performance improvement of DCPMM in memory and app-Direct modes for graph applications. [20, 21] evaluated the performance of DCPMM platform as volatile memory compared to DRAM for HPC applications. DCPMM performance for database systems were shown in [16, 65–68] both as a memory extension and for persisting data. Works such as [15, 18, 24, 69] also shows the characteristics and evaluations of DCPMM when working alone or alongside of DRAM. Specifically, [18] has identified the deviation of DCPMM characteristics from earlier simulation assumptions. While these works shed light on the usage of DCPMM for data-intensive applications, in our work, based on the memory characteristic findings of these work, we analyzed the performance of DCPMM for large data data-center production workloads. Our work focus on utilizing the DCPMM platform to the best of its capability and study its possible usage as a cost-effective memory extension for future data-center system designs.

Hybrid DRAM-SCM systems: Previous works studied hybrid DRAM-SCM systems to understand how we can utilize these memories with different characteristics, together and how they influence the existing system and software designs. [70–73] have shown the need for a redesign of existing key-value stores and database systems to take into account the access latency differences between DRAM and SCM. Similarly, by noting the latency differences in these memories, we carefully place hot blocks in DRAM and colder blocks in SCM in our implementations. When deploying hybrid memory, another question that arises is, how to manage data placement between DRAM and SCM. In these aspects, [74] demonstrated efficient page migration between DRAM and SCM based on the memory access pattern observed in the

memory controller. In addition, [75–83] perform data/page transfer by profiling and tracking information such as memory access patterns, read/write intensity to a page/data, resource utilization by workloads, and memory features of DRAM and SCM, in hardware, OS, and application level. These works aim to generalize usage of DRAM and SCM to various workloads without involving the application developer, hence requiring hardware and software monitoring that is transparent to the application developers. But in our case, the RocksDB application-level structure exposes separate reads and writes paths and frequency of access of data block. These motivated us to implement our designs in software without requiring any additional overhead in the OS and hardware.

RocksDB performance improvements: [84] demonstrated how to decrease the memory footprint of MyRocks, which is built on top of RocksDB, using block access based nonvolatile memory (NVM) by implementing secondary block cache. While their methods also decrease DRAM size required in the system, the block-based nature of NVM increases read amplification. This is because, the key-value size in RocksDB is significantly less than the size of the block, whereas in our methods, using byte addressable SCM avoids such issues.

9 Conclusion

The increasing cost of DRAM has influenced data centers to design servers with lower DRAM per compute ratio. These servers have shown to decrease the TCO for scalable workloads. Nevertheless, this type of system design diminishes the performance of large memory footprint workloads that relies on DRAM to cache hot data. Key Value stores based on RocksDB is one such class of workloads that is affected by the reduction of DRAM size. In this paper, we propose using Intel® Optane™ PMem 100 Series SCMs (DCPMM) in AppDirect mode to extend the available memory for RocksDB to mitigate performance loss in smaller DRAM designs while still maintaining the desired lower TCO of smaller DRAM systems. We carefully studied and redesigned the block cache to utilize DRAM for the placement of hot blocks and SCM for colder blocks. Our evaluations show up to 80% improvement to throughput and 20% improvement in P95 latency over the existing small DRAM platform when we utilize SCM alongside DRAM, while still reducing the cost by 43-48% compared to large DRAM designs. To our knowledge, this is the first paper that demonstrates practical cost-performance trade-offs for potential deployment of DCPMM in commercial datacenters.

Acknowledgments

We like to thank our shepherd, Tudor David, and the anonymous reviewers for their thorough comments that greatly improved this work. We are also grateful to Yanqin Jin, Jesse Koh, Darryl Gardner, Siying Dong, Pallab Bhattacharya, Shumin Zhao, and many others at Facebook for their support and suggestions in this research project.

First Responder: Persistent Memory Simultaneously as High Performance Buffer Cache and Storage

Hyunsub Song Shean Kim J. Hyun Kim Ethan JH Park Sam H. Noh
UNIST (Ulsan National Institute of Science and Technology)

Abstract

Persistent Memory (PM) is a new media with favorable characteristics that can vastly improve storage I/O performance. While new PM based file systems have been developed to exploit PM, most work have not been successful in fully integrating PM media with traditional storage media such as SSDs and HDDs. We present First Responder (FR), a means to exploit the beneficial features of PM, while making use of modern and mature file systems such as Ext4 developed for traditional storage devices. Conceptually, FR is much like a buffer cache, but much more is involved such as maintaining consistency under failure and providing featherweight management overhead. FR brings about multiple benefits. First, we retain the maturity of existing file systems allowing deployment of FR at settings where traditional file systems are deployed. Second, traditional storage devices supported by these file systems can be used allowing easy integration of PM with traditional storage. Finally, FR allows in-order file system semantics at close to PM device latency. With experimental evaluations with the Intel DC PMM, we show that FR, when used in cache form, can outperform Ext4 by more than 9×, while providing durable in-order file system semantics, whereas Ext4 cannot. We also show that when used as part of a typical file system, performance is comparable with NOVA and Ext4-DAX.

1 Introduction

Persistent Memory (PM) is a new media with favorable characteristics such as nonvolatility and close to DRAM performance that can vastly improve storage I/O performance. To exploit these characteristics, new PM based file systems are being developed [7, 8, 19, 23, 52, 58]. These file systems, while providing high performance, suffer from the following two limitations. First, as the time to maturity for a file system is long and a file system is a complex beast [11, 30, 42], most of these relatively young and immature file systems will not survive the test of time. For example, among the many file systems proposed, currently, NOVA [52] and DAX [36] are the only ones that are stable and being maintained. Second, how

these file systems will integrate with existing storage devices such as SSDs and HDDs is not straightforward. For example, both NOVA and DAX assume that the storage media is PM. In the long run, PM will fill up and some form of migration may be needed to vacate PM, which some file systems are not designed to do. Efforts to resolve this have been proposed. In their seminal paper, Kwon et al. propose a cross-media file system called Strata that can span a set of heterogeneous storage devices such as PM and traditional devices [23]. Separately, Ziggurat, proposed by Zheng et al., is a tiered file system that supports a combination of devices [58]. However, both proposals suffer from the first limitation; Strata, at the time of this writing, still is not fully functional [46] and Ziggurat is not open sourced and thus, its status is unknown.

The goal of this study is to encompass the goals of previous PM file system developments. More specifically, the goals of previously proposed PM based file systems can be summarized as follows. First, file system performance should extract the benefits that PM brings as storage media. This is an obvious goal when deploying PM. Second, it should support the more natural in-order file system semantics [23] brought upon by PM. In-order file system semantics is where all file system operations, including writes, occur in the exact order in which they are executed. Typically, this has been impossible due to the writes, which were too slow to persist in order because of the slow devices. Thus, application developers had to choose between performance and durability. While it is true that some applications do not require durability of writes or are highly optimized to minimize sync's, many applications knowingly choose performance over durability, being aware of the negative consequences of failures [10, 37, 42]. With the advent of PM, such choice seems unnecessary as providing in-order file system semantics should be natural and easy [23, 42, 52]. However, to date, supporting such semantics is possible only with a total revamp of the file system. Third, it should support traditional storage media alongside PM (similarly to Strata and Ziggurat) [23, 58]. Our work encompasses these goals and yet, instead of developing yet another file system, our design allows to retain the modern, mature, constantly evolving

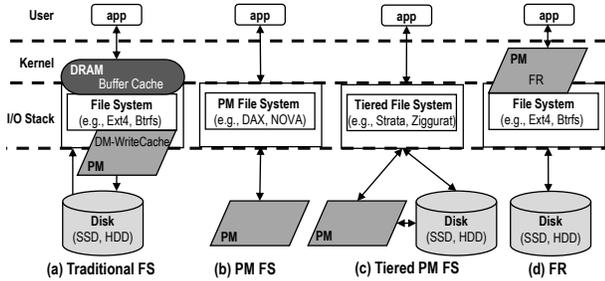

Figure 1: Comparison of PM use scenarios for file systems

file systems such as Ext4 developed for traditional storage devices.

In this study, we introduce First Responder (FR), the solution that we propose. FR, like a buffer cache, absorbs requests at the topmost layer of the I/O stack in PM, as shown in Figure 1(d), then immediately responds to the requests (hence, the name). For reads, the requests end there, while for writes, the requests are forwarded to the traditional file system, in effect, hiding the entire I/O stack overhead.

At first glance, FR simply appears to be nothing but a buffer cache that is persistent, but in reality, a lot more is involved. In fact, FR is a union of storage and a cache. As it will become more evident later, FR is storage as the contents that reside in FR are consistent and permanent like any that is stored in traditional storage media that have gone through the entire storage stack. Thus, in that sense, flushing to the traditional file system underneath is optional. FR is also a cache as the size is limited (though generally large) and eventually, it is flushed to the traditional storage media through the I/O stack. Naturally, the design of FR is much more involved as maintaining consistency under failure and providing featherweight management overhead become technical issues that need to be dealt with. We elaborate on these issues later.

There are two key benefits to FR. First, writes are immediately durable. Thus, even applications that do not require in-order semantics, but that issue occasional `fsync()` can benefit. Second, FR can coexist largely independently of the underlying traditional file system. This allows for any mature file system to take advantage of the benefits of PM. This is especially important as efforts to move to disaggregation of resources is gaining traction [3, 43, 48]. Thus, much extra effort to integrate PM based file systems to any conventional setting including disaggregated settings is not necessary with FR. While we concentrate on the Ext4 file system in most of our discussions, we also show performance results when using Btrfs [5, 41] as the underlying file system.

Our performance evaluations with the Intel DC PMM using an FIO generated synthetic workload show that FR, when used in cache form, can outperform Ext4 by more than 9 \times , despite providing durable in-order file system semantics, while Ext4 cannot. Using the Filebench and YCSB benchmarks, we also show that when FR is used as part of a typical file system, performance is comparable with the default Ext4, Ext4 with DM-WriteCache, NOVA, and DAX, while, again, providing

durable in-order file system semantics.

In the remainder of the paper, we first discuss progress on work related to PM and distinguish how FR is different from them. Then, we present the design of FR in two separate sections; Section 3 discusses the overall design and in Section 4, we present a detailed discussion of how FR maintains consistency as this is key in providing a correct, yet efficient system to users. In Section 5, we perform a comprehensive evaluation of FR using the Intel DC PMM platform. We compare FR with NOVA and DAX, the two open source PM supporting file systems, and the default Ext4 and DM-WriteCache, which do not provide immediate durable in-order semantics supported by PM file systems. Then, we conclude in Section 6.

2 Related Work

Persistent Memory (PM) technologies represented by PCM (Phase Change Memory) [38] and STT-MRAM [22] are being considered as high performance storage mediums as they are nonvolatile and yet, provide random byte addressability and latency similar to DRAM. Intel recently commercialized the Optane DC PMM, the only product currently available in the market [15, 17, 53]. It can be used in one of various forms, specifically, as storage, as memory with DRAM as its cache, and as an extension of memory [14]. While many recent studies have considered file systems for PM [7, 8, 19, 23, 52, 58], our work is not about developing a new PM file system, but rather on integrating PM with existing modern file systems developed for traditional storage devices.

The closest set of related work are studies on the buffer (or page) cache. The buffer cache, as depicted in Figure 1(a), is a DRAM layer that attempts to hide the low performance of storage and has been a topic of study for generations, mostly concentrating on the replacement or prefetching policy issues [2, 18, 50]. This was important as performance between DRAM and storage was many orders of magnitude different. With the advent of higher performing storage devices, there have been arguments as to the need for the buffer cache [8, 21, 52] as well as attempts to revisit this topic [20, 24, 51]. In particular, the DM-WriteCache [20] is an interesting optimization that introduces a new nonvolatile layer, as PM or SSD, just before the slower storage device, which could be an SSD or HDD, as depicted in the lower part of Figure 1(a). DM-WriteCache, supported from Linux 4.18 and beyond, is a writeback cache that helps to improve performance by caching writes from the page cache to the storage media. However, as writes are first written to the page cache,

in-order file system semantics is not supported. The contrast between Figures 1(a) and (d) show how DM-WriteCache and FR are different by design.

There are also studies of the buffer cache that exploit the nonvolatile nature of PM [25, 40, 51]. UBJ, one of the first studies in this realm, makes use of PM based main memory as a buffer cache that unifies the functionalities of journaling and caching [25]. Tinca is a PM based buffer cache located in the external disk cache below the DRAM-based main memory [51] that uses a similar technique proposed in UBJ. FR is different from these studies in that durability is provided from the earliest layer of the I/O stack allowing immediate response. This requires careful design for consistency with the underlying file system, which these earlier studies neglect.

Retaining consistency is a key design issue for FR. Similarly, consistency has been the central issue in the design of numerous studies on data structures for PM. With efforts to reduce instructions that control write order [13, 35] such as `clwb` and `sfence` as these instructions incur considerable overhead [17], while, at the same time, abiding to the 8-byte failure atomicity restriction to maintain consistency, various data structures for PM have been proposed [12, 27, 31, 55]. FR conforms with these efforts as it carefully designs the use of 8-byte writes with `clwb` and `sfence`.

Other related studies include PM based file systems. Recent studies have proposed many optimizations including user-level approaches to avoid crossing the kernel boundary in an effort to improve performance [7, 19]. While so, only NOVA and DAX are stably supported in Linux. They all, more or less, share the common layout shown in Figure 1(b). Out of these, as mentioned previously, Strata and Ziggurat, are unique in their support of traditional storage media in the form depicted in Figure 1(c). These diagrams contrast the differences between them and FR. Finally, a recent study presents Assise, a new distributed file system based on Strata, where PM is used as a client-local cache layer [4]. The use of PM cache and its effectiveness is coordinated in a distributed setting through replication and choices between pessimistic and optimistic consistency modes. This is different from our approach where we exploit existing file systems and consistency is always immediate, though locally ensured. Table 1 summarizes how previous local file systems differ from FR.

3 First Responder: The Design

In this section, we present the design of First Responder (FR). Before moving on, we set the premise on which our discussion is presented. First, even though FR could be implemented in either the user or kernel layer, we will describe it within the latter layer as we implement it in the VFS layer. Second, as the main dealings of FR are with the `read()` and `write()` calls and as `read()` follows trivially from `write()`, we concentrate on `write()` in the following discussions. We first discuss the assumptions, then the design choices that we make based on the challenges we face.

3.1 Basic Architecture and Design Choices

Like many previous studies that assume memory to be a hybrid of traditional DRAM and PM, FR works under this assumption [4, 33, 52]. PM used by FR is a temporary storing ground, and yet it is also storage. That is, what is stored in PM is durable and consistent, though eventually, we anticipate its contents to be stored in traditional storage media such as SSDs and HDDs.

Traditional systems support two types of write modes, namely, synchronous and asynchronous. In FR, all aligned full chunk and/or new writes are synchronous, that is, they are persisted immediately into PM by FR. Writes of partial chunks already residing in underlying storage must first be read into PM for consistency, but we find them to be only a small portion of writes. FR manages the data and the location of where the data should be placed within PM, guaranteeing consistent and durable writes as PM is nonvolatile. Thus, applications upon receiving the response can continue execution being assured that the write I/O request was serviced successfully. Note that this has the consequence of dramatically reducing the I/O path for such synchronous writes compared to traditional file systems.

In the previous section, we mentioned that FR is like a buffer cache, but that much more is involved. We now discuss the two specific issues that must be resolved, that is, maintaining consistency upon failure and providing feather-weight management overhead, which the traditional buffer cache cannot support.

Handling Overhead: Recall that the traditional buffer cache was developed as an optimization to alleviate the burden due to slow storage, which was orders of magnitude slower than DRAM. Thus, the buffer cache maintained separate data structures and elaborate replacement algorithms were developed. Compared to accessing slow disks, maintaining such data structures and running these algorithms were negligible. However, as previously observed, software overhead considered to be negligible in the past is no longer so with faster media [26, 45, 54]. This becomes more important as PM is close to DRAM performance, which means that every little overhead counts. Thus, management with such high cost is unacceptable with PM systems.

To alleviate such overhead, FR chooses a simple, static indexing scheme for placement as well as replacement as we explain below. However, we must first argue that this is a valid approach. For this, we perform our own set of experiments to quantify the software effects of managing a cache, which we elaborate on in Section 5.2. Briefly, we implement indexing structures such as the Radix tree and the LRU replacement policy and find the overhead to be an order of magnitude higher than the static approach that we propose, concluding that with faster media such as PM, software overhead is profound.

The obvious question here, then, is, won't this static indexing increase the miss ratio? The obvious answer, of course, is yes; but we argue that this is true only under the traditional

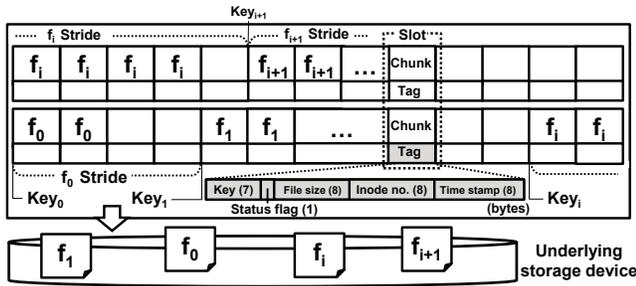

Figure 2: Internal organization and components of FR

assumption that the cache size is a very small fraction of storage capacity. This leads to our more important argument that, if the cache is sufficiently large, then, we may be able to avoid most cache misses. For reads, a miss is inevitable on the first read from storage. However, aside from these, it is well known that as the cache grows, the effect of the caching policy diminishes. For writes, a miss can be defined as a forced storage access when the new write collides with a block that is dirty. Then, so long as we keep all blocks clean, that is, synchronized with storage, then all misses can be eliminated. We show below that, under simplifying assumptions, if the cache is large enough all write misses can be avoided.

Imagine the cache to be organized in array form with the index i and S_b denoting the location and block size of the cache, respectively. Let C_s be the cache size and assume that for our system, the time to flush a block to storage and receive an acknowledgement (in order to synchronize) takes at most t_f time. Let us assume that the peak write rate for the cache media is r_{peak} GB/s. Assume that a very large write that is purely sequential arrives consecutively in S_b units and in t_i intervals, being placed from index $i = 0$ of the cache. To avoid all misses, the cache should be large enough such that when the entire cache fills up and wraps around to the beginning of the cache, the cache entries there are all clean. Thus,

$$t_f \leq \frac{C_s}{r_{peak}} \leq \frac{C_s \times t_i}{S_b} \Rightarrow C_s \geq \frac{t_f}{t_i} \times S_b \quad (1)$$

Then, with C_s satisfying Equation 1, no forced flushing of dirty blocks will occur for sequential writes.

Let us apply Equation 1 on an example. Assuming $S_b = 4$ KB, for current PM, we find that the peak write rate is roughly 4GB/s (not including any software overhead) when `clwb` and `sfence` operations are issued per chunk write. Thus, even when writes are coming in at full throttle, simple calculations show that a 128GB PM will need 32 seconds to wrap around the cache. In a recent article, Alibaba reported that it saw a peak order rate of 544,000/s [47]. While we understand that orders do not translate to actual I/O and, as Vuppapalati et al. report for the Snowflake infrastructure running on the Google Cloud Platform and Microsoft Azure [49], I/O requests come at more moderate rates, let us take the Alibaba numbers and say that an $S_b = 4$ KB request comes in every 2μ s, that is, $t_i = 2\mu$ s. Then, to wrap around the 128GB of PM, it takes 64 seconds.

In real life, of course, not all writes are sequential and other factors come into play. Also, keeping a cache in the GB range was not considered the norm though this is changing. One example is the Memory Mode use of PM where all of DRAM (which is in the many GB range) is used as a cache of PM [14]. However, as we will see later, sequential allocation of files is an important strategy in FR. Furthermore, as FR is based on the premise that PM is in the size range used by PM based file systems such as NOVA and DAX, for example, at least 128GB, this sufficiently large cache size allows the accommodation of a static indexing scheme, which we now describe.

Figure 2 shows, at a high level, how FR manages its space. FR uses a simple indexing structure based on a key associated with each file. (The details of what comprises chunks and slots as well as the how the indexing structures are maintained are given in Section 4.) Specifically, the index is simply calculated using $key_{c+1} = key_c + stride$ where key_c is the current key (initially 0) and $stride$ is a value dynamically determined for the workload. (Details of terms and their use are discussed in Section 4). In short, every file has its destined location within FR with no PM allocator involved, resulting in very little overhead for placement. Similarly, there is no need for replacement victim selection.

Handling Consistency: FR is a management module for data that resides in PM. That is, when a user requests a write, FR is the module that provides the response. The writes are made to PM, and they must be made durable such that they are recoverable upon system failure. For example, we cannot have torn writes; upon recovery from failure, its state should be either before the write or after the write. Also, as FR is the first responder to the underlying file system, eventually all data (and metadata) writes must reach the underlying storage, be it SSD or HDD. For example, consider a case where an overwrite of a block A, which resides in traditional storage happens. Upon a write, the user could receive an acknowledgement immediately after the data is placed in PM. However, this data and block A in storage are not in sync. Ensuring immediate in-order file semantics so that what the user perceives as valid data is indeed the (eventual) actual data, even in case of failures, is not a trivial matter. This may incur considerable performance overhead or require a completely new design of a PM-aware data structure, which is not an easy task as exemplified by previous studies [12, 27, 31, 59].

For this consistency issue, we develop a protocol under the PM 8-byte failure atomicity assumption. Like previous methods, the basic idea is to keep a dual copy of the data [16, 32], but the devil is in the details. Thus, a detailed and lengthy discussion is required, which we continue in the next section, along with a discussion on the failure recovery mechanism.

4 Data Consistency and Recovery Protocol

In this study, we say data in a file is consistent if, upon a write request to that file by an application, the data in the file is as before the write request or reflects all of the contents of

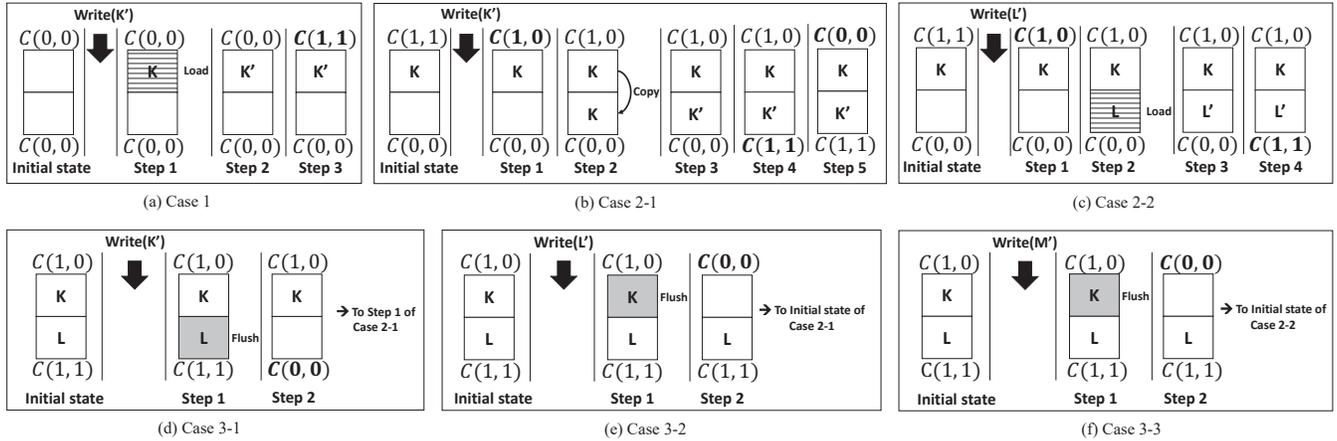

Figure 3: The figure shows the steps taken based on the initial condition of a slot when a write is requested. The $C(V,N)$ values on top and below the slot, that is, the two chunks are the status flags associated with each chunk. The changes to these status flags, denoted by the bold characters, are done atomically.

the issued write. Furthermore, guaranteeing data consistency means that write requests that have been acknowledged as having been written are eventually made durable and found through the underlying file system. In this section, we present the protocol that FR uses to guarantee data consistency.

4.1 The Basic Components

Figure 2 also shows the inner components of FR. There are a total of P continuous *chunks*, where a chunk is the load/store unit to storage, and P *tags*, with each tag being associated with one chunk. The chunks are organized in pairs, which we call a *slot*. As will be evident later, both chunks within a slot are used in full, making full use of the entire PM. The tag consists of the *key*, bits to represent the status of the corresponding chunks, the file size, the inode number, and the timestamp. The key is a unique number associated with the file slot assigned to it by FR upon file creation and stored in the inode of the file. This key is simply a global key maintained by FR, initialized to 0 and monotonically increased in *stride* increments upon every file creation, where the stride is set to reduce collisions, where a *collision* is defined as an allocation of two (or more) files to the same slot. We discuss how the stride is set in Section 4.3. Thus, the number of files that can be created is limited by the number of bits used to represent this value. In our current implementation, we use 56 bits and, for now, we make no effort to remedy this limitation as we think this is enough to represent the number of files for a system lifetime. There are other metadata in the tag, but they are discussed as the need arises.

4.2 Data Consistency Protocol

With PM, design for consistency must be done with the 8-byte failure-atomic write supported by the architecture. With traditional systems, providing durability with consistency becomes complex as the critical path to durability can be quite long.

However, as we elaborate below, with FR, no allocation algorithm is invoked and only a few bytes are needed to guarantee data consistency of the file system.

Writes: With FR, it is vital that writes to chunks are done in an atomic manner, and thus, immediately durable. We now present the core design of FR that quickly enables durable in-order semantics of the data written to the file system.

For our discussion, we assume that the key and status flag in the tag are written with 8-byte failure atomicity guarantee supported by the hardware, where the status flag contains 2 flags V and N (and other information that we ignore for now). V distinguishes valid versus invalid and N with value 1 denotes the new, more recently written chunk in the slot. We denote the flag states of chunk C as $C(V,N)$, and further, denote the states of the pair of chunks in slot S as $S[C_1,C_2]$. We regard $S[C_1,C_2]$ and $S[C_2,C_1]$ the same as the algorithm works in the same way given the two states.

The series of figures in Figure 3 show how an incoming write is managed. Upon a chunk write, the slot to place the chunk is determined by $(key \bmod \lfloor \frac{P}{2} \rfloor)$, which designates the first chunk of the file determined by the key attribute *key* assigned to each file upon creation, and its displacement from the start of the file. The write that is serviced by FR is denoted $Write(X)$, and X is an object that is of any size, though in our discussion, for simplicity, we assume that X is smaller than or equal to the chunk size. (If X is larger, then it simply takes multiple chunks, which we discuss separately in Section 4.4.) The pair of chunks in the slot indexed can be in one of three states, denoted above and below the chunks in Figure 3:

- $S[C(0,0),C(0,0)]$, the slot is empty, that is, both chunks of the pair contain no data (empty/invalid)
- $S[C(1,1),C(0,0)]$, only one chunk has valid data
- $S[C(1,1),C(1,0)]$, both chunks have valid data.

We now discuss each of the cases in detail. **Case 1:** This is when both chunks of the slot are invalid, that is, $S[C(0,0),C(0,0)]$. We can choose any chunk of the

pair to write to. Upon `write(K')`, if a chunk of the unmodified `K` exists in storage, it is first read in to the chunk.¹ Then, `K'` is written to the chunk and persisted with the `clwb` and `sfence` operations. Then, the tag `C(0,0)` is set to `C(1,1)`, and only after this setting is the request acknowledged.

Note that `clwb` and `sfence` operations must be performed by default for writes to FR for the write to persist. Hence, we assume that they follow by default unless otherwise mentioned and will be omitted in discussions hereafter. We reiterate that, here and throughout our discussion, these flags are part of the tag and changes to them are done atomically. The state of the chunk pair in FR before and after `write(K')` is shown in Figure 3(a).

Case 2: Here one chunk holds a valid object `K` while the other is invalid, that is, $S[C(1,1), C(0,0)]$. There are two cases to consider here; first is when `K` is being modified and the other is when a new object is being written, which can be distinguished by the uniqueness of the key. When `K` is updated, denoted by `write(K')`, `C(1,1)` is first modified to `C(1,0)`, stating that `K` is still valid but is no longer the new chunk. Then, `K` is copied to the chunk with state `C(0,0)` and the update is reflected in this chunk. Then, `C(0,0)` is modified to `C(1,1)`, and finally, `C(1,0)` is changed to `C(0,0)` to reflect that this chunk is now invalid. Thereafter, `write(K')` is acknowledged. This case is depicted as Case 2-1 in Figure 3(b).

Note that `K'` cannot be written to the first chunk directly, but must be overwritten on a copy of the chunk containing `K`. This is because the write may be an overwrite and failure during this write may result in a torn write. Also note that this case covers consecutive writes to the same chunk of the same file, and that in such cases all writes are being handled within the PM without any interaction with the storage device.

The second case within Case 2 is when a new object `L'` is written to the same slot as the chunk containing object `K` as in Figure 3(c). This will happen only when a different file is allocated to the same slot, that is, upon collision. Starting from the same initial state, `C(1,1)` is first modified to `C(1,0)` as this chunk will no longer be the new chunk in this slot. If `L'` is an overwrite of a chunk in storage, then the chunk containing `L` must first be read into the chunk with state `C(0,0)`, unto which object `L'` is written. Finally, `C(0,0)` is modified to `C(1,1)` as object `L'` is now valid and new.

Case 3: The final case is when both chunks in the slot are valid, that is, $S[C(1,1), C(1,0)]$, and a different valid chunk needs to be put into this slot. The initial states of such cases are shown in Figures 3(d)~(f). Let us assume the initial situation in these figures, where chunks containing `K` and `L` occupy the slot, with `L` being the newer of the two chunks. Note that this situation can arise only when a collision has already occurred as `K` and `L` must be of different files. Let us also assume for now that both `K` and `L` are dirty. There are three cases to

¹Note that if the write size is equal to the chunk size, then it need not be read from storage. Here, we are considering the worst case. This holds for subsequent discussions as well.

consider. The first two are updates of an existing object `K` or `L`. In these cases, the chunk containing the object that is not being updated is first flushed. This is to synchronize the dirty chunk with that in storage, which has the effect of making the chunk clean. Figures 3(d) and (e) depict these cases.

For Case 3-1 (and Case 3-2) where the older chunk `K` (the newer chunk `L`) is being overwritten, the other chunk `L` (`K`) is flushed and awaits the acknowledgement that the flush has completed. Once it arrives, `C(1,1)` (`C(1,0)`) is changed to `C(0,0)`, which results in a state identical to the initial state of Case 2-1. Thus, from here, the steps are the same as Case 2-1. Note that all flushes in FR are done by writing in Direct I/O mode (to be specific, with the `write_iter()` call).

Finally, the third case is when a new object is written to FR. This would be another collision with a new file on this slot. Case 3-3 in Figure 3(f) depicts this situation with `write(M')`. Similarly to the previous two cases, we must flush a chunk, and for this, we choose to flush the older chunk. Hence, in our example, the chunk containing `K` is flushed. Once the acknowledgement of the flush is received, `C(1,0)` is changed to `C(0,0)`. This results in the same initial state as Case 2-2. Thus, we proceed in the same steps as Case 2-2.

Note that, as described, Case 3 always incurs a flush to the storage device, which can be a source of overhead as the lock to the slot must be held until the acknowledgement for the flush is returned. Such flushes occur when a collision occurs and the chunk to be flushed is valid and dirty. However, note that if that chunk is either invalid or clean, the chunk need not be flushed. Fortunately, FR minimizes such flushes by design; the first source, that is, collision, is remedied by dynamically and judiciously assigning the stride value, while the second source, that is, dirty chunks, is remedied by periodically flushing the chunks in the background to make chunks clean, which we discuss in more detail in the next section. But first, we discuss how reads are handled.

Reads: Reads are similar to writes. First, the key is used to find the relevant slot. Then, a read hit is trivial as they are simply serviced out from FR. Upon a miss, we need to bring in data from storage. This case is similar to writes in that the invalid chunk will be used or if there is no invalid chunk, the old valid and dirty chunk will first be flushed out to a clean chunk. Then, the data requested will be brought in overwriting the clean chunk. The process of flushing, atomically changing the tag values, and loading follow similar steps as writes.

4.3 Strides, Periodic Flushing, and Metadata

Stride Setting: In FR, as a file is created, it is assigned a unique key, whose value is used to designate a fixed slot location in FR. Ideally, the files will be assigned as shown in Figure 2 with no overlap to avoid collisions. However, this is difficult to achieve as we need prior knowledge of the files that are created, even for those that may be appended to later on. If estimated to be too small, then collisions will occur, possibly incurring forced flushes. If estimated too large

(for example, f_0 in Figure 2), then internal fragmentation may occur leading to quicker wrap-around, for example, f_i in Figure 2. A wrap-around forces collision that could lead to forced flushes, leading to degraded performance.

We take an empirical approach in setting the stride. The basis of our approach is that file sizes are, in general, relatively homogeneous depending on the workload. For example, files in scientific workloads are small ranging in the few tens to hundreds of kilobytes [1, 28, 39], while files in database workloads are quite large being in the tens of MB to tens of GB range [29, 44]. Taking this observation, we create a Stride Table with $\langle \text{file size}, \text{file count} \rangle$ pairs where the ‘file size’ is a set of fixed numbers, and ‘file count’ is the number of files that are smaller but closest to ‘file size’. When a new file is created, we select the next larger ‘file size’ of the entry with highest ‘file count’ value as the stride value. The next larger one is selected as a larger value will lead to less possibility of collisions. As actual writes occur, the Stride Table is updated, possibly, decrementing one entry while incrementing another. Maintaining this table take only minimal memory, which in our implementation is 32KB.

Periodic Flush: While stride setting is one aspect of avoiding collision, periodic flushing is an active measure to avoid forced flushing due to collisions. Recall that forced flushing could have a negative effect on performance. To minimize this effect, we choose to periodically flush the dirty valid chunks to make them clean. Note that periodic flushing has no bearing on the consistency of data as FR is simultaneously storage and a cache. Thus, the period, p , can be set to 0 or to any value lower than the time to wrap around.

In selecting p , we take hints from Equation 1. For a sufficiently large C_s value such as 128GB or more, the t_f value may be sufficiently small to satisfy Equation 1 even under severely high request rates. Thus, a reasonable value that will not overload the underlying file system may be chosen. For our study, we choose to use $p = 10$ milliseconds as the default as this is the value that is generally used for the page cache.

Metadata: The discussion so far primarily focused on data and maintaining its consistency. As data is flushed to the underlying file system in periodic intervals, the metadata that is also maintained in the file system will only be synchronized within interval bounds. To remedy this, FR can take two measures. The first is regarding the time-related metadata such as `atime` or `mtime`. For this, FR keeps the actual timestamp for these metadata in the FR tag and flushes them as flushes occur, whether periodically or by forced flushes. The second measure is to modify metadata reading calls such as `stat()` to first flush the relevant chunks, and then, read the metadata. In FR, we have implemented the first measure, but only the `stat()` call for the second measure.

4.4 Multi-chunk Writes

While we have described writes for a single chunk, in reality writes may be composed of multiple chunks. We refer to such

writes as multi-chunk writes, which we now describe.

Fundamentally, multi-chunk writes are the same as single chunk writes. The key difference is that we provide a means to act upon the multi-chunks in an atomic manner. As accesses to chunks are controlled through individual locks, we acquire locks for each of the chunks in sequence from the first chunk to the last. Writes to chunks happen along with the acquiring of the locks. On writing the first chunk, the *not-complete* flag (another bit in the status flag byte in the tag) of this chunk is set to designate that the multi-chunk write has not yet completed. Then, the subsequent chunks are written to, along with the timestamp tag, where the timestamp of the first chunk is written. This timestamp plays a vital role in identifying all the chunks written from the same `write()` call when recovering from a failure. When all the chunks have been written to, the not-completed flag is reset, the write requesting application is notified, and the locks for all chunks are released, in this order.

4.5 Failure Recovery

The contents of FR are always recoverable from faults, be it hardware or software faults. The only exception is recovery from PM device failure where PM content is irrecoverable due to media failures or partial or full data corruption. Due to space, we only give the gist of recovery from single chunk write failure, which is that, for all faults occurring at any step in Figures 3(a)~(f), the recovered state will either be one of the initial states of the figures (in terms of the tags, specifically, $C(V,N)$ values of the chunks) or have already completed the intended write. For example, if a failure occurs during Step 1 of Case 3-2, that is, while waiting for the synchronous flush of chunk K to complete, when FR recovers, it will simply return to the initial state $S[C(1,0), C(1,1)]$ of Case 3-2.

Recovery from multi-chunk write failures is more involved, the key to the solution being the use of the not-complete bit to make sure recovery is done for all. However, we omit the detailed description as well as the experimental validation results, which we conducted, due to space.

5 Performance Evaluation

In this section, we evaluate the effects of FR on Ext4 performance, which we implement in Linux kernel version 4.18. A total of ~ 3000 lines of code were added; ~ 2900 for the FR module, ~ 70 in the VFS layer, and the rest in the Ext4 file system.

In the implementation, we modify five system calls, two of which are major and three are minor changes. In particular, minor changes are made to `creat()`, to assign the key, `fsync()`, to bypass the page cache, and `unlink()`, to clear the tag values once the chunks of the file to be deleted are found using the key. Major changes are made to `read()`, to make use of the key and Direct I/O in reading, and `write()`, to implement the consistency protocol, described in Section 4, with Direct I/O. One limitation of our current implementation of FR is that it does not support `mmap()`. This is because

Table 2: System configuration

	Description

Storage	Samsung V-NAND SSD 860 EVO (1TB)
OS	Linux Ubuntu 18.04.3 LTS (64bit) kernel v4.18

`mmap()` is supported upon the page cache, but FR bypasses it. Thus, the semantics of a file simultaneously opened and accessed via `mmap()` and FR does not conform to POSIX. Resolving this issue is left for future work. The chunk size is set to 4KB and the 7-byte key, which contains the unique number assigned to the file upon file creation that is also stored in the inode, and the 1-byte status flag, which contains the V, N, the *dirty*, and not-complete bits, comprise the 8 bytes that are written in failure atomic manner.

5.1 Experiment Platform and Benchmarks

Table 2 lists the specifications of the basic experimental platform that we use. Our system is equipped with an Intel Xeon Gold 6242 CPU with 16 physical cores with 128GB DRAM and an underlying SATA SSD with 1TB capacity. The 512GB Intel Optane DC PMM is run on App Direct `fsdax` mode [14]. To format FR to the device and control the PM size used, we use `ioremap()`. Thus, all storage I/O occurs through this `ioremapped` FR region. For FR, as default, we make use of 128GB of the 512GB as storage, and periodic flushing occurs every 10ms as mentioned previously (denoted FR-10m or simply FR). We make use of a synthetic workload derived with the FIO tool as well as two sets of benchmarks that we describe in detail later.

5.2 PM as a Cache

In a typical storage setting, the underlying file system manages a large storage device. Also, typically, this storage is not in full use, filled with data only to some capacity, which we refer to as the dataset. Of this dataset, a fraction of it would be accessed at any given time, which will be the working set. This working set will grow and shrink as time evolves as files being accessed will come and go, and access intensities to them will also vary with time. The role of an effective cache is to hold the working set in the cache.

To evaluate FR as a cache on a general workload, we make use of synthetic workloads generated, in the following manner, using FIO [9], which is an I/O testing tool. Using FIO, we generate 21 distinct files using the characteristics shown in Table 3, whose dataset size is the aggregate of all the file sizes, that is, 154GB. The files themselves all have distinct access characteristics that are randomly selected from the bounds shown in the table. For example, one file will be 2GB in size, the file accessed in 8KB units with Pareto 0.1 distribution, with a read:write ratio of 95:5 of which 2% of the writes are synchronized, with a request interval of 1 microsecond, which

Table 3: Characteristics of the 21 files used to generate the synthetic workload. Numbers in brackets are number of files in the particular mix. N: Normal, R: Random.

	Description
File size	1~14GB [whole numbers only: 1 to 2 files of each]
Distribution	Pareto 0.1/0.5 [2/2], Zipf 0.2/1.2 [5/1], N [6], R [5]
IO unit	4KB [14], 8KB [7]
Read:Write	1:0 [4], 19:1 [9], 1:1 [8]
Fsync	0~5% [whole numbers only: 2 to 5 files of each]
Intensity	Request interval: 1μs~1ms (randomly distributed)

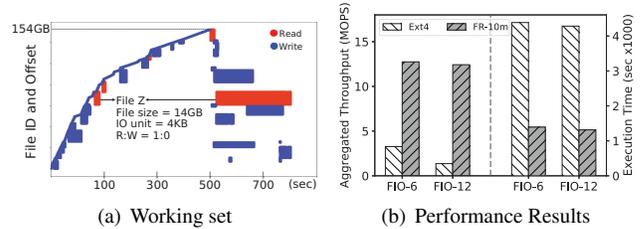

Figure 4: (a) Changing of the working set with time for the synthetic workload, only showing the first 900 of a 1300 second run. (b) Performance comparison between FR and Ext4 for light and heavy synthetic workloads.

is the request intensity of the Alibaba workload [47]. Note that the request interval of 1 millisecond would be the intensity of the Snowflake workload [49], so overall, the intensity is quite high. 21 files, each with a unique set of characteristics are generated. Then, we control the working set by controlling the number of files that are accessed in parallel. Figure 4(a) shows how the working set changes, where the y-axis represents the files accessed (by accessed offsets within the file), accumulated by the file access order from bottom to top, with time on the x-axis. The maximum number of files accessed in parallel at any point in time is set to 6, for light workload (FIO-6), and 12, for heavy workload (FIO-12), periodically starting new file accesses to meet this number. The working set of the light workload tops at roughly 50GB, while for the heavy workload, it is roughly 100GB. As all the 21 files finish off its accesses, the same 21 files are once again accessed repeatedly, but in random order starting another round of accesses. The second round of activities are shown to start just before the 500 second mark in the x-axis in Figure 4(a), and we observe that the access order is now changing. We also observe that the same files are being accessed much longer in the second round. For example, for the file marked File Z, which is a read-only file, the bar length, which represents time, is much longer on the second round than the first. (The height of the bar represents the file’s footprint.) This is because, it turns out, the number of files being accessed together is larger than at the first round, taking it longer to execute. While to the naked eye, the coloring of the bars look the same, when observed more closely, the longer right bar is considerably more sparse than that on the left meaning that it is taking longer to execute the same set of requests. To fully stress the

Table 4: Average latency for managing FR for various indexing and management policies. The average latency for FR static indexing is 67ns while for hashed indexing it is 75ns. (* Insert includes mechanism to find empty blocks.)

Activity		Radix-tree + LRU	Hash + LRU
Radix-tree / Hash	Hashing	-	78ns
	Search	35ns	162ns
	Insert*	19 μ s	19 μ s
	Delete	190ns	43ns
LRU	Touch	161ns	153ns
	Add	73ns	65ns
	Remove	88ns	82ns

system, we repeat this rounding two more times for a total of four rounds of accesses, randomly selecting the files to execute as time progresses. The total I/O for these experiments was around 575GB, and it is similar for both workloads as they are essentially making requests with the same characteristics. For FR the number of wrap-arounds took place about 19 times. To access individual files in parallel, each sequence of accesses to a file is generated by a separate thread run on a separate physical core. As the number of files accessed for these experiments is small, instead of the stride size to be that based on the most often seen file size, the size of the largest file seen is used. This has the negative effect of increasing the number of wrap-arounds, thereby increasing collisions.

Figure 4(b) compares the results of Ext4 and FR, the left bars showing the aggregated throughput of all the file accesses and the right bars showing how long the experiments took to finish. Note that we use the exact same file access sequence for the two cases, by monitoring the file access sequence when first executing with FR and then using that to execute Ext4. The results show that FR provides more than $9\times$ higher aggregate throughput and ended over $3\times$ faster than Ext4, despite the fact that FR is providing immediately durable in-order semantics. Note that write synchronization is light, with only relatively low write requests of which the sync rate is a maximum of 5%. We find that slight increase to sync rates to be bounded to 10% (which we believe is still light) diminishes Ext4 performance by roughly another 10-fold. Finally, we emphasize again that NOVA and DAX could not execute because the dataset was larger than the PM size.

PM Management Overhead: Another important aspect regarding the cache is its management. One could argue that instead of the rather radical static placement approach that FR uses, a more intelligent scheme based on sophisticated replacement algorithms could benefit FR. We briefly mentioned earlier that this would be too heavy when used with PM. Or, if it is going to use a static scheme, why not just use hashing? To check this, we implement multiple variations for managing PM such as hashing with LRU replacement, a file-based Radix tree just like that used in the Linux page cache along with the LRU replacement policy as well as just hashing for static indexing without a replacement policy. For the hash-

ing function, we found several open sourced ones and out of those used djb2 [57], which showed the best performance. All other code, except for the LRU policy, which was an in-house implementation, were taken from Linux. Table 4 shows the average overhead of the various components for managing the FR layer with the various schemes, when run with the Fileserver benchmark (whose characteristics are presented in the next section). We observe that the overhead can be orders of magnitude higher than our approach.

We conducted experiments using these data structures with the Fileserver workload and found that they were around $13\times$ slower compared to FR. (The benchmarks and the execution platform are described in the next section.) When simple hashing alone is used for placement, the overhead itself is low at 75ns, but we find that too many FR collisions (not hash collisions) occur incurring too much overhead for it to be a feasible approach.

5.3 Smaller than Cache Size Workloads

To compare FR performance with state-of-the-art PM file systems such as NOVA or DAX, we need to reduce the dataset size. In this section, we discuss the results for such a setting. Along with baseline Ext4, we also compare with Ext4 with PM DM-WriteCache (denoted DM-WC). However, it must be noted that DM-WC uses double the resources of the other schemes as it makes use of the entire DRAM as the page cache as well as 128GB of PM for the DM cache. Finally, we also attempted to compare with Assise [4]. Unfortunately, it would only run stably with a single thread and only for the workloads that the authors provided, that is, Fileserver and Varmail. As of this writing, other workloads did not execute properly even for single threaded execution. Multi-threading also was not supported. Thus, we do not include their results.

Benchmarks: As we can make use of traditional benchmarks in this setting, we make use of two benchmarks for our experiments whose characteristics are summarized in Table 5. The first is the Filebench benchmark, but of these we use only the Fileserver (F), Varmail (V), and OLTP (O) benchmarks. While it may be considered inappropriate to select particular workloads out of a benchmark suite, as FR supports in-order file system semantics these three benchmarks represent the extreme ends of the spectrum of workloads. Varmail and OLTP are workloads that have a considerable number of `fsync()` calls, while Fileserver is one that does not have any such calls.

The second benchmark is YCSB [6], which is generally used to evaluate NoSQL database systems, with the underlying database server being RocksDB. YCSB-A (YA) and YCSB-F (YF) are write heavy workloads (1:1 reads/writes), YCSB-B (YB) and YCSB-D (YD) are read intensive, YCSB-C (YC) is read-only, and YCSB-E (YE) is a range query workload. We follow the execution sequence recommended by the original YCSB authors [56] including the loading phases, but do not report the results for the load phases. All experiments are performed in async mode, thus data loss may occur for

Table 5: Characteristics of benchmarks. Request distribution for YCSB-D (YD) is Latest, while all others are Zipfian.

Filebench	R:W	Mean file size	# of files	Key-value store	Records Aggregated	R:W
Fileserver	1:2	128KB	200K	YA, YF	4GB	1:1
Varmail	1:1	32KB	800K	YB, YD, YE	4GB	19:1
OLTP	1:1	1.5GB	20	YC	4GB	1:0

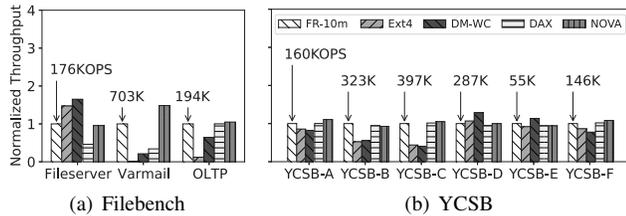

Figure 5: Filebench and YCSB throughput normalized to FR, with its absolute performance numbers shown.

Ext4 and DM-WC, while for DAX, NOVA, and FR, which provide in-order semantics, no loss will occur.

For all the workloads, we employ 16 threads as our system has 16 physical cores, except for OLTP, which employs 10 write threads and 20 read threads. For the Filebench workloads, the file size and number of files are set so that the dataset amounts to roughly 32GB. During execution, files are constantly being created and deleted, but overall the dataset does not deviate much from 32GB. For the YCSB workloads, we set the `recordcount` to 4 million, the `fieldcount` to 10, and the `fieldsize` to 100 bytes for records aggregated to 4GB. With these setting, the number of files created is around 450 and the average file size is roughly 80MB resulting in the dataset being in the 32GB vicinity. Our observations while these workloads are running on these datasets show that the maximum use of the page cache (for Ext4) at any time is roughly 10GB. Note that this setting allows the native file system to perform at its peak as the entire workload will fit into the page cache throughout its execution. All results reported are the averages of at least five runs each. We note beforehand that in multiple occasions, we only present partial results for particular discussions, unfortunately, due to space.

Filebench Performance: Figure 5(a) shows the performance results for the Filebench workloads. All results hereafter, unless otherwise mentioned, are shown relative to FR with the absolute values of FR indicated. For Fileserver, the results show that FR performs worse than Ext4 and DM-WC, while compared to DAX and NOVA, it does better. The reason Ext4 and DM-WC does better is that they provide the best environment for Fileserver as nearly all reads and writes are occurring in DRAM. This is because Fileserver does not make any `fsync()` calls (thus lacking durable in-order file system semantics). In contrast, for FR all access are at PM. PM read is roughly 3 times slower [17] and one-third of the workload are reads, and with the added peculiarities of PM [53], Ext4 and DM-WC should do better. In contrast to Fileserver, we see that for the Varmail and OLTP workloads, which are `fsync()`

Table 6: Various characteristics of workload execution. (M: million, WA: wrap-arounds)

	Flush/Access	Mem cpys	# of files	Average stride \times 4KB	Footprint (GB)	# of WA
F	1M/70M	35M	1M	614KB	572	9
V	0.6M/64M	52M	4M	410KB	1536	24
O	0/19M	22M	21	1.6GB	32	0.5
YA	100/25M	25M	450	268MB	112.5	2

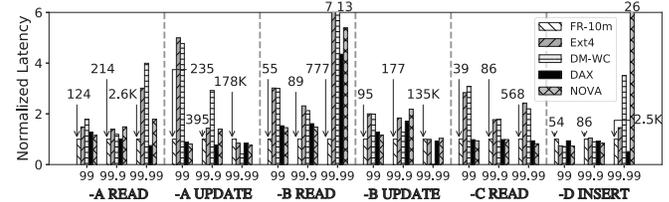

Figure 6: YCSB 99th, 99.9th, and 99.99th percentile tail latency as reported by YCSB normalized to FR. Numbers pointing to FR bars are absolute latency for FR in microseconds.

heavy, performance of FR is, respectively, roughly $94\times$ and $8\times$ better than Ext4 and roughly $4.5\times$ and $1.5\times$ better than DM-WC. Compared to NOVA and DAX, FR performance is slightly lower than NOVA, while DAX suffers for Varmail.

YCSB Performance: Figure 5(b) shows the results for YCSB. We observe that FR, NOVA, and DAX show similar performance, while Ext4 and DM-WC do the worst for the YCSB-A, YCSB-B, and YCSB-C workloads, while for YCSB-D, YCSB-E, and YCSB-F they are comparable or do better. However, we emphasize once more that neither Ext4 nor DM-WC guarantee in-order semantics. Note, in particular, the results for YCSB-C. As this is a read-only workload, one would expect Ext4 to perform similar to or better than FR as the entire dataset should be accessed from the page cache. However, we observe the contrary. This is because we run the workload with RocksDB, which issues around 50 `fsync()`s to manage a small number of files and perform compaction (movement between levels). In contrast, in terms of collisions in FR, YCSB-C is ideal as none occurs. Nuances of the effect of media are also observed when we compare the YCSB-C results from Figure 5(b) and Figures 9(a) and 9(b) that uses faster NVMe SSD and slower HDD media. We observe that the results for FR are the same for all three media, while for Ext4, performance is proportional to media performance, specifically, 436KOPS, 174KOPS, 153KOPS for NVMe SSD, SATA SSD, and HDD, respectively.

As YCSB also reports tail latency numbers we report them in Figure 6. The results show that Ext4 does worst in many cases. NOVA and FR are comparable but overall, FR does better, especially at the 99.99 tail.

Sources of Forced Flushing: We now analyze the sources of the performance differences. As FR works with large PM and the default periodic flushing is 10ms, one should expect FR to be free of any forced flushing. This is not what we observe.

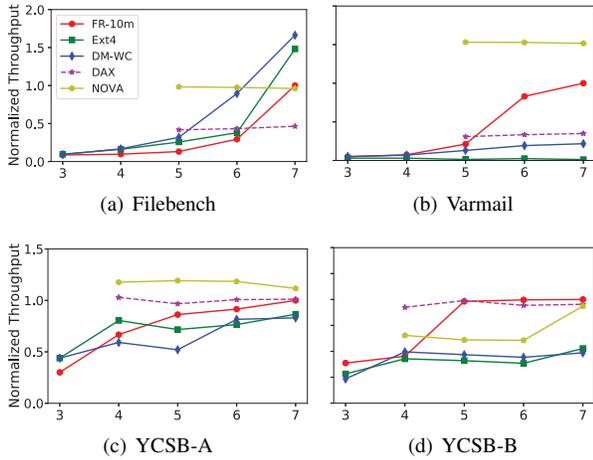

Figure 7: Performance results for PM size of 2^x GB, where x is value of points in x -axis, normalized to the performance of FR when $x = 7$.

To help understand, we make use of Table 6, which shows how the workloads execute.

The ‘Flush/Access’ column shows the total chunk accesses of the workloads of which ‘Flush’ are the forced flush counts, while the next column shows the total number of copies that occurred between chunks within slots. The next two columns show the number of files and average space allocated for the files as calculated by the stride multiplied by chunk size. These are different from those of Table 5, whose numbers are settings to run the workload, while here, they are those observed during execution, counting all files that were created. The final two columns show the footprint of the files within FR obtained by multiplying the values of the previous two columns and how many times the workload wrapped around, respectively, during the entire execution of the workload.

As observed from the ‘Flush/Access’ column, forced flushing occurs for around 1% of the accesses. There are two sources of forced flushes. The first is stride mis-estimation. While strides are set dynamically based on request size, it cannot foresee files that will grow. Hence, as files grow, overlap between neighboring files can occur, resulting in forced flushes. Detailed analysis (not shown) show that for the Filebench workloads, these situations are rare, but for YCSB-A, they account for all 100 flushes. The second source is wrap-around, as files are allocated in sequence in FR. We find that most of the forced flushes for Fileserver and Varmail are due to this. We observe from Table 6 that over a million files are being created, and the last two columns show that each slot is being shared by many files. Thus, collisions occur, possibly forcing flushes and resulting in performance loss.

5.4 Other Factors

Effect of PM Size: Figure 7 shows the performance of a select group of workloads (again, for clarity) when we vary the

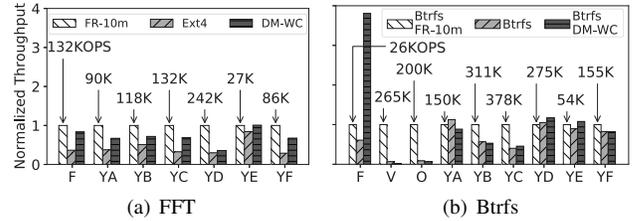

Figure 8: (a) YCSB executed with FFT modules taking up 108GB of DRAM capacity and (b) FR applied to Btrfs.

PM size, reducing it by half for each point to the left, for the various schemes. For DM-WC, both the DRAM and PM size is reduced by halves. All performance numbers are normalized to the 128GB FR results. There are two observations that can be made. First, the overall trend for FR, Ext4, and DM-WC are similar, though the drop in performance for FR is slightly greater. FR is performing similarly to the other two caching methods as the cache size gets tight. Second, for NOVA and DAX, there is barely any performance drop with the size drop. However, as PM drops beyond 32GB/16GB, they are not able to execute. This is the same situation as the synthetic workload experiments where the dataset exceeds the PM size at which point they are not able to execute. This, again, shows the limitations of PM based file systems.

Compensating for Extra PM: In our system configuration, PM is extra cost, but FR frees up DRAM used for the page cache. To evaluate this effect, we set up an environment where we have a memory intensive application, the FFT workload of Splash2x in the Parsec version 3.0 benchmark suite [34] set to use 12GB of memory, to run concurrently with the original workloads. Nine of these modules are invoked to take up 108GB of memory. The results are shown in Figure 8(a).

Overall, the results show that, while the absolute performance drops compared to those shown in Figure 5, the performance gap between FR over Ext4 and DM-WC grows. In particular, for Fileserver, we now see FR performing considerably better than both Ext4 and DM-WC. These results show that FR can effectively segregate I/O and memory intensive workloads relieving DRAM capacity for other use.

Btrfs: To show that FR is applicable to other file systems, we present results for FR with Btrfs [41], where changes are made to roughly ~ 30 LOC. As shown in Figure 8(b), the results are similar to FR-Ext4, with many cases performing better when FR is deployed, despite the fact that Btrfs is not providing durable in-order semantics. Notable differences compared to Figure 5 are that 1) FR-Btrfs does better even for Fileserver compared to Btrfs though in terms of absolute throughput, Btrfs does considerably worse than Ext4, 2) performance improvements with DM-WC are large, and 3) for YCSB-A and YCSB-D, Btrfs does better than FR-Btrfs.

Effect of Storage Media: We consider how FR is affected when the underlying storage media is changed to a higher-end Samsung 1TB V-NAND 970 PRO NVMe SSD and a

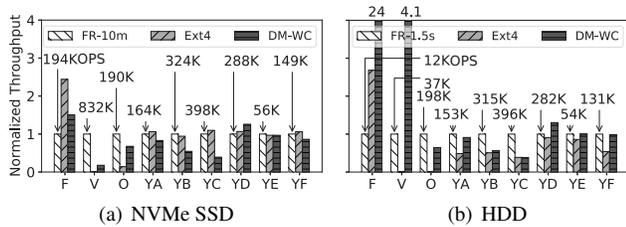

Figure 9: Performance with different storage devices.

lower-end Seagate 1TB Barracuda SATA3/7200/64M HDD. Figure 9(a) shows that with the NVMe SSD, the absolute throughput of FR improves benefiting more the Filebench workloads. More interestingly, we see that the stock Ext4 benefits considerably especially for the YCSB workloads. This is due to the bandwidth of the media. That is, FR is physically organized using a single PM chip with a throughput of 0.58GB/s, while the NVMe SSD throughput is 2.7GB/s. In some cases, Ext4 is able to exploit this, resulting in performance surpassing FR as exemplified by some of the YCSB results. Note again, however, that FR is providing immediate durability, while Ext4 and DM-WC are not, and that DM-WC uses double the resources. Note also that FR still shows superior performance for applications where synchronization is prevalent as shown by the Varmail and OLTP results. Another implication of these results is that we may not need to move to these more expensive devices if PM is deployed appropriately. The YCSB results shown in Figures 5 and 9 show that they are all similar irrespective of the underlying storage media be it an SSD or an HDD. However, the Filebench results forbid us from generalizing so easily. The reasoning behind these discrepancies are left for future work.

For the experiments with HDD, the periodic flushes for FR is set to 1.5 seconds to accommodate the slow HDDs. If set to the default 10ms, we find that performance drops considerably because the HDD cannot sustain service for such heavy I/O. (We have studied the sensitivity of period setting on performance, but omit them due to space.) The results show that 1) even with the large period, for Fileserver and Varmail, the request rate is too high for the HDD to hide and thus, we see drops in throughput from 194KOPS to 12KOPS and 832KOPS to 37KOPS for Fileserver and Varmail, respectively, when the media is changed from NVMe SSD to HDD, and 2) for other workloads, we see performance that is similar to that of FR when using the SATA SSD (Figure 5).

Let us now focus on DM-WC that takes on the best of both worlds by using DRAM as a read cache and PM for the write cache (though, using double the resources). We observe in Figure 9(b), with HDD, how DM-WC is almost always superior over Ext4 and even sometimes performing better than FR. Interestingly, as we move to a faster device (SATA SSD in Figure 5), the improvements diminish, sometimes even resulting in performance worse than Ext4. Then, with the fastest device (NVMe SSD in Figure 9(a)), we see the effect

of DM-WC diminishing further, with the majority performing worse than Ext4. There are two reasons for this degradation. One is device performance. DM-WC was devised to take advantage of superior device performance (PM, in this case), which is evident with the HDD results. However, for SATA SSD (0.52GB/s bandwidth), its performance is similar to that of PM (0.58GB/s). Thus, using PM should bring only a small improvement if any, meaning that, for example, for YCSB-A and YCSB-F, the write intensive ones in Figure 5, we should see comparable or slightly better performance for DM-WC compared to Ext4. However, we observe that DM-WC performs worse than Ext4. This is because of the second reason for performance degradation, that is, management overhead. DM-WC goes through an elaborate sequence of calls within (omitting the details, it goes through eight or so function calls). This incurs considerable overhead of around 35 microseconds of which the majority is overhead for indexing. This is pure overhead and is compounded as more writes are issued. Thus, write intensive workloads YCSB-A and YCSB-F are taking the blow. These results are evidence of the need for light management mechanisms such as that we propose. Finally, with the NVMe SSD, Ext4 performs better because the SSD has higher bandwidth (2.7GB/s vs 0.58GB/s). However, the added capacity does help DM-WC for some workloads.

6 Conclusion

In this paper, we presented First Responder (FR), a means to exploit the beneficial features of PM. While FR shares the goal of all PM based file systems in exploiting the performance benefits of PM as a storage device, its approach is unique in that it allows the use of existing modern file systems. Conceptually, FR is much like a buffer cache, but we showed that much more is involved as consistency had to be maintained under failure while providing light management. Built at the VFS layer, while the rest of the I/O stack, including the specific file system layer, remained largely unchanged, FR was able to provide immediate response to users from this layer. In experimental evaluations with the Intel DC PMM, we showed, with the FIO synthetic workload, FR, when used in cache form, can outperform Ext4 by more than $9\times$, while providing durable in-order file system semantics. Using the Filebench and YCSB benchmarks, we also showed that FR, when used as part of a typical file system, performs comparably with the default Ext4, Ext4 with DM-WriteCache, NOVA, and DAX, while also providing durable in-order semantics.

Acknowledgements

We thank our shepherd Professor Sasha Fedorova and the anonymous reviewers for their invaluable comments. We also thank Choulseung Hyun, Sunghwan Kim, Se Kwon Lee, and our colleagues from the NECSST lab for their numerous discussions that helped shape this research. Abstract

We evaluate a new *processing-in-memory* (PIM) architecture from UPMEM that was built and deployed in an off-the-shelf server. Systems designed to perform computing *in* or *near* memory have been proposed for decades to overcome the proverbial memory wall, yet most never made it past blueprints or simulations. When the hardware is actually built and *integrated* into a fully functioning system, it *must* address realistic constraints that may be overlooked in a simulation. Evaluating a real implementation can reveal valuable insights. Our experiments on five commonly used applications highlight the main strength of this architecture: computing capability and the internal memory bandwidth *scale with memory size*. This property helps some applications defy the von-Neumann bottleneck, while for others, architectural limitations stand in the way of reaching the hardware potential. Our analysis explains why.

1 Introduction

The memory wall has plagued computer systems for decades. Also known as the *von Neumann bottleneck*, it occurs in systems where the CPU is connected to the main memory via a limited channel, constraining the bandwidth and stretching the latency of data accesses. For decades, computer scientists have pursued the ideas of *in-memory* and *near-memory* computing, aiming to bring computation closer to data. Yet most of the proposed hardware never made it past simulation or proprietary prototypes, so some questions about this technology could not be answered. When we obtained early access to soon-to-be commercially available DRAM with general-purpose processing capabilities, we recognized a unique opportunity to better understand its limitations when integrated into existing systems. Most solutions proposed in the past required specialized hardware that was incompatible in some way with currently deployed systems [2, 3, 9, 14, 16]. The hardware we evaluate was designed specifically to be used as a drop-in replacement for conventional DRAM, which has

imposed some limitations that are not present in many of the simulated architectures.

UPMEM's DRAM DIMMs include general-purpose processors, called *DRAM Processing Units* (DPU) [5]. Each 64MB slice of DRAM has a dedicated DPU, so *computing resources scale with the size of memory*. Playing to the strengths of this hardware, we ported five applications that require high memory bandwidth and whose computational needs increase with the size of the data. We observed that, indeed, application throughput scaled with data size, but scaling was not always the best that this hardware could achieve. The main reasons were the difficulty of accessing data located inside DPU-equipped DRAM from a host CPU without making a copy, the limited processing power of the DPUs, and the granularity at which the DPUs are controlled.

The main contribution of our work is understanding the limitations of PIM when it is integrated into off-the-shelf systems. We approach it via a case study of a particular implementation. We are not aware of any similar hardware that we could access, so a comparison to other architectures was outside the scope of this work. Although a comparison to other accelerators was not our goal either, we did compare with GPUs where it helped deepen our analysis.

2 Architecture

Many PIM architectures were proposed in the past [2, 3, 6–8, 10, 12, 21, 27, 28, 30, 32], ranging from logic gates embedded in each memory cell up to massive arrays of parallel processors that are located close to the memory. They all share the goals of overcoming the limitations of memory bandwidth but differ vastly in design. Nguyen et al. [22] introduce a classification system for various designs based on the distance of the compute units from the memory. We study specific hardware from the *COMPUTE-OUT-MEMORY-NEAR* (COM-N) model. This model includes compute logic that is located outside of the memory arrays but inside the memory package (same or different silicon die). This is sometimes called CIM (compute-in-memory) but is more widely known

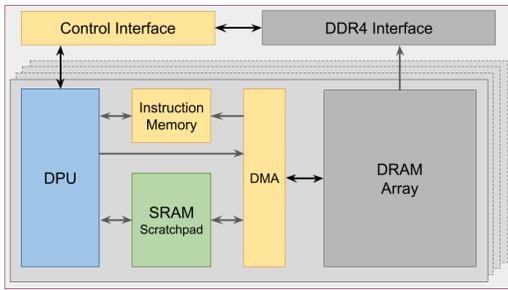

Figure 1: DPU Architecture

as PIM (processing-in-memory). After our study was concluded, Samsung announced the production of similar PIM hardware (called FIMDRAM) that also falls into the COM-N model [15]. While we could not perform an in-depth comparison, some similarities are apparent from the published design. These common design points are likely to appear in new designs as well and the lessons we learned from studying UPMEM-hardware will be generally applicable to this class of PIM.

Organization In the architecture we study, DRAM is organized into ranks (two ranks per DIMM), and each rank contains eight memory chips. Each DRAM chip includes eight DRAM Processing Units (DPUs). Each DPU is coupled with a 64MB *slice* of DRAM. There are 64 DPUs per rank and 128 DPUs per 8GB memory DIMM. Since the DPUs and DRAM are built on the same silicon die, introducing the DPUs comes at the cost of some DRAM capacity. With this design, the sum of DPUs and DRAM is limited by the silicon area on the die and the process density (number of transistors per unit area). Our experimental system has 36GB of DPU DRAM and 576 DPUs.

DPU Capabilities A DPU is a simple general-purpose processor. UPMEM’s design only supports integer operations (no floating-point hardware). Each DPU has exclusive access to its slice of DRAM over a private bus. The more total DRAM there is, the more DPUs there are. In other words, we get an additional unit of computation, and an additional bus, with each additional unit of memory – *computing capacity and intra-DIMM bandwidth scale with the size of memory*. Figure 1 shows a schematic view of a single DPU and its periphery. Before a DPU can compute on the data, it must copy it from DRAM to a 64KB private SRAM buffer, called the *working memory*. The copy is performed with an explicit, blocking DMA instruction. The DMA engine can copy up to 2KB in a single operation but the copy time increases linearly with the size. To hide DMA latency, each DPU has 24 hardware threads, called *tasklets*, that can be scheduled for execution simultaneously. Because it is an interleaved multi-threading (IMT) design [31], only one tasklet can advance at each cycle. When a tasklet is blocked on a DMA operation, other tasklets can still make progress.

DPU Speed Processing capabilities of DPUs are well below that of a common host CPU. DPUs have a simple, in-order design, and are clocked at anywhere from 266MHz (in our experimental system), to 500MHz (projected in commercial offerings). This was necessary to fit within the power envelope of commodity systems.

DPU communication In DRAM there are no communication channels between individual slices of memory dedicated to DPUs. Thus, DPUs cannot share data, other than by copying it via the host. Communication between DPUs on different chips would require additional pins in the package which would change the form factor from standard DRAM. Creating a communication bus between DPUs on the same chip is theoretically possible, but severely restricted by the number of available metal layers. Therefore, we cannot expect any PIM designs in the COM-N model to have any DPU-to-DPU communication until these problems can be solved. This constraint implies that programs running on DPUs must shard data across DPUs ahead of the execution and use algorithms that don’t require data sharing.

Interleaving At the chip level, interleaving dictates the ordering of bytes as they are written into DRAM. In the DIMMs in our test system, each DRAM chip connects to the DDR4 bus by an 8-bit interface. 8 chips together form the 64-bit wide bus. When a 64-byte cache line is committed to memory, the data is interleaved across DRAM chips at byte granularity, the first byte going into *chip 0*, the second byte into *chip 1*, etc. So when the write is done, the first chip receives bytes 0, 8, 16, ..., 56. Interleaving at this level is used to hide read and write latency by activating multiple chips simultaneously. Interleaving is transparent to the host since the data is reordered appropriately in both directions (i.e., during reads and writes). But a DPU, which can only access data in its own slice, only sees what is written to that particular chip (i.e., every *n*th byte of the data). This property makes it difficult to access the data by the host CPU and the DPU in the same location. Unless a program running on the DPU can be modified to operate on non-contiguous data, we must make a separate copy, *transposing* it in the process, so that each DPU receives a contiguous portion of the data.

Transposition UPMEM’s SDK counteracts the interleaving by transposing the data. While the cost of the transposition is small (the current SDK provides an efficient implementation that uses SIMD extensions), the cost of data copy, which requires going over the DRAM bus, is not. For applications that can place their dataset into the DPU memory and compute on it using only DPUs, the one-time cost of the copy can be negligible, but for applications where the data is short-lived or both the DPU and host CPU must access it, frequent copying will stress the memory channel – the very bottleneck this architecture aims to avoid.

Control granularity Accessing multiple chips in each bus cycle also means it is natural to schedule DPUs across those chips as a group. With the current SDK implementation, a

full rank must be scheduled as a single unit. We can only send a command to an entire rank of DPUs and cannot launch a DPU or read its memory while another DPU in the same rank is executing. Similarly, the host cannot access any memory in a rank if any DPU in that rank is executing. In practice, this results in treating DPU-equipped memory as an accelerator, rather than part of main RAM. The host typically keeps programs and data in the “normal” DRAM (i.e., *host DRAM*), copies data for processing into the *DPU DRAM*, and copies back the results. Finer-grained execution groups will likely improve the performance of algorithms that “stream” data such as *grep*.

3 Evaluation

3.1 Workloads

Considering DPU architecture properties we chose programs that need more computational resources with the increasing data size, that could be easily parallelized and where data sharing is minimal.

The SDK for the DPU architecture includes a C compiler and libraries with functions to load and launch DPUs, copy and transpose the data, etc. While we could write the code in a familiar language, the main challenges had to do with memory management (as the DPU needs to copy data from DRAM into the working memory prior to processing it), and with efficiently controlling ranks of DPUs.

Snappy Snappy is a light-weight compression algorithm designed to process data faster than other algorithms, such as *gzip*, but at the cost of a lower compression ratio [11]. Snappy divides the original file into blocks of a fixed size (typically 64KB) and compresses each block individually. The original implementation is designed for sequential (i.e., single-threaded) processing. The file format concatenates compressed blocks head to tail, without any separation marker. The result is that to decompress block n , the program must first decompress blocks $0 \dots n-1$. To enable parallelism, we changed the compressed file format by prepending each block with its compressed size. This small change enables the host program to quickly locate the start of each compressed block without having to decompress the previous blocks. We also modified the header by adding the decompressed block size. That enables us to experiment with different block sizes. Snappy is bandwidth-intensive because of the small amount of processing, especially during decompression. The majority of the time is spent copying literal strings or previously decoded strings.

Hyperdimensional computing Hyperdimensional Computing (HDC) [13] is used in artificial intelligence to model the behaviour of large numbers of neurons. It relies on vectors with high dimensionality (at least 10,000 dimensions), called *hypervectors*, to classify data and find patterns. Our HDC application performs classification of raw electromyography

(EMG) signals into specific hand gestures [25]. We built upon a prior reference implementation [20]. The classification works by computing the Hamming distance between a previously encoded input hypervector and previously trained vectors. Our implementation distributes the raw signal data among DPUs, which then encode it into hypervectors and perform the classification.

AES Encryption The Advanced Encryption Standard (AES) is a symmetric-key algorithm designed to be highly secure and run efficiently on a variety of hardware. Our analysis focuses on AES-128, using the implementation by Rijmen, Bosselaers, and Barreto found in OpenSSL [26]. Encryption is an ideal problem; the data can be divided into small individual blocks, the algorithm can operate in parallel, and the data access pattern makes it simple to optimize DMA transfers. AES can be operated in a variety of modes. We use ECB (electronic code book) mode which ensures each block can be processed individually without dependencies on the other blocks.

JSON filtering JSON is a flexible and human-readable format for storing and exchanging data. Due to its ASCII representation, parsing is notoriously slow [17, 19, 29]. When analytics systems filter records in JSON, they parse each one and check the filter condition. Parsing is performed for *all* records, even for those not meeting the filter criteria. Instead, Sparser [24] showed that it is better to filter records *before* parsing them by running string comparisons over raw (unparsed) JSON. Raw filtering is highly parallel and memory-intensive [9], and hence promising for our study. We modified Sparser [23] to offload raw filtering to DPUs, while the host performs the rest of the parsing.

Grep *Grep* [1] is a command-line utility for searching plain-text for lines that match a regular expression. We implement a subset of *grep*, which searches only for exact text matches. Our design uses the DPUs in a work pool by preparing files in small batches, and starting the search as soon as enough DPUs are ready to perform the work.

To address the challenge of DPUs needing to be controlled in large groups we must balance the work across all DPUs in the rank. By balancing the work, we minimize the difference in running time between the fastest DPU and slowest DPU, which minimizes the idle time in the rank while waiting for the slower DPUs. Preparing the work on the host consumes a significant portion of the time so it is more important to prepare the files quickly rather than efficiently packing them into DPUs. To fill the rank as evenly as possible within the time constraints, files are assigned to DPUs in a round-robin fashion in the order they appear in the input. We do not spend the time to sort the files by size, and even limit the number of files that can be processed by a single DPU to save time during preparation. A maximum of 256 files was determined empirically to have the best results.

Our baseline for performance comparison is a single host

CPU¹ since our focus is to understand when the DPU architecture overcomes the von Neumann bottleneck and when it does not.

3.2 Memory bandwidth scaling

In the DPU architecture, each additional slice of DRAM gets its own DPU along with the working memory and the DMA channel. Herein lies its main strength: *scaling computing capacity and intra-DIMM bandwidth with the size of memory*. To demonstrate, we ran a simple program where all DPUs iterate over the data in DRAM, copying every byte from their respective DRAM slices into the working memory. As shown in Fig. 2, the data processing bandwidth increases with the size of the data, reaching roughly 200GB/s for 36GB worth of DRAM (approximately 350MB/s per DPU). For a system with 128GB of DRAM and DPUs clocked at 500MHz (which is the target for commercial release) the aggregate bandwidth attained by all DPUs would reach 2TB/s.

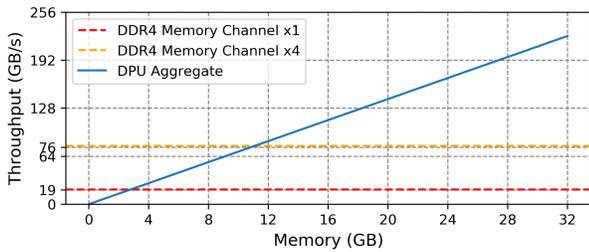

Figure 2: Memory bandwidth scales with memory capacity.

For applications whose compute and bandwidth needs grow with the size of the data, scaling of compute and bandwidth resources with memory has a direct and positive impact on performance. E.g., Fig. 3 shows the throughput of *Snappy compression* as the file size (and the number of DPUs sharing the work) increase. We use the optimal number of DPUs for each file size – i.e., using more DPUs yields no additional speedup. The input data resides in host DRAM; the experiment copies the data to DPU DRAM, allocates and launches the DPUs to run compression, and copies the compressed data back to host DRAM. As the file size grows *so does the throughput* – a direct result of compute capacity and internal bandwidth scaling with additional memory.

Breaking down the runtime, we observe that the execution time on DPUs (*Run* in Fig. 4) remains roughly the same even as we increase the file size, because more DPUs are doing the work. Again, this is the effect of scaling compute resources with data size. The DPU execution time does increase for 512MB and 1GB file sizes, because as we reach the limits of our experimental hardware, each DPU gets more data to

¹Our host machine is a commodity server with an Intel(R)Xeon(R) Silver 4110 CPU @ 2.10GHz with 64GB of conventional DDR4 DRAM.

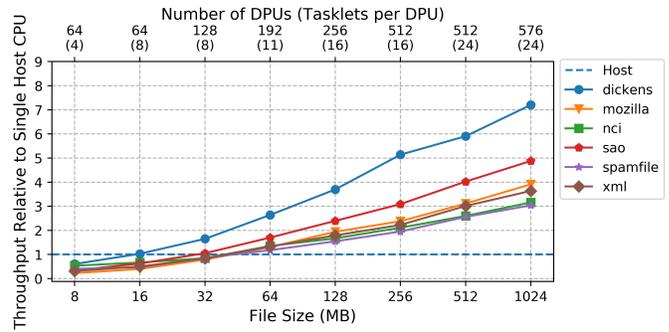

Figure 3: Snappy compression throughput

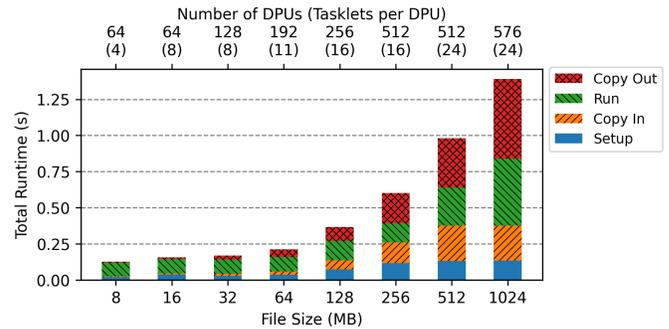

Figure 4: Runtime breakdown for compression

process. The non-scalable components of runtime in Fig. 4, *Copy In*, *Copy Out* and *Setup*, are discussed in §3.3.

A final experiment illustrating the strength of scaling involves a comparison with the GPU², an accelerator that shares similarities with DPUs (massive parallelism, high memory bandwidth), but does not have the property of scaling computational resources with memory. Fig. 5 shows the throughput relative to a host CPU (same as in the DPU experiments) of *snappy compression* as the file size grows. Contrary to the DPU architecture, the GPU scaling is flat and the throughput does not surpass that of the host CPU by more than 5×. This coincides with the internal memory bandwidth of the GPU, which is approximately 5× higher than that of the CPU.

Where each DPU has a dedicated working memory and a DMA channel, all GPU cores within an SM (streaming multiprocessor) share an L1 cache. This data-intensive workload with a random access pattern caused thrashing in the small 64KB L1 cache. Memory fetching became the bottleneck and as a result, we obtained the best performance by launching kernels consisting of a single thread per compute block (and hence one thread per SM) to reduce contention for the cache. The input file fit in the GPU memory, so there were no fetches

²We used an RTX 2070 GPU with 8GB of GDDR6 and 448GB/s global memory bandwidth. There are 36 SMs, with 64 CUDA cores per SM, clocked at 1.4GHz. There is a 64KB L1 cache per SM, and 4MB L2 cache shared by all SMs.

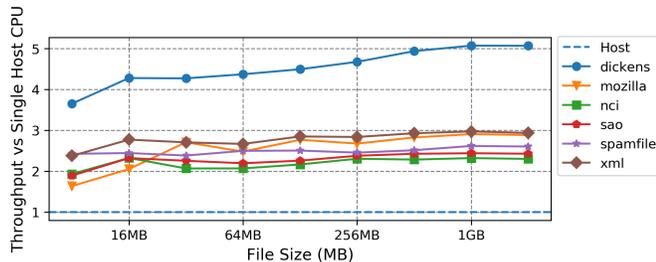

Figure 5: Snappy compression on GPUs

over the PCIe bus once processing started. In other words, the GPU fell victim to a variant of the von Neumann bottleneck. In workloads where memory bandwidth is not the main limitation, DPUs will not reach the throughput of a GPU due to their less powerful execution engine – a limitation we discuss in §3.4.

3.3 Data copy

As we discussed in §2, the need for de-interleaving (transposing) data for DPUs means that it is difficult to avoid making copies when data needs to be accessed by both DPUs and host CPUs. For applications where DPUs can be used exclusively, the data can be copied to DPU memory just once and reside there for the rest of the runtime, making copy overhead negligible. In programs where data is ephemeral or must be accessed by both the host CPU and DPUs, frequent copying will be subject to memory channel limitations – the very von Neumann bottleneck PIM aims to address.

The compression runtime breakdown presented in the previous section (Fig. 4) illustrates this point. The DPU execution time remains roughly constant as data size increases, because each DPU has a dedicated DMA channel to its DRAM slice. In contrast, the time to copy input data to DPU memory and copy the output back increases with the file size and is limited by the DRAM channel.

Setup overhead in compression does not scale, because dividing up the work requires sequential parsing of the input file. This is a property of the workload and implementation, and not fundamental to the architecture. Copy overhead, on the other hand, is fundamental to the system and is the reason why the compression throughput in Fig 3 grows sublinearly with the increasing number of DPUs.

HDC is less affected by the copy-in overhead than Snappy and has negligible copy-out cost due to the small dataset. Overall, copying takes about 10% of the total runtime, and thus HDC enjoys better scaling, as shown in Figure 6. HDC and other AI applications, where DPUs can repeatedly perform inference on long-lived data that remains in DPU memory are therefore well-positioned to circumvent the memory channel bottleneck.

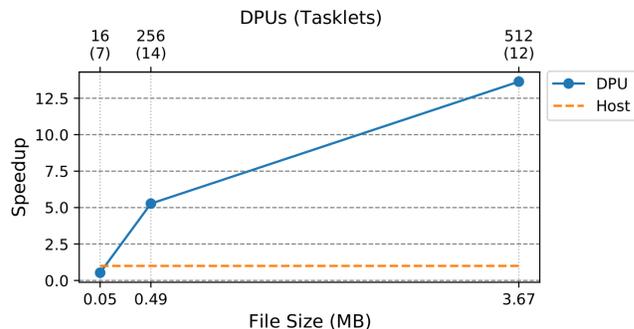

Figure 6: HDC speedup over the host as file size increases

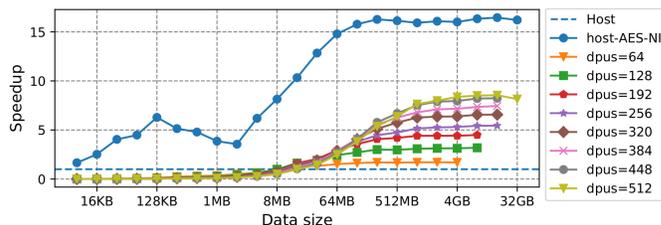

Figure 7: Encryption throughput relative to a single host CPU.

3.4 DPU Speed

Encryption provides an excellent illustration of a scenario when DPU processing power becomes a limitation. Figure 7 shows encryption throughput (bytes per second) relative to a single host CPU as the amount of data increases. We show a separate curve for each number of DPUs, to emphasize that processing power matters. Both Snappy and HDC required fewer DPUs for smaller datasets and more DPUs for larger data sets, but compute-hungry encryption relishes the highest number of DPUs we can muster, no matter the data size. Further, the far superior performance on the host with AES-NI [4] acceleration confirms that general-purpose DPUs cannot compete with specialized instruction sets.

Another example where DPU processing power was less impressive compared to other available accelerators was snappy decompression (figures omitted for brevity). On the DPU, this workload performed very similarly to compression. On the GPU, in contrast with compression, L1 cache was not the bottleneck: decompression works with smaller input block sizes and is largely write-intensive. As a result, the GPU showed similar scaling trends as on the DPU and outperformed the host CPU by up to 24×, while DPUs’ advantage was at most 8×.

3.5 Communication and control granularity

Compliance with the DDR interface and software limitations in the current SDK makes it inefficient to control DPUs one at a time: as long as a single DPU in the rank is busy, all

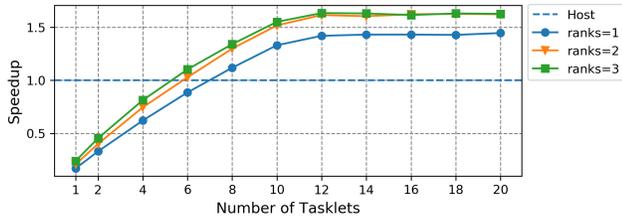

Figure 8: Speedup of `grep` over the host with varying ranks and tasklets.

others are inaccessible. This means that the program must decide how it will divide the data between DPUs in a rank and launch them all at once. While this is a trivial decision for embarrassingly parallel workloads, other workloads might under-utilize the hardware as a result. The fact that DPUs cannot communicate and steal work from one another makes matters worse. Our experience with `grep` demonstrates these challenges.

Figure 8 shows the throughput relative to a single host CPU of `grep` executed on the 875MB Linux source tree for the varying number of ranks. The throughput gain relative to the host is modest, and there is no advantage from using more than two ranks (128 DPUs). The reason is that it is very difficult to distribute the work evenly between DPUs ahead of the launch. Input source files vary in size and even organizing them into equally-sized buckets per DPU does not guarantee that the processing time on all DPUs will remain similar. As a result, `grep` used the hardware inefficiently: the ratio of execution times on the fastest and slowest DPUs was 116 \times , indicating the presence of stragglers that held up the entire rank. In contrast, `JSON filtering`, a workload very similar to `grep` but where dividing the work evenly was easy, enjoyed the fastest/slowest execution ratio of 1 (no stragglers) and similar scaling properties as the rest of the workloads (figure omitted for brevity).

3.6 System cost

We conclude with the analysis of system cost, showing that for applications with high bandwidth requirements, a system that uses DPU memory is cheaper than the one without it.

With a memory-bound workload, increasing the number of processors without increasing the memory bandwidth does not improve performance by a significant amount [3, 18, 33]; we need a CPU with a high number of memory channels that can supply the cores with data and avoid starvation. CPUs are designed with a wide range of cores but do not include additional memory channels for a higher number of cores. Therefore, we must use more sockets and faster memory to scale up the memory bandwidth in a CPU-only system. Table 1 shows an estimated price comparison of system configurations with the maximum possible memory bandwidth with

off-the-shelf Intel systems (1.6TB/s) assuming Snappy compression as the representative workload. We use the nominal price of \$60 for an 8GB DIMM and \$300 for an 8GB PIM module [5]. The costs shown include CPU, memory and PIM (where applicable). We assume DDR4-2400 (19.2 GB/s) with a Xeon 4110 (\$500) for all configurations except the last, which uses DDR-3200 (25.6 GB/s – 33% more bandwidth) and a Xeon 8380 (\$8100). With our conservative estimations, a CPU-only system is less expensive for applications below 500GB/s. However when scaling up, a CPU-only configuration is approximately 3.8 \times more expensive to attain the same Snappy compression throughput.

DRAM	PIM	Snappy throughput	Cost	Cost per MB/s
Low bandwidth requirements				
48GB	-	512MB/s	\$860	\$1.68
48GB	32GB	512MB/s	\$2160	\$4.21
High bandwidth requirements				
48GB	448GB	7168MB/s	\$17660	\$2.46
448GB	-	7263MB/s	\$68640	\$9.45

Table 1: System cost per MB/s for Snappy compression.

4 Conclusion

Memory-bound applications are limited by the conventional memory hierarchy, and adding more CPUs does not improve performance substantially. We have shown several real-world applications that can be accelerated by PIM by scaling memory bandwidth with compute resources. PIM shares many attributes (such as massive parallelism) with other accelerators but the distribution of processing units inside the memory gives it a unique advantage in certain cases. The architecture we evaluated has some limitations that prevent exploiting the full capabilities of the hardware, which remain as challenges for future designs. Costly data transfers which must be performed in order to share data between the host CPU and PIM memory adds significant overhead to processing time but can be mitigated by reusing data in-place. Despite the limitations, we find that PIM can be effective when applied to the correct class of problems by scaling the processing power with the size of the dataset.

Abstract

Implementing the filesystem in user space reduces development complexity [28, 30] and decreases dependency on the underlying OS platform. Implementing the filesystem at the user level as opposed to inside the OS kernel, however, has traditionally meant lower performance [11, 17, 22]. This performance overhead is increasingly limiting with high performance storage devices based on new persistent memory technology (e.g. 3D XPoint [13]) and advanced networking techniques (e.g. RDMA [14]). User space file systems have also been associated with poor reliability, availability and serviceability (RAS) characteristics [26]. As a result, there is a tendency to consider user space filesystems as prototypes and proof-of-concepts. In this paper, we systematically analyze the concerns with deploying user space filesystem to provide production file storage services. We present XFUSE, a filesystem in user space framework that addresses the performance and RAS concerns, and that enables file storage services to be effectively deployed at the user level. Our performance analysis indicates that XFUSE enables filesystem requests made through standard kernel interfaces to be processed at the user level with latency in the 4 microseconds range, and offers throughput exceeding 8 GB/s.

1 Introduction

User space code is generally easier to develop and maintain than kernel code. Thus filesystems with advanced functionality tend to be developed as user space filesystems (e.g. [3, 5, 24, 31, 32]). However, because filesystems are traditionally incorporated into the OS kernel, applications have been largely developed using standard kernel filesystem interfaces. This means that user space filesystems will incur additional performance overhead from passing messages between the kernel and the user space filesystem [11, 17, 22]. This overhead is especially limiting with the use of high performance storage devices and networking that routinely offer latency in the microseconds range and throughput of several GB/s [13, 14].

The use of user level networking [16, 18] and I/O helps to reduce the overall impact of crossing into user space to reach the filesystem but the performance hit is still significant. In particular, metadata operations such as stat and other operations that benefit from filesystem caching may be fast in kernel mode filesystems, but will be slower in user space filesystems due to additional communication cost between the operating system kernel and user space file systems [22].

Moreover, ensuring reliability, availability and serviceability (RAS) for user space filesystems has additional complexity because the rest of the system may continue to operate when the filesystem is down. For example, if a user space filesystem aborts, the application using the filesystem may continue to execute and wait for its requests to be completed. This partial failure possibility requires additional handling but it also provides a basis for the user space filesystem to be upgraded without disrupting the application. Such non-disruptive upgrade facilitates the deployment of new releases in production environments. There has been some previous work [26] on supporting restartable user space filesystems. However, the prior work requires significant kernel changes and do not support advanced filesystem features such as direct I/O and multi-threading.

Workloads are increasingly executed on the cloud in virtual machines (VMs) and sandboxed containers [4, 8, 12] to enable efficient resource utilization and increase agility. Cloud service providers can offer additional storage services to their customers through a storage client such as a filesystem gateway to object storage, optimized NAS client, etc. For the aforementioned reasons, it is advantageous to implement this storage client in user space. Furthermore, if the storage client can be deployed outside of the customer VMs and in the VM host, cloud service providers will be able to clearly separate the storage client from the user VM and independently manage the client as part of the storage service. There has been some recent work in this area. For example, virtio-fs [9] builds upon FUSE to allow VMs to access a host filesystem directory.

In this paper, we focus on enabling the deployment of pro-

duction storage services using user space filesystems. We evaluate prior approaches to understand what remains to be done to make this a reality. We propose XFUSE, a software framework patterned after FUSE [7] that addresses the performance and RAS concerns generally associated with user space filesystems. We believe that the improvements that XFUSE provides over FUSE can be applied to FUSE-based approaches such as virtio-fs [9] to better support running the user space filesystem in the VM host as opposed to inside the VMs that are running user applications.

Our contributions include:

- Systematically analyze the path a kernel filesystem request takes from being issued by an application to being handled by a user space filesystem and have the results communicated back to the application.
- Design and implement an optimized framework for user space filesystem that is backward compatible with FUSE and that takes advantage of the growing number of cores available on modern systems to achieve low latency and high throughput for fast storage devices.
- Demonstrate that such a framework enables kernel filesystem requests to be processed in user space with latency in the 4 microseconds range and throughput exceeding 8 GB/s.
- Extend the framework to provide features such as support for online upgrade and crash recovery that are critical for deploying user level filesystems in production.

The rest of this paper is organized as follows. In the next section, we survey related work. In Section 3, we introduce the design and implementation of XFUSE. In Section 4, we evaluate XFUSE performance. Section 5 concludes this paper.

2 Background and Related Work

FUSE is a widely adopted framework to support a filesystem in user space [7]. Figure 1 shows its highlevel architecture. FUSE consists of a Linux kernel module and a user space library that is linked to a user space filesystem daemon process. Conceptually, the FUSE kernel module consists of two parts: filesystem handler which is the code that processes filesystem operations including the code that invokes VFS, and device handler which interacts with the user space filesystem via a special device, `/dev/fuse`.

The filesystem handler and device handler run in different process contexts. The former runs in the context of the application process while the latter runs in the filesystem daemon process context. Communication between the two parts is coordinated through kernel events and incurs context switch cost. More specifically, there is a context switch when an application process sends a filesystem request to the filesystem daemon process, and there is another context switch when

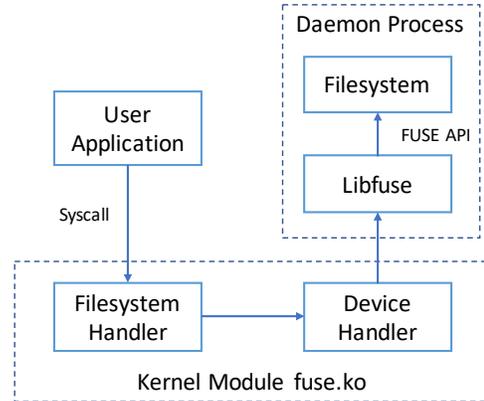

Figure 1: FUSE (and XFUSE) Architecture.

the filesystem daemon process responds to the application’s request. Therefore each filesystem operation submitted by the application incurs at least two context switches with FUSE. In addition, FUSE has a single pending request queue from which threads of a filesystem daemon process pick up incoming requests for processing. Under load, this global queue becomes a source of contention.

There has been a large body of work on analyzing and improving the performance of FUSE (e.g. [11, 17, 22, 30]). ExtFUSE [11], for instance, extends FUSE so that a filesystem in user space can register a piece of simple code in the OS kernel to handle selected filesystem operations without incurring a context switch. There have also been alternatives to FUSE. For example, AVFS [1] uses the environment variable `LD_PRELOAD` [15, 21] to intercept libc POSIX API entry and invoke filesystem operations without context switch.

More recently, ZUFS [10] has been proposed as an alternate framework for user space filesystem that eliminates one data copy by having the kernel module copy data directly from the source to the destination. ZUFS and XFUSE share many of the same performance goals. We attempted to evaluate ZUFS but encountered issues. Our queries, as well as those from others, on the ZUFS project page on GitHub went unanswered. It appears that ZUFS is no longer maintained.

There has also been work on implementing the filesystem as an embeddable library running in user space (e.g. NVFUSE [6]) and on providing the filesystem as a separate user space process that communicates with each application through a private communication channel (FSP [19]). These approaches require applications to be rebuilt. They also bypass the VFS layer which provides important functionality such as as permission checking, file sharing coordination and buffer management.

The idea of transparently restarting the filesystem upon failure is explored in [25] and a specific framework that provides support for restartable user space filesystems is proposed in [26]. This framework, however, requires significant kernel

changes and does not support advanced filesystem features such as direct I/O and multi-threading [26]. The shadow driver concept proposed in [27] inspired us to keep track of incoming requests and eventually led to the crash restart algorithm proposed in this paper.

There has been a lot of recent interest in enabling VMs (and sandboxed containers [4, 8, 12]) to share a host directory. In particular, virtio-fs [9] builds upon FUSE to allow a VM to access files on the host. It provides a direct access (DAX) mode whereby data in the host page cache can be mapped into a VM and then accessed directly from within the VM. For non-DAX mode operations, virtio-fs is essentially FUSE with virtio [23] as the channel between the filesystem and device handlers. From this perspective, we believe that the improvements XFUSE provides over FUSE should be applicable to virtio-fs as well.

3 XFUSE

XFUSE is designed to achieve low latency and high throughput for fast storage devices, and scale with the increasingly large number of CPU cores available in today’s systems. Besides supporting user space filesystems in general, XFUSE is specifically designed for deploying the following types of filesystems:

- Filesystems that use high speed storage devices such as those based on persistent memory technology. To effectively leverage the very low read and write latency (microseconds range) that these devices offer, software overhead must not dominate.
- Filesystems that use SSDs and distributed storage systems based on high performance network technology such as RDMA. Such storage systems can deliver low I/O latency (on the order of 100 microseconds) and high throughput (several GB/s).
- Filesystems that are used in a production environment where availability of service is critical and disruption of users should be kept to a minimum. In particular, recoverable faults and maintenance activities such as filesystem upgrade should not materially impact service to the user.

FUSE has been widely adopted to deploy user space filesystem. Thus XFUSE is designed to be backward compatible with FUSE. To end users, an XFUSE mount is almost identical to a FUSE mount. To filesystem developers, XFUSE supports the FUSE API and extends it to enable additional functionality such as support for online upgrade and crash restart. Just as with FUSE, XFUSE consists of a kernel module, `xfuse.ko`, and a library, `libxfuse.a`, that needs to be linked into the filesystem daemon.

3.1 Performance

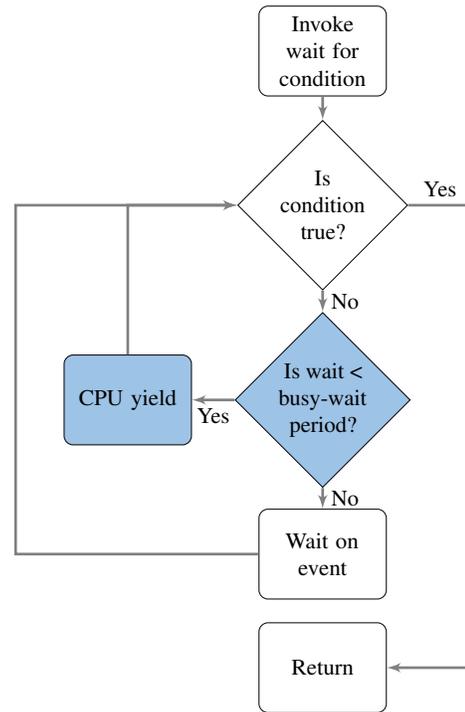

Figure 2: Busy-Event Wait.

3.1.1 Adaptive Waiting

XFUSE is patterned after FUSE [7] and has a similar architecture. Figure 1 can be used to describe the XFUSE architecture as well. From the figure, a FUSE request flows from the user application to the filesystem daemon process through the filesystem handler and the device handler. After the filesystem has processed the request, it sends a response in the reverse direction through the device handler and the filesystem handler. FUSE uses kernel events to coordinate the flow between the filesystem and device handlers. The latency for a FUSE request thus includes the time required by the filesystem daemon to handle the request and the time for two event waits - one by the device handler to obtain an incoming request and the second by the request handler to obtain the response from the filesystem daemon.

A kernel event notification takes on the order of a few microseconds to be delivered. For requests that can be handled quickly by the filesystem, the overhead of two event waits is very costly. For example, the latency of filesystem metadata requests that operate on in-memory data is dominated by the two event waits. The event waits also mask the low-latency benefit provided by high performance storage devices such as those based on persistent memory technology.

To avoid this overhead, XFSUSE introduces an initial period of busy waiting or busy polling to the event wait. This wait scheme is depicted in Figure 2. If the condition being sought by a process is satisfied during the busy waiting period, the process continues without incurring the cost of an event wait. However, if the condition being sought is not met within the busy-wait period, the scheme falls back to regular event wait. We term this scheme *busy-event wait*.

With XFSUSE, the device handler running in a filesystem daemon thread checks for new requests in a busy loop for a short period of time. If a pending request arrives during this busy waiting period, it is found and handled immediately by the daemon thread. If no new request arrives within the short period of time, the thread falls back to waiting on an event that is signalled whenever a request is submitted. The device handler sends a reply back to the filesystem handler in the same manner. If the filesystem daemon can handle a request fast enough, the filesystem handler may still be busy waiting when the reply becomes available. In this case, the end-to-end latency as observed by the application process can be as low as 3-4 microseconds.

The effectiveness of busy waiting has some dependence on whether the application threads and filesystem daemon threads are running on the same or different CPUs. We evaluate this factor in Section 4.1.2. In setting the busy-wait period, there is a tradeoff between request latency and CPU utilization which affects throughput. The busy-wait period should be set based on the performance characteristics of the filesystem and the underlying storage system. Later in Section 4.1.1, we evaluate this parameter and find that a busy-wait period on the order of 10 microseconds achieves a good balance for systems based on persistent memory technology as well as those based on SSD.

To further reduce CPU consumption and potentially increase throughput, we can dynamically adjust the busy-wait period based on the latency observed in the system. In particular, if the actual time required to service a request exceeds the busy-wait period, attempting to busy wait is futile and only wastes CPU resources. We thus experimented with a simple scheme that dynamically disables busy waiting whenever the last observed latency exceeds the busy-wait period by more than the net overhead of event wait, and reenables it whenever the last observed latency falls below this threshold. We refer to this scheme as *adaptive busy-event wait*. Results reported in Section 4.1.1 show that adaptive busy-event wait is very effective at avoiding unnecessary busy waiting, thereby increasing throughput.

3.1.2 Increased Parallelism

With the growing number of cores available on modern systems, increasing the number of requests that can be processed in parallel is the key to increasing throughput. XFSUSE enables multiple filesystem daemon threads to work on different

requests in parallel, and supports the asynchronous processing model to enable each thread to handle multiple concurrent requests.

More specifically, XFSUSE provides multiple communication channels between the filesystem handler and device handler. Each channel has two queues. One is the free queue containing request slots that can be used for new requests. The other is the processing queue containing requests that are inflight. The filesystem handler selects a channel for an incoming request using a channel selection policy. At the other end of each channel is a filesystem daemon thread waiting for new requests. There can be multiple requests in the processing queue per daemon thread. XFSUSE also ensures that threads working on different channels do not have lock contention between them. The number of channels and the number of request slots per channel determine the maximum concurrency that XFSUSE can deliver to the filesystem daemon. In order to make effective use of the multiple channels and associated filesystem daemon threads that XFSUSE supports, thread placement and channel selection policies are important considerations. We discuss and evaluate these policies later in Sections 4.1.2 and 4.1.3.

In contrast, FUSE uses a single request queue to hold incoming requests. When there are many concurrent accesses, the single request queue may become a source of contention and limit the throughput that FUSE can achieve. As we shall see later in Section 4, XFSUSE is able to drive much higher throughput than FUSE through increased parallelism.

3.2 RAS

3.2.1 Online Upgrade

Scheduling service downtime to perform an upgrade is very disruptive in production settings. By operating outside of the kernel, a user space filesystem can potentially be upgraded without disrupting the application. Such a non-disruptive or online upgrade capability will ease the introduction of new features and big fixes, and facilitate the deployment of user space filesystems in production environments.

When a filesystem daemon terminates, all the file descriptors to the special device `/dev/fuse` are closed. This leads the kernel to unmount the filesystem automatically. In order to keep the kernel from unmounting the filesystem during an upgrade of the filesystem daemon, XFSUSE provides a monitor service to hold all the XFSUSE device file descriptors while the old filesystem daemon exits and a new daemon executing the upgraded software takes over to serve running applications.

XFSUSE includes a library, `libxfuse` to facilitate the interaction between the filesystem daemon and the XFSUSE monitor service. `Libxfuse` extends the FUSE `libfuse` library with new functionalities and APIs that allow user space filesystems built with it to support online upgrade.

Figure 3 illustrates the XFSUSE-assisted filesystem online

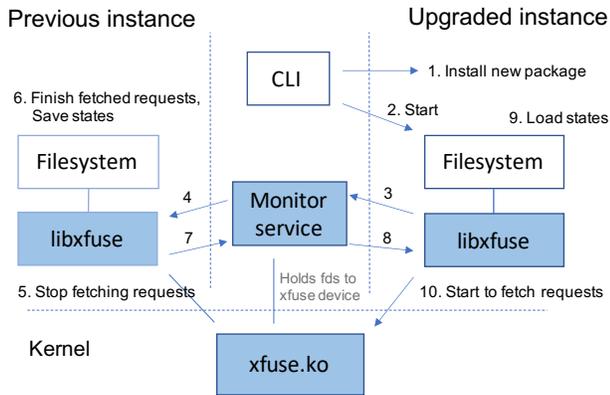

Figure 3: Filesystem Online Upgrade Workflow.

upgrade workflow. Figure 4 shows the XFUSE state transitions in both filesystem daemons during the upgrade process. The numbered actions in the two figures match. Certain details, such as error handling, are omitted to reduce clutter.

1. The upgrade workflow starts with an operation to update the filesystem software package. In Figure 3, this operation is triggered through a CLI (command line interface) command to install the new software package.
2. After installation, a filesystem daemon process running the new software is started. This filesystem daemon initializes its XFUSE stack with parameters to interact with the XFUSE monitor service, and provides libxfuse with a number of callback functions. The usage of those callbacks is depicted in Figure 4.
3. Upon starting, libxfuse connects to the XFUSE monitor service on behalf of the filesystem daemon and fetches all the file handles to the XFUSE device. As discussed earlier, having the monitor service create and hold XFUSE device handles ensures that the filesystem service can remain online to applications during the upgrade.
4. When a filesystem daemon is running, it maintains a communication channel with the XFUSE monitor service. Through this channel, the monitor service notifies the current filesystem daemon that it is being upgraded.
5. Libxfuse in the current filesystem daemon stops fetching new requests from the kernel. However, XFUSE device read operations issued moments earlier may still be returning from the kernel. The filesystem may also be replying to just-processed requests. Libxfuse waits for all pending requests to drain.
6. The filesystem continues processing requests. When libxfuse is certain that there are no more inflight requests, it notifies the filesystem to save its transient state. As an

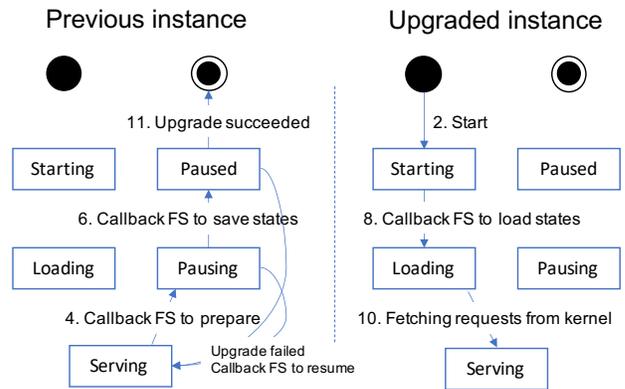

Figure 4: State Transitions during Filesystem Online Upgrade.

optimization, libxfuse can notify the filesystem earlier in Step 4 to start preparing for an upgrade so as to reduce the time needed to save the transient state after incoming requests are paused.

7. Libxfuse notifies the XFUSE monitor service on behalf of the current filesystem daemon that it is paused and that its transient state has been saved. The saved state includes open file handles, file locks and all other runtime data necessary for a new filesystem daemon to take over and continue serving running applications.
8. The XFUSE monitor service notifies the new filesystem daemon that the saved state is ready to be loaded.
9. Libxfuse in the new filesystem daemon calls back into the filesystem to load the saved state and prepare to handle incoming requests.
10. The new filesystem daemon starts to fetch requests from the kernel. Past this point, the previous filesystem daemon exits. The online upgrade has been successfully completed.

We have implemented a user space filesystem with the ability to save and restore its transient state, and integrated it with XFUSE to enable us to upgrade the filesystem software with minimal user impact. The filesystem and XFUSE components are deployed and serving production workloads. In Figure 5, we plot the performance as observed by the fio benchmark [2] operating against the filesystem as the filesystem is upgraded. At 34 seconds into the plot, the upgrade is initiated. This triggers a series of steps to verify and install the new software package. A filesystem daemon process running the new software is then started. Throughout this time, the current filesystem daemon continues to serve I/O requests. At 55 seconds into the plot, the current filesystem daemon is asked to stop processing incoming requests. By 57 seconds into the plot, the current filesystem daemon has completed all

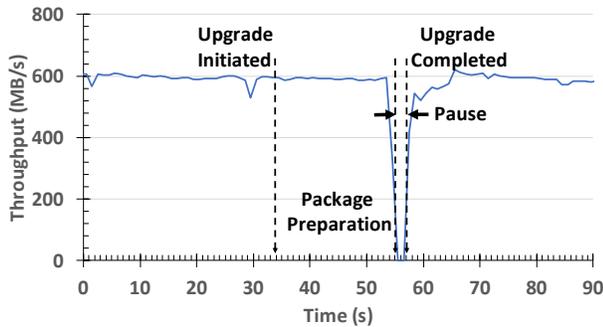

Figure 5: Throughput During Online Upgrade of Filesystem.

pending requests and saved all of its transient state. The new filesystem daemon loads the saved transient state and starts to serve incoming requests. At this point, the old filesystem has served its purpose and terminates itself. There is a ramp up in performance as the new filesystem establishes its cache.

3.2.2 Crash Restart

The online upgrade process forms the basis for supporting crash restart of the filesystem daemon process. Just as for online upgrade, in order to support crash restart, the filesystem must be able to remember its transient state and reinstate it via the new filesystem daemon instance. After the new instance is up and has restored the previous state, it can start to replay any pending requests. The kernel module does not know the exact point at which the filesystem daemon process crashed and restarted. It simply resends all the pending requests that it has already sent to the previous instance and for which it has not received the response.

The new filesystem daemon instance, however, cannot simply re-process all the requests because filesystem requests are not idempotent. For example, suppose a user successfully removes a file *P*. If the file removal operation were to be applied again, it would fail because the file *P* no longer exists.

To handle crash restart in the face of such non-idempotent requests, the filesystem daemon saves information about recent requests in a request-response table. This table records the response for requests that have already been processed by the filesystem daemon. For each incoming request, the filesystem daemon replies with the saved response if the request is recorded in the table. Otherwise it processes the requests normally. To uniquely identify a request, the kernel module assigns a request ID, which encodes a consecutive sequence ID, to each incoming request. To ensure that IDs are assigned consecutively, the filesystem daemon needs to persist the largest request ID it has processed. After a restart, the new daemon instance passes this value as a mount flag to the kernel.

The size of the request-response table is bounded by the number of requests that may be in flight. Conceptually, the XFUSE kernel module keeps a queue of the requests that

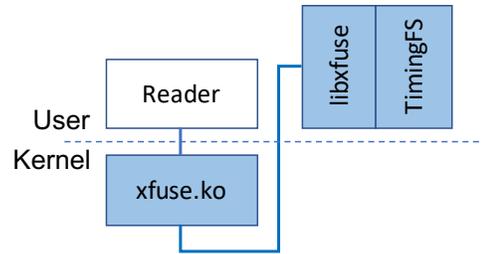

Figure 6: Experimental Setup for Parametric Analysis.

it has received the response for. When sending the next request, it dequeues a completed request and sends its request ID along with the new request. The filesystem daemon uses the completed request ID to prune its request-response table. In practice, the tracking of completed requests and their responses is done on a per channel basis to avoid introducing points of contention in this process. Each channel only needs to keep track of up to queue depth number of recent requests.

4 Performance Evaluation

To evaluate the performance characteristics of XFUSE, we first use a controlled environment to explore the different aspects of XFUSE individually. The goal of this analysis is to systematically understand how these aspects are affected by policy choices and tuning parameters, and to project the performance that can potentially be achieved by a filesystem daemon that is optimized for XFUSE. We then measure actual system performance on real systems when the filesystem requests are looped through XFUSE and FUSE, and compare the results with directly accessing kernel-mode EXT4 [20].

4.1 Parametric Analysis

In this section, we use the experimental setup depicted in Figure 6. The setup is designed to provide a controlled environment where various aspects of XFUSE can be isolated and the associated parameters can be tuned systematically. Because existing user space filesystems have not been optimized beyond what FUSE can drive, this setup also serves to project the kind of performance that XFUSE can potentially achieve with a user space filesystem that is optimized for it. The setup consists of a reader composed of multiple reader threads each synchronously reading 4 KB of data from a random location in a large file. These read requests are sent via XFUSE to TimingFS, a simple filesystem daemon that emulates the timing characteristics of persistent memory and SSD.

TimingFS supports only `readdir`, `getattr` and `read` operations. `Readdir` and `getattr` operations are supported only to the extent necessary for a filesystem to be mounted and a file within the filesystem to be opened for read. The main purpose of TimingFS is to respond to read requests of the opened file. In

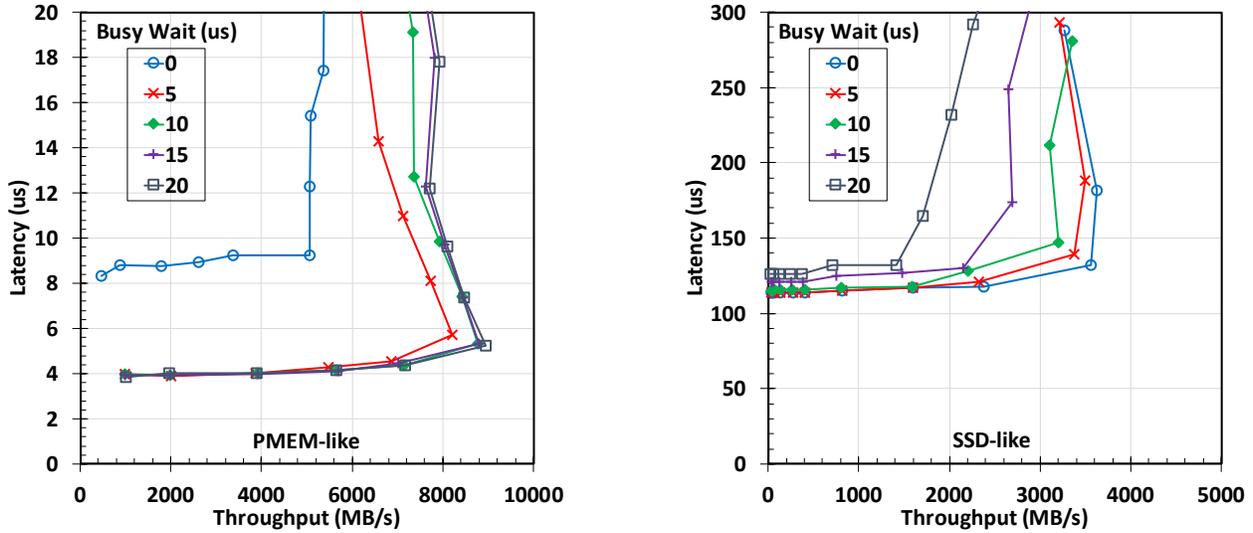

Figure 7: Performance with Busy-Event Wait.

the persistent memory mode, TimingFS handles the file read requests by immediately copying the requested amount of data from the specified location in a memory pool standing in as the file. In the results, this case is denoted as PMEM-like. In the SSD mode, TimingFS enqueues the read request and a worker thread handles the enqueued request after a delay of 100us. This case is denoted as SSD-like in the results. We use a file size of 1 GB to ensure that the memory footprint exceeds the L1 and L2 processor caches as is typically the case for I/O requests because of the amount of data involved. For 4 KB requests, ensuring that the data does not reside solely in the processor caches adds about 1 us to the read latency.

All the experiments in this analysis were performed using dedicated servers running Linux 4.19.91 on the Alibaba Cloud. Each server has dual Intel(R) Xeon(R) Platinum 8163 CPUs operating at 2.50GHz for a total of 48 physical cores. We restricted the experiments in this section to using the first 24 physical cores.

4.1.1 Waiting Strategy

Figure 7 summarizes the effect of introducing an initial period of busy waiting to event wait. Note that with a busy-wait period of 0, busy-event wait degenerates into event wait. Observe that adding on the order of 10 us of busy waiting is very effective at lowering latency and increasing throughput for PMEM-like storage. On the other hand, adding busy waiting is not effective for SSD-like storage. In fact it degrades performance significantly for SSD-like storage, and the degradation increases with the busy-wait period. This is because the service time with SSD-like storage exceeds the busy-wait period so that the busy waiting is wasted and only serves to drive up CPU utilization which affected the throughput.

We next investigate enabling busy waiting only when it

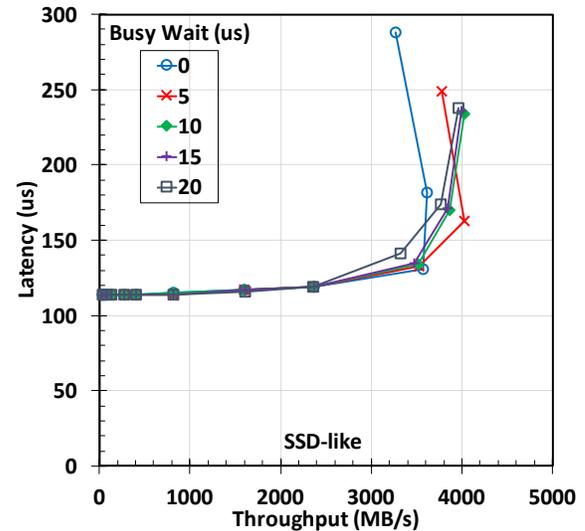

Figure 8: Performance with Adaptive Busy-Event Wait.

is beneficial. The basic idea is that if the current wait is going to be longer than the busy-wait period, we should skip the busy waiting and go straight to event waiting. We use a simple method of predicting the current wait time based on the observed latency of the last completed wait. Now, the last wait could have been completed by an event notification so a conservative threshold for enabling busy waiting is that the last observed latency is within the busy-wait period plus the net overhead of event wait. In other words, we disable busy waiting when the last observed latency exceeds the busy-wait period by more than the net overhead of event wait and reenables it when the last observed latency falls below this threshold. From Figure 9, the latency achieved with busy

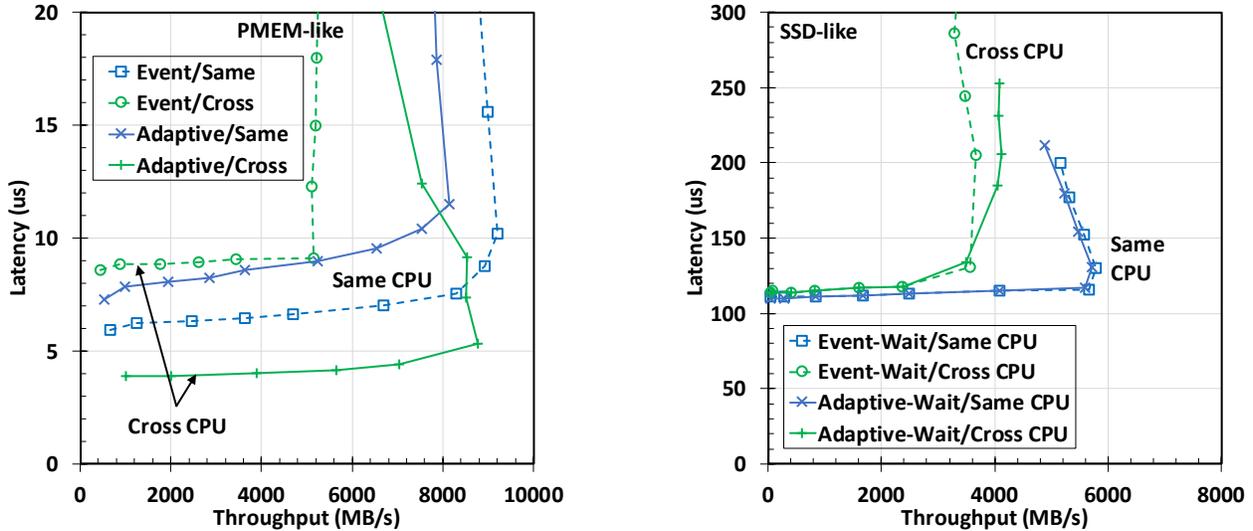

Figure 9: Effect of Thread Placement.

waiting can reach just under 4 us while that with event waiting is around 9 us, suggesting that the net event overhead is about 5 us in our experimental setup.

As shown in Figure 8, with such an adaptive busy-event wait scheme, the latency becomes relatively insensitive to the busy-wait period because futile busy waiting is avoided. With adaptive busy-event wait, a busy-wait period in the 10 us range works well for both the PMEM-like and SSD-like configurations. Observe further that throughput is increased beyond event-wait even though the service time with SSD-like storage far exceeds the busy-poll periods under consideration. Recall that there are two waits in the system. One is by the device handler to obtain an incoming request and the second is by the request handler to obtain a response from the filesystem daemon process. For SSD-like storage, the device handler running in the filesystem daemon thread to pick up incoming requests benefits from the busy waiting when under load. Thus adaptive busy-event wait offers a performance benefit even for relatively slow SSD-like storage.

4.1.2 Thread Placement

The overhead of busy waiting and event waiting depends on whether the application threads and filesystem daemon threads are executing on the same CPU. If the application thread and corresponding filesystem daemon thread run on different CPUs and use busy waiting to send messages to each other, the number of context switches will be greatly reduced. On the other hand, if the two threads are scheduled on the same CPU, context switches between the 2 threads are needed to accept the request and receive the response. Furthermore, the scheduler typically implements a per CPU run queue so that local CPU event notification is likely to be delivered faster. There are also cache locality considerations when it

comes to scheduling the application threads and filesystem daemon threads, but our evaluation shows that this effect is secondary.

In Figure 9, we investigate the effect of thread placement on performance by controlling the CPU on which each application and filesystem daemon thread runs, and the mapping of requests to channels. Specifically, we affine each application thread to a CPU and map each request to a channel based on the CPU ID of the application thread issuing the request. On the filesystem daemon side, we consider two cases - one where the thread listening on a channel is affined to the same CPU as the application thread whose requests are mapped to that channel (denoted same CPU), and the second where the listening thread is affined to a different CPU (denoted cross CPU). Observe that for PMEM-like storage, cross CPU busy waiting offers the lowest latency of just under 4 us, outperforming same CPU busy waiting by between 3-5 us. On the other hand, same CPU event waiting significantly outperforms cross CPU event waiting. In the SSD-like case, the long service time with SSD-like storage means that busy waiting does not improve latency. Thus for SSD-like storage, the lowest latency is obtained by scheduling the application threads and corresponding filesystem daemon threads on the same CPU.

In some production environments such as those where large server farms are used to provide a specific set of services to many customers, the thread placement on each server can be controlled as we have done in these experiments. When PMEM-like storage is used in these types of environments, the application and corresponding filesystem daemon threads should be placed on different CPUs and adaptive busy-event wait should be used so as to achieve a significant improvement in latency. For SSD-like storage, the application and corresponding filesystem daemon threads should be placed

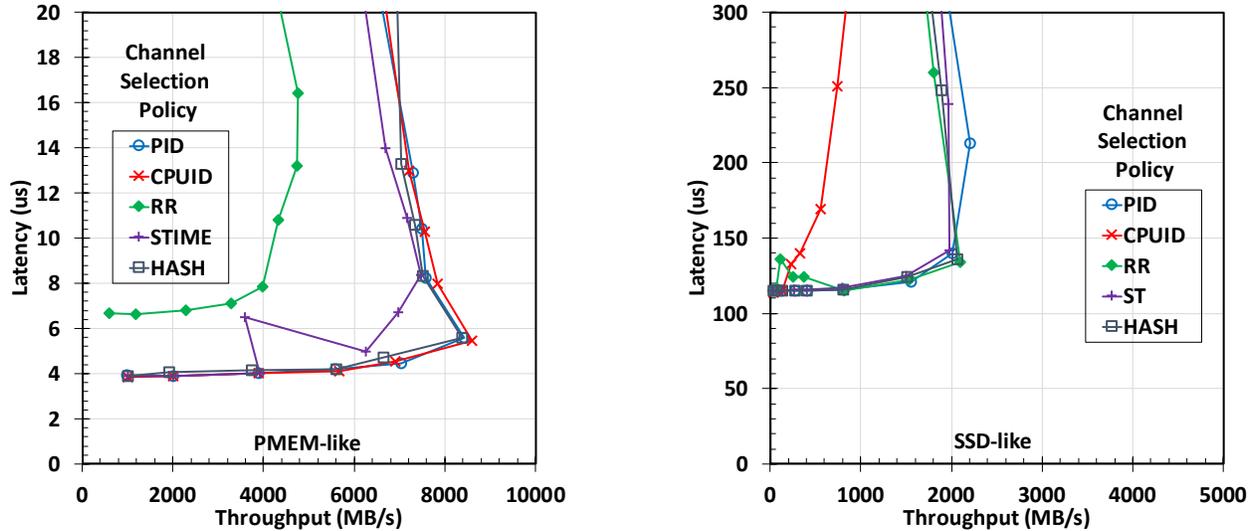

Figure 10: Effect of Channel Selection Policy.

on the same CPU. In this case, adaptive busy-event wait does not improve performance but does not hurt either.

4.1.3 Channel Selection

In other environments where thread placement cannot be explicitly managed, the performance achieved depends on how the scheduler maps the application and filesystem daemon threads to CPUs, and on how the requests are mapped to the channels. In Figure 10, we evaluate various channel selection policies when the thread placement is left entirely up to the scheduler.

The best strategy in this case is to evenly distribute requests across the channels so that multiple filesystem daemon threads can be brought to bear on handling the requests. There is one caveat in that if the policy keeps switching to an idle channel, it will render busy waiting ineffective. In the figure, RR denotes the round robin channel selection policy. In the PMEM-like case where busy waiting can be effective, RR performs worse than other policies because it keeps rotating to a channel where the corresponding filesystem daemon thread is no longer busy waiting. In order to leverage busy waiting, the channel selection policy needs to have a bias towards a specific channel.

We also evaluate using the CPU ID, thread ID and thread start time to map requests to channels. Depending on where the scheduler places the application threads, using the CPU ID to select channels may result in a very skewed channel distribution. Thread start time may also collide and result in a less than balanced distribution. We find that using thread ID is much more stable in terms of yielding an even distribution because the thread ID is at least unique. To further avoid the risk of a skewed distribution, we can use hashing techniques on the thread ID to avoid colliding on the same channel. The

HASH selection algorithm uses 3 hash functions to identify candidate channels and selects the channel with the shortest queue. In the case of a tie, it always selects the first candidate channel to avoid defeating busy waiting. HASH consistently avoids skewed distribution.

4.1.4 Performance Potential

XFUSE is designed to provide an efficient conduit between the kernel file system interface and a user space filesystem daemon. The performance that it can deliver ultimately depends on the capability of the user space filesystem. Here, we use our simple filesystem daemon, TimingFS, to project the best-case performance that XFUSE can achieve with a user space filesystem that is optimized for it. We configure XFUSE based on the analysis results discussed above. Specifically, we use adaptive busy-event wait with a busy-wait period of 10 us and an event overhead of 5 us. We also set up XFUSE with 24 channels and corresponding TimingFS threads, one for each of the physical cores that are used for the experiments.

Figure 11 presents the results. Notice that in the PMEM-like configuration, XFUSE is able to achieve latency in the 4 us range and throughput exceeding 8 GB/s. FUSE, on the other hand, has a latency of 10 us and throughput of less than 2 GB/s. Across both PMEM-like and SSD-like configurations, XFUSE significantly outperforms FUSE both in terms of latency and throughput. The improvement is especially dramatic for the PMEM-like configuration because the storage is so fast that even small overheads become hugely significant.

4.2 System-Level Performance

In this section, we use system-level benchmark workloads to evaluate the performance potential of XFUSE. The experi-

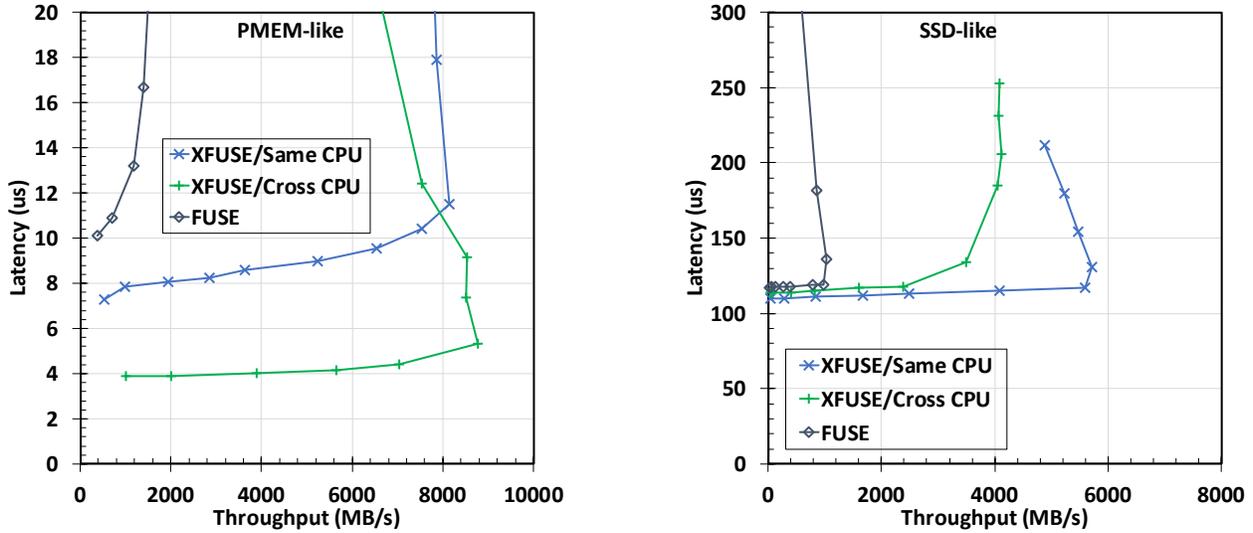

Figure 11: Performance of XFUSE and FUSE with TimingFS.

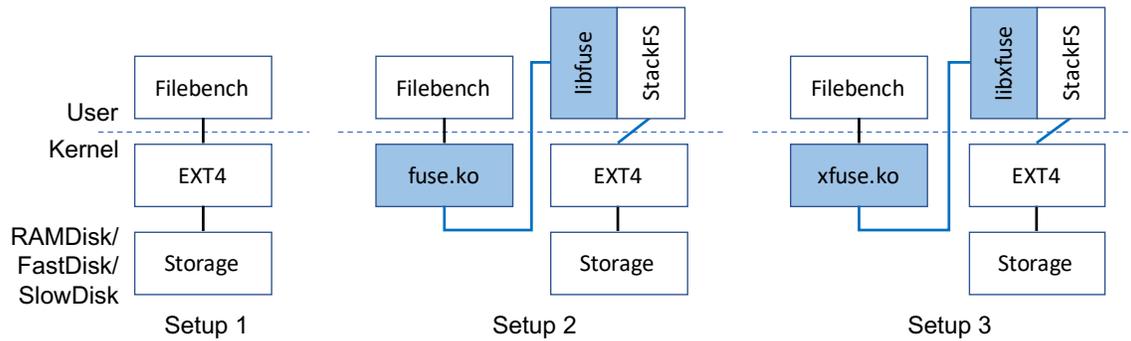

Figure 12: Experimental Setup for Evaluating System-Level Performance.

mental setup is depicted in Figure 12. The setup is designed foremost to provide a common basis for comparing XFUSE with FUSE and regular kernel-mode EXT4, and errs on the side of being conservative for XFUSE. Specifically, in this setup, XFUSE and FUSE rely on StackFS [30] to route calls back to kernel-mode EXT4. StackFS is a simple stackable passthrough filesystem originally developed to evaluate FUSE performance. StackFS has not been reworked to take advantage of the low-latency and high parallelism that XFUSE can deliver.

As discussed in [30], existing techniques such as the kernel page cache and FUSE’s readahead are effective at masking the performance of user space filesystems in several types of workload. In this section, we present results focusing on those cases where FUSE has a significant gap with kernel-mode EXT4, namely the Filebench random read, file create and webserver workloads, as previously defined and made public [29, 30]. We ran these workloads as is and without specifying CPU affinity.

We performed the measurements using dedicated servers running Linux 4.19.91 on the Alibaba Cloud. The FUSE version used is 3.6.1. Each server has 48 physical cores (dual Intel(R) Xeon(R) Platinum 8163 CPUs operating at 2.50GHz) and 768GB of memory. All the experiments in this section were limited to using the first 24 physical cores and 256 GB of memory. The remaining 512 GB of memory was allocated as a RAM disk. We configured XFUSE based on the analysis results presented in the previous section, meaning that we used adaptive busy-event wait with a busy-wait period of 10 us and an event overhead of 5 us. We also set up XFUSE with 24 channels and corresponding StackFS threads, one for each of the physical cores.

The first config uses the RAM disk as the storage device. This config is meant to illustrate the potential performance achievable when using XFUSE to access a user mode persistent memory based filesystem. We refer to this setup as RAMDisk. In the second config, we use the fastest cloud disk available. The average latency for a 4 KB read is about 115 us

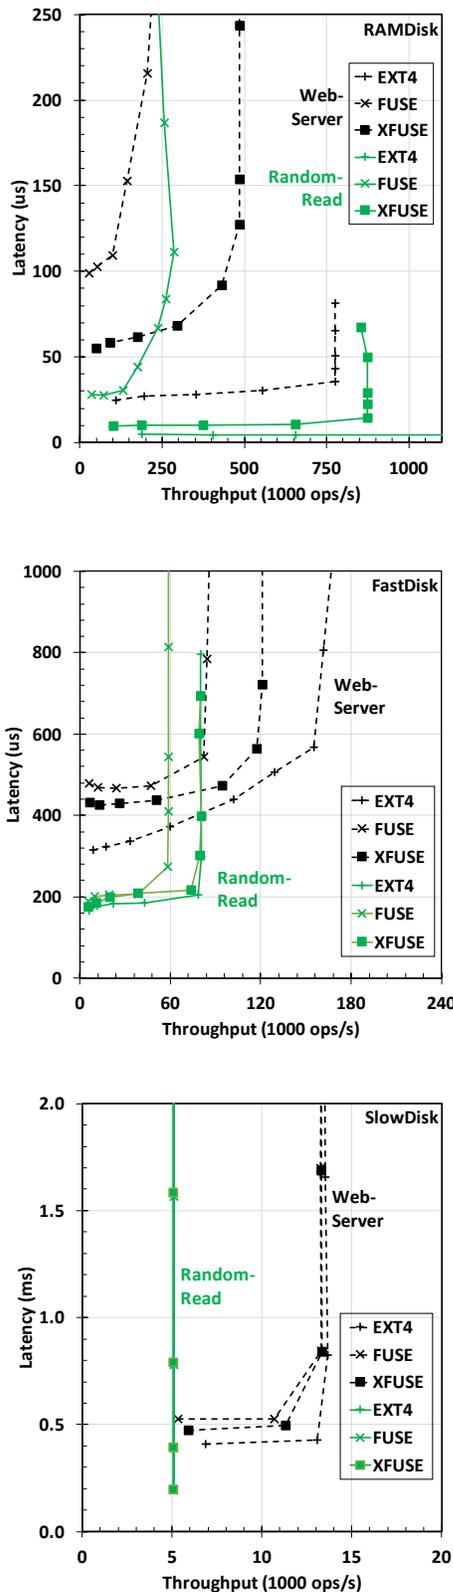

Figure 13: Performance of Random-Read and Web-Server Workloads.

on this disk. Based on its provisioned size, the throughput for this disk is capped at 80K IOPS. We refer to this setup as FastDisk. In the third config, we use the slowest cloud disk available. The average 4 KB read latency is about 250 us for this disk and it is limited to 5K IOPS. We refer to this setup as SlowDisk.

Figure 13 summarizes the performance results for the Random-Read and Web-Server workloads. With RAMDisk, kernel-mode EXT4 outperforms FUSE by a large margin across the 2 workloads. XFUSE closes the gap significantly both in terms of latency and throughput. For Random-Read, latency with XFUSE comes in at 9 us versus 28 us with FUSE. Throughput with XFUSE exceeds 874K ops/s while FUSE can only achieve 285K ops/s. This represents a 3x improvement. The improvement is similarly large for the Web-Server workload. The gap with kernel-mode EXT4 is still significant as expected because the XFUSE results are obtained by looping requests to user space and back into kernel-mode EXT4. We expect the gap to be reduced with an actual filesystem daemon running in user space that is optimized for XFUSE.

Observe that as the storage is slower, the gap between kernel-mode EXT4 and FUSE shrinks as does the benefit of XFUSE over FUSE. With SlowDisk, there is virtually no performance difference between XFUSE and FUSE. This is to be expected because when the storage is slower, the performance is bottlenecked more by the storage than by the conduit to user space. For FastDisk, which is the storage that performance-critical workloads are most likely to be using, XFUSE offers significant benefit over FUSE. For example, for the Web-Server workload, latency with XFUSE is 425 us versus 466 us with FUSE, and throughput is 125K ops/s versus 86K ops/s with FUSE. Note that the throughput of FastDisk is capped at 80K IOPs based on its provisioned size. For the Random-Read workload, XFUSE is able to deliver the full throughput of FastDisk, matching the throughput achieved by kernel-mode EXT4.

The results for the File-Create workload are summarized in Figure 14. To reduce clutter, the results for FastDisk are not presented. XFUSE outperforms FUSE for both FastDisk and RAMDisk, but not by as large a margin as in the case of the Random-Read and Web-Server workloads. For the File-Create workload, the throughput with kernel-mode EXT4 is several times higher than that with either FUSE or XFUSE. The File-Create workload creates millions of small files and each create requires several calls into StackFS to perform getattr and pathname lookups. StackFS in turn dynamically allocates memory and uses internal global locks and states to translate the requests it receives back to POSIX calls to the underlying EXT4. These roundtrips between the kernel and StackFS as well as the implementation of StackFS restrict the performance of File-Create with FUSE and XFUSE. Notice further from the figure that the File-Create workload does not scale in performance beyond 4 threads on kernel-mode EXT4. This limits the benefit that XFUSE can provide over

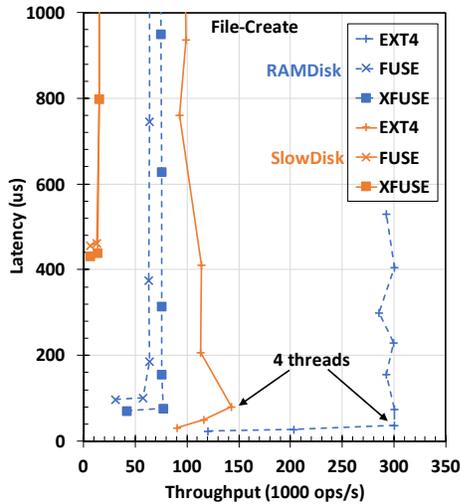

Figure 14: Performance of File-Crete Workload.

FUSE because the increased parallelism that XFUSE provides cannot be brought to bear on this workload with EXT4 as the backing filesystem.

The results underscore the point that XFUSE is designed to provide an efficient conduit between the kernel filesystem interface and a user space filesystem. The performance that it can achieve depends ultimately on the capability of the user space filesystem. Our measurements indicate that even with an existing FUSE-targeted StackFS, XFUSE offers significant performance improvement over FUSE. We anticipate that the improvement will be even more pronounced with user space filesystems that are designed to take advantage of the low latency and high parallelism that XFUSE can deliver.

5 Conclusion

This paper presents XFUSE, a user space filesystem framework that addresses the performance and RAS concerns generally associated with user space filesystems. XFUSE is backward compatible with FUSE and takes advantage of the growing number of cores available on modern systems to achieve low latency and high throughput for fast storage devices. XFUSE can enable filesystem requests made through standard kernel interfaces to be processed at the user level with latency in the 4 microseconds range, and offers throughput exceeding 8 GB/s. XFUSE also provide features such as support for on-line upgrade and crash recovery that are critical for deploying user level filesystems in production.

Acknowledgments

This paper would not have been possible without the collaboration of our storage and kernel teams. We are grateful to

our shepherd and anonymous reviewers for helping us improve the paper, and to the many who have worked on FUSE and on whose shoulders we stand. We are working towards contributing XFUSE to the community.

MAX: A Multicore-Accelerated File System for Flash Storage

Xiaojian Liao, Youyou Lu, Erci Xu, and Jiwu Shu*

*Department of Computer Science and Technology, Tsinghua University
Beijing National Research Center for Information Science and Technology (BNRist)*

Abstract

The bandwidth of flash storage has been surging in recent years. Employing multicores to fully unleash its abundant bandwidth becomes a necessary step towards building high performance storage systems. This paper presents the design and implementation of MAX, a multicore-friendly log-structured file system (LFS) for flash storage. With three main techniques, MAX systematically improves the scalability of LFS while retaining the flash-friendly design. First, we propose a new reader-writer semaphore to scale the user I/Os with negligible impact on the internal operations of LFS. Second, we introduce file cell to scale the access to in-memory index and cache while delivering concurrency- and flash-friendly on-disk layout. Third, to fully exploit the flash parallelism, we advance the single log design with runtime-independent log partitions, and delay the ordering and consistency guarantees to crash recovery. We implement MAX based on the F2FS in the Linux kernel. Evaluations show that MAX significantly improves scalability, and achieves an order of magnitude higher throughput than existing Linux file systems.

1 Introduction

The bandwidth of solid-state drives (SSDs) has been quickly increasing over the past decade [23, 24, 55]. To unleash full throughput potentials from such improvement, efficiently utilizing multicores to handle concurrent I/Os becomes a must. Currently, Non-Volatile Memory Express (NVMe) protocol [9] and multi-queue block layer [13] have already laid a multicore-friendly foundation at the driver layer. Additionally, in the upper software stack, great efforts have been made to increase the scalability [29, 38, 40, 43, 50, 56].

Nonetheless, an important question is still left unanswered: whether the log-structured file systems (LFS) atop the flash-based SSDs adapt well to the scaling of cores. LFS, initially introduced in Sprite LFS [52], builds on a simple idea: organizing the address space as an append-only log. This design essentially converts random writes into sequential ones, which not only aligns with the I/O preference of legacy hard

disk drive (HDD), but also is a common practice of file system for flash storage [35, 37, 49]. First, due to the intrinsic NAND idiosyncrasies, the sequential performance of most flash SSDs is still significantly higher than the random performance [24–28, 53, 54]. Second, the zoned namespace (ZNS), an optimized interface for flash SSDs, is available in NVMe spec and under increasing promotion [4, 6, 12, 58]. ZNS favors log-structured writes, and existing LFSes (e.g., F2FS [37]) can directly run atop it. Therefore, LFS is a promising architecture for flash SSD, and understanding its performance in the multicore context yields great significance.

Hence, we start this paper with a study on file systems (esp. LFS) throughput under concurrent and independent I/Os (§2). By increasing the number of CPU cores, we observe that most file systems scale relatively well on traditional storage devices (i.e., HDD and SATA SSDs). Surprisingly, the performance of file systems atop the modern NVMe SSDs suffers greatly from scaling. Most notably in F2FS, an LFS optimized for NVMe SSD, the performance peaks at only 18 cores, and a further scaling to 72 cores causes throughput drop by nearly 30%. The I/O utilization of F2FS on NVMe SSD is only 20%.

Through profiling, we conclude that the unscalable data structures of the file system cost a considerable amount of CPU cycles and thus bottleneck the performance. The root cause of the inefficiency comes from a legacy choice: using shared data structures to aggregate file operations and I/Os for high performance. Such philosophy essentially trades CPU cycles for high device I/O utilization. However, for NVMe SSD, this trade-off breaks as the CPU cycles are no longer negligible for high performance drives.

While many research have been conducted to understand and improve such inefficiency [29, 48, 56], they mostly focus on journaling file systems (e.g., Ext4 [44]) and therefore can not directly be applied to LFS due to different designs. For instance, LFS uses a checkpoint mechanism instead of journaling for persistence and consistency, thereby unable to use techniques such as parallel journaling for scalability [29, 56]. Hence, we first analyze the root causes inside the LFS.

Here, we decompose the LFS internals from top to bottom into three levels, the Concurrency Control (CC) level, the In-Memory Data Structure (IMDS) level and Space Allocation (SA) level, as shown in Table 1. We find that the lock con-

*Jiwu Shu (shujw@tsinghua.edu.cn) is the corresponding author.

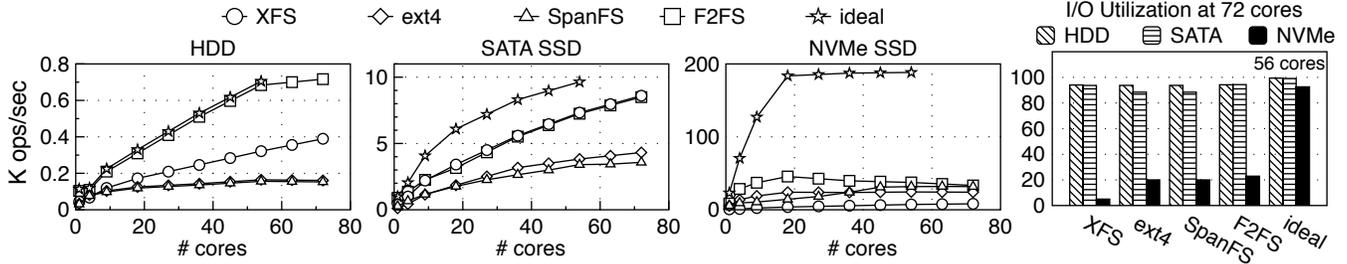

Figure 1: **Scalability problem evaluation.** We make two major observations: (1) On slow hard disk drive and SATA SSD, most file systems scale well, and the storage device is almost saturated. (2) In contrast, on high performance NVMe SSD, the performance of almost all file systems starts to drop after 18 cores, and the device is underutilized. HDD: Seagate ST1000NX0313; SATA SSD: Samsung 850 Pro; NVMe SSD: Intel DC P3700. Described in §2.

Lock level	Shared mode	Exclusive mode
Concurrency Control (CC)	write operations (e.g., write)	global operations (e.g., sync)
In-Memory Data Structure (IMDS)	index read operations (e.g., write)	index write operations (e.g., create)
Lock level	Mutual exclusion lock	
space allocation (SA)	durability operations (e.g., fsync)	

Table 1: **Current practices of the file system sharing.**

tentions caused by the shared data structures in each level serialize independent I/Os, and further prevent applications from taking full advantage of multicore-friendly design of NVMe and the abundant bandwidth of flash storage.

In this paper, we introduce the following three design principles to reduce the lock contentions of each level, and further scale the multicore performance of LFS for flash storage (§3).

- In CC level, parallelizing the external I/O requests (e.g., read and write syscalls) while keeping the internal operations (e.g., LFS checkpoint) efficient.
- In IMDS level, scaling the IMDS access while delivering flash- and concurrency-friendly on-disk format for concurrent persistence functions (e.g., fsync).
- In SA level, paralleling persistence functions while delegating (some) ordering and consistency to crash recovery.

We implement these ideas in MAX (§4), a multicore accelerated file system for high performance flash storage, with a set of modifications of F2FS. MAX replaces a global reader-writer semaphore (rwsem) of F2FS with a tailored rwsem (§4.1), reorganizes the IMDS (§4.2) and on-disk layout (§4.3) and slightly changes the crash recovery procedure (§4.4). During the development of MAX, we surprisingly find some optimizations of F2FS restrict the multicore performance. We describe our solutions to maintain these optimizations while offering better scalability (§4.5). In a nutshell, MAX restructures F2FS, enabling independent I/Os to concurrently enter the file system, concurrently access the IMDS and concurrently reach the persistent storage. We further study MAX’s performance (§5). Under a wide variety of micro- and macro-benchmarks, we show that MAX achieves up to an order of magnitude higher

throughput than existing Linux file systems. Further, evaluation against memory-backed tmpfs [51] indicates that, for certain file operations (e.g., appending blocks to private files), the performance of MAX almost reaches the upper bound of VFS (virtual file system).

In summary, we provide three major contributions.

- We perform a study on the multicore scalability of LFS and demonstrate that the lock contentions from different levels as the major culprits.
- We propose MAX removes unnecessary sharing of different levels by using a novel reader-writer semaphore, a new in-memory data structure abstraction and log partitions.
- Our evaluations show that MAX outperforms existing Linux file systems by up to an order magnitude. For some file operations, MAX comes close to the upper bound of VFS.

2 Background and Motivation

2.1 Understanding the Performance

We start with measuring the throughput of 5 file system setups (XFS [18], Ext4 [44], SpanFS [29], F2FS [37] and ideal) on three types of storage devices (HDD, SATA SSD and NVMe SSD). In the ideal setup, we partition the drive and run an independent F2FS on each partition. This enables each parallel process to execute in its dedicated file system without software level contention. As fdisk [2] only allows at most 56 partitions, we do not include performances of ideal setup beyond that. §5 further describes other details of the testbed.

In the experiment, we attach each core with one process and scale the number of cores from 1 to 72 (i.e., X axis in Figure 1). Each process runs for 60 seconds, and executes the following operations. First, the process creates a file in its own directory. Then the process issues 4 KB writes, invokes the fsync on each file and then deletes the file.

Figure 1 plots the results. First, we observe that existing file systems scale poorly on NVMe SSDs. For HDD and slower SATA SSD, the performance of many file systems (e.g., F2FS and XFS) is close to that of the ideal setup. For NVMe SSDs, the throughput of existing file systems is far from ideal. Instead of benefiting from the scalability, most file

Operations	Lock/Sharing	Overhead	Lock level	Description
<code>write()</code>	<code>sbi->cp_rwsem</code>	50.98%	CC	Mutual exclusion between checkpoint and write operations.
<code>create()</code>	<code>nm_i->nat_tree_lock</code>	3.74%	IMDS	Protecting a radix tree indexing of inode table.
	<code>sbi->inode_lock</code>	3.22%	IMDS	Protecting a list indexing of dirty inode.
	<code>curseg->curseg_mutex</code>	1.84%	SA	Serializing log-structured space allocation.
	<code>nm_i->nid_list_lock</code>	1.09%	IMDS	Protecting a central ever-increasing inode ID allocator.
<code>unlink()</code>	<code>nm_i->nat_tree_lock</code>	22.68%	IMDS	Protecting a radix tree indexing of inode table.
	<code>im->ino_lock</code>	6.54%	IMDS	Protecting a list and radix tree indexing of cached inode.
	<code>sbi->inode_lock</code>	3.05%	IMDS	Protecting a list indexing of dirty inode.
	<code>node_inode</code>	2.66%	IMDS	A user-invisible inode structure to trace all inode pages.
	<code>sit_i->sentry_lock</code>	2.41%	SA	Synchronizing concurrent access to segment info table.
<code>fsync()</code>	<code>sbi->writepages</code>	45.76%	SA	Enforcing the sequential log access.
	<code>sit_i->sentry_lock</code>	1.07%	SA	Synchronizing concurrent access to segment info table.

Table 2: **The scalability bottlenecks of F2FS.** `write()`: overwriting blocks of private files, `create()/unlink()`: creating/deleting files in private directories, `fsync()`: invoking `fsync` on private files. Described in §2.2.

system actually suffer from the increasing number of cores. For example, F2FS peaks at 18 cores, then starts to decline and ends up with a 30% performance loss. Further, in the rightmost plot of Figure 1, we observe that, even at the scale of 72 cores, most file systems do not efficiently utilize the I/O bandwidth of NVMe SSD.

The results from this experiment suggest that the performance of existing file systems are no longer bounded by the underlying device or the drive layer. Instead, the file system itself becomes the bottleneck and can not efficiently exploit the bandwidth of high performance drives.

2.2 Identifying Root Causes

Next, we investigate the CPU overhead distribution to identify the root causes of poor scalability in F2FS atop the NVMe SSDs. We use Linux performance analysis tools `perf` [8] to measure the overhead of each function call in terms of CPU cycles. We focus on four representative system calls (i.e., `write`, `create`, `unlink` and `fsync`) in a 72-core-scaling setup of F2FS. We observe that lock contention caused by unscalable data structure organization is a major source of overhead. Hence, we single out expensive lock operations, and identify their levels. Table 2 shows the overall results.

Lock cache coherence at CC level. The operations of LFS can be broadly classified into three categories: user read operations (e.g., `read` and `stat`), user write operations (e.g., `write` and `create`) and LFS internal operations (e.g., checkpoint). Most Linux file systems (FS) control the concurrency among user read operations and write operations by a relatively simple way: using a file-level inode reader-writer semaphore¹. The concurrency control among independent writes and the global checkpoint is more complicated; as shown in Table 1, LFS usually employs a traditional reader-writer lock (e.g., `cp_rwsem` of F2FS and `ns_segctor_sem` of NILFS2 [35]) at CC level to grant access for writes and checkpoint. Independent writes can concurrently update disjoint parts of the

¹In early Linux versions, the inode lock is implemented using a mutex.

FS image, and thus hold the reader-writer lock in the shared mode². As the checkpoint requires a consistent and quiescent FS image, it holds the lock in exclusive mode to prevent other writes from modifying the FS.

For `write`, we can see that more than half (50.98%) of CPU cycles are used on grabbing locks for accessing the file system. Exclusive-mode lock only allows exclusive access and thus yields expensive overhead due to serialization. Yet, global operations (i.e., checkpoint) are invoked by OS-wide `sync` syscall or periodically (e.g., 30s), which is usually less frequent, and hence do not significantly influence the throughput. The shared-mode lock, on the other hand, permits concurrent accesses, but its counter is shared among cores. As concurrent writes (i.e., shared-mode lock) are prevalent, the cache coherence on the lock counter value can be increasingly severe with the scaling, resulting in a considerable slowdown. **Serialization at IMDS level.** After entering the file system through CC level, the process needs to access and update IMDS (i.e., the in-memory indexing and data cache). Typically, LFS tends to split IMDS into different regions (e.g., inode table, inode and data) based on functionality. F2FS manages each region via a radix tree, and uses a reader-writer lock on each tree for correct concurrent execution. As shown in Table 1, for file modification operations, such as `create` and `unlink`, they require a exclusive-mode lock as they may alter the indexing. Unlike CC level, writers can be quite popular at IMDS level. With an increasing amount of concurrent writers, serialization in accessing the three radix trees becomes severe and further leads to performance drop. From Table 2, we can see that lock operations at IMDS level are the most expensive ones with 9.89% and 37.34% in total respectively, for both `create` and `unlink`.

Serialization at SA level. Finally, to persist the data blocks in a crash safe manner, the process needs to allocate space and submit the I/O requests in the correct order. LFS typically

²In this paper, to avoid confusing the FS reader/writer with the lock reader/writer, we refer to the shared-mode lock as the reader lock and the exclusive-mode lock as the writer lock.

uses only one logical space allocator to avoid overlapping allocation (i.e., concurrent writes on the same address). The space allocator uses mutually-exclusive locks for granting access. In this case, concurrent writes converge on the allocator, and wait to be scheduled in a serialized fashion before being sent to the device, which limits the overall throughput.

F2FS extends the single log schema into multi-head logging for data temperature separation. Specifically, for inode and data region, F2FS statically defines up to 3 types of temperature and employs multiple logs (6 log heads in total) on disk, each mapped to each temperature. However, from Table 2, lock contention at SA level can consume nearly half (i.e., 46.83%) of CPU cycles.

This is because the intrinsic dependencies among the temperature logs serialize the data persistence. In particular, for the crash consistency of F2FS, the data blocks must be durable before inode blocks and the file inode must be durable before the directory data blocks. As a result, in face of a `fsync`, these logs are almost processed serially although F2FS has multiple logs. Hence, the multi-head logging design of F2FS has little effect on scaling the I/O throughput.

3 MAX Design Principle

To exploit the benefits of multicore architecture and modern NVMe SSD, we formulate the following MAX design principles and describe the intuition behind them.

Principle 1: *In the CC level, using OS scheduler-assisted consensus to efficiently coordinate the external I/O requests (e.g., user writes) and internal operations (e.g., LFS checkpoint).*

LFS coordinates writes and checkpoint using traditional reader-writer lock. Recall that our study in §2.2 shows that the major overhead at CC level comes from cache coherence on the shared lock counter. Thus, a straightforward solution can be setting a local reader lock counter for each core, like scalable locks with per-core reader counters [41, 42]. A writer, to guarantee exclusive access, can simply block all further readers, and then either aggressively query the per-core counters or await until all on-going readers finish (i.e., all counters reduced to zero). While this naïve solution successfully minimizes the cache coherence among readers, the writer may either cause excessive overhead by aggressive querying or high latency due to the lazy waiting. For instance, the interrupt-processor interrupt-based aggressive query [42] is likely to interfere the latency-critical tasks on other cores, e.g., increasing the user-visible latency of read syscall. The lazy waiting approach [41] may experience periodical OS scheduling interval (e.g., 1-10 ms) and further increase the checkpoint latency. The millisecond-scale latency may be tolerable for HDD and SATA SSD, but is unacceptable for NVMe SSDs with ten to hundreds of microsecond latency.

On the other hand, an outstanding advantage of the kernel FSes is that they run on the OS control plane. This has not

been exploited to assist concurrency control of LFS. For example, to guarantee process fairness, the process in the kernel mode frequently invokes the OS scheduler for scheduling. A typical case is the exit of FS syscall, implying the end of I/O.

MAX uses a new reader-writer semaphore namely Reader Pass-through Semaphore (RPS) for concurrency control. The RPS uses per-core counters to reduce cache coherence overhead, and introduces *scheduler-assisted consensus* to coordinate the external and internal operations with less overhead.

Principle 2: *In the IMDS level, the IMDSes are partitioned by the file inode ID for concurrent file-level in-memory indexing and caching. Further, the IMDSes of the same file are repacked to avoid page-level (e.g., 4 KB) false sharing, so as to facilitate the concurrent file-level persistence functions.*

Earlier in § 2.2 we showed that serialization of accessing indexing trees at IMDS level is expensive. A feasible way to accommodate concurrent writers is to split the trees into multiple ones, similar to the non-volatile main memory FS [57]. Partitioning the memory-based storage system is relatively flexible due to fine-grained access granularity (e.g., byte-scale) of the main memory. However, such a partition method can not be directly applied to block-based SSD FS due to different and coarse access granularity. Traditionally, the FS for block storage often stitches small-sized file metadata and file system metadata into a shared block, which introduces extra contention. Therefore, scaling the IMDS while delivering flash- and concurrency-friendly on-disk layout remains a challenge for MAX.

In MAX, we propose a new IMDS abstraction, *file cell*, to repack data and metadata to allow multiple indexing entities, thereby lowering the chance of serialization. Additionally, we realize SSD- and concurrency-friendly on-disk format for file cell by setting a dedicated page for each inode and stitching the small unaligned flushes as pages. In this way, MAX can access the IMDS and write the buffered pages to the persistent storage with less contention.

Principle 3: *In the SA level, the drive space is divided into multiple independent logs; independent file operations can allocate space and be distributed to minor logs concurrently. The ordering and consistency of dependent file operations among multiple logs are delegated to crash recovery.*

Our study in §2.2 shows that having only one space allocator for each type of data can introduce considerable overhead for concurrent writers. MAX addresses this issue by partitioning the log space, like other log-based storage systems [10, 57]. Log partitioning introduces challenges to maintain the concurrency and crash consistency over multiple minor logs (mlog).

For concurrency control, leveraging the file interfaces and semantics of FS, MAX distributes complete file operations (not simply data blocks) to a mlog. In other words, when persisting files (e.g., `fsync`, or `write` a file with `O_SYNC` flag), MAX submits the data blocks that need to be persisted atomically to the same mlog. This avoids concurrency control over multiple mlogs and brings higher concurrency.

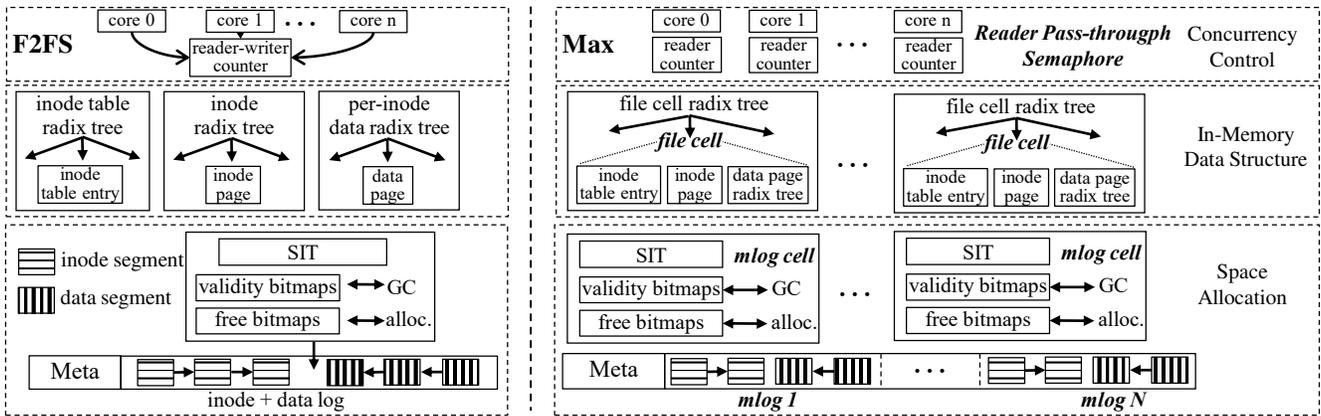

Figure 2: A comparison of F2FS and MAX. MAX introduces Reader Pass-through Semaphore (RPS) (§4.1) at CC level, file cell (§4.2) at IMDS level and mlog cell (§4.3) at SA level for higher concurrency.

For crash consistency, each mlog keeps its localized consistency just like traditional LFS. In MAX, the same file of different versions can be distributed to different mlogs. MAX embeds a global version number in each inode block to record the ordering across multiple independent mlogs, and finds the newest file during crash recovery using the global version.

By persisting independent file operations to independent mlogs and delaying the persistence ordering to recovery, MAX enables highly concurrent persistent functions.

4 MAX Implementation

We implemented MAX by modifying F2FS. Figure 2 shows a side-by-side comparison between MAX and F2FS.

4.1 Reader Pass-through Semaphore

MAX replaces the traditional reader-writer semaphore of F2FS (i.e., `cp_rwsem`) with Reader Pass-through Semaphore (RPS). We use Figure 3 (referred by arrow numbers) and Algorithm 1 (referred by line numbers) to elaborate the RPS control flow. **Concurrent readers.** RPS borrows the idea of per-core reader lock counter. With a private counter for each core, concurrent readers can independently increase or decrease the counter value without cache coherence from different cores (lines 1-8). The major overhead (i.e., 50.98% in Table 2) at the CC level is thus removed.

Exclusive writer. RPS introduces a “Scheduler Free Rides” mechanism to avoid high overhead and latency for exclusive-mode lock. The key idea is to leverage the CPU scheduler to efficiently check the counter value of each core. The original design goal of the CPU scheduler is to coordinate processes, which lets it frequently access the cores. Scheduling itself searches several queues, so adding RPS logic (i.e., check the reader counter) atop it costs extra little. Hence, the counter values of different cores are frequently retrieved with low overhead, thereby taking the free rides of the scheduler.

Specifically, the pending writer first locks `wsem` (i.e., Linux writer semaphore) on each core to block all further incoming readers and writers (line 15, arrows ① and ④). The writer sets the per-core notification flags, and then goes to sleep and waits for all flags cleared (i.e., readers on all cores have left the critical section, lines 16-19). Next, the on-going readers continue as usual except the last reader on each core finishes by yielding the execution to the CPU scheduler (lines 9-10, arrow ②). The CPU scheduler then clears the per-core notification flag, which indicates that the on-going readers of that core are all finished. For cores with no on-going readers, the RPS utilizes the opportunity of kernel preemption to let the scheduler check the counter value and clear the notification flag (lines 27-28, arrow ⑤). With all notification flags cleared, the scheduler can then wake up the writer and let it start to execute (lines 18-19 and 29, arrow ⑧).

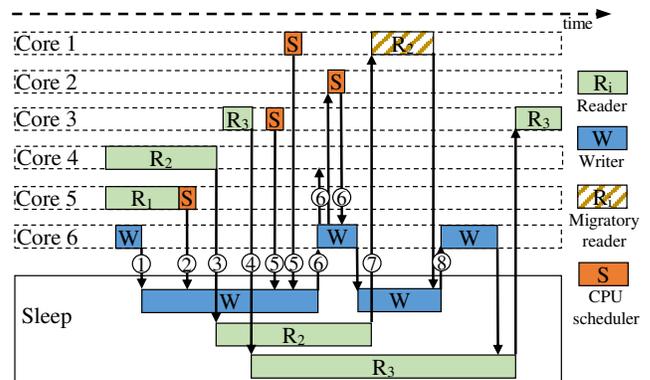

Figure 3: “Scheduler Free Rides” mechanism of RPS. Described in §4.1.

Corner cases. In our original RPS design, there are two corner cases: late preemption and task migration. First, in the “Scheduler Free Rides” mechanism, the scheduler relies on opportunities of kernel preemption to check the reader lock counter on zero-reader cores. While preemptions are usually frequent, a worst-case scenario can take up to 10 ms (i.e., tick

Algorithm 1: RPS Pseudo-code

```
1 def read_lock (rps):
2   while rps.wsem ≠ FREE do
3     wait(rps.wsem == FREE) /* woken up by line 25 */;
4     this_cpu_inc(rps.percore_reader);
5 def read_unlock (rps):
6   readers ← this_cpu_read(rps.percore_reader);
7   if readers > 0 then
8     readers ← this_cpu_dec_return(rps.percore_reader);
9     if rps.wsem ≠ FREE and readers == 0 then
10      yield();
11  else if readers == 0 then /* migration reader exists */
12    if atomic_dec_test(rps.migration_cnt) then
13      wake_up_writer();
14 def write_lock (rps):
15   lock(rps.wsem);
16   for core ∈ get_online_cpu() do
17     per_cpu_set(rps.noti_flag, core, 1);
18   for core ∈ get_online_cpu() do /* wait for all flags cleared */
19     wait_timeout(per_cpu(rps.noti_flag, core) == 0, TIMEOUT);
20     if timeout then
21       cores_unfinished ← check_notification_flags();
22       send_ipi(cores_unfinished);
23   wait(atomic_read(rps.migration_cnt) == 0) /* woken up by line 13 */;
24 def write_unlock (rps):
25   unlock(rps.wsem);
26 def schedule (core, task):
27   if this_cpu(rps.percore_reader) == 0 then
28     this_cpu_set(rps.noti_flag, core, 0);
29     wake_up_writer();
30 def migrate_task (task, src, dst):
31   /* Tasks holding RPS are off the src and dst CPU now, so it's safe to
32    modify the per-core reader counter */;
33   per_cpu_dec(task.rps.percore_reader, src);
34   atomic_inc(task.rps.migration_cnt);
```

preemption interval) for the scheduler to check all counters. This delay is unbearable for high performance SSDs and can cause a long writer latency. To handle this, RPS sets the writer to wake up periodically. Then the writer actively invokes inter-processor interrupts to check reader counters of unfinished cores (lines 20-22, arrow ⑥). Note that the wake-up interval is configurable in RPS (100 us by default).

The second corner case is the task migration. In the multicore execution environment, a reader on one core can be migrated to another core (arrows ③, ⑦). Therefore, RPS sets up a global migration counter. Upon task migration, the RPS decreases the local counter of source core by one and also increases the global migration counter by one (lines 31-33). The migrated reader therefore decreases the global migration counter instead of the local one when finishes (lines 11-12). Thus, the pending writer needs to wait until both local counters and the migration counter all decreased to zero before accessing (line 23, arrow ⑧).

4.2 File Cell

As shown in Figure 2, MAX organizes the IMDSeS using the file cells and indexes them by multiple trees. This subsection describes the indexing and the format of file cell in details.

File Cell indexing. Each file cell encompasses the inode table entry, inode page³, and data page of a single file. MAX then divides the file cells into multiple groups and indexes each group using a radix tree. MAX places each file cell to a tree by hashing the inode ID of the file (i.e., inode ID modulo the number of trees). Each radix tree accepts the inode ID as key and outputs associated file cell. Note that the number of indexing entities (i.e., radix trees) is configurable. Having more trees yields a lower chance of serialization but can also lead to high memory consumption. We set the number as half of the number of cores as we observe that setting more trees beyond that does not lead to better performance (see § 5.4 for details). Thus, MAX lowers the chances of serialization as well as the number of indexes.

File Cell data format. MAX uses a dedicated page for the inode of each file. To reduce memory consumption, we use the following approach. If the unaligned data can fit in the inode page, MAX appends that to the end of the inode page. If not, the inode owns the entire page. For example, consider a file with 6 KB data and a 256 B inode. MAX sets two pages for that file cell. The first one is a 4 KB data page. The second one is the inode page that contains the 256 B inode plus the 2 KB unaligned data.

Unlike the journaling FS that inodes are placed in a pre-determined location, inodes of LFS are updated in an out-of-place manner, thereby forcing the inode table to be placed in a fixed on-disk location for indexing. Additionally, information similar to the inode table entries must be persisted simultaneously to locate the newest inode. However, the inode table entry is extremely small (e.g., 9 B). This brings challenges for LFSes to achieve high concurrency, low write amplification without breaking the fixed-location property.

MAX realizes high concurrency and persistence of inode table entries using two representations. For in-memory representation, with the byte-addressability of DRAM, MAX partitions the inode table, and distributes the inode table entries to each file cell. All operations, except checkpoint, access or modify the inode table entries inside the file cell only in the memory. Second, we reuse the classic representation (i.e., compacting different entries in pages) on disk to guarantee entries are always stored in the pre-determined locations. We rely on the periodical checkpoint to persist entries. Note that, in this design, updates on inode table entries since the most recent checkpoint can be lost in the face of a sudden crash. We further discuss how MAX uses roll-forward recovery to reconstruct inode table entries in §4.4.

4.3 Mlog

MAX extends the multi-head logging of F2FS by splitting the larger log into minor logs (mlogs), as shown in Figure 2. Each mlog keeps the data and inode logs each with up to three

³In this paper, we use the commonly-used inode table entry and inode to refer the specific node address table (NAT) and node structure of F2FS.

temperatures as in F2FS. The number of mlogs is configurable. Ideally, the number of mlogs can be the same as the number of cores to achieve the highest concurrency. However, for small capacity drives, having too many mlogs makes it hard to accommodate large files due to limited capacity per mlog. We further evaluate and discuss how to choose the appropriate number of mlogs in §5.4.

Mlog cell. To support mlog, MAX splits the allocation-related IMDSes, forming individual mlog cells. Following the design of F2FS, MAX uses segment info table (SIT), validity bitmaps and free bitmaps for space allocation. Yet, different from F2FS, MAX splits and co-locates the table with the two kinds of bitmaps in mlog cells, as shown in Figure 2.

The SIT maintains the validity of all blocks for the corresponding mlog. The free bitmap records the free 4 KB blocks. Upon data flushing (e.g., fsync), MAX selects a mlog cell in a round-robin fashion and searches the free bitmap for free blocks. Then, MAX sends the data to the corresponding mlog.

Garbage collection. Each mlog cell performs garbage collection (GC), i.e., victim selection and block identification and migration, independently. As GC performs at the granularity of the *section* (consecutive 2 MB *segments*), MAX keeps the validity bitmaps to record both the dirty segments that need GC, and the valid blocks per segment in the section.

For each mlog cell, MAX uses existing victim selection policies [32, 52] and the slack space recycle (SSR) [37] technique of F2FS; MAX always performs GC for inode log and we explain this in §4.4 by Figure 5. Since the data/inode blocks can be spread across different mlogs, MAX identifies not only the valid block in the mlog, but also the freshness of that block among all mlogs, by comparing the address of the block (in the mlog) with the newest address of the file data/inode; MAX migrates only the valid and newest block. If a space allocation can not find enough space in all mlog cells (e.g., the used disk volume is higher than 95%), MAX turns back to the single logging as in F2FS. While, in this case, the SA level concurrency is sacrificed, MAX avoids severe fragmentation.

4.4 Consistency

Concurrency Consistency. In traditional Linux file systems, the concurrency consistency is mostly handled by the Virtual File System. The actual file system only needs to lock on the target file(s). Therefore, with VFS remains intact, MAX simply locks on the file cells of the target files to ensure correct execution order.

Crash Consistency. After a crash (e.g., power outage), MAX recovers the state by the following two steps: (1) roll back to the latest consistent checkpoint; (2) perform roll-forward recovery on all mlogs.

Here, we use an example in Figure 4 to present the roll-forward of MAX. First, for each mlog, starting from the latest checkpoint, MAX rebuilds the inode log and forms lists of inode blocks (b.1). Next, MAX merges the per-mlog inode list.

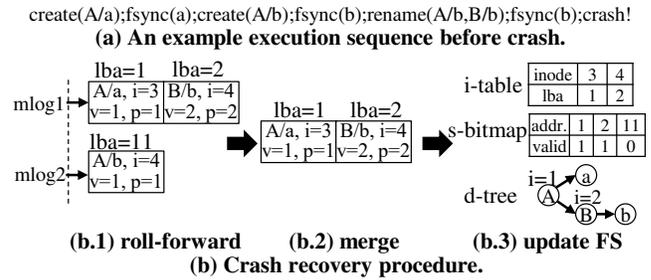

Figure 4: An example of MAX’s crash recovery. *lba*: logical block address, for recovering space bitmap (*s-bitmap*); *i*: inode number, for recovering inode table (*i-table*); *v*: global version, for merging; *p*: parent’s inode number, for reconstructing the FS directory tree (*d-tree*). Described in §4.4.

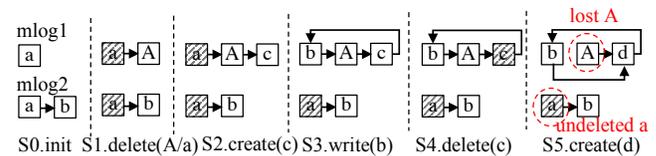

Figure 5: Performing inode GC in SSR mode.

Recall that MAX uses round-robin placement to writes. Therefore, outdated versions of an inode may still exist. For example in Figure 4(a), the file *b* is modified twice; `create(A/b)` is located in *mlog2*, and `rename(A/b, B/b)` is distributed to *mlog1*. Such different versions can bifurcate the merged inode list. To overcome this, MAX embeds a global version number (*v*) inside the inode block during each flush, and uses it to identify the latest inode block during recovery (b.2) if needed. Finally, MAX updates the inode table, the space bitmap and the directory tree with the merged inode list (b.3).

The inode list can also be affected by the GC policy. For example, using SSR, a state-of-the-art space allocation policy, can lead to an inode loop, causing consistency issues. Specifically, in Figure 5, the user deletes file *a* in directory *A*. Now, the inode of *a* is invalidated, and its parent inode *A* is updated (S1). Later when there are no more clean segments, MAX switches to SSR mode and directly reuses the obsolete blocks (e.g., *b* of S3). In this case, an inode loop is formed, and a further inode update may bifurcate original inode list, resulting in updates loss (S5). In S5, the latest *A* is lost, and the deletion of *a* is lost as well. During next roll forward, the invalid *a* in *mlog2* would be considered valid. Therefore, in SSR mode, MAX still uses common GC for the inode log.

4.5 Other Important Implementations

This subsection describes how MAX’s approach retains other aspects of the design of F2FS while improving concurrency.

Extent cache. F2FS uses bitmaps to record the addresses of the data blocks for a file. A bitmap-based approach is efficient for lookups of a specific point in a file but unfriendly when scanning continuous ranges of addresses. Thus, F2FS uses

per-inode extent cache to speed up address lookup (esp. range lookup). However, the per-inode extent cache is indexed by a global radix tree (`extent_tree_root`) protected by a mutex (`extent_tree_lock`), similar to the single inode radix tree. MAX splits the extent cache to each file cell for concurrent extent cache access.

Inode table journal. As we mentioned in §4.2, the inode table entry of F2FS is extremely compact (9 B). Directly updating the inode table entry to its original location is likely to incur many small I/Os, which is not friendly to performance and lifetime of flash storage. Therefore, F2FS employs an inode table journal in the spare space of the Meta region. To quickly find the dirty inode table entries that need to be journaled, F2FS uses a global linked list guarded by a spinlock (`nat_list_lock`). This introduces significant contention on the shared list when the number of threads is large. MAX only links the inode table entries for each file cell group to alleviate the contention on the list. During checkpoint, MAX scans the per-group linked list to generate the inode table journal.

Resource counters. Similar to many FSes, F2FS uses delayed allocation techniques to postpone resource allocation until the data blocks are finally sent to the persistent storage. F2FS uses many resource counters (e.g., `total_valid_block_count`) to pre-reserve FS resources for incoming I/Os. These counters are shared globally under the protection of a spinlock (`stat_lock`), and become scalability bottlenecks in the multicore environment. Actually, the FS only requires the approximate value of these counters, i.e., only needs to determine whether the incoming request fits in the FS. Hence, MAX replaces these counters with scalable approximate counters (`percpu_counter` [33]).

These modifications made by MAX do not change the write ordering, the consistent metadata format or crash recovery logic, and thus do not impact consistency.

5 Evaluation

We first evaluate MAX against state-of-the-art Linux file systems on file operations (§5.1) and applications (§5.2). Then, we perform experiments of MAX under high volume utilization (§5.3). Next, we study the performance contributions of individual design aspects of MAX (§5.4). Finally, we examine the memory consumption by running MAX (§5.5).

Testbed. The testbed is equipped with 4 Intel Xeon Gold 6140 CPU processors; each CPU has 18 physical cores (totally 72 cores) running at 2.30 GHz. The platform has 250 GB DRAM, but only 10% DRAM (i.e., 25 GB, the Linux default configuration) is used for page cache. The experiments in this section are performed on a flash-based Intel DC P3700 SSD, whose performance is presented in Table 3.

File systems setups. We compare MAX with four Linux file systems (ext4 [44], SpanFS [29], XFS [18] and F2FS [37]) in Linux kernel version 4.19.11. Ext4 and XFS are popular journaling FSes used by many Linux distributions and storage

Type	Model	Seq. Bandwidth	Rand. IOPS
NVMe	Intel DC P3700 2TB	Read: 2800 MB/s	Read: 450K
		Write: 1900 MB/s	Write: 175K

Table 3: SSD Specifications.

backends. SpanFS is a recent scalable journaling FS built on Ext4. We set the number of the parallel journals of SpanFS to 72, the same as the number of physical cores. All tested FSes are mounted with default options. The numbers of file cell radix trees and mlog cells are set to 36 and 8 respectively. For upper bound comparison, we use an alternative MAX-mem by disabling the `fsync` and page cache writeback functions of MAX to avoid duplicated copy.

Workloads. FxMark [48] is used to test multicore scalability. FxMark concurrently and repeatedly executes individual file operations or application processes. All tests last for at least 30 seconds and issue over 50 GB data.

5.1 Microbenchmark

5.1.1 File Operations Evaluation

Overwrite. Figure 6a shows the results of DWOL workload of FxMark. MAX achieves nearly 56× speedup at 72 cores for overwrite operations. MAX outperforms F2FS and SpanFS (the second-best) by 35× and 2× at 72-cores respectively. The key contributing factor to MAX’s overwriting performance is the RPS. Overwrite operations are performed in parallel by updating individual data pages and hence do not frequently trigger page cache flushes. Thus, the major overhead occurs at the CC level. While F2FS is bounded by the CC level reader cache coherence, MAX achieves high concurrency with per-core counters in the RPS. SpanFS and XFS use multiple in-memory journal buffers, and thus serve concurrent overwrites in parallel. Nonetheless, the journaling process adds extra overhead compared to MAX.

Append write. Figure 6b reports the results of DWAL workload of FxMark. We find that MAX delivers the best performance, and achieves almost 2× the throughput of F2FS. The major contributing techniques here are the file cell and the mlog. As append writes quickly fill the page cache and trigger flushes, the I/O becomes the major bottleneck. Specifically, append writes require new data pages and new inode pages, resulting in insertions into the indexing trees. Such operations of the traditional FS incur frequent serialization at IMDS level. MAX reorganizes the IMDS with file cells and uses multiple indexing trees. Hence, the chance of serialization becomes significantly lower. Moreover, at SA level, MAX allocates space from individual mlog cells, and flushes new blocks to individual mlogs. In F2FS, the NVMe SSD is however underutilized due to the single sequential log allocation and access.

File creation. Figure 7a presents the results of MWCL workload of FxMark. We observe that, on file creation operations at 72 cores, MAX achieves 2.8× higher performance than SpanFS (the second-best) and 18.6× higher than F2FS. File creations

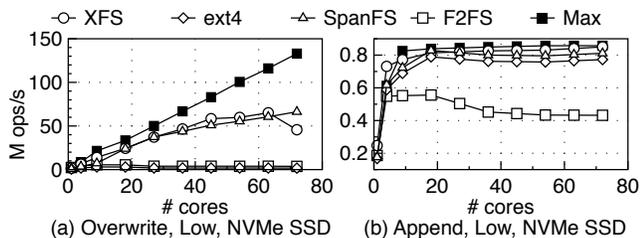

Figure 6: **Data scalability with FxMark.** ((a): overwriting blocks of private files, (b): appending blocks to private files.)

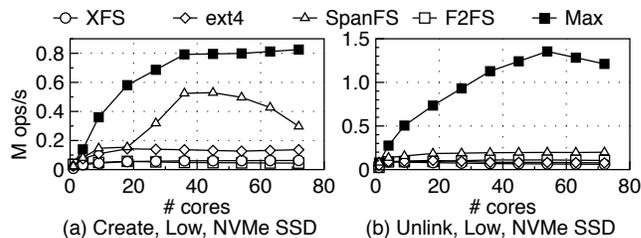

Figure 7: **Metadata scalability with FxMark.** ((a)-(b): creating or deleting empty files in private directories.)

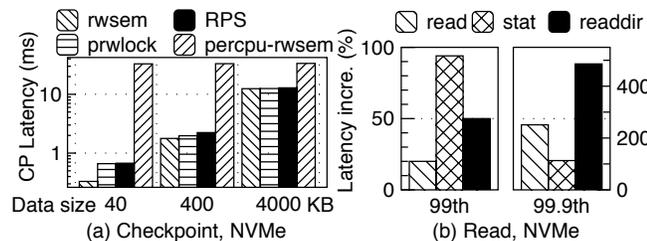

Figure 8: **Checkpoint and read latency with different lock techniques.** (a): Checkpoint latency with different data size and locks. (b): Read long tail caused by IPIs.

mainly consist of three steps: allocating file inode, growing directory data/inode blocks and writing back data/inode page. MAX scales well in all steps. First, file inode allocation in MAX includes the file cell allocation and insertion. MAX employs a per-core inode ID allocator and multiple file cells radix trees, thereby avoiding contention on the inode and file cell allocations; multiple radix trees also lower the chance of serialization at insertion operations to the indexing. Second, directory data and inode block grow concurrently in all tested file systems without hurting the concurrency. Third, when dirty pages are evicted from the page cache, mlog cells of MAX enable the threads to allocate space concurrently, and to distribute the dirty inode blocks to individual mlogs.

File deletion. Figure 7b shows results of MWUL workload of FxMark. MAX achieves $11.5\times$ and $6.1\times$ performance at 72-cores against F2FS and SpanFS (the second-best) respectively. The reasons for MAX's good scalability on file deletion are similar to that of file creation. In MAX, directory entries and inode pages are truncated independently in file cells. Also, mlog cells reclaim disk space in parallel. We observe that MAX's throughput declines since 54 cores. Further analysis suggests that the root cause is the page cache lock contention (i.e., `i_wb_list`) from VFS.

Checkpoint. We replace traditional `rwsem` in F2FS with several alternatives, and then collect the latencies when checkpointing variable-sized data. Figure 8a shows the results; we observe that `prwlock` [42] and RPS hardly affect the checkpoint latency. However, Linux `percpu rwsem` slows the checkpoint significantly, as its exclusive-mode lock requires RCU-based quiescence detection, where all cores have done a context switch and executed a full memory barrier.

File read. We co-run multiple foreground tasks, i.e., reading

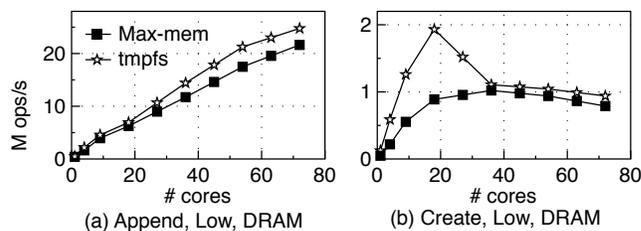

Figure 9: **Upper bound evaluation with FxMark.** ((a): appending blocks to private files, (b) creating empty files in private directories.)

files (read), listing file attributes (`stat`), reading directories (`readdir`), which are conflict-free and pinned to cores, with a background task which triggers checkpoint periodically. We then re-run the above scenario without the background task and compare the results. We find that the foreground tasks are almost unaffected by `percpu rwsem` or RPS. However, we observe that the foreground tasks are susceptible to the inter-processor interrupts (IPIs) of `prwlock`. Figure 8(b) shows a performance decline: the 99.9th latency increases by up to 486%. The reason behind the long tail is that these read-dominant tasks mostly complete in a short time by hitting cache or accessing memory, which are easily affected by the forced context switch caused by IPIs.

Comparison with SpanFS. Through the aforementioned tests, we note that SpanFS scales well on single-file operations (i.e., overwrite, append write), but yields suboptimal performance on multiple-files operations (i.e., create, unlink). This is because of the global consistency maintenance across multiple journaling services. For instance, the newly created files can be distributed to a different journaling service from its parent, and the connection between the new file and its parent's directory entry (`dentry`) must be established which is quite expensive. MAX, due to the out-of-place update nature of LFS, can directly dispatch the newly created file along with the `dentry` to an arbitrary free mlog.

5.1.2 Max-mem Performance Evaluation

We use MAX-mem to measure the performance improvement led by a sufficiently large bandwidth (i.e., using memory as backend). For comparison, we adopt `tmpfs`, a simple wrapper of VFS, as the theoretical upper bound [48]. Figure 9a reports

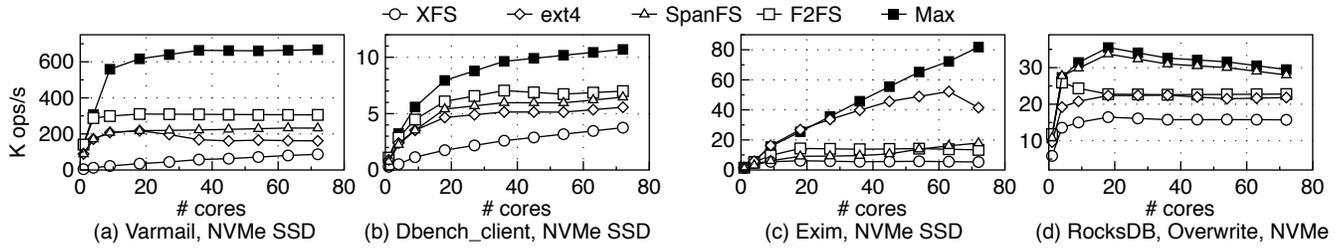

Figure 10: **Macrobenchmark.** The workloads are write-intensive and stress underlying device. Described in §5.2.

Workload	Average file size	# of files	Directory width	I/O size	R/W ratio
Fileserver	128 KB	10K	20	1 MB	1:2
Varmail	16 KB	1K	1M	1 MB	1:1
Dbench	client.txt, default configuration				
Exim	split spool directory, smtp_accept_max = 500				
RocksDB	overwrite, value_size=8k, disable compression				

Table 4: **Application workload characteristics.**

the results of append write operations. The throughput of both Max and tmpfs scale linearly. The little gap is caused by the overhead of supporting block storage and pre-checking the availability of FS resources (e.g., the number of data blocks).

Figure 9b indicates that the throughput of file creations of Max-mem comes close to tmpfs. Max-mem does not continue to scale mainly due to the VFS-wide spinlock `s_inode_list_lock` that serializes new inode insertions into the `s_inodes` list. We also notice the huge gap between MAX-mem and tmpfs at 18-core. Tmpfs only stores in-memory states. While in MAX, the dentry and inode also contain information for on-disk states, such as the dentry hash table and data block indexes. This introduces significant costs for create operation. However, when the VFS-wide spinlock kicks in, the gap becomes much smaller.

5.2 Macrobenchmark

We use Filebench [46], Dbench-client [7], RocksDB [22] and Exim [1] from FxMark to evaluate Max’s scalability under applications workloads. Table 4 summarizes the characteristics of these workloads. The main rationale for choosing these four workloads is that they are both write- and I/O-intensive and can thus stress the multicore scalability.

Varmail. Varmail contains frequent metadata operations and `fsync`. Figure 10a shows the results of Varmail. Max outperforms SpanFS by 2.9× and F2FS by 1.1×. For independent file operations, MAX updates the in-memory file cells concurrently with 36 indexing groups. When `fsync` is invoked, Max chooses a free mlog cell and persists the inode pages and data pages of the file cells. In contrast, F2FS uses only three shared radix trees and need to serialize concurrent threads for space allocation. Notably, SpanFS performs even worse than F2FS due to its inefficiency in handling the file creation and deletion followed by a `fsync`.

Dbench-client. Figure 10b shows the results of Dbench. Max

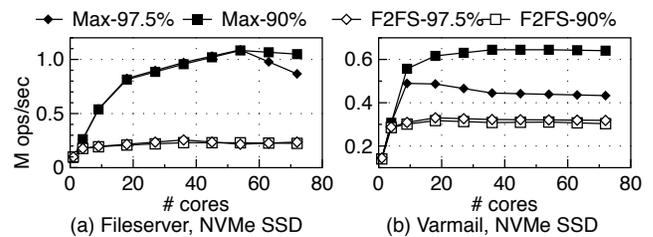

Figure 11: **Performance under high disk volume utilization.** The number next to the file system is volume utilization.

performs best among all tested file system. F2FS stops to scale at 36 cores while MAX continues to. This is because the Dbench-client performs a sequence of read, write, create, unlink, stat, rename and sync operations. For non-durable operations, such as write, create and unlink, MAX delivers higher concurrency by executing operations inside each cell.

Exim. Exim focuses on small files creation and deletion. Here, we use the scalability-friendly version of Exim from the FxMark, where create and delete are performed almost in private directories. However, Figure 10c shows that only MAX scale well in this modified version, outperforming F2FS by 6×. The reason for MAX’s good scalability is the same as file creation and deletion in §5.1.1.

RocksDB. RocksDB introduces multi-threaded flush and compaction to boost performance. We use `db_bench`, which runs four client threads to put keys in a single RocksDB instance atop a native FS. Then, we increase flush and compaction threads up to 72 threads. Figure 10d shows the result. MAX outperforms its peers. Note that the throughput of MAX starts to decline after 18 cores. We assume this can be caused by the following three reasons. First, RocksDB frequently invokes durability functions and hence occupies a large fraction of the device bandwidth, lowering throughput of user requests. Second, scaling over 18 cores (maximum cores of a single CPU) incurs Non-Uniform Memory Access and PCI bus routing. This throttles IOPS due to the inefficiency of remote access. Third, RocksDB manages all its files including metadata files and SSTable files under the same directory, causing a medium level contention on the shared directory.

5.3 High Volume Utilization Evaluation

We evaluate the performance under high file system volume utilization and high GC overhead in this subsection. We for-

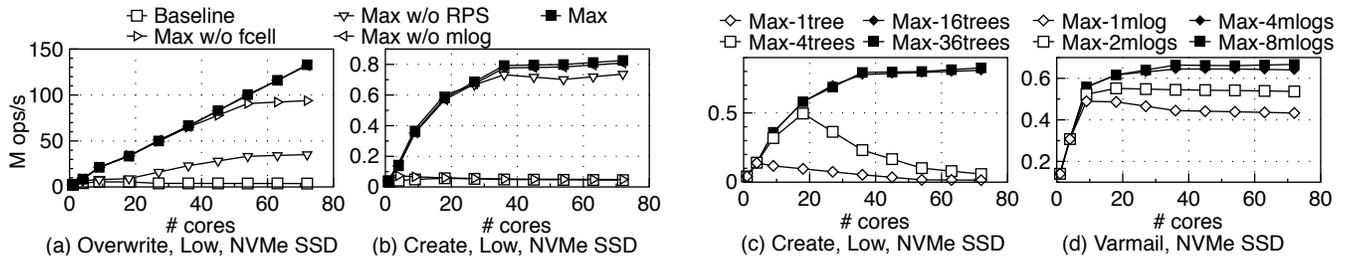

Figure 12: **Performance contributions.** Described in Section 5.4.

mat the 2 TB NVMe SSD and create a 200 GB partition for the test. This ensures that the device GC rarely occurs during the test. After filling up the tested file systems with two utilization ratios (90%, 97.5%), we issue another 200 GB of random overwrites to make the file system further fragmented.

Figure 11 plots the results of Fileserver and Varmail workload with FxMark. At 90%, MAX outperforms F2FS by 4.4× and 2.1×, in Fileserver and Varmail, respectively. In this case, both MAX and F2FS switch to the SSR mode. In SSR mode, besides concurrent access to file cells, MAX still offers concurrent space allocation. However, in this case, the inode updates need cleaning. The serialized checkpoint after each cleaning limits the further performance increase of MAX.

The 97.5%-utilization MAX, at 72-cores, outperforms F2FS by 3.5× and 36% in Fileserver and Varmail, respectively. We observe that the throughput of MAX starts to decline after 18 cores in Varmail. This is because MAX regresses to single logging under high volume utilization ratio. In this scenario, as RPS and file cell continue to contribute, MAX survives greater performance drop due to the single log access.

5.4 Understanding the Performance

We individually analyze the contribution of *file cell*, *mlog* and *RPS* to the performance of MAX. We setup MAX with different configurations (the left half of Figure 12): (1) F2FS (baseline), (2) MAX without file cell (Max w/o fcell), (3) MAX without mlog (Max w/o mlog), (4) MAX without RPS (Max w/o RPS), (e) full-fledged MAX (MAX). The tests are the same as that in §5.1.1 and §5.2, i.e., DWOL, MWCL and Varmail.

Figure 12a-d show that, compared to the baseline, all three techniques improve the performance. Specifically, RPS has a greater boost on overwrite operations, as heavy cache coherence takes up to several milliseconds but in-memory updates only cost hundreds of nanoseconds. The file cell is more effective for complex create operations as modifying IMDS is (e.g., inode initialization and hash calculation) expensive. Mlog cell does not exhibit significant impact on Figure 12a-b because these tests are not I/O intensive.

We also study the sensitivity of MAX to the number of IMDS radix trees and the number of mlogs. Figure 12c-d plot the results of varying the number of trees and mlogs. We choose create operation for trees as it frequently modifies the indexing structure, and Varmail for mlogs due to its heavy

fsync. We observe that MAX does not gain improvement after more than 36 trees. The major reason is that the bottleneck, after 36 trees, has shifted from file system to the VFS. For write intensive workload, 8 mlogs have almost saturated the throughput. This is because MAX, following the design of F2FS, performs checkpoint to shrink cached entries (e.g., inode table, inode). In current single-threaded checkpoint design that blocks all write operations, assigning each CPU two logs in our platform is enough currently.

5.5 Memory Consumption

We examine the extra memory consumption introduced by deploying MAX. We measure the peak memory usage for each workload when running 72 processes. Table 5 reports the result. The memory usage is categorized into two sets: (1) static: memory used by the data structures of each file system, and (2) cache: memory used by page cache. We find that MAX does not introduce much memory overhead for static memory use. At CC level of MAX, the single RPS keeps two per-core counters. At IMDS level, MAX has to maintain 36 file cell radix trees. At SA level, the segment info table and all bitmaps are physically partitioned and distributed to mlog cells, which requires no extra memory. Hence, we assume that the extra static memory usage from three levels is acceptable.

For page cache, MAX consumes more memory than F2FS at peak. This is because with file cell, the dirty pages aggregate faster to the page cache (i.e., increase memory consumption). Meanwhile, the mlog cells can also write back dirty pages faster (i.e., decrease memory consumption). As a result, extra page cache memory consumption is tolerable.

Workload	Static (MB)			Cache (MB)		
	F2FS	MAX	Incr.	F2FS	MAX	Incr.
Varmail	24.90	24.97	0.3%	1411	1484	5.2%
Dbench	24.90	24.97	0.3%	310	345	11.3%
RocksDB	24.90	24.97	0.3%	15	18	20%

Table 5: **Peak memory consumption during workload execution.** Static: data structures, cache: page cache.

6 Related Work

File system scalability study. Multiple studies have discussed the scalability issues in the FSES [14, 15, 17, 48]. Fx-

Mark [48] argues that file system scalability does not depend much on the storage media (i.e., Figure 1 of [48]) which is different from our observation in §2. The root cause is that, in FxMark, file operations are performed in memory with no `fsync`. Yet, when cache has little effect on absorbing I/O traffic, file system scalability *does* depend on the storage media. Such scenarios include: (1) file operations in Direct I/O mode (e.g., QEMU none cache mode [3]); (2) applications contain frequent `fsync` or `fdatasync` calls (e.g., SQLite [5]); (3) frequent cache eviction (e.g., high memory pressure).

File system scalability improvement. Another group of prior work focus on improving the file system scalability. Commuter [17] and ScaleFS [11] employ scalable software design by connecting scalability to interface commutativity. Both Commuter and ScaleFS target on a more scalable kernel (i.e., `sv6`) with relaxed POSIX semantics. MAX studies the multicore scalability on mature, widely-used Linux and POSIX interface. Park *et al.* [50] and Son *et al.* [56] improve the scalability of journaling. MAX focuses on LFS instead.

File system partition. SpanFS [29] and IceFS [43] partition the journaling FS. SpanFS distributes files and directories under each *domain* for scalability. IceFS partitions the file system into directory subtrees called *cubes* for failure isolation. Unfortunately, IceFS and SpanFS can incur significant overhead from maintaining the global hierarchical namespace (e.g., sharing a single physical journal in IceFS and coordination across journals in SpanFS). MAX partitions the file system at the granularity of file operations, where the file operations to `mlogs` are totally independent of each other.

Scalable NVMM FS. Some non-volatile main memory (NVMM) file systems [36,57] employ per-core or per-process data structures, which seem to be the direct solutions to SSD-based FS. The major difference of the scaling SSD-based and NVMM-based FS lies in the access granularity. NVMM FS can partition the FS at a finer granularity (e.g., 8 bytes); for example, NOVA [57] atomically updates the 8 B inode pointer to ensure the persistence and consistency of a file write operation. Such fine-grained partitioning is unfriendly to SSD FS with block access granularity (e.g., 4 KB). If MAX directly isolates the inode pointer (i.e., inode table entry) for each file and directly persists each pointer to SSD, MAX would suffer from huge write amplification and extra PCIe round trips. Hence, MAX introduces the file cell to repack the data structures to align the block granularity as well as to scale the file-level performance.

For concurrent space allocation, NVMM FS can partition the drive space with finer granularity, e.g., per-file log. Such fine-grained partitioning is unnecessary, or even inefficient for SSD FS. Fine-grained partition trades scalability for fragmentation. In MAX, we take a sensitivity study to find the appropriate number of logs in §5.4. Further, NVMM FS such as NOVA uses a journal to maintain consistency over multiple log partitions. MAX takes a different and more SSD-friendly approach: distributing the atomic operation to a coarse-grained log par-

tion without spanning. To maintain the consistency over multiple log partitions, MAX embeds a global version number in each inode block instead of using a journal.

Scalable lock designs. Myriad work [16, 19, 21, 30, 31, 34, 39, 41, 42, 45, 47] devise scalable locks. One category [19–21, 30, 31, 39] employ distributed reader indicators (e.g., per-NUMA node reader indicators) or similar designs to reduce the cache coherence traffic across NUMA nodes or CPU cores in the common case, which is similar to RPS. RPS uses per-core reader indicators for optimal reader-reader scalability, and uses a different “scheduler free rides” mechanism to soften the impact on the exclusive-mode lock. This mechanism aims to leverage the CPU scheduler to increase the responsiveness of the lock writers while reducing the impact (e.g., forced context switch) on other CPU cores, which we found very effective for the LFS concurrency control. RCU [47] and its extensions [34, 45] allow readers just for read-only traversals. Hence, they can not be directly used in the LFS concurrency control, as readers need to perform updates. RPS maintains the number of readers in per-core reader counters, the same as in [16, 41, 42]. RPS differs from them in the writer procedure. Before updating protected data structures, the writer of Linux `percpu rwsem` [41] must wait a significantly long grace period [42]. The writer of `prwlock` [42] actively broadcasts IPIs to check reader status, which causes unnecessary context switches of the on-going readers. RPS leverages the CPU scheduler to retrieve reader status; the last reader of RPS voluntarily yields cores to the CPU scheduler, which enables the writer to check readers efficiently without affecting readers.

7 Conclusion

The bandwidth of SSDs has been surging over the last decade. However, through a performance study, we notice that modern Linux file systems do not offer enough multicore scalability and hence can not fully exploit the abundant bandwidth of high performance drives. We propose MAX, a multicore file system to effectively alleviate the lock contention of the file system. MAX introduces reader pass-through semaphore for efficient concurrency control, file cell for scalable in-memory data structures and `mlog` for concurrent space allocation. Through evaluation, we show that MAX outperforms modern Linux file systems with the scaling of cores. The source code of MAX is available at github.com/thustorage/max.

Abstract

File system journaling critically limits the scalability of a file system because all simultaneous write operations coming from multiple cores must be serialized to be written to the journal area. Although a few scalable journaling approaches have been proposed, they required the radical redesign of file systems, or tackled only a part of the scalability bottlenecks. Per-core journaling, in which a core has its own journal stack, can clearly provide scalability. However, it requires a journal coherence mechanism because two or more cores can write to a shared file system block, so write order on the shared block must be preserved across multiple journals. In this paper, we propose a novel scalable per-core journal design. The proposed design allows a core to commit independently to other cores. The journal transactions involved in shared blocks are linked together through order-preserving transaction chaining to form a transaction order graph. The ordering constraints later will be imposed during the checkpoint process. Because the proposed design is self-contained in the journal layer and does not rely on the file system, its implementation, Z-Journal, can easily replace JBD2, the generic journal layer. Our evaluation with FxMark, SysBench and Filebench running on the ext4 file system in an 80-core server showed that it outperformed the current JBD2 by up to approx. 4000 %.

1 Introduction

The number of concurrent cores accessing a file system is ever increasing as the number of cores installed in a system increases. However, existing file systems show poor scalability for a few file system operations [16]. Especially, because write requests coming from all cores must be serialized to be written on the single journal, the journal layer acts as a representative scalability bottleneck [8, 16, 17, 19, 20].

The serialization occurs at two points in journaling; writes to the in-memory journal data structures, and to the on-disk journal area. The in-memory data structure accesses are parallelizable to some degree by applying lockless parallel data

structures [19]. However, the parallelized memory operations, in the end, should be serialized for the on-disk journal writes. The serialization at the on-disk journal works as the more serious inhibitor for the file system scalability because the storage performance is still significantly slower than the main memory. In addition, the serialized journal writes hinder the performance gain earned from the ever-increasing internal-parallelism of modern SSDs [4].

A few research results have been proposed to achieve scalability in journaling. However, they require an explicit separation of the file system space [8], byte-addressible non-volatile memory (NVM) as the journaling device [20], or tight coupling of file system and journal layer [2]. Therefore, in order to apply them to existing systems, application modification, adoption of NVM, or radical changes to the file system design are necessary, respectively.

Not only performance but also stability and reliability are important criteria for choosing a file system. The file systems being used in production systems have obtained their reliability and performance through decades of improvement and refinement. Consequently, it is a difficult choice to migrate to a radically redesigned file system. This leads to the large demand for the scalable generic journal layer that can replace the existing ones, such as Journaling Block Device 2 (JBD2) [22].

The most intuitive approach to realize a scalable journal is having independent journal space and journal stack per-core. If the thread running on a core can write to the journal dedicated to the core independently to the other threads, the file system can achieve the complete performance scalability to the point of the maximum disk performance.

However, when two or more threads simultaneously perform write operations to the same file system block, inconsistency between write order to the in-memory buffers and that to the on-storage journals may occur. For example, as shown in Figure 1, let us suppose that core 0¹ modifies block 0 and block 1. In turn, core 1 updates block 0 and block 2.

¹For brevity, we will use *core* to denote the thread running on the core unless otherwise stated.

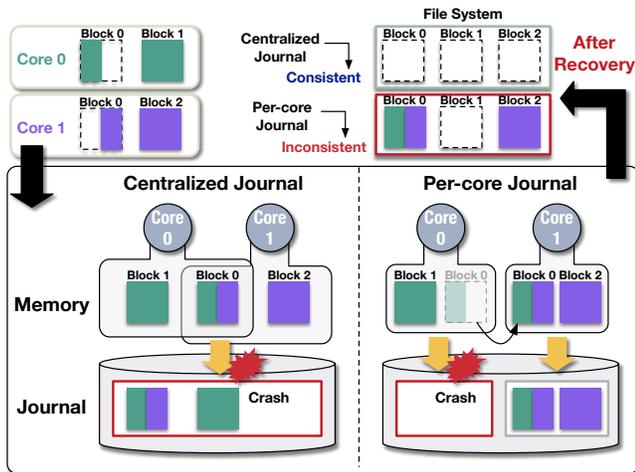

Figure 1: Inconsistency between write order to in-memory data and that to on-storage journal caused by per-core journaling without a coherence mechanism.

In this case, the journal commit issued by core 1 may finish earlier than that by core 0 when they independently operate. If a system crash occurs when core 1 committed, but core 0 did not, block 0 will be restored to a state that includes the modifications from both core 0 and core 1 during the recovery procedure. Because core 0 has not committed its modifications, the valid shape of block 0 after recovery must exclude the modifications by core 0, or have no modifications at all. This kind of inconsistency cannot happen in the conventional centralized journal.

Commonly, cores share metadata or files. Two cores have to share the metadata blocks even when they do not share any files if their files happen to be stored in the same block group [1], which is false sharing in this case. Regardless of whether being false or true, sharing blocks among cores is inevitable when the multiple cores access the same file system. Therefore, a scalable per-core journaling scheme must have a journal coherence mechanism that keeps the write order for the shared block modification.

This paper proposes *Z-Journal*, a scalable per-core journal scheme. *Z-Journal* includes a novel coherence mechanism. *Z-Journal*'s coherence mechanism allows each core to commit transactions to its journal area independently to other cores. However, when shared-block writes exist in the journal transactions, *Z-Journal* forms write-order graphs among transactions sharing blocks through *order-preserving dependent transaction chaining* and commits them with the transactions. Imposing order-constraints over transactions will be performed when checkpointing the committed transactions. Through this journal coherence mechanism, *Z-Journal* enables scalable per-core journaling while keeping crash consistency.

Z-Journal is designed to provide an identical interface to

JBD2. Therefore, it can be easily applied to the existing file systems that use JBD2, such as ext4 and OCFS2 [6], as their journal mechanism. However, to maximize the effectiveness of per-core journaling, it is desirable to eliminate false sharing among files coincidentally placed in the same block group. For this, we additionally propose a core-aware block-group allocation algorithm for the ext4 file system.

We implemented *Z-Journal* in the Linux kernel and applied it to the ext4 file system as its journal layer. For evaluation, we measured the performance and scalability of the *Z-Journal* and ext4 combination while executing *FxMark* [16], *Sys-Bench* [12] and *Filebench* [21, 23] in an 80-core server.

The remainder of this paper is organized as follows. Section 2 introduces the background and motivation of this research. Section 3 proposes the design and implementation of *Z-Journal*, and Section 4 evaluates the proposed scheme using various benchmark workloads. After the related work is introduced in Section 5, Section 6 concludes our research.

2 Background and Motivation

2.1 Design of JBD2

A file system operation usually relates to the modification of multiple file system blocks. The conventional storage devices are unable to guarantee atomic writes of multiple blocks. When a sudden crash occurs during a file system operation, only a part of the modifications may be reflected on the storage, and the file system metadata and actual data may eventually mismatch each other. The partial update of the metadata or the mismatch between metadata and data can destroy the validity of the file system.

The journaling mechanism is a measure to ensure consistency by logging the file system changes caused by an operation in the predetermined location. After the file system commits the series of changes caused by a file system operation, the journal reflects the logged changes to the file system through the checkpoint operation. Once a file system operation is committed to the journal, the journal guarantees that the changes are reflected in the file system because it can replay the committed changes even after a system failure.

JBD2 is a generic journaling layer used in the Linux kernel. JBD2 groups a series of file system changes during an interval together into a unit called a transaction. A transaction is committed to the journal area, periodically, or on the conditions explained later. When a transaction is successfully committed to the journal, JBD2 leaves the commit block at the end of the journal record. When JBD2 performs recovery after crash or failure, it checkpoints the transactions having a commit block and discards the transactions without a commit block.

A transaction undergoes a few phases during its life cycle from its creation to checkpoint. Figure 2 shows the organization of transactions in different phases. A transaction is in one of the four states: ① *running*, ② *locked*, ③ *committing*,

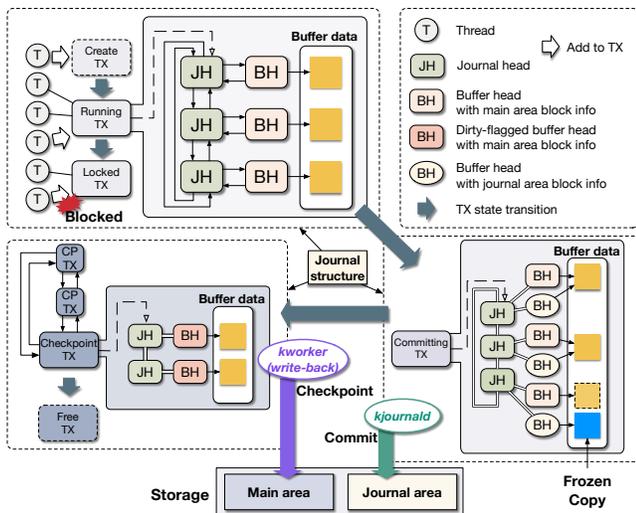

Figure 2: Organization and life cycle of a transaction in JBD2.

and ④ *checkpoint*, respectively. (The intermediate states are omitted here for brevity.) The journal structure is the central data structure of JBD2, and has three pointers pointing to the running transaction, committing transaction and checkpoint transaction list, respectively. There can be up to a single running transaction and up to a single committing transaction at a time point. The checkpoint transaction list pointer points to the head node of the doubly linked list of transactions to be checkpointed. Its head node is the oldest transaction in the list.

The buffered image of a file system block in the main memory is called a *buffer*. A buffer in the main memory is unique for a file system block. Therefore, all cores share and access the same buffer when accessing the same file system block. A buffer has its buffer head. The buffer head contains the information about the buffer and its corresponding file system block, such as the block device, logical block number, data size, etc. A buffer head is inserted in a transaction through a journal head data structure. A journal head is allocated for and bidirectionally connected to a buffer head. In a transaction, the journal heads of modified buffers are chained in a doubly-linked circular list, as shown in the upper left side of Figure 2. The oldest journal head in a transaction becomes its list head. Modifications of buffers grouped in a transaction are considered an atomic operation.

Since JBD2 only allows a single transaction to run at a time, it is trivial to order the writeback of the updated buffers. It simply writes them back they were inserted into the list of committed transactions. Later, we will explain how Z-Journal relaxes these requirements and allows multiple transactions to run concurrently.

The running transaction accommodates the modified buffers produced by file system operations. If there is no

running transaction when an operation is issued, a new transaction is created and becomes the running transaction. When a core writes to a buffer, its buffer head will attach to a new journal head, and the journal head will be inserted into the journal space of the running transaction. At this moment, the journal space must be reserved for the inserted buffers so that later the running transaction can be committed without space allocation. If the journal space is insufficient, the user-level thread performs checkpoint to free up the journal space.

Later, *kjournald*, which is a kernel thread in charge of the commit operation, starts to commit the running transaction upon one of these three conditions: (1) the transaction timeout occurs, which is by default 5 seconds; (2) the transaction capacity, which is by default a quarter of the journal area, is exhausted; or (3) the *fsync* system call is invoked by a process. Once the commit operation begins *kjournald* turns the running transaction to the locked transaction.

When the transaction enters the locked state, it cannot accommodate any more updated buffers, except the ones from the file system operation accepted to join the transaction but did not finish yet. When the last modified buffer is inserted into the locked transaction, its state is changed to the committing state. A new running transaction cannot be created while the locked transaction is waiting for its closure. Therefore, a thread issuing a new file system operation should be blocked until a new running transaction becomes available after the locked transaction becomes the committing transaction.

As shown in the bottom right corner of Figure 2, *kjournald* creates another buffer head for each buffer. This buffer head contains the information of the journal block to which the corresponding buffer will be committed. After this, *kjournald* writes the buffers of the committing transaction to their assigned journal blocks.

Usually, the original buffers remain attached to the buffer heads in the committing state. However, when a thread tries to modify the buffer included in the committing transaction before *kjournald* begins writing to the journal, the thread makes a replica of the buffer called a *frozen copy*, and replaces the original buffer with the frozen copy. The original buffer can then be freed from the committing process, and the thread can modify the buffer.

When the commit is finished, the buffer heads will be marked as dirty to denote that their buffers are required to be written to their originated file system blocks during checkpointing. After this, *kjournald* finally converts the committing transaction to a checkpoint transaction and insert it at the end of the checkpoint transaction list.

The checkpoint operation is handled by the write-back kernel thread, *kworker*, every 5 seconds, or by a user-level thread performing file operations when it finds out that there is not enough space left in the journal area for the write operation. *kworker* moves the dirty buffers of the transactions that have stayed in the checkpoint list for longer than 30 seconds to

their originated file system blocks and mark them as clean.

Because a journal head uses a separate pointer to be connected to a checkpoint transaction, a buffer can belong to a running transaction and a checkpoint transaction at the same time. When a thread tries to modify a buffer already in a checkpoint transaction, it will be inserted to the running transaction, and at the same time, its dirty flag will be cleared so that it will not be checkpointed. In this situation, the running transaction is allowed to modify the buffer.

kjournald later frees the clean buffers from the checkpoint transaction. It also frees the empty checkpoint transactions from the checkpoint list and the corresponding commit transactions from the journal area to make free space.

In case of a system crash, kjournald initiates the recovery process. It searches for the committed transactions in the journal area, and replays them in order. This guarantees that the file system remains consistent and committed data are preserved in the file system.

2.2 Scalability Bottlenecks in JBD2

The current JBD2 design has multiple scalability bottleneck points as follows.

At a given time point, there is only a single running transaction, which is the only transaction that can accept the modified buffers. Therefore, when multiple cores perform file operations in parallel, they have to compete for the lock acquisition for the running transaction [19].

Secondly, when the running transaction is closed, a new running transaction can be created only after the current committing transaction finishes, and the closed transaction becomes the committing transaction. Therefore, when the locked transaction waits for the committing transaction to finish, all cores that issue file operations must wait altogether. The larger the number of waiting cores, the more this convoy effect adversely impacts the overall file system throughput.

Last but not least, the current JBD2 does not fully utilize the internal-parallelism provided by the modern NVMe SSDs because the kjournald thread solely issues a serialized stream of buffer writes to the storage. To utilize the high-performance of modern storage devices, the journal mechanism should be able to commit in parallel.

These problems commonly stem from that there is only a single running transaction and a single committing transaction in the system. However, blindly parallelizing the running and committing transactions or entire journal stack for achieving scalability complicates keeping the write orders of the shared blocks as stated in Section 1 because a buffer head can belong to only a single transaction in the current design. If a buffer head is allowed to simultaneously exist in multiple transactions, the coherence mechanism to guarantee the write order consistency across multiple transactions to the shared buffers is necessary. This problem was referred to as a *multi-transaction page conflict* by Won et al. [24].

An approach that makes a frozen copy of a buffer whenever the file system modifies it and inserts the copy to the journal transaction instead may allow simultaneous writes to the same buffer coming from multiple threads. However, it still requires the ordering of block copies when committing a transaction so that the preceding block modifications are guaranteed to be committed before. This will be another serialization point. In addition, adding buffer copy operations to the file system write path will notably retard the write latency. Therefore, journaling with a parallel transaction requires an efficient coherence mechanism that can preserve the write orders to the buffers, while allowing as much parallel buffer modification and independent transaction management as possible.

3 Our Approach: Z-Journal

In Z-Journal, each core has its journal area on the storage device, and its kjournald, which handles the commit operation. Because kjournald is bound to each core and executed locally, this also improves the memory access locality in non-uniform memory access (NUMA) systems. The journal stack of each core has the running transaction, committing transaction, and the checkpoint transaction list the same as JBD2, and their life-cycles are identical as well.

This per-core journal approach removes the aforementioned serialization points in the journal layer and thus obtains scalability. First, because each core has its running transaction, a thread does not need to compete with the other threads for acquiring access to the running transaction. Second, when the running transaction of a core closes, and the core waits for the previous committing transaction to finish to create a new running transaction, this waiting only applies to that core. Therefore, this convoy effect is confined in the core boundary. Finally, because multiple kjournald are able to commit in parallel, Z-Journal can fully utilize modern high-performance storage devices.

However, as stated earlier, the per-core journal approach must deal with the mismatch between the in-memory buffer write order and the on-disk transaction commit order to guarantee the crash consistency.

3.1 Analysis of Journal Coherence Problem

In the per-core journal design, a thread inserts modified buffers to the running transaction allocated for the core it runs on. However, the buffer may have already belonged to a transaction of other cores as shown in Figure 1. Figure 3 categorizes this situation into three cases. In Figure 3, two cores modify two unrelated buffers, but also both modify a shared buffer. The same as JBD2, when a core tries to write to a buffer that is in a checkpoint transaction, the buffer can be inserted to the running transaction of the core without breaking the crash consistency because its last image is safely stored

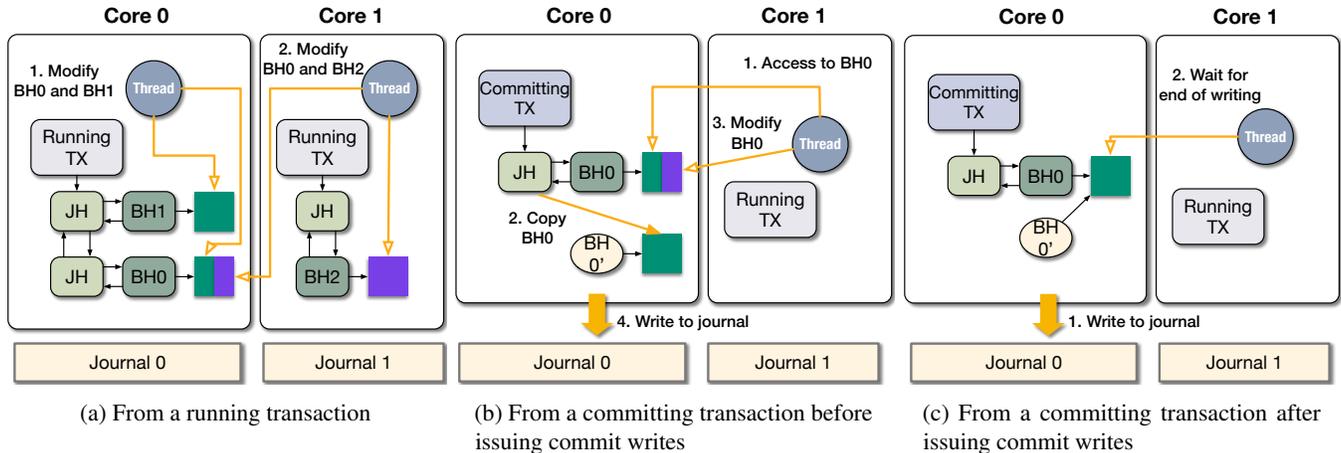

Figure 3: Three different cases that a running transaction tries to access a buffer head that already belongs to another transaction in the per-core journal system.

in the journal area. Therefore, this case is not considered in the journal coherence mechanism.

In Figure 3a, both cores modify the shared buffer before either begins to commit. Since we only maintain one copy of the shared buffer, we can no longer separate the updates made by the two cores. However, if we treat both transactions of these two cores as parts of one large transaction, we can allow uninterrupted parallel access to the shared buffers while guaranteeing the crash consistency. Their commits should be considered as valid only when both are committed; otherwise, both must be voided.

In Figure 3b and Figure 3c, one core begins to commit its running transaction before the other touches the shared buffer. In Figure 3b, the buffer has not yet been scheduled for commit, so we can create a frozen copy. In JBD2, the frozen copy will be attached to the buffer head for the commit to the journal area, and the buffer head for the original buffer is kept in the committing transaction. Because the original buffer head is no longer used by the committing transaction, it can be modified by the other cores. This allows an immediate update of the shared buffer in Figure 3b. In Figure 3c, the shared buffer is already being written to the journal area by the first core. At this point, it is too late to make a copy of the buffer for concurrent modifications, since the file system page cache would continue to point to the copy that is being written. Therefore, core 1 must wait for core 0 to complete its commit operation before modifying the shared buffer. If a committing transaction always creates frozen copies for all of its buffers and use them for commit block writes, this waiting can be eliminated.

However, in both Figure 3b and Figure 3c, to guarantee crash consistency, core 1's commit must be performed after core 0's commit finishes. This serialization may suspend core 1's file system operations because a new running transaction can be created only after core 1's current running transaction

turns into the committing transaction, which again can be possible only after the current committing transaction finishes. If there is a long chain of transaction dependency, this will result in poor scalability. However, if we can enforce a rule that a committed transaction can be checkpointed only after the transactions it depends on are committed, we can allow both of core 0's committing transaction and core 1's running transaction to be committed independently.

Analysis of the three conflicting cases revealed that the conditional recognition of the committed transactions, which checkpoints the committed transactions only when their dependent transactions are committed as well, allows them to be committed independently to each other. In addition, the proactive use of frozen copies for committing allows immediate writes to the buffers being shared with the committing transaction. Based on this observation, we propose the journal coherence mechanism for Z-Journal.

3.2 Journal Coherence Commit

The journal coherence mechanism of Z-Journal imposes the write order between transactions during checkpoint so that each core can commit its transactions without being interrupted by activities of other cores. In Z-Journal, the committed transaction will be considered as *valid* only after all transactions preceding the transaction in the write order are committed. Z-Journal checkpoints only the valid commits.

To realize this, Z-Journal should be able to identify the ordering relationships between transactions, and to record them in the transaction commit. We propose order-preserving transaction chaining for this.

In Z-Journal, a transaction maintains the information about the transactions having ordering relationship with it by recording their unique identifiers into its *chained-transaction lists* as shown in Figure 4. The number of lists in a transaction is

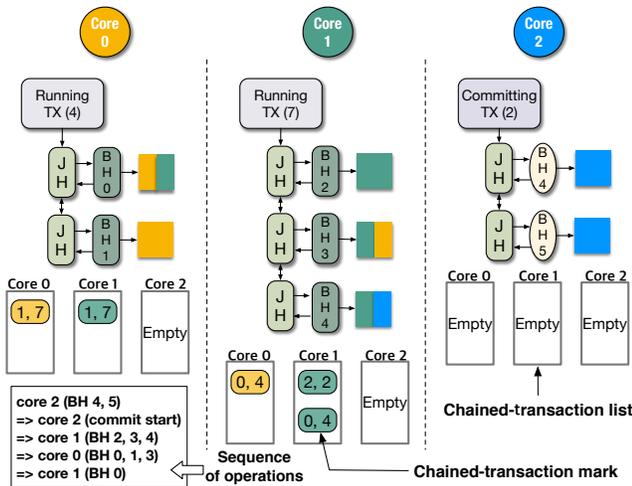

Figure 4: Example of order-preserving transaction chaining.

equal to the number of cores in a system; hence each core can update its corresponding list in any transactions without acquiring a lock. A transaction has a transaction identifier (ID), which monotonically increases in a per-core journal. Accordingly, a unique identifier of a transaction is a pair of a core ID and a transaction ID. When a transaction has an entry of (j, t) in its chained-transaction lists, the transaction is valid only after transaction t of core j is committed.

When two running transactions share a buffer, as discussed on Figure 3a, they should form a bi-directional transaction chain. If a running transaction tries to write to a buffer that belongs to a committing transaction as in Figure 3b, they should form a uni-directional chain that the running transaction follows the committing transaction.

For example, in Figure 4, buffer 4, written by transaction 2 of core 2, is about to be modified by transaction 7 of core 1. Because transaction 2 of core 2 is already in the committing state, core 1 leaves (2,2), which means transaction 2 of core 2, in core 1's list of transaction 7. By this, an uni-directional chain is formed between (1,7) and (2,2).

When core 0 writes to buffer 3, core 0 is allowed to do so while buffer 3 remains in journal 1's running transaction. In such case, these two running transactions must be considered as a single super-transaction. Therefore, core 0 leaves (0,4) in core 0's list of journal 1's running transaction and (1,7) in core 0's list of journal 0's running transaction at the same time. This forms an all-or-nothing relationship on the two running transactions. Later, when core 1 writes to buffer 0, core 1 will leave (1,7) in core 1's list of journal 0's running transaction and (0,4) in that of journal 1's because core 1 is not aware of the chained-transaction marks left by core 0 at this moment.

When each core independently modifies non-shared files, no chain will be created over their transactions. In this situa-

tion, the order in which the transactions are committed may be different from the original write operation order. For example, a process can perform metadata operations to different files on two different cores, respectively, and the second may commit when the first does not. The POSIX semantics does not guarantee the durability of write operations before finishing `fsync` of the corresponding file descriptor. Therefore, reversing the commit order between the transactions that have no ordering relationship does not violate the POSIX semantics. Even when the first invokes `fsync` before the second commits, the second may commit before the first and this is also allowed in the POSIX semantics because `fsync` is supposed to commit write operations only of a given file descriptor.

When a synchronous write from `O_SYNC` or `O_DSYNC`, is issued, the transaction chains related to the current write, if existing, should have been already formed or will be formed by the current write. Therefore, after every write operation, Z-Journal commits only the running transactions chained to the running transaction of the current write. However, when a core calls `fsync`, Z-Journal enforces all cores to commit their running transactions because `fsync` is supposed to flush all transactions related to the given file descriptor, and they can be in any core without being chained to the running transaction of the current core.

Since `fsync` does not add a new buffer head to the transaction nor allocate journal space, the commit time takes up most of the `fsync` latency. In Z-Journal, the commit operation must be performed in all cores to finish `fsync`, but the delay from it is not significant because the commit operation is executed in parallel in each core. Rather, when `fsync` is called in parallel on multiple cores, it is significantly advantageous in terms of throughput because multiple `fsync` invocations, which must be serialized in JBD2, can be parallelized in Z-Journal.

When a transaction enters the committing state, Z-Journal proactively creates frozen copies of its buffers regardless of their sharing states to prevent buffer update from waiting for finishing the commit operation as shown in Figure 3c. Through this *proactive frozen copy* approach, a committing transaction is disconnected from the original buffers and accesses only their frozen copies. Therefore, in Figure 4, when core 1 writes to buffer 4, buffer 4 can be inserted to transaction 7 without waiting because transaction 2 of journal 2 is using the frozen copy of buffer 4.

The proposed order-preserving transaction chaining scheme enables Z-Journal to keep track of write orders among transactions in a scalable and efficient way. Based on this, Z-Journal puts off the enforcement of write-order constraints to the checkpoint time and allows cores to independently commit transactions regardless of their sharing status. Because the usual checkpoint interval is a lot longer than the transaction life span, it is highly likely that almost all transactions become valid at the time of the checkpoint. Therefore, Z-Journal's journal coherence mechanism to the checkpoint duration is expected to be minimal.

The proactive frozen copy approach enables the immediate sharing of a buffer that is currently in use of a committing transaction. Combined with the order-preserving transaction chaining, this enables all transactions to simultaneously proceed to the checkpoint state without waiting. However, the proactive frozen copy generates a significant amount of memory copy operations and increases memory consumption. In addition, the order-preserving transaction chaining requires additional writes to the lists, although they are lockless. Nevertheless, because these overheads involve the in-memory structures, not the on-disk journal structures, their impact on the scalability and overall performance will be negligible compared to the expected benefits.

3.3 Journal Coherence Checkpoint

The same as JBD2, in Z-Journal, there is a single kworker thread in the system, and it periodically performs the checkpoint operation. Also, the same as JBD2, a user-level thread can conduct checkpoint when its write operation is delayed due to the insufficient free journal space.

As stated earlier, not all committed transactions become objects of checkpointing in Z-Journal. To implement this, when kjournald changes the state of a transaction to the checkpoint state, it skips over setting dirty flags of transaction's buffers. Instead, when kjournald converts its running transaction to the committing transaction, it checks whether the transactions in its checkpoint transaction lists are valid. If a transaction turns out to be valid, its buffers will be marked as dirty. Later, they will be checkpointed by kworker, which periodically iterates and checkpoints dirty buffers in the background.

For a committed transaction to be valid, its direct preceding transactions must be not only committed but also valid. Therefore, to check the validity of a committed transaction, kjournald traverses the transaction chain graph, which was created from the chained-transaction marks of the transaction and its ancestors, and checks whether all of their ancestors are valid. Every transaction has a field that shows its validity. If every ancestor of a transaction is identified as valid during the search, kjournald sets its validity field to prevent redundant search over its ancestors in the future.

This validity check is performed not only by kjournald, but also by user-level threads. When kjournald finds out an uncommitted ancestor, it stops the search and starts processing the next checkpoint transaction. However, in such a case, a user-level thread will initiate committing the uncommitted ancestor. It continues after the commit finishes because it cannot proceed with its file system operation without freeing journal space.

A valid transaction can be checkpointed anytime independently from its chained transactions. Therefore, the checkpoint order of valid transactions may be different from their dependent transaction orders. However, the removal of a transaction from a journal can be allowed only after its chained

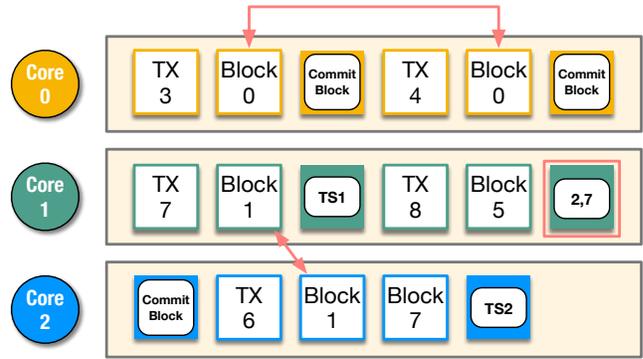

Figure 5: Snapshot of per-core journals after system crash.

transactions are all checkpointed because all chained transactions must be replayed together during the recovery.

The commit operation is conducted using frozen copies. However, the journal heads of a checkpoint transaction point to their original buffers. Therefore, checkpointing a valid transaction always updates the file system blocks with the up-to-date images of dirty buffers regardless of the checkpoint order.

3.4 Recovery Procedure

A committed transaction stored in a journal area has three kinds of blocks the same as JBD2: transaction descriptor blocks, data blocks, and a commit block. The transaction descriptor blocks, which store the information about the following data blocks, are located at the head of a committed transaction. Next, the data blocks are stored. Finally, The commit block is written to indicate the successful completion of the commit.

In Z-Journal, the commit block also stores the chained-transaction lists of the transaction. In addition, the commit block also has the timestamp [9] of the commit start time for the global ordering of transaction commits across multiple journals.

The recovery process first searches for the transactions with the commit block from all journals to find the valid transactions. After this, it creates the transaction order graphs based on their chained-transaction lists. Similarly to the checkpoint procedure, the recovery process traverses the graphs to find valid transactions. Finally, it updates the file system blocks with the latest buffer images from the valid transactions.

When a buffer redundantly appears in two valid transactions connected through an ordered chain, the buffer image from the latter transaction in the graph is the latest one, which will be used for recovery. If two transactions are tied together through a bi-directional chain constructed from sharing between two running transactions, a buffer cannot exist in both transactions simultaneously. Finally, when two transactions

are not chained together but have the same buffer, the buffer image of the latter transaction, which is determined by the timestamp, will be chosen because this case means that the latter transaction overwrote the buffer after the former transaction completely committed. These rules are transitively applied to the cases involving multiple transactions.

Figure 5 shows the snapshot of the per-core journals after a system crash. Transaction 8 of core 1 is invalid, although it has the commit block because the transaction 7 of core 2, which must precede it, is not written in the journal. Therefore, it is discarded in the recovery process. Block 0 is in transaction 3 and 4 of core 0, both of which are valid transactions. However, transaction 4 has the larger transaction ID, block 0 of transaction 4 will be restored. Block 1 also appears in transaction 7 of core 1 and transaction 6 of core 2 at the same time. They do not have a dependency relationship. Therefore, the recovery process compares the timestamps of both transactions to determine the latest buffer image to restore, which is that of transaction 6 of core 2 in this case.

3.5 Core-Aware Block Group Allocation

Block grouping is leverage inherited from the legacy spinning disks to provide a faster seek time [5]. The block group allocator of ext4 decides which block group a new inode or data block should be allocated in. The current block group allocator aims at increasing the access locality and minimizing seek times to obtain performance benefit from the underlying spinning disks [13].

The block group allocator of ext4 disperses the directory allocation over as many block groups as possible. However, when creating a file, it tries to place the inode of the new file in the same or nearby block group with its parent directory. It allocates file’s data blocks in the same block group with the file inode when the file size is smaller than a predefined value, `stream_req`. When larger than that, data blocks will be allocated from the last block group in which the data blocks for a large file were allocated. If the block group cannot accommodate the request, the block group allocator will sequentially try the following block groups.

The current block group allocator does not benefit when using a flash SSD because it does not have seek time. On the contrary, it increases false sharing of metadata among cores because the allocated blocks are unevenly distributed over a few block groups, and the block group placement of files and directories are blind to who will access them.

In Z-Journal, as sharing between transactions gets more frequent, the lengths of transaction chains tend to be longer. The large transaction order graphs will incur large checkpoint overhead. Therefore, we propose a *core-aware block group allocator* for ext4 that allows the group of blocks requested by one core to be allocated exclusively to other cores as much as possible.

When i -th core requests a block or metadata entry, the pro-

		Specification
Processor	Model	Intel Xeon Gold 6138 × 4 sockets
	Number of Cores	20 × 4
	Clock Frequency	2.00 GHz
Memory		DDR4 2666 MHz 32GB × 16
Storage		Samsung SZ985 NVMe SSD 800GB
OS	Kernel	Linux 4.14.78

Table 1: System configurations for evaluation.

posed block group allocator sequentially checks from block group $\lfloor \frac{\text{number of block groups}}{\text{number of cores}} \rfloor \times i$ to find a block group that can accommodate the requested item. The data block allocation for a file is served in the same way regardless of the file size.

This simple core-aware block group allocator is proposed for analyzing the benefit from reduced false sharing, not for production use, and does not consider the long-term consequences from the core-partitioned distribution of allocated blocks and the interactions with other performance-sensitive factors. The in-depth research on core-aware or sharing-aware block group allocators is beyond the scope of this paper.

4 Evaluation

In this section, we evaluate Z-Journal to verify its performance and scalability for various file system operations under different sharing conditions. In addition, We also analyze the overhead and benefit of the proactive frozen copy scheme and Z-Journal’s `fsync` handling mechanism. Finally, we show the overall file system performance and scalability of Z-Journal for benchmarks imitating real-world workloads.

4.1 Evaluation Environment

Table 1 shows the system configurations used for the evaluation. We implemented Z-Journal in the Linux kernel² and modified the ext4 file system to recognize per-core journals and to use Z-Journal instead of JBD2. We also modified the block group allocator of ext4 as described in Section 3.5. In addition, we modified `mke2fs` to format an ext4 file system to have multiple journals. The ext4 file system was modified so that the super block can have multiple journal control structures and the mount operation recognizes them.

We compared the performance of Z-Journal (denoted as ZJ on the graphs) with ext4 with JBD2 (denoted as JBD2 on the graphs), and ext4 without journaling (denoted as *no-journal* on the graphs). Because we are not aiming at the scalability of the overall file system, the performance of ext4 without journaling can be considered the best possible value Z-Journal can achieve. We also measured the performance of Z-Journal without proactive frozen copy (denoted as *w/o PFC* on the graphs), and without core-aware block group allocator

²The source code of the Z-Journal-patched Linux kernel is available at <https://github.com/J-S-Kim/journal>

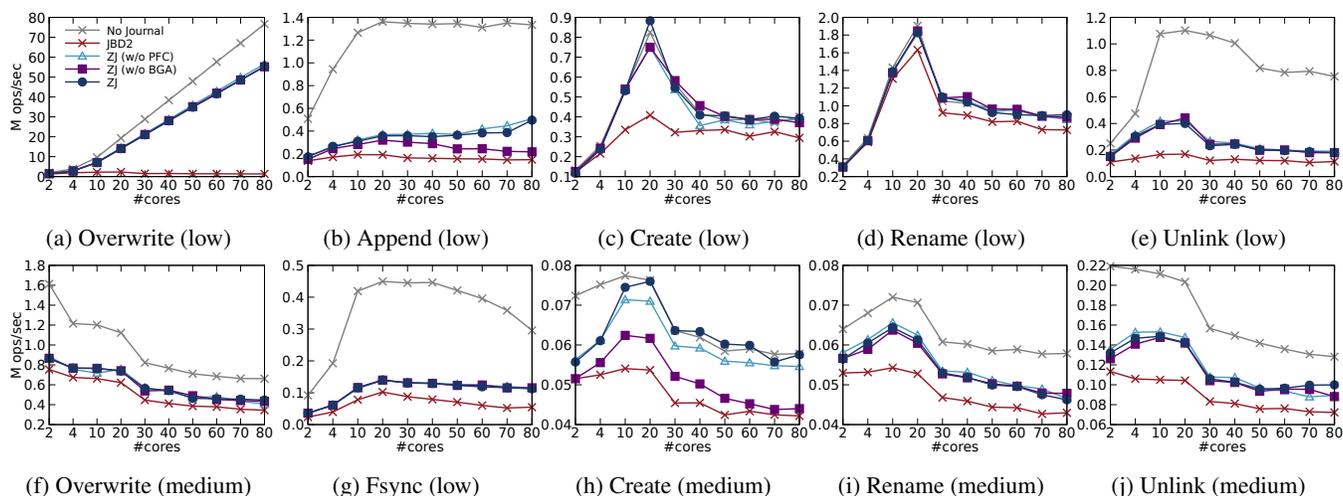

Figure 6: Throughput of FxMark write workloads while varying number of cores under different sharing conditions.

(denoted as *w/o BGA* on the graphs). All experiments were conducted in the `data=journal` mode [18] (The results obtained in the `data=ordered` mode are also presented in the appendix).

4.2 Scalability of File System Operations

To assess the scalability of Z-Journal when performing file operations under various block sharing conditions, we used FxMark [16]. The write workloads of FxMark consists of overwrite, append, fsync, create, unlink, and rename operations executed in the low and medium sharing level, respectively. In the low sharing condition, each core performs the target file system operation for private files in its dedicated directory. In the medium sharing level, the overwrite workload lets all cores access the same file, and the other workloads perform the given operation in the same directory. The append and fsync workloads provide only the low sharing level mode. Figure 6 shows the experiment results.

The favorable condition for Z-Journal against JBD2 is where the file system scalably performs, but the resulting performance is poor for the serialization at the journal layer. overwrite (low) barely modifies metadata and frequently writes to data blocks of files stored in non-shared per-core directories. Therefore, it is the most favorable workload in FxMark.

Z-Journal showed a close performance to no-journal for overwrite (low) excluding the slow down from the double writing overhead, and its performance scaled well to the number of cores. Z-Journal showed 41 times higher throughput in comparison to JBD2 at 80 cores. However, in the case of overwrite (medium), the file system scalability was poor due to sharing, and the performance of the journal layer was also poor for the same reason. Even in this case, Z-Journal gained 30% of performance improvement at 80 cores compared to JBD2 through its parallel journaling mechanism.

In the case of append (low), the difference between no

journal and journal group was very large. The metadata manipulation overhead without journaling is very low because delayed allocation is possible when allocating a new data block. Z-Journal without BGA scaled gently up to 20 cores, but performance decreased after that. This was due to increased false sharing caused by the current block group allocator. When the core-aware block group allocator was used, the performance steadily increased up to 80 cores. Z-Journal showed 3.34 times the performance of JBD2 at 80 cores.

For create (low) and rename (low), the journal’s scalability bottleneck was not revealed due to the scalability problem of the ext4 file system [16]. However, since commits were performed in parallel, there were 33 % and 24 % performance improvements at 80 cores, respectively. In terms of create (medium), Z-Journal without BGA obtained performance improvement of up to 15 % at 10 cores and about 4 % at 80 cores. Z-Journal showed similar performance to no-journal. Because it allocated block groups for each core, although the files were in the same directory, metadata sharing was greatly reduced, and this leads to improved performance. This performance gain was mostly from the file system, not from the journal layer. This result shows that the block group allocator in a file system is one of the major obstacles to scalability.

In the case of unlink, no-journal also showed scalability characteristics similar to create and rename. The big difference in performance between no-journal and the journaling group is from the heavy checkpointing operations occurring in the measurement interval caused by the preparation stage, in which the large file set was created, and their data blocks were written. For unlink (medium), Z-Journal achieved the maximum performance improvement of 42 % at 10 cores, and 38 % at 80 cores compared to JBD2.

In the fsync workload, where all cores write to their files and call `fsync`, Z-Journal also showed an average throughput improvement of 70 % in comparison to JBD2. When a core

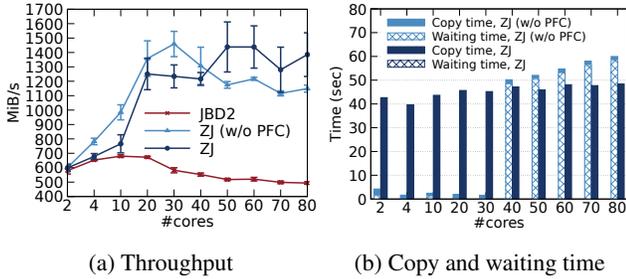

Figure 7: Throughput and journaling delay of SysBench.

called `fsync` in Z-Journal, all cores were suspended because they had to commit their running transactions together. However, the commit of each core in Z-Journal was a lot faster than that in JBD2 because per-core `kjournald` could commit in parallel while a single `kjournald` had to process alone.

Z-Journal showed a scalability pattern similar to that no-journal when the file system’s scalability was good in a low sharing situation. Even when the scalability of the file system was poor, its parallel committing scheme achieved superior performance compared to JBD2. However, in the workloads where shared writes and metadata updates frequently occurred, the performance gain was diminished due to the validity check procedure during the checkpoint process.

In the experiment for each file operation, most of the performance was better when proactive force copy was not applied. Only, low sharing create and medium sharing create achieved an average of 4 % and 5 % improvement by applying proactive force copy, respectively. It was because FxMark’s write workloads mainly produced metadata sharing and not much file sharing. If write accesses to the shared block do not occur frequently, proactive force copy will generate only meaningless overhead.

4.3 Analysis of Design Components

We used SysBench [12] to analyze the performance of Z-Journal and the impact of proactive force copy when data block write sharing frequently occurs. SysBench performs random overwrites on files in the file set created in advance. Therefore, when the number of cores increases, the occurrences of metadata block and data block sharing increase as well. We configured SysBench to randomly overwrite 4 KB data over 80 files, each of which has 1 GB size.

Figure 7a shows the throughput measured while increasing the number of cores, and Figure 7b shows the sum of the journal waiting time and the time to create frozen copies in Z-Journal and Z-Journal without proactive frozen copy, respectively. The waiting time refers to the time for a running transaction to wait for the committing transaction having the shared buffers to finish.

Both proactive frozen copy and waiting for shared buffers can be carried out by `kjournald` as well as user-level threads

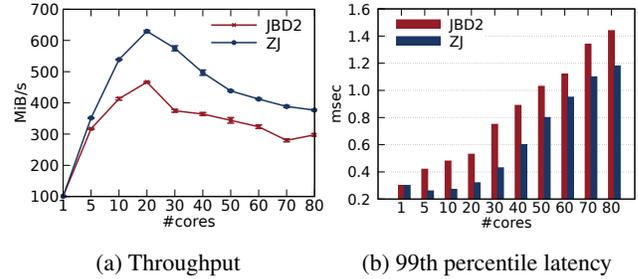

Figure 8: Throughput of `fsync`-invoking SysBench and tail latency of `fsync` operations observed.

writing to files. However, proactive frozen copy is mostly performed by `kjournald` in the background. Because it is off from the write path, the proactive frozen copy has little impact on the user-perceived performance. At 50 cores in Figure 7b, the copy time in Z-Journal and the waiting time in Z-Journal without PFC are similar, but unlike Z-Journal without PFC waiting in the write path, proactive frozen copies are mostly conducted by `kjournald`. Therefore, Z-Journal showed a 22 % better performance than Z-Journal without PFC.

The sudden increase in waiting time at 50 cores in Figure 7b was because, as mentioned in Section 3.1, long chains of dependent transactions were created. On the other hand, the copy time did not significantly increase even though the throughput of Z-Journal increased. This is because SysBench writes to the same file set repeatedly, and therefore, the number of shared buffers is limited.

As a result, as shown in Figure 7a, up to 40 cores Z-Journal without PFC outperformed Z-Journal by an average of 13 %. However, after 50 cores, proactive frozen copy improved the average throughput by 19 %. Based on this observation, we conclude that the proactive frozen copy scheme should be applied adaptively to the degrees of parallelism and cross-core file sharing.

To assess the throughput and latency of `fsync` on Z-Journal, we altered SysBench so that it calls `fsync` once every 100 write operations, and measured its throughput and 99th percentile tail latency of the `fsync` operation. Considering that `fsync` is intensively performed while cores are writing on a shared data set, this can be regarded as a notably hostile condition for Z-Journal.

As shown in Figure 8a, Z-Journal still performed better than JBD2 at all core counts. However, as the number of cores increased, unlike the results of the original SysBench, the throughput of Z-Journal also decreased similar to JBD2 because the validity check overhead of `kjournald` offset a significant part of the performance improvement earned from parallelized journaling. However, as shown in Figure 8b, the tail latency of `fsync` on Z-Journal was significantly better than that on JBD2. It was 18 % shorter at 80 cores even though the difference between JBD2 and Z-Journal narrowed as the number of cores increased as expected in Section 3.2.

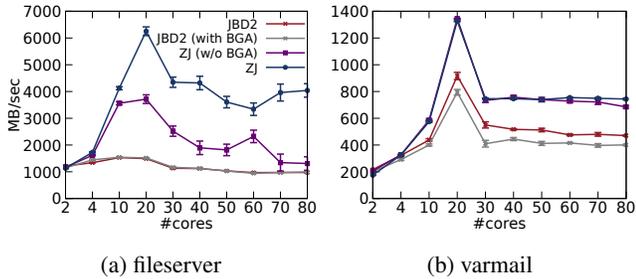

Figure 9: Throughput of Filebench workloads.

4.4 Overall File System Performance

To assess the performance impact of Z-Journal in the environment, which has a mixture of reads, writes, and metadata operations, we used the *fileserver* and *varmail* workloads of Filebench [21,23]. *fileserver* repeatedly conducts create, write, append, read, and deletion operations over a file set of relatively large files. *varmail* also continually performs create, read, append, and `fsync` operations over a file set of small files.

Figure 9a shows the throughput of *fileserver*. Since a large number of cores repeatedly created and updated files in a small number of directories, the throughput of JBD2 peaked at 10 cores and decreased as the number of cores increased. Z-Journal showed significantly better performance than JBD2 in every case. However, in the absence of BGA, false sharing increased rapidly with the increase in the number of cores, and the gap between the throughput of Z-Journal and that of JBD2 gradually shrunk as the number of cores increased. BGA significantly reduced false sharing and enabled Z-Journal to achieve 315 % performance improvement. When BGA was applied to JBD2, no throughput improvement was observed. This tells that the scalability of JBD2 was not limited only by metadata sharing. Z-Journal performed best at 20 cores, and the performance gently declined beyond that point due to the NUMA effect [7] resulting from the rapid increase in remote memory access across domains.

Figure 9b shows the throughput of *varmail*. *varmail* also showed a similar throughput change pattern with *fileserver*, and Z-Journal improved performance by 58 % at 80 cores. However, unlike *fileserver*, *varmail* frequently called `fsync`, and the performance improvement for `fsync` by Z-Journal is smaller than that for other file operations. Therefore, the performance gap between JBD2 and Z-Journal was smaller than that in *fileserver*. The effect of false sharing reduction from applying BGA was mostly concealed by the frequent suspension for processing `fsync`. As a result, BGA could obtain only 9 % performance improvement in comparison to Z-Journal without BGA. Rather surprisingly, when BGA was applied to JBD2, the performance deteriorated by up to 26 %. This was because the number of committed blocks was significantly amplified from reduced metadata sharing.

5 Related Work

Min et al. studied the scalability of file systems on manycore systems and left insights to design scalable file systems [16].

SpanFS [8] achieved scalability by partitioning files and directories into multiple domains. While this partitioning enables parallel write operations to each domain, careful data partitioning is important to achieve scalability. When two cores each write to two files in the same domain, SpanFS needs to serialize the write operations although they are independent of each other. In contrast, Z-Journal does not require explicit data partitioning and minimizes the serialization of journaling operations.

IceFS [15] also partitioned files and directories for performance isolation but its main goal was not multi-core scalability since multi-threads on a single partition (called a cube) can cause scalability bottleneck.

ScaleFS [2] decouples an in-memory file system from an on-disk file system and allows scalable file system operations since highly concurrent data structures are used in the in-memory file system. File system modifications are flushed to on-disk file system structures through per-core parallel journaling. However, the dual file system approach with the integrated journal layer of ScaleFS cannot be applied to the existing file systems. For example, journaling in ScaleFS can have multiple images of a buffer in memory by logging changes to the buffer per-core. This allows parallel journaling. However, in ext4 and most other conventional file systems, a buffer in memory must be unique and up-to-date. Z-Journal maintains this invariant while allowing parallel commits.

A few studies have addressed the scalability bottleneck caused by coarse-grained locking during write operations. They proposed to use a fine-grained range lock to increase the concurrency of write operations [10, 14]. The use of a file-grained lock is complementary to our approach.

iJournaling [17] proposed to use a per-file journal transaction for `fsync`. Accordingly, only necessary blocks need to be flushed to reduce the `fsync` latency. Since the per-file transaction uses a logical logging scheme, concurrent `fsync` processing can be possible. However, it also maintains the original file system journaling, causing serialization during write operations.

Son et al. [19] proposed to improve the concurrency of JBD2 by aggressively using concurrent and lock-less data structures and multi-threaded journal writes. While their approach enhanced the concurrency of journaling, the inherent serialization from committing to a single journal area remains.

BarrierFS [24] improved the concurrency of journaling by allowing multiple committing transactions in a journal file, which improves the concurrency of journaling. However, it has a limited concurrency due to waiting-based dependency handling, which is eliminated by Z-Journal's journal coherence mechanism.

The journaling mechanism for block devices is unsuitable

for NVM due to the write amplification of metadata journal. Chen et al. [3] proposed a fine-grained metadata journal mechanism optimized for journaling in NVM aiming at reduction in write amplification.

Sul et al. [20] proposed an NVM-optimized journaling scheme in which the use of parallel journals is similar to our proposal. However, its journaling operation aggressively exploits NVM's byte-addressable characteristic, which hinders its application to block devices.

Koo et al. [11] analyzed blocking of I/O operations due to the transaction in the locked state. To resolve this issue, they proposed a transaction lock-up elimination scheme that optimizes the transaction commit procedure.

6 Conclusion

Most modern file systems use the journal to guarantee crash consistency. However, because conventional journaling schemes are performed serially from transaction generation in memory to journal commit on disk, it acts as a serious scalability bottleneck when file system operations are run simultaneously in many cores.

In this paper, we proposed Z-Journal, a scalable journal design using per-core journals, which retains the interface of JBD2. Z-Journal includes a journal coherence mechanism, which provides complete parallelism for unshared buffer modification and guarantees crash consistency by order-preserving transaction chaining for shared buffer modification.

Our evaluation showed that Z-Journal achieves a steady increase in throughput in journal-bottlenecked workloads, showing up to approximately 4000% improvement in comparison to JBD2. It also showed 29% throughput improvement on average even under unfavorable conditions by allowing parallel journaling.

Appendix

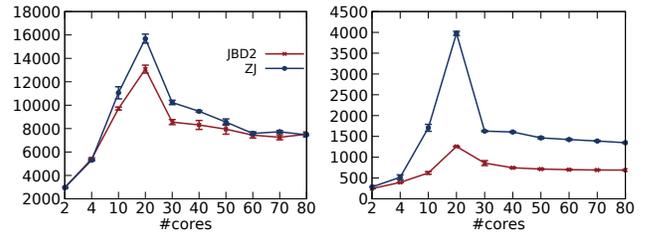

We also evaluated Z-Journal in the data=ordered mode. The performance gain from Z-Journal was less in the ordered mode than in the journal mode because the amount of buffers written to the journals was significantly smaller in the ordered mode. However, the patterns of performance improvement from applying Z-Journal in the ordered mode were similar to that in the journal mode. Figure 10 and Figure 11 show the ordered mode counterparts of Figure 6 and Figure 9, respectively. These are not included in Section 4 for the readability of the graphs and the limited space.

LODIC: Logical Distributed Counting for Scalable File Access

*KAIST, Korea [†]Hanyang University, Korea [‡]Dankook University, Korea [§]Virginia Tech, USA

Abstract

We develop a memory-efficient manycore-scalable distributed reference counter for scalable file access, *Logical Distributed Counting* (LODIC). In Logical Distributed Counting, we propose to allocate the local counter on a *per-process* basis. Our process-centric counter design saves the kernel from the excessive memory pressure and the counter query latency issues in the existing *per-core* based distributed counting schemes. The logical distributed counting is designed to dynamically incorporate the three characteristics for reference counting: i) the population of the object, ii) the reference brevity, and iii) the degree of sharing. The key ingredients of the logical distributed counting are *Memory mapping*, *Counter Embedding*, and *Process-space based reverse mapping*. Via mapping a file region to the process address space, LODIC can allocate the local counter at the process address space. With Counter Embedding, the logical distributed counting defines the local counters without the significant changes in the existing kernel code and without introducing significant memory overhead for the local counters. Exploiting the virtual memory segment allocation algorithm of the existing Linux kernel, the process-space based reverse mapping locates the local counter of the physical page without the substantial overhead. Logical Distributed Counting increases the throughput by $65\times$ against stock Linux in reading the shared file block. LODIC exhibits as good performance as the ideal scalable reference counter when deployed in the RocksDB (key value storage) and NGINX (web server) applications.

1 Introduction

Reference counting is a vital part of the modern Operating System (OS). Various kernel objects, e.g. page frame, inode, and file descriptor table maintain the reference counter to prohibit them from being reclaimed prematurely while allowing them to be accessed concurrently by a number of processes without the exclusive lock. The contention on updating the reference counter makes the associated cacheline

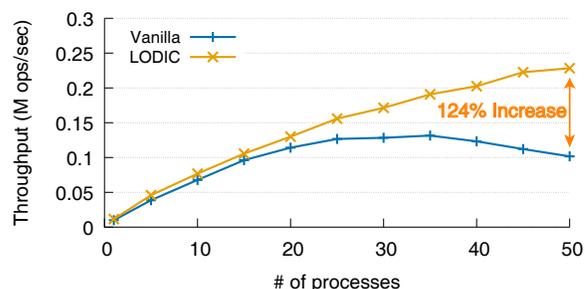

Figure 1: Web server performance accessing the shared web page: wrk benchmark [69] of NGINX web server engine, 120 CPU-cores (Intel Xeon E7-8870 v2 processors, 8 sockets and 15 cores per socket) and 780GB DDR3 DRAM

to be fetched across the CPU cores, and renders the scalability failure due to the cacheline bounce. The importance of the scalable reference counting gets emphasized further as the computer system is loaded with a larger number of CPU cores [17, 23, 31, 40]. Recent demands for the larger main memory in Deep Learning [22], Graph Analysis [48], Virtual Machine consolidation [35, 68], and Big Data Analytics [41] applications make the Operating System to host a larger number of kernel objects and compound the importance of the scalable and the memory-efficient reference counting. Machines with hundreds of the cache coherent cores and the multi-terabytes of the main memory are currently available in the market today: SGI’s Ultra Violet 3000 [10], Dell’s PowerEdge R920 [7], and HPE’s Superdome X servers [37]. In the foreseeable future, we expect a system with thousands of cache coherent low-processing power cores and with even petabytes of main memory [38].

Reading a file block is one of the most essential operations in the computer system, e.g., accessing the web page, searching the database, scanning the key-value file, and etc. Immature implementation of the reference counter for the page frame in the modern Operating Systems makes the shared file block access easily vulnerable to cacheline bounce associated with the reference counter update, leading to scalability and performance collapse [51].

We examine the performance of web server where a popular web page is shared by the number of clients. We increase the number of clients that request for the same web page. Web server daemon deploys multiple processes. Each process services the web page requests from the clients. Fig. 1 illustrates the results. In vanilla Linux that adopts the global reference counting for the page cache entry, the web server throughput saturates at 30 cores. With our logical distributed counting, the web server throughput increases as much as by $2.23\times$ when there are fifty processes. This simple experiment shows that from the application's point of view, reference counting is a vital component in making the shared file block access scalable.

A fair number of works have been proposed to mitigate the contention on the global reference counter [5, 14, 17, 23, 26, 31, 40]. They mitigate the contention on the global counter via allocating the per-core local counters and subsequently via distributing the accesses to the global counter to a number of local counters. They represent a global state of the references using a set of local counters. These works trade the memory pressure and the counter query latency for the scalability for the counter update. To mitigate the memory pressure for the local counters, the recent works propose to allocate the counter cache for each core. The per-core counter cache hosts the recently accessed counters [16, 18, 23, 40].

The existing distributed counter designs are grounded upon the view that the cacheline bounce is caused by the contention among the processors. This processor-centric view on the cacheline contention leads the kernel to define the local counters for each processor core. They blindly define the same number of local counters for all objects regardless of the access popularity. The per-core based distributed counting schemes fail to take into account the actual degree of sharing and impose overly pessimistic estimation on the number of local counters that are required to mitigate the counter contention.

In this work, we view that the cacheline contention in updating the reference counter is driven by the contention among the *processes*, not by the contention among the *processors*. Based upon this new view, we propose to allocate the local counters for a given object in *per-process* basis. We allocate the local counters for a given object to each process that accesses it. We call this distributed counting scheme, *Logical Distributed Counting*, LODIC for short. We call it a *logical* counter since the local counters are associated with the logical entity, the process, not with the physical entity, the processor. In LODIC, the counter query latency is governed by the actual number of processes that share a given file block.

LODIC is designed to address the scalability issue in reading the shared file block [40, 51]. There are three characteristics that need to be incorporated in designing the reference counting scheme: the degree of sharing, the object population, and the reference brevity. Each kernel object, e.g., page frame, dentry entry, inode, and file descriptor table, has widely dif-

ferent reference characteristics along these three axis. The reference counter design should be tailored with respect to the characteristics of the object.

The Logical Distributed Counting consists of three key ingredients: (i) file mapping, (ii) counter embedding, and (iii) process-space based reverse mapping. The first ingredient is to map a file region that needs to be shared to the process address space. This plain and simple mechanism provides a foundation for the logical distributed counting. Via attaching the file-backed page frame to the process address space, LODIC enables the kernel to define the reference counter for the page frame in the process address space, i.e., in per-process basis. The second ingredient is Counter Embedding. With Counter Embedding, LODIC represents the logical counter using the unused bits in page table entry (PTE). Counter Embedding eliminates the need to define a new kernel data structure to represent the local counter and makes the logical counter memory-efficient. The third ingredient is process-space based reverse mapping. Locating the page table of a given page frame is the most expensive task in accessing the local counter in logical distributed counting. For reverse mapping, LODIC scans the virtual memory segments of the process, the *process-space*, unlike the existing reverse mapping feature, `rmap()` [24] that scans the virtual memory segments associated with the file, the *file-space*. The virtual segment allocation algorithm of Linux tends to place the file mapped segments at the high-end of the process virtual address space. Exploiting this nature, the process-space based reverse mapping of LODIC can locate the page table for a given page frame in nearly constant amount of time regardless of the degree of sharing and successfully scales with the degree of sharing. The contribution of LODIC can be summarized as follows.

- Logical Distributed Counting allocates the local counters with respect to the *actual degree of sharing*. The number of local counters for a file block corresponds to the number of processes that map the block which can be substantially smaller than the total number of CPU cores in the large scale manycore system.
- Logical Distributed Counting scheme develops a scalable reverse mapping technique, *process-space based reverse mapping*. It effectively exploits the virtual memory allocation algorithm of existing Linux and can locate the logical counter within a constant amount of time in common cases. The process-space based reverse mapping makes the reverse mapping overhead sufficiently small, whose performance impact associated with accessing the local counter becomes hardly visible from outside.
- Logical Distributed Counting is nearly memory free. The logical counter in LODIC exploits the unused bit space in the page table entry to represent the reference counter. LODIC successfully addresses the memory pressure issue in the logical counting.
- With all these benefits, LODIC increases the performance

of shared block read by $64\times$ compared to the stock Linux. When the file block is shared and accessed by 120 cores.

2 Background and Motivation

2.1 Reference Counting in File Block Access

Page Cache and Reference Counting. OS kernel manages the page cache (or buffer cache) to speed up the file access by caching the frequently accessed disk contents to memory. Linux kernel (and many other OSes) manages per-file (inode) page cache. A page cache maintains the mapping information from a file offset to a physical page frame that holds the associated disk content. In servicing a read/write system call, OS kernel first looks up the page cache to avoid costly storage access. OS kernel tends to keep as much file contents as possible in a page cache. However, under the memory pressure, OS kernel evicts infrequently accessed pages to secure more free memory. One invariant is that OS kernel should not reclaim a page which is still being accessed. Reference counting is commonly used to track the page access count in many OS kernels including Linux. For instance, OS kernel (atomically) increases per-page reference counter before accessing a page in the page cache and decreases it after the access completes. A positive page reference counter means that the page is being accessed and that the page should not be reclaimed.

Page Cache Reference Counting in Linux Linux kernel maintains per-inode page cache (`address_space`) using a radix tree (`XArray`). The page cache maps a file offset to `struct page`, which is metadata on a physical page frame. Linux kernel maintains two atomic reference counter per-page. They are defined in the `struct page`; `_mapcount` representing how many times a page is `mmap`-ed and `_refcount` representing how many tasks are accessing a page [50]. When a file is shared among the multiple processes concurrently, the concurrent update on the `_refcount` becomes the performance bottleneck [51]. When a page frame is chosen for the reclamation, the kernel unlinks it not only from the page cache but also from any page table entries that map a given page cache entry. To quickly locate the associated page table entries, the kernel maintains a reverse mapping from a page frame to a page table entry [24, 25, 43, 67]. Linux kernel maintains an interval tree, which is a set of virtual memory segments mapping a given port of a file to virtual address space (stored in `mapping` field under `struct address_space`).

Challenges in Page Cache Reference Counting. There are two challenges in page cache reference counting. First, the number of reference counters can be prohibitively large. For example, 1 million `_refcounts` are needed to cache 40 GB in Linux. Next, the access characteristics (*e.g.*, access frequency) of a page cache reference counter is determined by the applications that accesses the files, which is out of kernel's control. Therefore, any reference counting scheme for

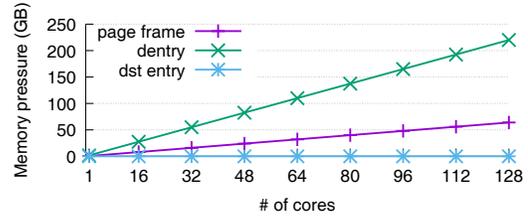

Figure 2: Memory consumption of sloppy counters for page frame (`struct page`, `dentry` and `dst_entry`) when DRAM size is 256GB, the number of `struct page` is 67M, the number of `dentry` is 220M, and the number of `dst_entry` is 32K.

page cache should be memory-efficient to deal with the large memory capacity and should be adaptable to application's file access behavior.

2.2 Scalable Reference Counting

Per-Core Distributed Reference Counting. To avoid the performance collapse caused by cacheline bouncing in atomic counter (used in stock Linux kernel), per-core distributed reference counting schemes – *e.g.*, Scalable Non-Zero Indicator (SNZI) [31], Sloppy Counter [17], and Approximate Counters [26, 27] – have been proposed. This approach manages the per-core local counters in addition to the central object counter. In the common case, each thread accesses its per-core local counter, not incurring cacheline bouncing.

While this approach solves the performance problem of the atomic counter, it has two critical problems that we opted out using it for page cache. First of all, its memory consumption linearly increases as the number of objects and the number of CPU's increase (see Table 1). When a large number of objects (*e.g.*, millions page frames [1,3]) exist in a multi-core machine having tens or hundreds of CPU's, its memory overhead is detrimentally large. For example, Figure 2 shows that sloppy counter requires 60GB of additional memory just to store the reference counters for the page frames (`struct page`) in a 128-core machine with 256GB DRAM (24%). Another drawback is the query performance – getting the true counter value – is often proportional to the number of CPU's. In sloppy counter, the entire local counters should be traversed to get the true value (see Table 1). In managing the page cache, the slow query can slow down the reclamation of page frames and can cause unnecessary swapping in the worst case.

Hash Table Based Reference Counting. To mitigate the excessive memory usage of the per-core schemes, per-core hash table based distributed counting schemes have been proposed. They store local counters at the per-core hash table to bound the memory usage regardless of the number of objects.

However, they do not fundamentally solve the limitation of per-core distributed reference counter. Still their memory consumption is proportional to the number of CPU's as shown in Table 1. Also, when the hash collision happens, they perform its slow path incurring the central contention:

	Atomic Counter	SNZI [31]	Sloppy Counter [17]	RefCache [23]	PayGo [40]	LODIC
Counting Overhead	Contending atomic ops	Non-contending atomic ops	Global lock	Non-atomic ops	Mostly non-atomic ops	Mostly non-contending atomic ops
Space Overhead	$O(N)$	$O(N \cdot C)$	$O(N \cdot C)$	$O(C \cdot H + N)$	$O(C \cdot H + N)$	$O(N)$
Query Overhead	$O(1)$	$O(1)$	$O(C)$	$O(1) + 2 \cdot epoch$	$O(C)$	$O(S)$
Time Overhead	None	None	Every threshold	Every epoch and collision	Every hash collision	None

N : # of objects C : # of CPUs H : size of hash table S : degree of sharing

Table 1: Comparison of reference counting techniques.

for example, RefCache [23] evicts the original entry to the central reference and PayGo [40] evicts to the central overflow counter list. Therefore, unless the hash table size is large enough (*e.g.*, $2 \times$ of active objects), they still suffer from the hash table collision and the slow path execution. Also, they do not improve the query performance because they have to traverse the entire per-core hash tables. In addition to the traversal overhead, RefCache has to wait for two epoch periods until the counter converges, which incurs more delay in getting the true counter value.

3 Design Principles of LODIC

In this section, we present three design principles of LODIC, a scalable reference counting scheme designed for page cache and file access. LODIC should be able to deal with a large number for objects in multi-core machines leveraging the skew of file access and the property of page cache access.

P1. Millions of Counters Are Not Uncommon. Recent advances in multi-core processors and memory technologies make a server equipped with hundreds of cores and hundreds GB to a few TB main memory prevalent. For example, a recent 2-socket Intel Xeon server has up to 112 logical cores and 9 TB memory (3 TB DRAM and 6 TB NVM). We expect more cores with larger memory will be prevalent to achieve higher performance in data-centric applications.

Reference counting should be scalable to the memory capacity and the number of CPU cores. It should scale at least millions of page frames (40 GB memory == 10M reference counters) with a hundred CPU's. To be future-proof, it should scale a few hundred millions (*i.e.*, TB scale) with a few hundreds CPU's. *Ideally, the memory consumption should solely depend on the number of reference counters and the query performance should not depend on the number of cores, which have been increasing.* While the counter caching approach using per-core hash table [23, 40] partly mitigates memory pressure, the current approaches relying on per-core structures [17, 23, 26, 27, 31] are not appropriate in both memory consumption and query performance.

P2. Not All File Pages Are Popular. It is well-known that real-world data access are skewed. Examples include the web page accesses [19], the popularity of the vocabularies in the dictionary [28], and the access distribution in the key-value store [20] to list a few. That implies that the accesses to a small subset of file pages account for dominant fraction of all file accesses while most file pages are not concurrently

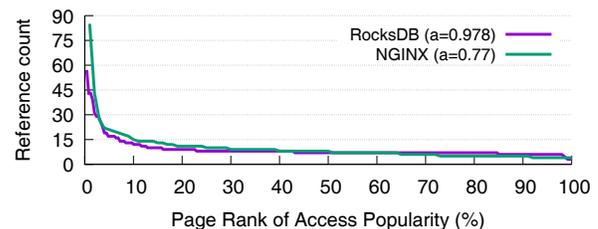

Figure 3: Maximum reference counter distribution of page frames for file access under real-world skewed key-value store and web server accesses on a 120-core server.

accessed at all. The existing distributed reference counting schemes relying on per-core structures [17, 23, 26, 27, 31] fail to exploit such access skew. These works assume that all objects are concurrently accessed from all CPUs. Subsequently, they blindly pre-allocate same number of per-core local counters or same amount of per-core counter cache (hash table) for all objects. The pessimistic assumption on the degree of concurrent access renders overly excessive memory pressure and the query overhead. *Ideally, reference counting scheme should allocate the local counters with respect to the actual degree of sharing, the actual number of processes that share a page.*

We examine the impact of access skew in reference counter design; we run RocksDB key-value store [34] and NGINX web server [60]. For key-value store access, we use the access skew of the English dictionary (Zipf distribution with $\alpha = 0.98$) [28]. For web page access, we use the measurement results for web page access (Zipf distribution with $\alpha = 0.77$) [19]. In this experiment, we record the largest reference counter value in each page frame, which we observed while running the workloads. 100 concurrent clients stress RocksDB having 17,000 key-value pairs with 100-byte values. NGINX runs with 100 concurrent workers. Both were run on a 128-core server. Figure 3 shows the distribution of the maximum reference counter values. X-axis denotes the popularity rank of the pages. Unsurprisingly, the distribution is highly skewed. The sum of the maximum reference counter values for the individual file pages corresponds to the upper bound on the total number of local counters, which are required to represent the concurrent accesses. The sloppy counter [17] allocates 120 local counters for each page. According to this experiment, sloppy counter creates $13.6 \times$ more local counters for RocksDB and $12 \times$ more local counters for NGINX than are actually needed, respectively.

P3. Reference Duration Is Extremely Short in File Access. One important factor in designing the distributed reference

scheme is how to handle the reference split. A process can be scheduled to the different core while the reference is active. Then, the original local counter becomes to reside at the different core from the core where the process is running as a result of the process migration. We call this situation as reference split.

There are two types of approaches to address the reference split problem. The first type of approach is to eliminate the possibility of the reference split. One can temporarily disable the interrupt [47] or the preemption [45] to prevent the process migration. Another type of approach is associated with resolving the reference split when it happens. When the reference split happens, the process can decrease (*i.e.*, unreference) either the local counter at the current core (*e.g.*, RefCache [23]) or the original local counter at the remote core (*e.g.*, PayGo [40]).

Each type of approaches has its own disadvantage; the limited usage, the excessive query latency and the memory overhead. The first is the limited usage. Disabling the interrupt or the preemption cannot be used if the code does not allow to disable the interrupt or the preemption. The second is excessive query latency. RefCache should wait for two epochs to get the real reference counter value. Refcache trades the query latency with the cost of decrementing the counter at the local core. The third is the memory overhead. PayGo requires not only the local counter but also the anchor counter at each core. Also, PayGo needs to maintain the anchor ID at each task struct to handle the reference split.

The above mentioned techniques for the reference split may not deserve its the overhead if the reference split is unlikely to happen. More importantly, all these elaborate schemes deserve its overhead only when the reference split happens frequently. *Therefore, an ideal approach should pay the cost of the reference split only when it really happens.*

To understand how often the reference split can happen in accessing the page cache, we measured the time interval between the reference and the unreference operations for five popular kernel objects including struct page. As Figure 4 shows, the reference duration of page is very short (0.14 μ sec). For page access, the reference split happens very rarely (0.0005%, 5 out of one million page references). To measure the reference duration of page, we repeatedly read 4KB file block for 30 seconds. *Based on our measurement, we carefully conclude that any feature for handling the reference split may hardly deserve its overhead for the reference counting for page cache.*

4 Design of LODIC

4.1 Design Overview

LODIC is designed to scale with a large amount of physical memory and with a large number of CPU's by leveraging the file access skew and the short access duration. We designed

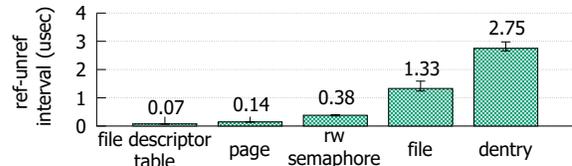

Figure 4: Reference duration for different kernel objects in Linux OS: file descriptor table (struct files_struct), physical page frame (struct page), read-write semaphore (rw_semaphore), file object (struct file) and directory entry (struct dentry).

LODIC in the following three key insights:

First, per-core local counter approaches are by design memory inefficient especially for the file-backed page frames. In file block accesses, the accesses towards a small subset of popular pages account for the dominant fraction of file block accesses as shown in Figure 3. To well exploit the characteristics of the shared file page access, we carefully argue that allocating the local counter in *per-process* basis than in *per-core* basis is appropriate for accessing the page frames. If the local counters are allocated only for the processes which actually share the given file, the memory pressure for the local counters does not increase linearly with CPU-core count but it is only dependent on the actual degree of page sharing. The memory saving of the per-process local counter against the per-core local counter can be particularly substantial in the large scale machine with hundreds of cores since the number of processes that share the given file can be much smaller than the number of CPU cores in the system. Moreover, LODIC reduces the query overhead substantially because it checks the local counters of only those processes that are actually sharing the file. In theory, the number of processes sharing a file can be greater than the number of CPU's. However, we believe such case is rare in practice because, for example, the administrator guides in many servers suggest not to create more (worker) processes beyond the number of CPU's to avoid unnecessary contention on the shared resources [58].

Next, we propose a *selective distributed counting scheme* that exploits the skew in the file accesses. LODIC can selectively apply the distributed counting for the fraction of a file. Not all file blocks in a file are frequently accessed. There may exist a hot region in a file whose reference counting becomes a bottleneck. Thus, we pay the extra overhead of distributed counting when only needed. For instance, the first few levels in B+-tree and log-structured merge (LSM) tree [59] and frequently accessed web pages are the typical examples of the hot file regions. Note that dynamically detecting the hot file blocks are well studied in the prior works [21, 52] and it is out of scope of this paper.

Lastly, we optimize LODIC's *design for the common case that reference split not happening* unlike the prior works [23, 40] preparing handling of the reference split all the time. As shown in §3, the reference split happens extremely rarely.

LODIC exploits two properties of the modern computer system design: (i) there exists a few unused bits left in PTE and

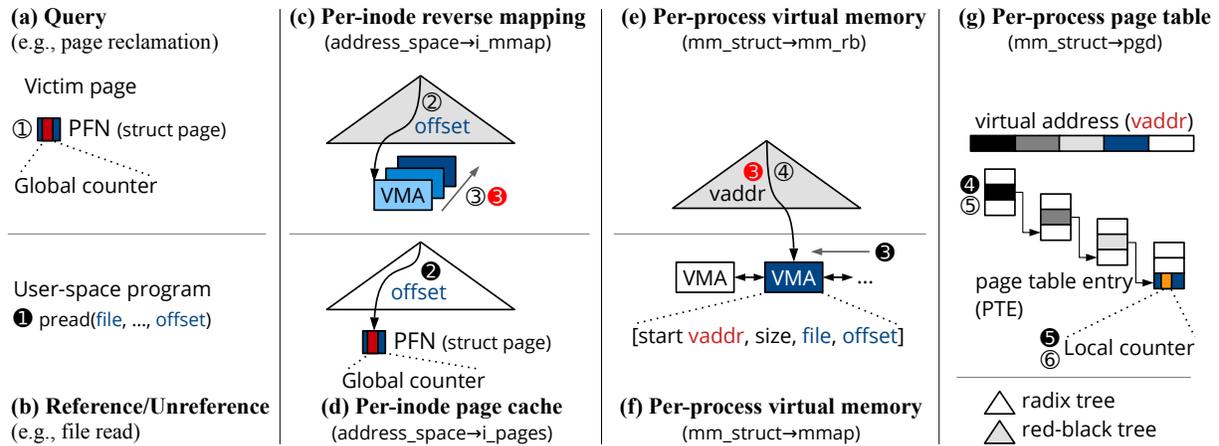

Figure 5: Illustrative examples of LODIC for reference/unreference operations (①) and a query operation (②). ③ is an unoptimized step, which is replaced by LODIC’s optimized step ④ (see the details in §4.4.2).

(ii) Operating System uses the search tree structures to organize the segments in a virtual address space. While the LODIC is currently built on top of Linux, it can be applied to the other Operating Systems. For example, similar to Linux that uses the red-black tree, FreeBSD and Windows use a splay tree and AVL tree, respectively, to manage process address space.

In the next sections, we present three main components of LODIC: (1) per-process selective distributed counting (§4.2), (2) efficient access of a local counter (§4.4), and (3) local counter embedding to page table entry (PTE) (§4.3). We then summarize how these are used for each LODIC operations (§4.5). Figure 5 illustrates the overview of LODIC design for reference/unreference and query operations.

4.2 Selective Distributed Reference Counting

LODIC realizes the per-process distributed counting by mmap-ing a file region to the process virtual address space. By doing so, LODIC allocates the local counters for the virtual pages in the mapped file region. When a program accesses the file block of the mapped file, instead of updating the global reference counter (`_refcount`) in the page frame (`struct page`), LODIC updates the local counters defined for the associated virtual page. The local counter is defined at the process virtual address space. The number of local counters for a given physical page corresponds to the number of virtual pages that map the given physical page frame. This approach deploys the distributed counters for the mapped file regions and for the processes that map a given file.

When a page frame is accessed (①② in Figure 5), LODIC kernel first checks if the given physical page is mmap-ed page or not. If the page is a mmap-ed one, the kernel performs reverse mapping to find a virtual address of the page (③ in Figure 5) then updates the local counter embedded in the associated page table entry (④⑤ in Figure 5). If the page is not mmap-ed (*i.e.*, `_mapcount == 0`) or the contention is low, the kernel falls back to updating the global reference counter in the page

frame. Currently, LODIC determines that the contention on the page is low when the page is shared by less than four processes (*i.e.*, `_mapcount < 4`).

4.3 Local Counter Embedding to PTE

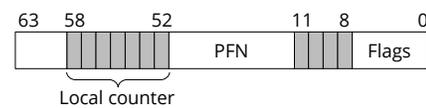

Figure 6: LODIC embeds a local counter to unused bits (colored in gray). In x86-64 architecture, a counter is embedded in bit [58:52].

In allocating the per-process local counter, we propose a *Counter Embedding* technique. With Counter Embedding, LODIC defines the local counter without allocating the separate memory. In Counter Embedding, we represent the per-process local counter using the unused (ignored) bits in the page table entry (PTE). Modern processor architectures leave a few bit in the PTE for software use. For example, x86-64 [12], ARM64 [15], and MIPS64 [53] have 11, 4, and 8 unused bits for software use, respectively. In Figure 6, LODIC in 64 bit x86 architecture is using 7-bit embedded local counter at bits [58:52]. Other CPU technologies also utilize the unused PTE bits (ARM ASID [9], Intel MKTME [39], and AMD SEV [13]). CPU’s with these technologies may leave a fewer bits available for the embedded counter. Regardless of the number of unused bits left in PTE, the design of LODIC remains unchanged. As the local counter embedded at PTE consists of a fewer bits, LODIC will more frequently access the global counter since the embedded counter tends to overflow more frequently. However, in our experimental experience, LODIC rarely accesses the global counter because the local counter overflows infrequently.

The counter embedding has two advantages: First, it does not require any additional memory for the local counter. With counter embedding, LODIC’s space overhead is $O(N)$ as presented in Table 1. In addition, it minimizes the kernel code

changes in implementing the local counter. It does not bring any new data structures nor does it modify any for local counter implementation.

LODIC updates the embedded local counter using an atomic compare-and-swap (CAS) instruction. We decided to use the atomic instruction on purpose. We can simply guarantee the correctness of the local counter update even when the reference split happens without relying on any additional mechanisms such as epoch based counter management in RefCache [23] and anchor counter in PayGo [40]. More importantly, using the atomic instruction does not slow down the common case operation because *non-contending* atomic operations are as cheap as non-atomic operations in modern processor architectures [63]. It is often used in designing the highly optimized lock-free data structures [54]. With 7-bit embedded counter, the embedded local counter overflows when the number of concurrent threads accessing a page is greater than 2^7 , which is extremely rare. To handle the overflow, LODIC falls back to using the global counter to represent the total number of references [61, 65].

4.4 Reverse Mapping from a Physical Page Frame to PTE

The performance and scalability of LODIC critically relies upon the efficiency of the reverse mapping (steps between ② and ④ in Figure 5). If the reverse mapping is slow or becomes a scalability bottleneck in concurrent accesses, it degrades performance significantly. Our evaluation results in §5.2.3 show that the legacy reverse mapping which is used in `rmap()` [24] can degrade the performance by 3 times. We first describe how the existing kernel handles the reverse mapping from a page cache to process virtual address space (§4.4.1) then propose our approach to accelerate the reverse mapping for LODIC (§4.4.2).

4.4.1 Process Space vs. File Space

Process Space: Virtual Address Space. A virtual address space of a process is composed of a set of virtual memory segments. We call this abstraction as *process space*. A virtual memory segment is a virtually contiguous memory region of a process having the same permission and file backend. It is represented by a start virtual address, the size, and backed file and offset (see Figure 5f). A virtual memory segment corresponds to `struct vm_area_struct` in Linux and `struct vm_space` in FreeBSD, respectively. In this paper, we use the segment and the virtual memory area (or VMA), interchangeably. OS kernel uses the process-space structure to check if a given virtual memory access is legal. For example, upon a page fault, OS first checks if the faulting address is legitimate in the process space then handles the fault (e.g., allocating physical page or copy-on-write, etc).

Existing OSes adopt difference data structures for process address space: e.g., red-black tree (Linux) [2], splay tree (FreeBSD) [36], and AVL tree (Windows) [62]. The leaf nodes correspond to the segments. The leaf nodes form a linked list. These data structures have pros and cons. Red-black tree and AVL tree guarantee the worst-case time complexity to $O(\log n)$ for search and update (insert and delete). Splay tree provides amortized time complexity to $O(\log n)$, i.e., the time complexity for k operations is $O(k \log n)$, but the worst-case time complexity of a single operation is worse than the red-black tree or AVL tree. All three OSes rely only on a single lock to protect the process-space structure from race conditions. A number of techniques have been proposed to make the process-space data structures friendly to the concurrent updates [23, 32, 66] to improve the scalability of virtual memory subsystem.

File Space: Page Cache and Reverse Map For each file, the kernel maintains the information associated with a set of the physical pages that cache its file blocks and a set of virtual memory segments that map its file regions if the file (or region of it) is memory mapped. We call this abstraction a *file space*. It corresponds to `struct address_space`¹ in Linux. File space encapsulates two mapping information in it; (i) a mapping from a tuple of (inode, file offset) to a physical page which caches the file block (Figure 5d) and (ii) a mapping from the physical page to the associated page table if the file block is memory mapped. The latter mapping is called *reverse mapping* since it is used to map the physical page to the associated virtual address or the associated page table equivalently. Linux uses a radix tree to organize the set of physical pages in a file space. When the kernel needs to locate the physical page for the given file block (e.g., `read()` and `write()` system calls Figure 5b), the kernel looks up the radix tree of the file space with the given file offset (i.e., `struct address_space` in Figure 5d). In addition, a file can be memory mapped to one or more processes. If the multiple processes map a given file region, the physical page that holds the memory mapped file block can be associated with the multiple process address spaces. To maintain the mappings from the physical page to multiple process address spaces, the kernel maintains the reverse mapping in per-file basis (Figure 5d) in the file space. One example of using the reverse mapping is for page reclamation (Figure 5b). Before the eviction, the kernel should make sure that the page is not being referenced by any threads. The associated page table entries should be invalidated after the page is reclaimed. To quickly invalidate the page table entries of the physical page, the kernel scans the reverse mapping in the file space.

When we map a file region to the process address space, we associate the page frames in a given file region not only to the file space but also to the process space.

¹The name `struct address_space` is, we believe, deeply mis-named.

4.4.2 Accelerating the Reverse Mapping for LODIC

The reverse mapping is the linkage between two spaces: process space and file space. As illustrated in Figure 5c, a reverse mapping (in Linux) maintains a mapping from a file offset to a list of virtual memory segments, which maps the file region. The main usage of the reverse mapping is page reclamation, which happens in every ten of seconds. When a file region is mapped by multiple processes, the kernel needs to examine all segments that map a given file region each of which is associated with different process (③ in Figure 5c) and then to look up the process space to locate the proper virtual memory segment (④ in Figure 5e). Unlike the page reclamation, where the reverse mapping is not in the critical path, LODIC needs to perform the reverse mapping in the critical path at every page cache access to locate the local counter. The existing reverse mapping relying on the file-space data structure does not meet the required level of performance and scalability for LODIC.

LODIC's approach of mapping a file region to the process address enables a new optimization for fast look up of the reverse mapping, which is impossible without mapping the file region. Since the page cache access (i.e., processing read() and write() system calls) is executed in the context of a calling user-space process context, LODIC can directly exploit the process-space data structure (i.e., `current->mm` in Linux) for efficient look up of the reverse mapping (⑤ in Figure 5f).

Leveraging the process-space data structure for the reverse mapping has two important advantages: First, the number of segment to examine is independent of the degree of sharing. Without mapping the file region and leveraging the process-space data structure, LODIC has to traverse the list of the virtual memory segments in the file-space to find out the corresponding virtual address argument. Hence the reverse mapping look up cost linearly increases as the file region is shared by more processes. Next, we can further optimize the reverse mapping look up operation by leveraging the OS's virtual memory layout, which we explain next.

Application	FxMark	RocksDB	NGINX
Number of segments	20	85	62
Position in the segment list	5	4	5

Table 2: Total number of segments in the applications and the position of a memory-mapped file segment in the segment list.

A process virtual address can have tens or hundreds of virtual memory segments. Table 2 illustrates the number of segments in a few popular applications. In reverse mapping, i.e. in locating the page table entry for a given physical page, LODIC exploits the way in which the Linux kernel maps the region of the file onto the process virtual address space (`arch_get_unmapped_area_topdown()`). Exploiting the very nature of kernel's memory mapping, LODIC can quickly locate the target virtual memory segment regardless of the total number of segments in the process virtual ad-

dress space. Linux maps the shared libraries and the memory-mapped files to the virtual address space as follows; when the process starts, the kernel defines the base address in the process virtual address space where the memory mapping starts, `mmap_base`. Starting from the base address, the kernel scans the process virtual address space towards the low end of the virtual address space and looks for the free virtual address region that can accommodate the given size of the file segment (or the shared library). When it finds the free virtual address region that can accommodate the given file segment, it reserves the region of the virtual address space, creates the virtual memory segment object (`struct vma`), and maps the created virtual memory segment to the allocated virtual address region. Due to this mapping mechanism, the virtual memory segment of the memory mapped file is likely to be located just below the stack and the `vDSO` [8]. Table 2 shows the position of the segment for the memory mapped file in the virtual segment list of FxMark, RocksDB and NGINX, respectively. FxMark has twenty virtual memory segments in its virtual address space. From `mmap_base`, the segment for the memory mapped file corresponds to the fifth one in the list of the virtual memory segments.

To leverage such layout property of memory mapped file regions, LODIC scans the segment list of process-space starting from `mmap_base` in reverse direction. By scanning the virtual memory segments in reverse direction (i.e., from high to low virtual addresses), LODIC can quickly find the segment associated with a given page frame (③ in Figure 5). Specifically, LODIC iterates the list of virtual memory segments (`mm_struct->mmmap`) in a reverse direction. It searches a segment that harbors a given page frame. For each segment, the kernel checks if the segment is associated with the same file as the given physical page. If they match, LODIC compares the file offset of the physical page and the file offset of the segment, and check if the page frame belongs to the segment. If we find the associated segment, then we obtain the virtual page number of the given physical page based upon the start virtual address of the segment and the offset of the given page frame within the segment. Once the segment is located and LODIC gets the virtual address of the mapped page, LODIC then walks the page table to locate the embedded local counter (④⑤ in Figure 5). In summary, LODIC can locate the page table entry within nearly constant amount of time independent of the degree of sharing and independent of the number of segments in the virtual address space.

4.5 LODIC Operations

We summarize how LODIC performs each operation with the examples in Figure 5.

Reference Operation. When a page frame in a page cache is accessed (①② in Figure 5), the kernel first performs a reference operation, increasing its reference counter. If the page is memory mapped and it is shared by more than four

processes (*i.e.*, `_mapcount >=4`), LODIC first looks up the corresponding segment by scanning process’s list of virtual memory segments in a reverse order using the file and offset as a key (③). After finding the segment, LODIC calculates the virtual address of the page using the start virtual address of the segment and offset of the mapping. With the virtual address, LODIC walks the page table to spot the page’s local counter (④⑤) and increases the local counter. LODIC relies on atomic CAS to update the page table entry to increase local counter value. If the page is not shared or it is shared by less than four processes, LODIC falls back to increasing page’s global counter (`_refcounter` in `struct page`).

Unreference Operation. After finishing the access of the page, the kernel performs an unreference operation, decreasing the page’s reference counter. The procedure is similar to the reference operation but LODIC handles the situation when the counter changes between the reference and unreference operations. LODIC first tries to decrements the page’s local counter if the page is memory mapped. The local counter can be zero if the number of sharing processes is increased beyond four after the reference operation. To handle such cases, LODIC decrements the global counter when the local counter is zero. Like the reference operation, LODIC relies on atomic CAS to decrement the counter. Since LODIC relies on atomic operation in updating the counter, LODIC does not need any other special mechanism to handle the reference split.

Query Operation. When the kernel reclaims the clean pages in the page cache to secure more free memory, it first performs a query on the page to check if the page is being accessed or not (① in Figure 5). LODIC first looks up the reverse mapping of a file with the file-backed page’s offset and gets the list of virtual memory segments associated with the page (②). For each virtual memory segment (③), LODIC calculates page’s virtual address (④). With the page’s virtual address, LODIC locates the page’s local counter embedded at the PTE (⑤⑥). If any of the page’s global counter and one of the local counters are not zero, LODIC returns the results as non-zero. Otherwise, it return zero so that the kernel can safely reclaim the page. For correctness of a query operation, the local counters and the global counter should remain unchanged while the query is in-flight. To ensure this, we use the same mechanism proposed in [40]; we define a flag for each physical page to denote if there is a query in-flight. Before the query starts, the kernel sets this flag. If this flag is set, the counter update operation blocks. We use `atomic_write` to set and to reset the flag [50].

Latency Analysis of Query Operation. LODIC can return the query operation as soon as it encounters the non-zero local or the global counters since all local counters are guaranteed to be non-negative. This is not possible in some distributed reference counting schemes, such as sloppy counter [17] and RefCache [23]. In these schemes, the local counter can become negative and the positive local counter does not guarantee that

the counter’s true value is positive.

To quantify the performance benefit, we analyze the number of local counter iterations for a query operation. Suppose that there are N counters. We denote the probability that the i -th counter is zero as $P(c_i = 0)$, where c_i is i -th counter value. When X is the number of local counters that the kernel has to examine until encountering a non-zero logical counter, $P(X = k) = p^{k-1}(1 - p)$, where p is $P(c_i = 0)$. Therefore, the expected number of local counter traversal is as follows:

$$E(X_N) = \sum_{i=1}^N i \cdot p^{i-1}(1 - p) = \frac{1 - p^N}{1 - p} \quad (1)$$

$E(X_N)$ grows slowly with N . When $N = 120$ and $p = 0.5$, we obtain $E(X_N) \approx 2$; the kernel examines less than two counters on the average until it encounters a non-zero counter.

5 Evaluation

We implemented LODIC on Linux v4.11.6. We examine the query latency, the memory pressure, and the application performance in five different reference counting schemes: Global Counter (Vanilla Linux), No Counter (NCount), RefCache [23], PayGo [40] and LODIC. We use the microbenchmark FxMark [51] and two data intensive applications – RocksDB key-value store [34] and NGINX web server [60]. Scalable file block read plays an important role in these applications. We choose RocksDB and NGINX in our evaluation because the multi-core servers are widely used in cloud environments, and a key-value store and a web server are the two most popular workloads in the cloud environment. No Counter (NCount) is a null counter that actually does not perform reference counting. This is to simulate the ideal scalable counter. The server has 120 CPU-cores (Intel Xeon E7-8870 v2 processors, 8 sockets and 15 cores per socket) and 780GB DDR3 DRAM. In the rest of this section, we first present how LODIC affects the performance of real-world applications (§5.1) then analyze how our design decisions affect the performance (§5.2).

5.1 Real World Applications

RocksDB. In key-value store, a number of processes can read the same database file, simultaneously. Especially in LSM-tree based key-value store, the run at level 0 can be read by a large number of users simultaneously and the efficiency of the distributed counting scheme can play a vital role in its performance behavior. We use modified `db_bench` [33] so that the multiple processes access the shared database. We perform sequential scan and search on the random key with a key size of 16 byte and a value size of 100 bytes on a working set of 1,000 records. With LODIC, the performance of RocksDB is as good as NCount, RefCache and PayGo (Figure 7). LODIC brings 23% performance improvement against the global counter under 100 processes.

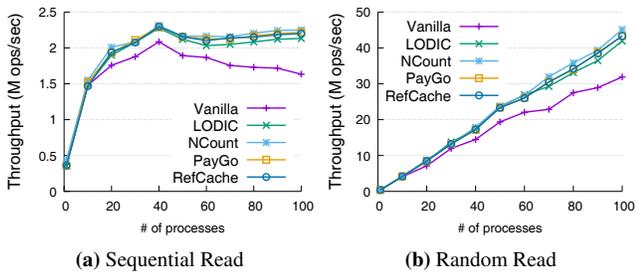

Figure 7: Performance of RocksDB key-value store.

NGINX. We examine the web server performance under the different distributed counting schemes. We vary the number of clients accessing the same web page using wrk benchmark [69]. We vary the number of clients from one to fifty. All clients access `index.html` (612 byte). Figure 8 illustrates the results. The LODIC, NCount, RefCache and PayGo yield the similar performance, showing $2.5\times$ performance improvement against vanilla Linux. Our evaluation results confirm that LODIC performs nearly as good as the ideal contention-less counting scheme (NCount) does.

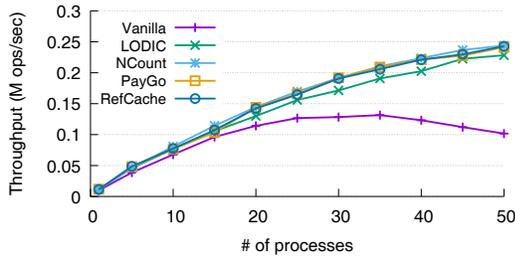

Figure 8: Performance of NGINX web server.

5.2 Analysis on LODIC Design

5.2.1 Memory Pressure

We compute the memory pressure for the RefCache, PayGo and LODIC (Figure 9). In RefCache and PayGo, the memory for distributed counting consists of the memory for the per-core hash tables and the memory for the per-page metadata (Table 1). Refcache and PayGo allocate 64 KB and 256 KB for per-core hash table (4096 entries), respectively. RefCache and PayGo need 16 bytes for each page frame to store the additional information, *e.g.*, lock, pointer, and epoch number. For our server with 780 GB memory (195 M page frames), the additional memory required for all physical page frames corresponds 3.1 GB ($195\text{ M}\times 16\text{ byte}$). Total amount of memory required for the distributed counting in RefCache and in PayGo correspond to 3.12 GB and 3.3 GB, respectively.

In LODIC, the total amount of memory for all local counters corresponds to only the page table pages that are required to map the file (or part of the file). For 4KB, 100MB and 1GB

files, the total amount of memory required for LODIC corresponds to 480KB, 24MB, and 240MB, respectively, when the file is shared by 120 processes. Unlike PayGO and RefCache, LODIC does not have the overhead of handling the hash collision and the cache miss that arise in the counter cache based distributed counting scheme. According to our experiment, as the hash collision increases, the performance of these schemes can drop by 40% from 186 Mops to 70 Mops for 4 KB read.

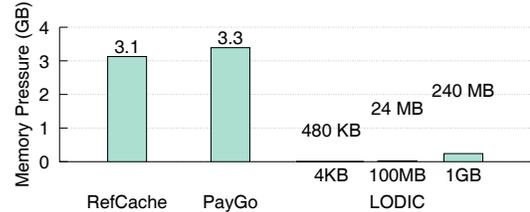

Figure 9: Memory consumption for RefCache, PayGo, and LODIC on a 120-core machine (the degree of sharing in LODIC is 120-core).

5.2.2 Query Overhead

We measure the latency of counter query under two scenarios: (1) the latency to reclaim all page cache entries for a given file (Figure 10) and (2) the latency to check if a given page frame can be reclaimed (Figure 11).

We examine the latency to reclaim all page cache entries of the 1 GB file under vanilla Linux (Vanilla), RefCache, PayGo, and LODIC. We use `fadvice` to trigger the page reclamation. In LODIC, we vary the fraction of the mapped pages (*i.e.*, hot page ratio) in the file; 10%, 20% and 100%. Figure 10 illustrates the results. ‘Vanilla’ renders the best case. Here, the kernel examines only the single global counter for each page frame to see if it can be reclaimed. The kernel repeats this process for all page frames for the given file. In per-core distributed counting schemes, the latency of reclaiming all page frames is problematic. It examines all per-core local counters for all pages in the file. The latency of `fadvice` corresponds to over 500 msec regardless of the number of processes that share the file. For the page reclamation, the LODIC uses the red-black tree (3 in Figure 5c) stored in `i_mmap` field of `struct address_space` like the Vanilla. In LODIC, the number of the local counters for a page frame is proportional to the number of the processes that map the file. For unmapped page, there is no local counter. The query latency of LODIC is longer than the vanilla Linux. However, LODIC successfully reduces the query latency properly incorporating the actual degree of sharing. When 10% of the entire file is hot region (100 MB is mapped), LODIC renders less than 1/4 of the `fadvice` latency of the per-core distributed counter when the file is shared by 45 processes. However, in the worst case (*i.e.*, the entire file is hot), which we believe unrealistic, the query latency of LODIC exceeds the query latency of the per-core distributed counting scheme when the number of processes is greater than 40. This is due to the overhead of reverse mapping in LODIC.

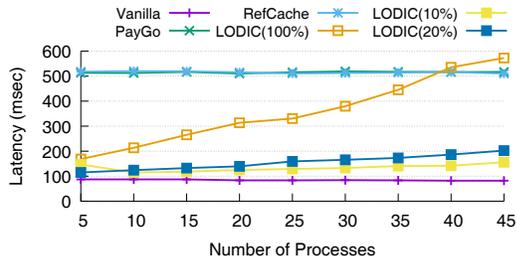

Figure 10: Query latency: reclaiming all page frames (fadvice).

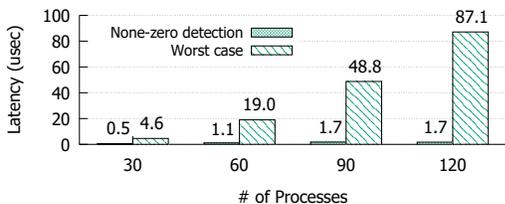

Figure 11: Query latency: reclaiming a page frame.

For counter query, we also measure the latency to determine if a given page is reclaimable. In LODIC, the kernel returns as soon as it encounters the non-zero local counter. As Figure 11 shows, LODIC examines only one or two local counters in most cases until it encounters non-zero local counter. The result well matches Equation 1. In the worst case, LODIC needs to scan all logical counters till it finds the non-zero local counter. In this case, the latency linearly increases with the degree of sharing.

5.2.3 Reverse Mapping Overhead

Performance and Scalability. We first examine the efficiency of the file-space based reverse mapping (3) in Figure 5) and the process-space based reverse mapping (3) in Figure 5). Figure 12 shows the time to perform the reverse mapping under two different reverse mapping schemes. The reverse mapping latency reduces to 1/20 when we use the process-space based reverse mapping instead of the file-space based reverse mapping.

Next, we examine the performance impact of the reverse mapping. We compare the latency to read 4 KB block from the different regions of a file: (1) from plain file in Vanilla Linux, (2) from the unmapped region of a file in LODIC-enabled Linux, and (3) from the memory-mapped region of the file

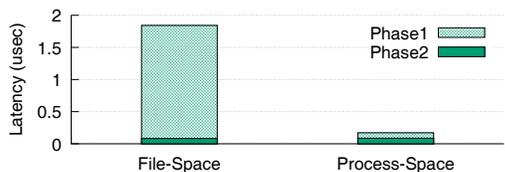

Figure 12: Latency break-down: file-space based reverse mapping vs. process-space based reverse mapping

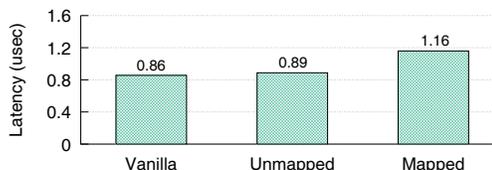

Figure 13: Read latency with various reverse mapping schemes.

in LODIC-enabled Linux. Figure 13 illustrates the result. In LODIC-enabled Linux, reading the memory-mapped file block renders 20% longer latency than reading the unmapped file block. In LODIC, the filesystem checks the map count of the file block before it performs reverse mapping. It performs the reverse mapping only when the map count is non-zero.

Lastly, we examine the performance of reading a shared file block under different reference counting schemes: (1) process-space based reverse mapping (LODIC), (2) file-space based reverse mapping (LODIC) and (3) vanilla Linux. We use DRBH workload of FxMark [51]. Figure 14 presents the results. Using the process-space based reverse mapping, LODIC achieves 65x performance against vanilla Linux under 120 CPU cores. The benchmark performance successfully scales linearly with respect to the increase in the number of processes (i.e., the number of active cores). On the other hand, the file-space based reverse mapping fails to scale due to its inefficient access path shown at 3) in Figure 5.

Different from the rests, XFS barely yields any performance gain under LODIC. We find that reference counter in per-inode rw-semaphore in XFS is the root cause of the scalability bottleneck here (Figure 14d). The performance bottleneck caused by this problematic inode reference counter has been out-shadowed by the severe scalability overhead of the reference counter for physical page. As LODIC effectively resolves the scalability issue in the reference counter of the physical page, the inefficiency of inode reference counter in XFS comes to the surface and prohibits XFS from scaling well. LODIC, however, is not entirely ineffective; LODIC brings as much as 2x performance in XFS (Figure 14d).

Interference with mmap. The mmap and munmap operation establish an exclusive lock on the process-space and the file-space structure to insert and delete the virtual memory segment. We examine how the mmap and munmap operations interfere with the performance of LODIC. There are 60 processes that read the shared file block. We create a background process that calls mmap, sleeps for one second and does munmap. We measure the performance of the shared file read with and without the background processes, respectively, and compute the performance ratio between the two.

Figure 15 shows the performance degradation varying the number of background processes. The performance of process-space based reverse mapping is barely affected by the background mmap/munmap. On the other hand, the performance of the file-space based reverse-mapping collapses to 1/100 when there are five or more background processes.

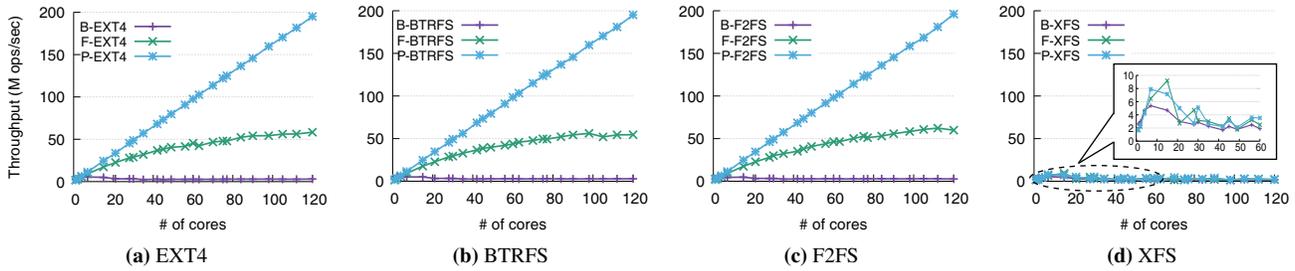

Figure 14: FxMark (DRBH): Baseline ('B'), File-based reverse mapping ('F'), Process-based reverse mapping ('P').

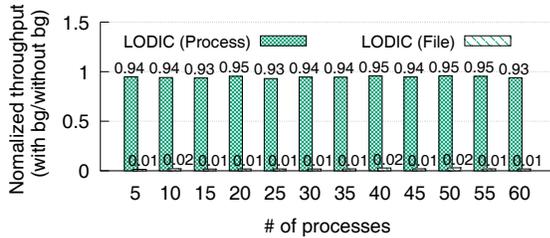

Figure 15: mmap() interference on the reverse mapping.

5.2.4 Counter Contention on the Local Counter

We examine the theoretical worst-case performance of LODIC; when the threads compete for updating the local counter. We create multiple threads in a process and have them access the same file block. We vary the number of threads per process to vary the contention on the local counters. We maintain the total number of threads in the system to be 120. Table 3 illustrates the performance. As the number of threads per process increases, the performance decreases. This is because PTE contention occurs when many threads of a process access the same file page at the same time. However, compared to the case using the global counter, LODIC is meaningful in that the contention is localized within a process because a PTE is shared by threads only within a process. We believe that in practice this situation can be avoided via properly limiting the number of threads per process. For example, it is common for server programs to provide tuning knobs to change the number of threads per process [56–58].

# of Threads	1	2	4	8	16
Throughput (M ops/sec)	164.16	58.87	32.54	19.61	8.79

Table 3: Effect of the contention on the local counters

6 Related Work

There were a number of sophisticated designs for the scalable reader-write lock. For the scalability, a few works exploit the memory barrier and the atomic instruction in the reader [44, 64]. Big-reader lock (brlock) uses an array of reader flags to avoid using the memory barrier [4]. Passive reader-write lock (prwlock) uses version-based con-

ensus protocol instead of the expensive mutex protected flags to avoid using the memory barrier [46]. A new reader-writer lock called percpu-rwlock in Linux [6] is known to work when the writers are rare. Bravo [30] uses the global hash table to address the memory pressure issue of the per-core reference counters [6, 17, 26, 27, 31] for rw-semaphore. SHFLLOCK [42] leverages a waiting thread to achieve high scalability in NUMA machines without introducing the additional memory consumption for NUMA-local locks. Hydralist separates the search layer and the data node for the manycore scalability of the index structure [49].

A few works adopt the actual degree of sharing to ease the contention [11, 29, 55]. Nerula et al. [55] detect the access conflict at run-time and distribute the conflict records to per-core basis. It cannot be applied to the generic workload. Dashti et al. [29] use the hardware profiling to detect the degree of sharing. It fails to scale when the sharing degree is high.

7 Conclusion

The per-core based distributed counting scheme has reached its limit due to the increase in the number of cores and the memory size in the recent computing system. In this work, we view that the counter contention is driven by the contention among the processes. This process-centric view enables us to devise a new counting scheme that can naturally incorporate the degree of sharing, the population and the reference brevity characteristics of the physical page frame. Via defining the local counter in per-process basis, LODIC is successful in striking the balance among the three factors of the reference counter: memory pressure, the counter query latency, and counter update performance. We show that software overhead of the proposed logical distributed counting is insignificant and hardly visible from outside.

UNISTORE: A fault-tolerant marriage of causal and strong consistency

Abstract

Modern online services rely on data stores that replicate their data across geographically distributed data centers. Providing strong consistency in such data stores results in high latencies and makes the system vulnerable to network partitions. The alternative of relaxing consistency violates crucial correctness properties. A compromise is to allow multiple consistency levels to coexist in the data store. In this paper we present UNISTORE, the first fault-tolerant and scalable data store that combines causal and strong consistency. The key challenge we address in UNISTORE is to maintain liveness despite data center failures: this could be compromised if a strong transaction takes a dependency on a causal transaction that is later lost because of a failure. UNISTORE ensures that such situations do not arise while paying the cost of durability for causal transactions only when necessary. We evaluate UNISTORE on Amazon EC2 using both microbenchmarks and a sample application. Our results show that UNISTORE effectively and scalably combines causal and strong consistency.

1 Introduction

Many of today's Internet services rely on geo-distributed data stores, which replicate data in different geographical locations. This improves user experience by allowing accesses to the closest site and ensures disaster-tolerance. However, geo-distribution also makes it more challenging to keep the data consistent. The classical approach is to make replication transparent to clients by providing strong consistency models, such as linearizability [33] or serializability [70]. The downside is that this approach requires synchronization between data centers in the critical path. This significantly increases latency [1] and makes the system unavailable during network partitionings [28]. Thus, even though several commercial geo-distributed systems follow this approach [18, 20, 26, 63, 71], the associated cost has prevented it from being adopted more widely.

An alternative approach is to relax synchronization: the data store executes an operation at a single data center, without any communication with others, and propagates updates to other data centers in the background [21, 66]. This minimizes the latency and makes the system *highly available*, i.e., operational even during network partitionings. But on the downside, the systems following this approach provide weaker consistency models: e.g., eventual consistency [66, 69] or *causal consistency* [2]. The latter is particularly appealing: it guarantees that clients see updates in an order that respects the potential causality between them. For example, assume that in a banking application Alice deposits \$100 into Bob's account (u_1) and then posts a notification about it into Bob's inbox (u_2). Under causal consistency, if Bob sees the notification (u_3), and then checks his account balance (u_4), he will see the deposit. This is not guaranteed under eventual consistency, which does not respect causality relationships, such as those between u_1 and u_2 . In some settings, causal consistency has been shown to be the strongest model that allows availability during network partitionings [7, 45]. It has been a subject of active research in recent years, with scalable implementations [3, 43, 48] and some industrial deployments [55, 67].

However, even causal consistency is often too weak to preserve critical application invariants. For example, consider a banking application that disallows overdrafts and thus maintains an invariant that an account balance is always non-negative. Assume that the balance of an account stored at two replicas is 100, and clients concurrently issue two `withdraw(100)` operations (u_5 and u_6) at different replicas. Since causal consistency executes operations without synchronization, both withdrawals will succeed, and once the replicas exchange the updates, the balance will go negative. To ensure integrity invariants in examples such as this, the programmer has to introduce synchronization between replicas, and, since synchronization is expensive, it pays off to do this sparingly. To this end, several research [9, 41, 42, 65] and commercial [5, 6, 29, 49, 58] data stores allow the programmer to choose whether to execute a particular operation under weak or strong consistency. For example, to preserve the integrity

*Also with the State Key Laboratory for Novel Software Technology, Software Institute.

invariant in our banking application, only withdrawals need to use strong consistency, and hence, synchronize; deposits may use weaker consistency and proceed without synchronization.

Given the benefits of causal consistency, it is particularly appealing to marry it with strong consistency in a geo-distributed data store. But like real-life marriages, to be successful this one needs to hold together both in good times and in bad – when data centers fail due to catastrophic events or power outages. Unfortunately, none of the existing data stores meant for geo-replication combine causal and strong consistency while providing such fault tolerance [9, 41, 42]. In this paper we present UNISTORE – the first fault-tolerant and scalable data store that combines causal and strong consistency. More precisely, UNISTORE implements a transactional variant of *Partial Order-Restrictions consistency (PoR consistency)* [31, 42]. This guarantees transactional causal consistency by default [3] and allows the programmer to additionally specify which pairs of transactions *conflict*, i.e., have to synchronize. For instance, to preserve the integrity invariant in our previous example, the programmer should declare that withdrawals from the same account conflict. Then one of the withdrawals u_5 and u_6 will observe the other and will fail.

The key challenge we have to address in UNISTORE is to maintain liveness despite data center failures. Just adding a Paxos-based commit protocol for strong transactions [19, 20, 35] to an existing causally consistent protocol does not yield a fault-tolerant data store. In such a data store, a committed strong transaction t_2 may never become visible to clients if a causal transaction t_1 on which it depends is lost due to a failure of its origin data center. This compromises the liveness of the system, because no transaction t_3 conflicting with t_2 can commit from now on: according to the PoR model, one of the transactions t_2 and t_3 has to observe the other, but t_2 will never be visible and t_2 did not observe t_3 .

UNISTORE addresses this problem by ensuring that, before a strong transaction commits, all its causal dependencies are *uniform*, i.e., will eventually become visible at all correct data centers. This adapts the classical notion of uniformity in distributed computing to causal consistency [16]. UNISTORE does so without defeating the benefits of causal consistency. Causal transactions remain highly available at the cost of increasing the latency of strong transactions: a strong transaction may have to wait for some of its dependencies to become uniform before committing. To minimize this cost, UNISTORE executes causal transactions on a snapshot that is slightly in the past, such that a strong transaction will mostly depend on causal transactions that are already uniform before committing. Furthermore, UNISTORE reuses the mechanism for tracking uniformity to let clients make causal transaction durable on demand and to enable consistent client migration.

In addition to being fault tolerant, UNISTORE scales horizontally, i.e., with the number of machines in each data center; this also goes beyond previous proposals [9, 41, 42]. To this end, UNISTORE builds on Cure [3] – a scalable implementa-

tion of transactional causal consistency. Our protocol extends Cure with a novel mechanism that distributes the task of tracking the set of uniform transactions among the machines of a data center. We also add the ability for data centers to forward transactions they receive from others, so that a transaction can propagate through the system even if its origin data center fails. Finally, we carefully integrate an existing fault-tolerant atomic commit for strong transactions [19] into the protocol for causal consistency.

We have rigorously proved the correctness of the UNISTORE protocol (§7 and [12, §D]). We have also evaluated it on Amazon EC2 using both microbenchmarks and a more realistic RUBiS benchmark. Our evaluation demonstrates that UNISTORE scalably combines causal and strong transactions, with the latter not affecting the performance of the former. Under the RUBiS mix workload, causal transactions exhibit a low latency (1.2ms on average), and the overall average latency is $3.7\times$ lower than that of a strongly consistent system.

2 System Model

We consider a geo-distributed system consisting of a set of data centers $\mathcal{D} = \{1, \dots, D\}$ that manage a large set of data items. A data item is uniquely identified by its *key*. For scalability, the key space is split into a set of logical partitions $\mathcal{P} = \{1, \dots, N\}$. Each data center stores replicas of all partitions, scattered among its servers. We let p_d^m be the replica of partition m at data center d , and we refer to replicas of the same partition as *sibling* replicas. As is standard, we assume that $D = 2f + 1$ and at most f data centers may fail. We call a data center that does not fail *correct*. If a data center fails, all partition replicas it stores become unavailable. For simplicity, we do not consider the failures of individual replicas within a data center: these can be masked using standard state-machine replication protocols executing within a data center [38, 56].

Replicas have physical clocks, which are loosely synchronized by a protocol such as NTP. The correctness of UNISTORE does not depend on the precision of clock synchronization, but large drifts may negatively impact its performance. Any two replicas are connected by a reliable FIFO channel, so that messages between correct data centers are guaranteed to be delivered. As is standard, to implement strong consistency we require the network to be *eventually synchronous*, so that message delays between sibling replicas in correct data centers are eventually bounded by some constant [24].

3 Consistency Model

A client interacts with UNISTORE by executing a stream of *transactions* at the data center it is connected to. A transaction consists of a sequence of operations, each on a single data item, and can be *interactive*: the data items it accesses are not known a priori. A transaction that modifies at least one data item is an *update* transaction; otherwise it is *read-only*.

A *consistency model* defines a contract between the data store and its clients that specifies which values the data store is allowed to return in response to client operations. UNISTORE implements a transactional variant of *Partial Order-Restrictions consistency (PoR consistency)* [31, 42], which we now define informally; we give a formal definition in [12, §B]. The PoR model enables the programmer to classify transactions as either *causal* or *strong*. Causal transactions satisfy transactional *causal consistency*, which guarantees that clients see transactions in an order that respects the potential causality between them [2, 3]. However, clients can observe causally independent transactions in arbitrary order. Strong transactions give the programmer more control over their visibility. To this end, the programmer provides a symmetric *conflict relation* \bowtie on operations that is lifted to strong transactions as follows: two transactions conflict if they perform conflicting operations on the same data item. Then the PoR model guarantees that, out of two conflicting strong transactions, one has to observe the other.

More precisely, a transaction t_1 precedes a transaction t_2 in the *session order* if they are executed by the same client and t_1 is executed before t_2 . A set of transactions T committed by the data store satisfies PoR consistency if there exists a *causal order relation* \prec on T such that the following properties hold:

Causality Preservation. The relation \prec is transitive, irreflexive, and includes the session order.

Return Value Consistency. Consider an operation u on a data item k in a transaction $t \in T$. The return value of u can be computed from the state of k obtained as follows: first execute all operations on k by transactions preceding t in \prec in an order consistent with \prec ; then execute all operations on k that precede u in t .

Conflict Ordering. For any distinct strong transactions $t_1, t_2 \in T$, if $t_1 \bowtie t_2$, then either $t_1 \prec t_2$ or $t_2 \prec t_1$.

Eventual Visibility. A transaction $t \in T$ that is either strong or originates at a correct data center eventually becomes visible at all correct data centers: from some point on, t precedes in \prec all transactions issued at correct data centers.

If all transactions are causal, then the above definition specializes to transactional causal consistency [3, 17]. If all transactions are strong and all pairs of operations conflict, then we obtain (non-strict) serializability.

When $t_1 \prec t_2$, we say that t_1 is a *causal dependency* of t_2 . Return Value Consistency ensures that all operations in a transaction t execute on a snapshot consisting of its causal dependencies (as well as prior operations by t). Transactions are atomic, so that either all of their operations are included into the snapshot or none at all. The transitivity of \prec , mandated by Causality Preservation, ensures that the snapshot a transaction executes on is *causally consistent*: if a transaction t_1 is included into the snapshot, then so is any other transaction t_2 on which t_1 depends (i.e., $t_2 \prec t_1$). The inclusion of the session order into \prec , also mandated by Causality Preservation,

ensures session guarantees such as *read your writes* [64]. The consistency model disallows the causality violation anomaly from §1. Indeed, since \prec includes the session order, we have $u_1 \prec u_2$ and $u_3 \prec u_4$. Moreover, Bob sees Alice’s message, and by Return Value Consistency this can only happen if $u_2 \prec u_3$. Then since \prec is transitive, $u_1 \prec u_4$, and by Return Value Consistency, Bob has to see Alice’s deposit.

Causal consistency nevertheless allows the overdraft anomaly from §1: the withdrawals u_5 and u_6 may not be related by \prec , and thus may both execute on the balance 100 and succeed. The Conflict Ordering property can be used to disallow this anomaly by declaring that `withdraw` operations on the same account conflict and labeling transactions containing these as strong. Then one of the withdrawal transactions will be guaranteed to causally precede the other. The latter will be executed on the account balance 0 and will fail.

Finally, Eventual Visibility ensures that strong transactions and those causal ones that originate at correct data centers are durable, i.e., will eventually propagate through the system.

To facilitate the use of causal transactions, UNISTORE includes *replicated data types* (aka CRDTs), which implement policies for merging concurrent updates to the same data item [57]. Each data item in the store is associated with a type (e.g., counter, set), which is backed by a CRDT implementation managing updates to it. For example, the programmer can use a counter CRDT to represent an account balance. Then if two clients concurrently deposit 100 and 200 into an empty account using causal transactions, eventually the balance at all replicas will be 300. Using ordinary writes here would yield 100 or 200, depending on the order in which the writes are applied. More generally, CRDTs ensure that two replicas receiving the same set of updates are in the same state, regardless of the receipt order. Together with Eventual Visibility, this implies the expected guarantee of eventual consistency [66]. Due to space constraints, we omit details about the use of CRDTs from our protocol descriptions.

4 Key Design Decisions in UNISTORE

Baseline causal consistency. A causal transaction in UNISTORE first executes at a single data center on a causally consistent snapshot. After this it immediately commits, and its updates are replicated to all other data centers in the background. This minimizes the latency of causal transactions and makes them highly available, i.e., they can be executed even when the network connections between data centers fail.

As is common in causally consistent data stores [3, 23, 43], to ensure that causal transactions execute on consistent snapshots, a data center exposes a remote transaction to clients only after exposing all its dependencies. Then to satisfy the Eventual Visibility property under failures, a data center receiving a remote causal transaction may need to forward it to other data centers, as in reliable broadcast [11] and anti-entropy protocols for replica reconciliation [54].

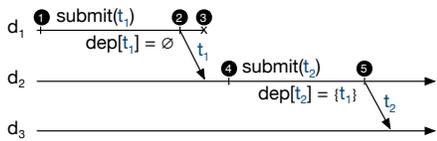

Figure 1: Why UNISTORE may need to forward remote causal transactions.

Figure 1 depicts a scenario that demonstrates how Eventual Visibility could be violated in the absence of this mechanism. Let t_1 be a causal transaction submitted at a data center d_1 (event 1). Assume that d_1 replicates t_1 to a correct data center d_2 (event 2) and then fails (event 3), so that t_1 does not get replicated anywhere else. Let t_2 be a transaction submitted at d_2 after t_1 becomes visible there, so that t_2 depends on t_1 (event 4). Transaction t_2 will eventually be replicated to all correct data centers (event 5). But it will never be exposed at any of them, because its dependency t_1 is missing. If data centers can forward remote causal transactions, then d_2 can eventually replicate t_1 to all correct data centers, preventing this problem.

On-demand strong consistency. UNISTORE uses optimistic concurrency control for strong transactions: they are first executed speculatively and the results are then *certified* to determine whether the transaction can commit, or must abort due to a conflict with a concurrent strong transaction [70]. Certifying a strong transaction requires synchronization between the replicas of partitions it accessed, located in different data centers. UNISTORE implements this using an existing fault-tolerant protocol that combines two-phase commit and Paxos [19] while minimizing commit latency. However, just using such a protocol is not enough to make the overall system fault tolerant: for this, before a strong transaction commits, all its causal dependencies must be uniform in the following sense.

DEFINITION 1. A transaction is *uniform* if both the transaction and its causal dependencies are guaranteed to be eventually replicated at all correct data centers.

This adapts the classical notion of uniformity in distributed computing to causal consistency [16]. UNISTORE considers a transaction to be uniform once it is visible at $f + 1$ data centers, because at least one of these must be correct, and data centers can forward causal transactions to others.

The following scenario, depicted in Figure 2, demonstrates why committing a strong transaction before its dependencies become uniform can compromise the liveness of the system. Assume that a causal transaction t_1 and a strong transaction t_2 are submitted at a data center d_1 in such a way that t_1 becomes a dependency of t_2 (events 1 and 2). Assume also that t_2 is certified, committed and delivered to all relevant replicas (events 3 and 4) before t_1 is replicated to any data center, and thus before it is uniform. Now if d_1 fails before

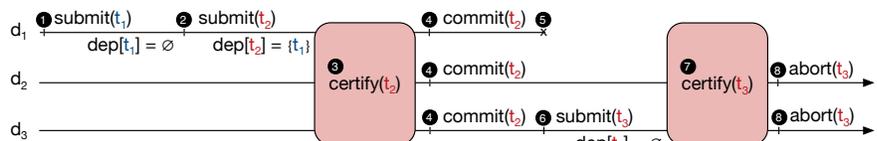

Figure 2: Why UNISTORE needs to ensure that the dependencies of a strong transaction are uniform before committing it.

replicating t_1 (event 5), no remote data center will be able to expose t_2 , because its dependency t_1 is missing. This violates the Eventual Visibility property, and even worse, no strong transaction conflicting with t_2 can commit from now on. For instance, let t_3 be such a transaction, submitted at d_3 (event 6). Because d_3 cannot expose t_2 , transaction t_3 executes on a snapshot excluding t_2 . Hence, t_3 will abort during certification (events 7 and 8): committing it would violate the Conflict Ordering property, since transactions t_2 and t_3 conflict, but neither of them is visible to the other. Ensuring that t_1 is uniform before committing t_2 prevents this problem, because it guarantees that t_1 will eventually be replicated at d_3 . After this t_2 will be exposed to conflicting transactions at this data center, which will allow them to commit.

Minimizing the latency of strong transactions. Ensuring that all the causal dependencies of a strong transaction are uniform before committing it may significantly increase its latency, since this requires additional communication between data centers. UNISTORE mitigates this problem by executing causal transactions on a snapshot that is slightly in the past, which is allowed by causal consistency. Namely, UNISTORE makes a remote causal transaction visible to the clients only after it is uniform. This minimizes the latency of a strong transaction, since to commit it only needs to wait for causal transactions originating at the local data center to become uniform. We cannot delay the visibility of the latter transactions due to the need to guarantee *read your writes* to local clients.

On-demand durability of causal transactions. Client applications interacting with the external world require hard durability guarantees: e.g., a banking application has to ensure that a withdrawal is durably recorded before authorizing the operation. UNISTORE guarantees that, once a strong transaction commits, the transaction and its dependencies are durable. However, UNISTORE returns from a causal transaction before it is replicated, and thus the transaction may be lost if its origin data center fails. Ensuring the durability of every single causal transaction would require synchronization between data centers on its critical path, defeating the benefits of causal consistency. Instead, UNISTORE reuses the mechanism for tracking uniformity to let the clients pay the cost of durability only when necessary. Even though UNISTORE replicates causal transactions asynchronously, it allows clients to execute a *uniform barrier*, which ensures that the transactions they have observed so far are uniform, and thus durable.

Client migration. Clients may need to migrate between data centers, e.g., because of roaming or for load balancing. UNISTORE also uses the uniformity mechanism to preserve session guarantees during migration. A client wishing to migrate from its local data center d to another data center i first invokes a uniform barrier at d . This guarantees that the transactions the client has observed or issued at d are durable and will eventually become visible at i , even if d fails. The client then makes an *attach* call at the destination data center i that waits until i stores all the above transactions. After this, the client can operate at i knowing that the state of the data center is consistent with the client's previous actions.

Currently UNISTORE does not support consistent client migration in response to a data center failure: if the data center a client is connected to fails, the client will have to restart its session when connecting to a different data center. As shown in [72], this limitation can be lifted without defeating the benefits of causal consistency. We leave integrating the corresponding mechanisms into UNISTORE for future work.

5 Fault-Tolerant Causal Consistency Protocol

We first describe the UNISTORE protocol for the case when all transactions are causal. We give its pseudocode in Algorithms 1 and 2; for now the reader should ignore highlighted lines, which are needed for strong transactions. For simplicity, we assume that each handler in the algorithms executes atomically (although our implementation is parallelized). We reference pseudocode lines using the format `algorithm#:line#`.

5.1 Metadata

Most metadata in our protocol are represented by vectors with an entry per each data center, where each entry stores a scalar timestamp. However, different pieces of metadata use the vectors in different ways, which we now describe.

Tracking causality. The first use of the vectors is as vector clocks [27, 47], to track causality between transactions. Given vectors V_1 and V_2 , we write $V_1 < V_2$ if each entry of V_1 is no greater than the corresponding entry of V_2 , and at least one is strictly smaller. Each update transaction is tagged with a *commit vector* $commitVec$. The order on these vectors is consistent with the causal order \prec from §3: if $commitVec_1$ and $commitVec_2$ are the commit vectors of two update transactions t_1 and t_2 such that $t_1 \prec t_2$, then $commitVec_1 < commitVec_2$. For a transaction originating at a data center d with a commit vector $commitVec$, we call $commitVec[d]$ its *local timestamp*.

Each replica p_d^m maintains a log `opLog[k]` of update operations performed on each data item k stored at the replica. Each log entry stores, together with the operation, the commit vector of the transaction that performed it. This allows reconstructing different versions of a data item from its log.

Representing causally consistent snapshots. The protocol also uses a vector to represent a snapshot of the data store

on which a transaction operates: a snapshot vector V represents all transactions with a commit vector $\leq V$. This snapshot is causally consistent. Indeed, consider a transaction t_1 included into it, i.e., $commitVec_1 \leq V$. Since any causal dependency t_0 of t_1 is such that $commitVec_0 < commitVec_1$, we have $commitVec_0 < V$, so that t_0 is also included into the snapshot. A client also maintains a vector `pastVec` that represents its *causal past*: a causally consistent snapshot including the update transactions the client has previously observed.

Tracking what is replicated where. Each replica p_d^m maintains three vectors that are used to compute which transactions are uniform. These respectively track the sets of transactions replicated at p_d^m , the local data center d , and $f + 1$ data centers. Each of these vectors V represents the set of update transactions originating at a data center i with a local timestamp $\leq V[i]$. Note that this set may not form a causally consistent snapshot. The first vector maintained by p_d^m is `knownVec`. For each data center i , it defines the prefix of update transactions originating at i (in the order of local timestamps) that p_d^m knows about.

PROPERTY 1. For each data center i , the replica p_d^m stores the updates to partition m by all transactions originating at i with local timestamps $\leq \text{knownVec}[i]$.

Our protocol ensures that $\text{knownVec}[d] \leq \text{clock}$ at any replica in data center d . The vector `knownVec` at p_d^m records whether the updates to partition m by a given transaction are stored at this replica. In contrast, the next vector `stableVec` records whether the updates to *all* partitions by a transaction are stored at the local data center d .

PROPERTY 2. For each data center i , the data center d stores the updates by all transactions originating at i with local timestamps $\leq \text{stableVec}[i]$. More precisely, we are guaranteed that $\text{knownVec}[i]$ at any replica of $d \geq \text{stableVec}[i]$ at any p_d^m .

Finally, the last vector `uniformVec` defines the set of update transactions that p_d^m knows to have been replicated at $f + 1$ data centers, including d .

PROPERTY 3. Consider `uniformVec[i]` at p_d^m . All update transactions originating at i with local timestamps $\leq \text{uniformVec}[i]$ are replicated at $f + 1$ datacenters including d . More precisely: $\text{knownVec}[i]$ at any replica of these data centers $\geq \text{uniformVec}[i]$ at p_d^m .

When `uniformVec` is reinterpreted as a causally consistent snapshot, it defines transactions that p_d^m knows to be uniform according to Definition 1:

PROPERTY 4. Consider `uniformVec` at p_d^m . All update transactions with commit vectors $\leq \text{uniformVec}$ are uniform.

Proof sketch. Consider a transaction t_1 that originates at a data center i with a commit vector $commitVec_1 \leq \text{uniformVec}$ at p_d^m . In particular, $commitVec_1[i] \leq \text{uniformVec}[i]$, and by Property 3, t_1 is replicated at $f + 1$ data centers. We as-

sume at most f failures. Then the transaction forwarding mechanism of our protocol (§4) guarantees that t_1 will eventually be replicated at all correct data centers. Consider now any causal dependency t_2 of t_1 with a commit vector $commitVec_2$. Since commit vectors are consistent with causality, $commitVec_2 < commitVec_1 \leq uniformVec$. Then as above, we can again establish that t_2 will be replicated at all correct data centers, as required by Definition 1. \square

5.2 Causal Transaction Execution

Starting a transaction. A client can submit a transaction to any replica in its local data center by calling `START_TX(V)`, where V is the client’s causal past `pastVec` (line 1:1, for brevity, we omit the pseudocode of the client). A replica p_d^m receiving such a request acts as the transaction *coordinator*. It generates a unique transaction identifier tid , computes a snapshot `snapVec[tid]` on which the transaction will execute, and returns tid to the client (we explain lines 1:2-3 and similar ones later). The snapshot is computed by combining uniform transactions from `uniformVec` (line 1:5) with the transactions from the client’s causal past originating at d (line 1:6). The former is crucial to minimize the latency of strong transactions (§4), while the latter ensures *read your writes*.

Transaction execution. The client proceeds to execute the transaction tid by issuing a sequence of operations at its coordinator via `DO_OP` (line 1:9). When the coordinator receives an operation op on a data item k , it sends a `GET_VERSION` message with the transaction’s snapshot `snapVec[tid]` to the local replica responsible for k (line 1:11). Upon receiving the message (line 1:18), the replica first ensures that it is as up-to-date as required by the snapshot (line 1:21). It then computes the latest version of k within the snapshot by applying the operations from `opLog[k]` by all transactions with commit vectors $\leq snapVec[tid]$. The result is sent to the coordinator in a `VERSION` message. After receiving it (line 1:12), the coordinator further applies the operations on k previously executed by the transaction, which are stored in a buffer `wbuff[tid]`; this ensures *read your writes* within the transaction. If the operation is an update, the coordinator then appends it to `wbuff[tid]`. Finally, the coordinator executes the desired operation op and forwards its return value to the client.

Commit. A client commits a causal transaction by calling `COMMIT_CAUSAL` (line 1:26). This returns immediately if the transaction is read-only, since it already read a consistent snapshot (line 1:28). To commit an update transaction, `UNISTORE` uses a variant of two-phase commit protocol (recall that for simplicity we only consider whole-data center failures, not those of individual replicas, §2). The coordinator first sends a `PREPARE` message to the replicas in the local data center storing the data items updated by the transaction (line 1:29). The message to each replica contains the part of the write buffer relevant to that replica. When a replica receives the message (line 1:36), it computes the transaction’s

Algorithm 1 Transaction execution at p_d^m .

```

```

prepare time ts from its local clock and adds the transaction to preparedCausal, which stores the set of causal transactions that are prepared to commit at the replica. The replica then returns ts to the coordinator in a PREPARE_ACK message.

When the coordinator receives replies from all replicas updated by the transaction, it computes the transaction's commit vector $commitVec$: it sets the local timestamp $commitVec[d]$ to the maximum among the prepare times proposed by the replicas (line 1:33), and it copies the other entries of $commitVec$ from the snapshot vector $snapVec[tid]$ (line 1:30). The latter reflects the fact that the transactions in the snapshot become causal dependencies of tid .

After computing $commitVec$, the coordinator sends it in a COMMIT message to the relevant replicas at the local data center (line 1:34) and returns it to the client (line 1:35). The client then sets its causal past pastVec to the commit vector. When a replica receives the COMMIT message (line 1:42), it removes the transaction from preparedCausal, adds the transaction's updates to opLog, and adds the transaction to a set committedCausal[d], which stores transactions waiting to be replicated to sibling replicas at other data centers.

5.3 Transaction Replication

Each replica p_d^m periodically replicates locally committed update transactions to sibling replicas in other data centers by executing PROPAGATE_LOCAL_TXS (line 2:1). Transactions are replicated in the order of their local timestamps. The prefix of transactions that is ready to be replicated is determined by knownVec[d]: according to Property 1, p_d^m stores updates to m by all transactions originating at d with local timestamps \leq knownVec[d]. Thus, the replica first updates knownVec[d] while preserving Property 1.

There are two cases of this update. If the replica does not have any prepared transactions (preparedCausal = \emptyset), it sets knownVec[d] to the current value of the clock (line 2:2). This preserves Property 1 because in this case a new transaction originating at d and updating m will get a prepare time at m higher than the current clock (line 1:39), and thus also a higher local timestamp (line 1:33). If the replica has some prepared transactions, then they may end up getting local timestamps lower than the current clock. In this case, the replica sets knownVec[d] to just below the smallest prepared time (line 2:3). This preserves Property 1 because: (i) currently prepared transactions will get a local timestamp no lower than their prepare time; and (ii) as we argued above, new transactions will get a prepare time higher than the current clock and, hence, than the smallest prepare time.

After updating knownVec[d], the replica sends a REPLICATE message to its siblings with the transactions in committedCausal[d] such that $commitVec[d] \leq$ knownVec[d], and then removes them from committedCausal[d]. In other words, the replica sends all transactions from the prefix determined by knownVec[d] that it has not yet replicated.

When a replica p_d^m receives a REPLICATE message with

Algorithm 2 Transaction replication at p_d^m .

```

```

a set of transactions txs originating at a sibling replica p_i^m (line 2:9), it iterates over txs in $commitVec[i]$ order. For each new transaction in txs with commit vector $commitVec$, the replica adds the transaction's operations to its log and sets knownVec[i] = $commitVec[i]$. Since communication channels are FIFO, p_d^m processes all transactions from p_i^m in their local timestamp order. Hence, the above update to knownVec[i] preserves Property 1: p_d^m stores updates originating at p_i^m by all transactions with $commitVec[i] \leq$ knownVec[i]. Finally, the replica adds the transactions to committedCausal[i], which is used to implement transaction forwarding (§4). Due to

the forwarding, p_d^m may receive the same transaction from different data centers. Thus, when processing transactions in the REPLICATE message, it checks for duplicates (line 2:11).

5.4 Advancing the Uniform Snapshot

Replicas run a background protocol that refreshes the information about uniform transactions. This proceeds in two stages. First, a replica keeps track of which transactions have been replicated at the replicas of other partitions in the same data center. To this end, replicas in the same data center periodically exchange KNOWNVEC_LOCAL messages with their knownVec vectors, which they store in a matrix localMatrix (lines 2:24 and 2:27); in our implementation this is done via a dissemination tree. This matrix is then used to compute the vector stableVec, which represents the set of transactions that have been fully replicated at the local data center as per Property 2. To ensure this, a replica computes an entry $\text{stableVec}[i]$ as the minimum of $\text{knownVec}[i]$ it received from the replicas of other partitions in the same data center (line 2:29).

In the second stage of the background protocol, sibling replicas periodically exchange STABLEVEC messages with their stableVec vectors, which they store in a matrix stableMatrix (lines 2:25 and 2:31). This matrix is then used by a replica to compute uniformVec, which characterizes the update transactions that are replicated at $f + 1$ data centers as per Property 3. To this end, a replica first enumerates all groups G of $f + 1$ data centers that include its local data center (line 2:33). For each data center j the replica performs the following computation. First, for each group $g \in G$, it computes the minimum j -th entry in the stable vectors of all data centers $h \in g$: $\min\{\text{stableMatrix}[h][j] \mid h \in g\}$. By Property 2 all update transactions originating at j with local timestamp \leq the minimum have been replicated at all data centers in g . The replica then sets $\text{uniformVec}[j]$ to the maximum of the resulting values computed for all groups $g \in G$, to cover transactions that are replicated at any such group. According to Property 4, the transactions with commit vectors \leq uniformVec are uniform, and now become visible to transactions coordinated by p_d^m (§5.2).

Replicas also update uniformVec in lines 1:2-3, 1:19-20 and 1:37-38 by incorporating $\text{snapVec}[i]$ for remote data centers i . This is safe because a transaction executes on a snapshot that only includes uniform remote transactions.

Finally, if a replica does not receive new transactions for a long time, it sends the value of its $\text{knownVec}[d]$ as a heartbeat (lines 2:8 and 2:16). This allows advancing stableVec and uniformVec even under skewed load distributions.

5.5 Transaction Forwarding

As we explained in §4, to guarantee that a transaction originating at a correct data center eventually becomes exposed at all correct data centers despite failures (Eventual Visibility), replicas may have to forward remote update transactions. To determine which transactions to forward, each replica keeps track

of the update transactions that have been replicated at sibling replicas in other data centers. To this end, sibling replicas periodically exchange KNOWNVEC_GLOBAL messages with their knownVec vectors, which they store in a matrix globalMatrix (lines 2:26 and 2:37). Thus, p_i^m has received all update transactions from p_j^m with $\text{commitVec}[j] \leq \text{globalMatrix}[i][j]$.

A replica p_d^m only forwards transactions when it suspects that a data center j may have failed before replicating all the update transactions originating at it to a data center i (this information is provided by a separate module). In this case, p_d^m executes FORWARD_REMOTE_TXS(i, j) (line 2:19). The function forwards the set of transactions txs received from p_j^m that have not been replicated at p_i^m according to $\text{globalMatrix}[i][j]$. For example, in Figure 1, UNISTORE will eventually invoke FORWARD_REMOTE_TXS(d_1, d_3) at replicas in d_2 to forward t_1 . The replica p_d^m sends the transactions in txs to p_i^m in a REPLICATE message. If there are no update transactions to forward, p_d^m sends a heartbeat to p_i^m with $\text{knownVec}[j]$.

UNISTORE periodically deletes from committedCausal transactions that have been replicated at every data center (omitted from the pseudocode for brevity).

5.6 On-Demand Durability and Client Migration

A client may wish to ensure that the transactions it has observed so far are durable. To this end, the client can call UNIFORM_BARRIER(V) at any replica in its local data center d , where V is the client's causal past pastVec (line 1:49). The replica returns to the client only when all the transactions from pastVec that originate at d are uniform, and thus durable. Then the same holds for all transactions from pastVec , because the protocol only exposes remote transactions to clients when they are already uniform (§5.2).

A client wishing to migrate from its local data center d to another data center i first calls UNIFORM_BARRIER(V) at any replica in d with $V = \text{pastVec}$, to ensure that the transactions the client has observed or issued at d will eventually become visible at i . The client then calls ATTACH(V) at any replica in i (line 1:51). The replica returns when its uniformVec includes all remote transactions from V (line 1:52). The client can then be sure that its transactions at i will operate on snapshots including all the transactions it has observed before.

6 Adding Strong Transactions

We now describe the full UNISTORE protocol with both causal and strong transactions. It is obtained by adding the highlighted lines to Algorithms 1-2 and a new Algorithm 3.

6.1 Metadata

The Conflict Ordering property of our consistency model requires any two conflicting strong transactions to be related one way or another by the causal order \prec (§3). To ensure this, the protocol assigns to each strong transaction a scalar

strong timestamp, analogous to those used in optimistic concurrency control for serializability [70]. Several vectors used as metadata in the causal consistency protocol (§5.1) are then extended with an extra *strong* entry.

First, we extend commit vectors and those representing causally consistent snapshots. Commit vectors are compared using the previous order $<$, but considering all entries; as before, this order is consistent with the causal order \prec . Furthermore, conflicting strong transactions are causally ordered according to their strong timestamps.

PROPERTY 5. For any conflicting strong transactions t_1 and t_2 with commit vectors $commitVec_1$ and $commitVec_2$, we have: $t_1 \prec t_2 \iff commitVec_1[strong] < commitVec_2[strong]$.

A consistent snapshot vector V now defines the set of transactions with a commit vector $\leq V$, according to the new $<$. The vectors $knownVec$ and $stableVec$ maintained by a replica p_d^m are also extended with a *strong* entry. The entries $knownVec[strong]$ and $stableVec[strong]$ define the prefix of strong transactions that have been replicated at p_d^m and the local data center d , respectively:

PROPERTY 6. Replica p_d^m stores the updates to m by all strong transactions with $commitVec[strong] \leq knownVec[strong]$.

PROPERTY 7. Data center d stores the updates by all strong transactions with $commitVec[strong] \leq stableVec[strong]$.

To ensure Property 7, the *strong* entry of $stableVec$ is updated at line 2:30 similarly to its other entries. We do not extend $uniformVec$, because our commit protocol for strong transactions automatically guarantees their uniformity.

6.2 Transaction Execution

UNISTORE uses optimistic concurrency control for strong transactions, with the same protocol for executing causal and speculatively executing strong transactions. To this end, Algorithm 1 is modified as follows. First, the computation of the snapshot vector $snapVec[tid]$ is extended to compute the *strong* entry (line 1:7), which is now taken into account when checking that a replica state is up to date (line 1:21). The *strong* entry of the snapshot vector is computed so as to include all strong transactions known to be fully replicated in the local data center, as defined by $stableVec[strong]$. To ensure *read your writes*, the snapshot additionally includes strong transactions from the client’s causal past, as defined by $V[strong]$. Finally, the coordinator of a transaction now maintains not only its write set, but also its read set $rset$ that records all operations by the transaction, including read-only ones (line 1:14). The latter is used to certify strong transactions.

After speculatively executing a strong transaction, the client tries to commit it by calling `COMMIT_STRONG` at its coordinator (line 3:1). The coordinator first waits until the snapshot on which the transaction operated becomes uniform by calling `UNIFORM_BARRIER` (line 3:2): as we argued in §4, this is crucial for liveness. The coordinator next submits the trans-

Algorithm 3 Committing strong transactions at p_d^m .

```

1: function COMMIT_STRONG(tid)
2:   UNIFORM_BARRIER(snapVec[tid])
3:   return CERTIFY(tid, wbuff[tid], rset[tid], snapVec[tid])

4: upon DELIVER_UPDATES(W)
5:   for all  $\langle wbuff, commitVec \rangle \in W$  in  $commitVec[strong]$  order do
6:     for all  $\langle k, op \rangle \in wbuff$  do
7:       opLog[k]  $\leftarrow$  opLog[k]  $\cdot \langle op, commitVec \rangle$ 
8:       knownVec[strong]  $\leftarrow$  commitVec[strong]

9: function HEARTBEAT_STRONG() ▷ Run periodically
10:  return CERTIFY( $\perp, \emptyset, \emptyset, \vec{0}$ )

```

action to a *certification service*, which determines whether the transaction commits or aborts (line 3:3, see §6.3). In the former case, the service also determines its commit vector, which the coordinator returns to the client. If the transaction commits, the client sets its causal past $pastVec$ to the commit vector; otherwise, it re-executes the transaction.

The certification service also notifies replicas in all data centers about updates by strong transactions affecting them via `DELIVER_UPDATES` upcalls, invoked in an order consistent with strong timestamps of the transactions (line 3:4). A replica receiving an upcall adds the new operations to its log and refreshes $knownVec[strong]$ to preserve Property 6.

Finally, a replica p_d^m that has not seen any strong transactions updating its partition m for a long time submits a dummy strong transaction that acts as a heartbeat (line 3:9). Similarly to heartbeats for causal transactions, this allows coping with skewed load distributions.

6.3 Certification Service

We implement the certification service using an existing fault-tolerant protocol from [19], with transaction commit vectors computed using the techniques from [30]. The protocol integrates two-phase commit across partitions accessed by the transaction and Paxos among the replicas of each partition. It furthermore uses white-box optimizations between the two protocols to minimize the commit latency. The use of Paxos ensures that a committed strong transaction is durable and its updates will eventually be delivered at all correct data centers (line 3:4). For each partition, a single replica functions as the Paxos leader. The protocol is described and formally specified elsewhere [19], and here we discuss it only briefly. Its pseudocode and formal specification are given in [12, §A] and [12, §C], respectively.

The certification service accepts the read and write sets of a transaction and its snapshot vector (line 3:3). Even though the service is distributed, it guarantees that commit/abort decisions are computed like in a centralized database with optimistic concurrency control – in a total *certification order*. To ensure Conflict Ordering, the decisions are computed using a concurrency-control policy similar to that for serializability [70]: a transaction commits if its snapshot includes all

conflicting transactions that precede it in the certification order. The certification service also computes a commit vector for each committed transaction by copying its per-data center entries from the transaction’s snapshot vector and assigning a strong timestamp consistent with the certification order.

7 Proof of Correctness

We have rigorously proved that UNISTORE correctly implements the specification of PoR consistency for the case when the data store manages last-writer-wins registers. The proof uses the formal framework from [14, 15, 17] and establishes Properties 1-7 stated earlier. Due to space constraints, we defer the proof to [12, §D].

8 Evaluation

We have implemented UNISTORE and several other protocols (listed in the following) in the same codebase, consisting of 10.3K SLOC of Erlang. We evaluate the protocols on Amazon EC2 using m4.2xlarge VMs from 5 different regions. Each VM has 8 virtual cores and 32GB of RAM. The RTT between regions ranges from 26ms to 202ms. Unless otherwise stated, our experiments deploy 3 data centers, thus tolerating a single data center failure: Virginia (US-East), California (US-West) and Frankfurt (EU-FRA). All Paxos leaders are located in Virginia. By default we use 4 replica machines per data center. Each machine stores replicas of 8 partitions, matching the number of cores. Clients are hosted on separate machines in each data center. We run each experiment for at least 5 minutes, with the first and the last minute ignored. Replicas propagate local update transactions (line 2:1) and broadcast vectors (line 2:23) every 5ms.

8.1 Does UNISTORE combine causal and strong consistency effectively?

We start by analyzing the performance of UNISTORE using RUBiS – a popular benchmark that emulates an online auction website such as eBay [41, 42]. It defines 11 read-only transactions and 5 update transactions, e.g., selling items, bidding on items, and consulting outstanding auctions. As in previous work [42], to make the benchmark more challenging, we add an extra update transaction `closeAuction` to declare the winner of an auction. We also borrow from [42] a conflict relation between RUBiS transactions that preserves key integrity invariants in the PoR consistency model. This marks four transactions as strong (`registerUser`, `storeBuyNow`, `storeBid` and `closeAuction`) and declares three conflicts between them. For example, `storeBid`, which places a bid on a item, conflicts with `closeAuction` if both act on the same item: this is needed to preserve the invariant that the winner of an auction is the highest bidder. Our RUBiS database is configured according to the benchmark specification: it is populated with 33,000 items for sale and 1 million users; client

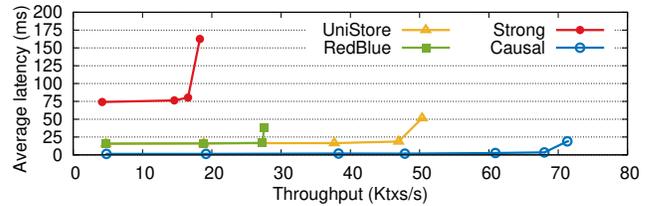

Figure 3: RUBiS benchmark: throughput vs. average latency.

think times are 500ms. We run the bidding mix workload of RUBiS with 15% of update transactions, which yields 10% of strong transactions.

We compare UNISTORE with STRONG, REDBLUE and CAUSAL. STRONG implements serializability [70] as a special case of UNISTORE where all transactions are strong and all pairs of operations conflict. REDBLUE implements red-blue consistency [41], which like PoR, combines causal and strong consistency. However, it declares conflicts between all strong transactions. REDBLUE certifies strong transactions at a centralized replicated service, with a replica at each data center. CAUSAL implements causal consistency as a special case of UNISTORE where all transactions are causal. It cannot preserve the integrity invariants of RUBiS, but gives an upper bound on the expected performance.

Throughput and average latency. Figure 3 evaluates average transaction latency and throughput. As the figure shows, UNISTORE exhibits a high throughput: 72% and 183% higher than REDBLUE and STRONG respectively at their saturation point. This is expected, as UNISTORE implements the consistency model that enables the most concurrency. STRONG classifies all transactions as strong. This impacts performance because executing a strong transaction is significantly more expensive than executing a causal one. REDBLUE uses a centralized certification service that saturates before the UNISTORE’s distributed service, creating a bottleneck. UNISTORE exhibits an average latency of 16.5ms, lower than 80.4ms of STRONG. The latency of REDBLUE is comparable to that of UNISTORE. This is because both systems mark the same set of transactions as strong. Still, REDBLUE declares conflicts between all strong transactions and thus aborts more transactions than UNISTORE: 0.12% vs 0.027%. The clients whose transactions abort have to retry them, thus increasing latency. Since the abort rate remains low in both cases, the difference in latency is negligible in our experiment. We expect a more significant difference in workloads with higher contention. Finally, in comparison to CAUSAL, UNISTORE penalizes throughput by 45%. This is the unavoidable price to pay to preserve application-specific invariants.

Latency of each transaction type. In UNISTORE, the latency of strong transactions is dominated by the RTT between Virginia (the leader’s region) and California (Virginia’s closest data center) – 61ms. Strong transactions exhibit a latency of 73.9ms on average. The latency varies depending on the

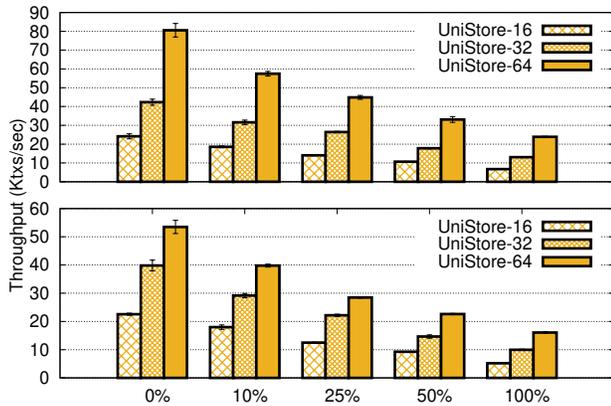

Figure 4: Scalability when varying the ratio of strong transactions with uniform data access (top) and under contention (bottom).

client’s location: from 65.4ms on average at the leader’s site to 93.2ms at the site furthest from the leader (Frankfurt). Since causal transactions do not require coordination between data centers, they exhibit a very low latency – 1.2ms on average, which is comparable to that of CAUSAL. This demonstrates that UNISTORE is able to mix causal and strong consistency effectively, as the latency of causal transactions remains low regardless of concurrently executing strong transactions.

8.2 How does UNISTORE scale with the number of machines?

We evaluate the peak throughput of UNISTORE as we increase the number of machines per each data center from 2 to 8, i.e., the number of partitions from 16 to 64. We use a microbenchmark with 100% of update transactions, where each transaction accesses three data items. We vary the ratio of strong transactions from 0% to 100% to understand their impact on scalability.

Scalability under low contention. For this set of experiments, the data items accessed by each transaction are picked uniformly at random. This yields a very low contention: e.g., with 16 partitions, the probability of two transactions accessing the same partition is 0.031. As shown by the top plot of Figure 4, UNISTORE is able to scale almost linearly even when the workload includes strong transactions: a 9.76% throughput drop compared to the optimal scalability. This is because, with uniform accesses, the task of committing transactions is balanced among partitions. Thus, when the number of partitions increases, so does the system’s capacity. The scalability is not perfect due to the cost of the background protocol that computes stableVec, which grows logarithmically with the number of partitions. The plot also shows that strong transactions are expensive: 25.72% of throughput drop on average with 10% of strong transactions. The performance is dominated by the number of strong transactions that a partition can certify per second.

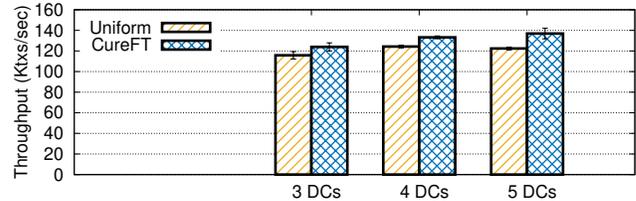

Figure 5: Throughput penalty of tracking uniformity.

Impact of contention. For this set of experiments, we set the ratio of strong transactions that access a designated partition to 20% to create contention. As shown by the bottom plot of Figure 4, UNISTORE is still able to scale fairly well under contention. But, as expected, contention has an impact on scalability: a 17.15% throughput drop from the optimal scalability compared to the 9.76% throughput drop in the experiments without contention.

8.3 What is the cost of uniformity?

We compare CUREFT to UNIFORM. CUREFT implements Cure [3], a causally consistent data store, and makes it fault tolerant by adding transaction forwarding (§4). UNIFORM is a simplified version of UNISTORE that removes all the mechanisms related to strong transactions. UNIFORM tracks uniformity and makes remote transactions visible only when these are uniform; CUREFT does not. We use a microbenchmark with only causal transactions and 15% of update transactions. Each transaction accesses three data items.

Throughput penalty. Figure 5 evaluates the cost of tracking uniformity. It shows the peak throughput when the number of data centers increases from 3 to 5. We first add Ireland and then Brazil. As we do this, the throughput remains almost constant. This is because each data center stores replicas of all partitions and the computational power gained when adding a data center is offset by the cost of replicating update transactions. As the figure shows, the cost of tracking uniformity is small: a 7.97% drop on average. The gap grows as we increase the number of data centers: a 10.61% drop on average with 5 data centers. This is because, to track uniform transactions, sibling replicas exchange messages: the more data centers, the more messages exchanged. The penalty can be reduced by decreasing the frequency at which sibling replicas exchange their stableVec (line 2:25), at the expense of an extra delay in the visibility of remote transactions.

Reading from a uniform snapshot. Figure 6 evaluates the delay on the visibility of remote transactions when reading from a uniform snapshot. We deploy four data centers: Virginia, California, Frankfurt and Brazil. We set $f = 2$ to tolerate 2 data center failures (when $f = 1$, UNIFORM shows no delay). Under such a configuration, a data center makes a transaction visible when it knows that 3 data centers store the transaction and its dependencies (§5.4). The figure shows the cumulative distribution of the delay before updates from

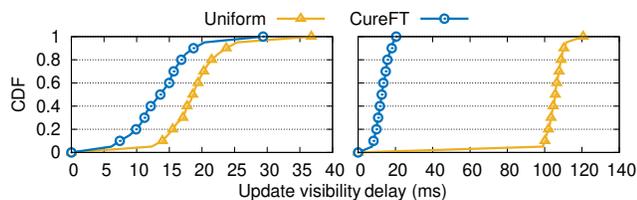

Figure 6: Left: California to Brazil (best case). Right: California to Virginia (worst case).

California are visible in Brazil and Virginia.

The extra delay at Brazil is only of 5ms at the 90th percentile. This is the best case scenario for UNIFORM because Brazil learns that Virginia stores a transaction originating at California only 2ms after receiving it. The worst case scenario for UNIFORM is when the origin and the destination data center are the closest ones. This is why the extra delay at Virginia is 92ms at the 90th percentile: Brazil learns that Frankfurt stores a transaction originating at California 88ms after receiving it. Note that when clients communicate only via the data store, the delay is unnoticeable. Even if clients communicate out of band, as the maximum extra delay is less than 100ms, it is unlikely that a client will miss an update.

9 Related Work

Systems with multiple consistency levels. A number of data stores have combined weak and strong consistency, including several commercial and academic systems that combine eventual and strong consistency [5, 6, 29, 49, 58, 65, 73]. Several academic data stores combined causal and strong consistency [9, 37, 41, 42, 59, 65]. Pileus [65] funnels all updates through a single data center. In the fault-tolerant version of lazy replication [37], causal operations require synchronization between replicas on its critical path. In both cases, causal operations are not highly available, defeating the benefits of causal consistency. Walter [59] restricts causal operations to a specific type and lacks fault tolerance due to the use of two-phase commit across data centers. The remaining works [9, 41, 42] support highly available causal operations, but are not fault tolerant. First, they do not make causal operations uniform on demand to guarantee the liveness of strong operations. Thus, they suffer from the liveness issue we explained in §4 (Figure 2). In addition, these systems do not use fault-tolerant mechanisms even for strong transactions. They guard the use of strong transactions using mechanisms similar to locks; if the lock holder fails before releasing it, no other data center can execute a strong transaction requiring the same lock. This occurs even when the service handing locks is fault-tolerant, as in [42]. Finally, the above systems either do not include mechanisms for partitioning the key space among different machines in a data center or include per-data center centralized services, which limits their scalability (§8.2).

Some group communication systems mix causal and atomic

broadcast [10, 68]. However, these systems do not provide mechanisms for maintaining transactional data consistency.

Several papers have proposed tools that use formal verification technology to ensure that consistency choices do not violate application invariants [9, 31, 34, 40, 51, 52]. Such tools can make it easier for programmers to use our system.

Causal consistency implementations. Our subprotocol for causal consistency belongs to a family of highly scalable protocols that avoid using any centralized components or dependency check messages [3, 23, 60–62]; other alternatives are less scalable [4, 8, 13, 22, 32, 43, 44, 48, 72]. While we base our causal consistency subprotocol on an existing one, Cure [3], we have extended it in nontrivial ways, by integrating mechanisms for tracking uniformity (§5.4) and for transaction forwarding (§5.5). Some of the above protocols [32, 61] use hybrid clocks instead of real time [36] to improve performance with large clock skews; this technique can also be integrated into UNISTORE.

SwiftCloud [72] implements *k-stability* [46], a notion similar to uniformity, to enable client migration. SwiftCloud relies on a single per-data center sequencer, which makes tracking *k-stability* easy, but the data store less scalable. Our protocol is more sophisticated, since we distribute the responsibility of tracking uniformity among the replicas in a data center.

Paxos variants. Several Paxos variants [25, 39, 50, 53] lower the latency by allowing commutative operations to execute at replicas in arbitrary orders. In contrast to them, UNISTORE implements PoR consistency, which allows causal transactions to execute without any synchronization at all.

10 Conclusion

This paper presented UNISTORE, the first fault-tolerant and scalable data store that combines causal and strong consistency. UNISTORE carefully integrates state-of-the-art scalable protocols and extends them in nontrivial ways. To maintain liveness despite data center failures, unlike previous work, UNISTORE commits a strong transaction only when all its causal dependencies are uniform. Our results show that UNISTORE combines causal and strong consistency effectively: 3.7× lower latency on average than a strongly consistent system with 1.2ms latency on average for causal transactions. We expect that the key ideas in UNISTORE will pave the way for practical systems that combine causal and strong consistency.

Abstract

We present a source-to-source transformation framework, GOCC, that consumes lock-based pessimistic concurrency programs in the Go language and transforms them into optimistic concurrency programs that use Hardware Transactional Memory (HTM). The choice of the Go language is motivated by the fact that concurrency is a first-class citizen in Go, and it is widely used in Go programs. GOCC performs rich inter-procedural program analysis to detect and filter lock-protected regions and performs AST-level code transformation of the surrounding locks when profitable. Profitability is driven by both static analyses of critical sections and dynamic analysis via execution profiles. A custom HTM library, using perceptron, learns concurrency behavior and dynamically decides whether to use HTM in the rewritten lock/unlock points. Given the rich history of transactional memory research but its lack of adoption in any industrial setting, we believe this workflow, which ultimately produces source-code patches, is more apt for industry-scale adoption. Results on widely adopted Go libraries and applications demonstrate significant (up to 10×) and scalable performance gains resulting from our automated transformation while avoiding major performance regressions.

1 Introduction

Golang [46] (or simply Go) is a modern programming language that has gained significant popularity over the last decade. It is being used to write enterprise software [20] (e.g., to implement backend services) in some of the largest technology companies as well as to develop large and widely used open-source applications (e.g., Kubernetes [47]) and libraries (e.g., Tally [88]). The design of Go is inspired by C, but unlike C, it supports concurrency as the first-class language construct. Even more importantly, and unlike other popular languages with first-class concurrency support (e.g., Java), the Go language goes to great lengths to simplify concurrent programming by making concurrency easy to use (and thus frequently used) by the developers [86] — any function in Go can be

scheduled to execute concurrently with the rest of the code as a *goroutine* [46] by simply prefixing its call with the `go` keyword.

Although Go makes writing concurrent programs easier, it still requires programmers to manage interactions between concurrently executing code — this can be accomplished either via passing messages through channels [46] or explicitly synchronizing accesses to shared memory. Shared memory is used more often than message passing by Go developers, and mutual exclusion via locks [11] remains the most widely-used synchronization mechanism across several applications [86]. It is, therefore, the focus of our work.

Locks may unnecessarily serialize concurrent execution, even if the code operates on disjoint data. Our work aims to improve the performance of concurrent Go code, particularly code hiding behind needlessly held locks. Our goal is to accomplish this while retaining the correctness of concurrent execution. We utilize the concept of *transactional memory* (TM) [53] to achieve this goal. The general idea behind TM is to decide on whether two (or more) pieces of code can be executed concurrently based on whether their accesses to the underlying data are *conflicting* [54] or not, that is, if at least one of the accesses is a write. Conflict-free executions are allowed to proceed in parallel. On the other hand, upon encountering a data access conflict, execution effects of at least one piece of code have to be *rolled back* (i.e., undone), and the computation must be restarted. TM machinery, which originally started in software (STM) [43, 77, 82, 93], is now available in commodity hardware as Hardware Transactional Memory (HTM) [41, 90, 92]. However, despite almost three decades of work in this area, TM’s promise of accelerating concurrent computations for real-life software has not been quite fulfilled. We speculate that there are two reasons why this is the case.

The first reason is that TM, while being a single concept, may have different realizations in terms of algorithms and implementations (e.g., eager vs. lazy versioning [80]) and different integration strategies at the language level (e.g., API-level solutions [77] or the compiler-assisted `atomic` construct used to demarcate TM-managed concurrent code [52]), resulting in different behavior from the programmer’s perspective. Conse-

quently, attempts to introduce TM as a separate language-level mechanism lead to significant semantic dissonance with respect to existing concurrency-related mechanisms [69, 79].

The second reason is that a lot of TM (particularly STM) work was focusing on designing and implementing TM algorithms but limiting empirical evaluation to synthetic benchmarks (e.g., STMBench7 [51]) or measuring the performance of only selected concurrent data structures. Unfortunately, unlike what was expected, TM techniques did not easily generalize to real-life applications [93]. A few attempts to apply TM to production code were unsuccessful (e.g., an attempt to rewrite the Quake game server to use TM [97]).

In this work, we attempt to rectify some of these limitations and show that TM can be effective in accelerating real-life concurrent code. We focus less on the algorithmic side of TM (we use state-of-the-art off-the-shelf HTM implementation from Intel), and more on how and when to apply the TM machinery to maximize the benefit. Additionally, we replace Go locks with HTM constructs without changing the code’s behavior in any way, which allows us to completely bypass complications related to transactional memory semantics. More specifically, we employ *transactional lock elision* (TLE) [73] — a well-known technique that attempts to execute a lock-protected critical section as an atomic hardware transaction, reverting to using the lock if these attempts fail.

Figure 1 depicts our solution. At a high level, our solution starts with using static analysis to identify candidate lock-protected critical sections to be instead protected by the HTM. Then we filter out non-desirable candidates using both static analyses (e.g., to eliminate regions containing I/O operations) and dynamic analysis (to eliminate regions where the application of the HTM would not be beneficial based on profile data collected at runtime). Finally, we rewrite the code to have candidate regions use HTM constructs provided by the HTM library we developed instead of Go locks [11]. GOCC transformations are guaranteed to be safe; developer involvement is optional but highly recommended to let developers ultimately decide whether or not they want to use HTM.

In summary, this paper makes the following contributions:

1. We present the design and implementation of a framework for identifying lock-protected critical sections and select the best candidates for lock elision based on static analysis and execution profiles of Go programs.
2. We describe the source-to-source code transformation to replace mutual-exclusion locks in Go programs with HTM concurrency control constructs.
3. We introduce a library extending vendor-provided HTM primitives with intelligent features such as runtime contention management. Specifically, we devise a lightweight perceptron [59, 84] that learns whether eliding a lock via HTM at a call site [50] is beneficial at runtime.
4. We demonstrate the effectiveness of GOCC for improving performance of real-life concurrent Go code by up to 10×.

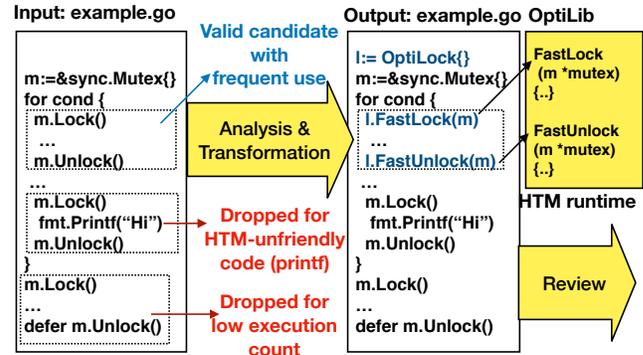

Figure 1: GOCC schematic diagram. Static analysis detects three legal lock-unlock pairs in the input file `example.go`. The top one is a valid replacement candidate. The middle one is filtered since it contains I/O operations in its critical section. The bottom one is dropped due to the infrequent use via the information provided by profiles. The transformed code calls `optiLib`, which executes the critical section via HTM. The resulting diff is given to the developer for review.

2 Challenges

Locks are widely used in the real-world Go code and a significant amount of execution time can be spent waiting to acquire them [15, 19, 27, 28, 68, 86, 89]¹. It is possible to replace a lock with a transaction that enables a critical section to be speculatively executed without actually holding the guarding lock. With the support of the HTM, such replacements can result in significant speedups. However, there are several challenges in performing these replacements correctly and robustly, and ensuring that they deliver high performance reliably.

First, automatically and accurately matching a lock with its corresponding unlock operation to precisely identify critical sections is a complex problem. Real-world programs can use locks with nesting intra- or inter-procedurally, which makes it significantly more involved. Additionally, certain lock-compatible instructions (e.g., IO and privileged instructions) will not work with HTM. A critical section including such instructions will not benefit from HTM.

Furthermore, Go provides a keyword that enables delaying lock release operation to all exit points of a function by prefixing the `Unlock()` operation with the `defer` [49] keyword². It not only complicates matching an unlock with a lock operation, it may unnecessarily lengthen a critical section, which according to a synthetic benchmark we wrote shows performance degradation. A scan of 21 million lines of industrial Go code, which includes about 8000 `Unlock()` operations, shows that about 76% are prefixed with the `defer` keyword. This indicates that handling `defer` statements is important.

Second, the Go language nuances [46] (e.g., pointer vs. value syntax, anonymous `Mutex` fields, lambda functions, etc.) make

¹ A limited study we performed in a large-scale industrial setting using thousands of different Go services showed up to 30% execution time being spent in lock-related code in certain Go programs; 5-10% was quite common.

² Any function can be deferred in Go.

it non-trivial to transform lock-based code to HTM-based code.

Third, HTM has startup and commit overheads. Even in non-concurrent code, where data-access conflicts do not happen, HTM can fail [14], and locks may outperform HTM, particularly on tiny critical sections [75].

Fourth, the critical section size can be hard to estimate in general. If we make the conservative design choice and do not replace the lock if the critical section size is unknown, we can miss the opportunity to generate significant performance improvement. Thus, we need some runtime mechanism that can handle critical sections of arbitrary sizes with low overhead.

Fifth, when HTM aborts for a genuine data-access conflict, naively falling back to using a lock can be detrimental to performance [42, 64]. Deciding when and how to retry HTM-based executions or fall back to using fine-grained locks must be handled very carefully to avoid pathologies [37, 42, 64].

Our tool, GOCC, attempts to solve the above challenges. GOCC is an end-to-end system for improving the performance of lock-based Go code using HTM. We devise a sophisticated program analysis to identify lock-protected critical sections (§ 5.2), support lock-to-HTM code transformation including non-trivial Go features (§ 5.3), and develop an efficient HTM library to handle issues manifested at runtime (§ 5.4).

3 Related Work

Herlihy and Moss proposed transactional Memory (TM) [53] in 1993 as an alternative to locks. While locks proactively prevent two or more threads from concurrently accessing shared data, TM takes the opposite approach — concurrent accesses are allowed as long as they do not conflict. A lot of work has been done around both software and hardware implementations of transactional memory [41, 43, 71, 77, 82, 90, 92], but only a few [61, 76, 93, 97] focused on evaluating the approach with real-life workloads, and none have done this for Go.

Intel’s TSX extension of x86 instructions set [5] implementing HTM is of specific interest here as it underlies parts of our implementation. It is widely available in modern Intel CPUs and offers software interfaces providing subtly different functionality. The RTM (Restricted Transactional Memory) interface allows programmers to execute arbitrary code as a hardware transaction. All operations within a transaction have atomic execution behavior — they all either appear to happen instantaneously or the entire transaction aborts and reverts the architectural state to before it was started. This can be trivially used to emulate the behavior of mutual-exclusion locks. In fact, this is precisely the kind of functionality that the HLE (Hardware Lock Elision) interface provides. However, HLE has been introduced mainly for backward compatibility with architectures that are not TSX-enabled and is not only very simplistic (e.g., with respect to contention management) but has also been shown to perform poorly compared to RTM [1]. Consequently, our solution uses the RTM interface as the low-level implementation mechanism to build a comprehensive

TM-based alternative for mutual-exclusion locks.

Lock elision, whether in software or hardware or a hybrid fashion, including gaining insights into them, has been extensively studied [22, 29, 34, 36–39, 44, 45, 57, 58, 63, 71, 71, 72, 74, 81, 91, 92, 95]. Our work uses many of those techniques; for example, the basic design of our runtime controller was inspired by Wang et al. [91]. Additional possibilities to bring more solutions from the literature to the design and implementation of both our static analysis tool and runtime controller also exist. Other attempts to use transactional memory for emulating mutual-exclusion locks exist as well [70, 96], but they have to cope with higher overheads and semantics-related complications due to using the STM, they target the Java language whose synchronization lock-like primitives (i.e., *monitors*) are easier to handle due to their lexical scoping and, most importantly, their evaluation is based exclusively on synthetic benchmarks.

4 GOCC Overview

A Go `Mutex` is a runtime object with `Lock()` and `Unlock()` operations on it. Two (or more) critical sections guarded by the same `Mutex` will not execute concurrently. When transforming locks into HTM, there are two possibilities.

1. A given `Mutex` guarding a set of critical sections is replaced with another object supporting operations analogous to `Lock()/Unlock()` but provided by the HTM. As a result, all critical sections previously guarded by the `Mutex` are now executed under HTM’s control.
2. `Lock()/Unlock()` operations of the `Mutex` are replaced with their HTM equivalents on a per critical section basis. As a result, some critical sections for a given `Mutex` are still guarded by the same `Mutex`, while the others execute under HTM’s control.

The former is doable only if it is beneficial to transform all `Lock()/Unlock()` operations using a given `Mutex`, and the `Mutex` object is defined in the code that we are rewriting. Assessing the benefit of transforming the `Mutex` object would require inspecting every critical section it protects. A “may alias” pointer analysis [55, 65] can answer such a question. The “all-or-none” coarse-granularity of this approach makes it unattractive because the imprecision of pointer analysis overapproximates the critical sections protected by a `Mutex`, disqualifying too many `Mutexes` from transformation.

This work adopts the latter approach, where we consider pairs of `Lock()/Unlock()` operations in the code for transformation, which provides fine-grained control over transformation. This approach has to handle pairing a lock with its corresponding unlock and support interoperability of HTM (where the code is transformed) with locks (where the code is not transformed). This kind of interoperability is well-studied in the literature [23, 32, 40, 41, 64] and is handled by our library.

Recall, from Figure 1, that input to GOCC is the source code for a Go package along with its execution profiles. The output

is a source code patch, where candidate `Lock()/Unlock()` operations are replaced with calls to a custom HTM library. GOCC consists of the following key components:

- Analyzer: performs static analysis on the input program and collects lock-unlock pairs for transformation (§ 5.2).
- Transformer: rewrites the program by replacing `Lock()/Unlock()` with `FastLock()/FastUnlock()`, which elide the lock using HTM (§ 5.3).
- Adaptive runtime (`optiLib`): implements HTM in Go and provides required runtime mechanisms including retry and rollback (§ 5.4).

The source code patch choice, rather than a compiler transformation, is motivated by the desire to keep the developers in the loop. Using HTM without developers' knowledge can prove unwelcome because developers often demand full visibility into their programs. Developers are becoming performance and variance sensitive [56, 67, 83], and an accidental regression can become hard to diagnose. As a side effect, the choice of source-code patch demands us to be surgical — injecting large, complicated HTM-handling boilerplate code is a non-starter. Consequently, we perform `Lock()/Unlock()` operations replacements with API calls to HTM logic hidden in the `optiLib` open-source library and do so only in places where benefits of HTM are likely (e.g., we minimize the number of modified code locations using execution profiles).

4.1 GOCC Guarantees and Limitations

- GOCC will transform properly synchronized code (i.e., where every lock operation will have a corresponding unlock operation) into the equivalent code without changing the code's behavior. Code not meeting this criterion will be either not transformed, or transformed and its runtime behavior will be unchanged.
- GOCC considers only those lock-unlock pairs that seem to operate on the same lock within the same function — inter-procedural `Lock()/Unlock()` operations are disregarded. Note, however, that in a critical section protected by GOCC transformed lock can make arbitrary function calls. The requirement to have both `Lock()` and its matching `Unlock()` operation be present in the same procedure scope is only our implementation choice and pragmatic in nature. Over 70% of the locks we inspected met this criterion.
- GOCC makes no effort to identify critical sections or code reachability in the presence of reflection [10].
- GOCC, as implemented, does not *statically* detect HTM conflicts or capacity limitations (see § 5.2 for the details).

5 GOCC Design and Implementation

Before diving into the details of GOCC's design and implementation, we define some common terminology.

5.1 Terminology

Go's `sync` package provides two kinds of shared memory objects: `Mutex` and `RWMutex`. GOCC handles them both, but in the following sections, without the loss of generality, we will only use the term `Mutex` for simplicity. From an HTM transformation viewpoint, an `RWMutex` is no different from a `Mutex`, except `RWMutex` offers additional APIs for read-only accesses.

A *critical section CS* is all code regions protected by a pair of lock and unlock operations on the same mutex object `m` — the notation for calling lock/unlock operations on `m` is `m.Lock()/m.Unlock()` where `m` is referred to as a *receiver*. *Lock-point*, abbreviated with letter *L* (*Unlock-point* abbreviated with letter *U*), is a static location in the code where the `Lock()` (`Unlock()`) function is invoked on a `Mutex`. **LU-points** is a set of *L* and *U* points. **LU-pair** is a candidate pair of one *lock-point* paired with an *unlock-point*. In the runtime context, fastpath/HTM-path means the use of HTM, and slowpath/fallback-path means the use of the original lock.

We utilize the Abstract Syntax Tree (AST), program Control Flow Graph [85] (CFG), and Static Single Assignment (SSA) [35] form of program representation prevalent in the compiler literature. In a CFG, nodes are basic blocks [85] of straight-line code, and edges are control flow relationships among them. GOCC first transforms the source code to the AST form (which is also used for code transformation as described in § 5.3) and then to the SSA form for CFG construction.

5.2 Analyzer

The goal of the analyzer is to find as many LU-pairs as possible. The LU-pairs that protect HTM-incompatible critical sections (e.g., those including IO operations) must be pruned. This filtering serves two purposes: it reduces the number of code changes and non-beneficial HTM transformations. Complicated lock usage patterns, several Go language quirks, and pointer imprecision complicate the static analysis. A comprehensive call-graph analysis is vital because critical sections often contain function calls.

Conflicts: A sophisticated static analysis may detect whether transactions conflict. Answering this question, however, is unlikely to be valuable because developers typically do not use a lock if a conflict is impossible. Assuming conflicts happen, there is no easy way to statically determine whether transactions do not “typically” conflict. We do not try to solve this problem and leave conflict resolution to `optiLib`.

Capacity: Although one can perform static analysis to estimate the memory footprint of a critical section, it may not be possible if the bounds of a loop are unknown. Also, without knowing the target architecture's HTM capacity, it would be premature to filter out candidate critical sections this way. We leave the capacity-related decisions also to `optiLib`.

In the rest of this section, we, first, define the scope of our transformation (§ 5.2.2); then, describe the process of

<pre> 1 2 m := &sync.Mutex{} 3 m.Lock() 4 m.Unlock() </pre>	<pre> 1 l := OptiLock{} 2 m := &sync.Mutex{} 3 l.FastLock(m) 4 l.FastUnock(m) </pre>
---	--

Listing 1: Original lock-based code. **Listing 2:** Transformed HTM code.

matching a lock with an unlock operation within a code region assuming no lock nesting and no function calls in a CS; extend our analysis to include nested locks (§ 5.2.3); expand the analysis scope to CSs that may contain function calls (§ 5.2.4); detail special case of Go’s defer statement (§ 5.2.5); and finally discuss profile-based filtering (§ 5.2.6).

5.2.1 Scope of Transformation

To simplify the analysis, if a Lock() /Unlock() operation is executed in the middle of a basic block, we break such basic blocks in the CFG so that each lock-point begins a new basic block and each unlock-point ends a basic block. A single-entry single-exit (SESE) region [60] (simply *region*) of a CFG is our smallest granularity of lock transformation. A region is a subgraph of a CFG. Control reaching any basic block in a region is guaranteed to have already executed a designated entry basic block; control leaving from any basic block in the region is guaranteed to eventually pass through a designated exit basic block.

A function is the largest granularity of our lock transformation; a function always forms a region because all exits from a function are considered to go through a dummy basic block. This choice is pragmatic in nature since LU-pairs spanning multiple functions are uncommon.

Regions can be nested within one another. A Program Structure Tree (PST) organizes regions into a hierarchical tree [60]. We visit regions inside out from most-nested to least-nested. Appendix B in the extended version of this paper [94] describes the region identification and visiting strategies, which are not central to this paper.

5.2.2 Matching LU-pair in the Absence of Nested Locks

This subsection discusses analyzing a candidate region R .

LU-points in R may be operating on different locks, which should be pruned. Some lock (unlock) operations may escape R , without a corresponding unlock (lock) operation in R , which should also be pruned. Below, we formalize these aspects.

Definition 5.1 (Points-to set $\mathcal{M}(L)$ of a Lock point L). *Every lock-point (L) operates on some receiver mutex pointer p .³ Such a mutex pointer may point to one or more mutex objects allocated in the program. The set of all possible Mutex objects that p may point to in the program is the Points-to Set of L , denoted by $\mathcal{M}(L)$.*

³At the source level p can be either a pointer or an actual object value, but at the SSA level it is always a pointer.

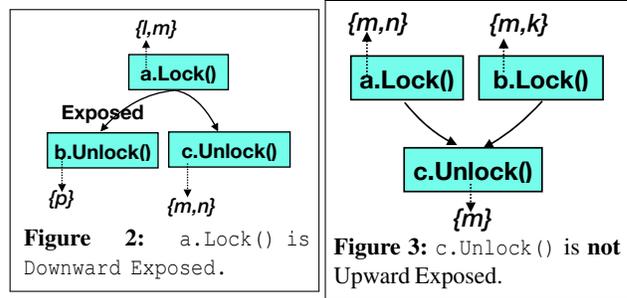

Figure 2: a.Lock() is Downward Exposed.

Figure 3: c.Unlock() is not Upward Exposed.

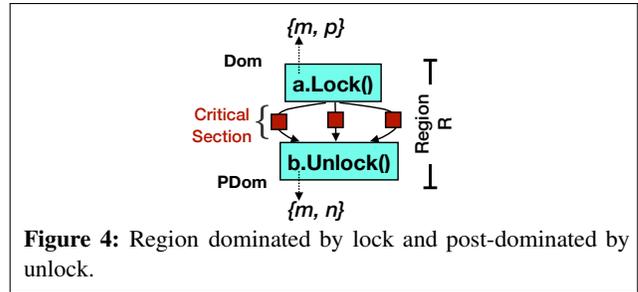

Figure 4: Region dominated by lock and post-dominated by unlock.

Similarly, the Points-to set of an Unlock point U is $\mathcal{M}(U)$. We employ Anderson’s flow-insensitive may-alias analysis [25] to obtain $\mathcal{M}(L)$ and $\mathcal{M}(U)$ on the whole program.

Definition 5.2 (Downward Exposed Lock-point (DELock)). *A lock-point, L , with points-to set $\mathcal{M}(L)$, is downward exposed in region R , if there exists at least one path from L to R ’s exit without any unlock-point on any mutex in $\mathcal{M}(L)$.*

Definition 5.3 (Upward Exposed Unlock-point (UEUnlock)). *An unlock-point, U , with points-to set $\mathcal{M}(U)$, is upward exposed in region R , if there exists at least one path from R ’s entry to U without a lock-point on any mutex in $\mathcal{M}(U)$.*

DELock identifies lock-points that *definitely* do not have any corresponding unlock-points in some execution paths in R ; and UEUnlock identifies unlock-points that *definitely* do not have corresponding lock-points in some execution paths in R .

Figure 2 exemplifies a downward exposed lock-point. Mutex pointer a ’s points-to set $\{l,m\}$, has an empty intersection with b ’s points-to set $\{p\}$; although it has a non-empty intersection with c ’s points-to set $\{m,n\}$. Figure 3 exemplifies an unlock-point that is *not* upward exposed. Mutex pointer c ’s points-to set $\{m\}$, has non-empty intersection with a ’s points-to set $\{l,m\}$ and b ’s points-to set $\{m,k\}$.

We eliminate all $DELock(R)$ and $UEUnlock(R)$ from the transformation in R . The remaining lock-points in R are the complement of $DELock(R)$, which is denoted by $\overline{DELock}(R)$. Similarly, the remaining unlock-points in R are the complement of $UEUnlock(R)$, which is denoted by $\overline{UEUnlock}(R)$.

Definition 5.4 (Feasible-HTM-Pair). *Let $L \in \overline{DELock}(R)$. Let $U \in \overline{UEUnlock}(R)$. L and U form a feasible HTM pair if all of the following conditions are true,*

- (1) $\mathcal{M}(L) \cap \mathcal{M}(U) \neq \emptyset$,
- (2) $(L \text{ DOM } U) \wedge (U \text{ PDOM } L)$,
- (3) The critical section $C \subseteq R$ guarded by L and U contains no LU-point X such that $\mathcal{M}(X) \cap (\mathcal{M}(L) \cup \mathcal{M}(U)) \neq \emptyset$, and
- (4) C contains no HTM-unfriendly instructions.

Condition (1) filters out those LU-points that are guaranteed to be operating on different `Mutex`s.

Condition (2) filters out infeasible control flows where unlock happens before lock and vice-versa. `DOM` and `PDOM` respectively represent dominator [85] and post-dominator [85] relationships in a CFG. Figure 4 shows an example, where all paths from lock-point `a.Lock()` are post-dominated by unlock-point `b.Unlock()`, whose all incoming paths are dominated by `a.Lock()`. Additionally, the set-intersection of the points-to set of mutex pointers $a = \{m, p\}$ and $b = \{m, n\}$ is non-empty. Any Feasible-HTM-Pair on L and U , forms an SESE-region by itself, where the entry basic block has L as its first instruction and the exit basic block has U as its last instruction. Condition (2) intuitively finds correct candidate LU-pairs in the absence of nested locks because if a lock operation L is performed on every path reaching any code in C and an unlock operation U is performed on every path exiting C , then LU must be operating on the same `Mutex`. Appendix A in the extended version of this paper [94] justifies our choice of `DOM/PDOM` relationships.

Condition (3) ensures that if we match an L with a U , there does not exist another lock-point or unlock-point in the same region that *may* operate on a `Mutex` in the same points-to set as that of L or U . The next subsection elaborates on lock nesting.

Condition (4) is an obvious requirement to ensure HTM does not abort. A region is unsafe if it contains any IO instructions.

Since we use “may alias” to match a lock-point with unlock-point, it is possible (but less likely) for our transformation to pair a lock with an unlock that may be operating on two different mutex objects at runtime. However, at runtime, we can obtain and memorize the address of the mutex object used at the lock-point, and compare it against the mutex object offered to the runtime at the unlock-point. In case of an address mismatch of the mutex objects used in the same LU-pair, we can abort the transaction and revert to a safe state and fall back to using the locks. A mismatch is impossible without nested locks because of the dominance and post-dominance relationship between the lock and unlock in an LU-pair.

5.2.3 Lock Nesting

Go supports nested locks, but reentrant [13] locks are not allowed. Condition (3) in Definition 5.4 allows nested locks but demands that they operate on disjoint `Mutex` objects.

HTM via Intel TSX allows nesting: if a nested transaction succeeds, hardware does not commit it until the outermost transaction commits. If a nested transaction fails, the control jumps to the starting code address of the nested transaction.

<pre> 1 a.Lock() //outer region start 2 3 4 b.Lock() // inner region start 5 b.Unlock() // inner region end 6 7 a.Unlock() //outer region end </pre>	<pre> 1 a.Lock() 2 3 l := OptiLock{} 4 l.FastLock(b) 5 l.FastUnlock(b) 6 7 a.Unlock() </pre>
--	--

Listing 3: Nested Locks.

Listing 4: HTMized.

<pre> 1 a.Lock() //outer region start 2 3 4 b.Lock() // inner region start 5 a.Unlock() // inner region end 6 7 b.Unlock() //outer region end </pre>	<pre> 1 a.Lock() 2 3 l := OptiLock{} 4 l.FastLock(b) 5 l.FastUnlock(a) 6 7 b.Unlock() </pre>
--	--

Listing 5: Hand-over-hand lock.

Listing 6: HTMized.

This facility allows us to safely transform locks into HTM even when they are nested.

Condition (3) in Definition 5.4 disqualifies a candidate LU-pair from the transformation in region R if there exists any other lock or unlock point whose lock/unlock operation *may* be operating on the same mutex as those in the LU-pair.

As an example, in Listing 3, assume the mutex pointers a and b point to the same points-to set. When inspecting the “inner region”, we find only one LU-pair, which obeys all Feasible-HTM-Pair conditions in Definition 5.4. Consequently, the lock usage on b in the inner region can be transformed to HTM. When inspecting the “outer region”, however, we see conflicting LU-points, and hence the locking operations on a will not be transformed. The resulting transformed code is shown in Listing 4, which is correct.

This approach complicates hand-over-hand locking [33, 62], sometimes used in the concurrent linked-list traversal, shown in Listing 5. As before, assume all four LU-points have a non-empty intersection of their points-to sets. When inspecting the inner region, the LU-pair `b.Lock()` and `a.Unlock()` passes all tests in Definition 5.4. Hence, they will be, incorrectly, paired and transformed to use HTM, as shown in Listing 6. This transformation violates the programmer’s intention. Subsequently, when visiting the outer region, condition (3) is violated, and hence the outer LU-pair will not be transformed. One could have discarded the transformation of the inner region when the conflict is visible in the enclosing region. However, we cannot distinguish this incorrect pairing from the correct pairing in the previous case. Our solution is to always apply the transformations on the candidates found in inner regions, and handle mismatches at runtime via HTM aborts iff executing on the fastpath. As mentioned at the end of § 5.2.2, a mismatch is easy to recognize at runtime by, first, making `FastLock()` store the address of the `Mutex` used at the lock-point in a field in `OptiLock` and, second, checking whether the `Mutex` passed to `FastUnlock()` is the one present in `OptiLock`. The transactional abort is needed (and possible) only on the fastpath. Appendix C in the extended version of this paper [94] details the correctness of transforming nested locks into HTM via GOCC.

5.2.4 Critical Sections with Function Calls

When the critical section protected by a candidate LU-pair contains function calls, we need to extend the analysis beyond the current function. Conditions (1) and (2) in Definition 5.4 are local to R . Conditions (3) and (4) require inter-procedural analysis.

We need to ensure that the transitive-closure of all code regions protected by a candidate LU-pair, including the blocks reachable via function calls, neither contains any HTM-unfriendly instructions nor contains any LU-points whose points-to set may overlap with the points-to sets of L or U . Otherwise, we discard the candidate LU-pair.

To accomplish this, we first build a static call graph using rapid type analysis [7, 26]. Next, we precompute summary information for each function on its own without its transitive closure of function calls; the summary contains (a) the fit of the function for HTM based-execution (i.e., no HTM-unfriendly instructions), and (b) the union of all points-to sets of all LU-points in the function, denoted by \mathcal{P} .

For a candidate LU-pair meeting all the conditions in Definition 5.4 within the region R , we proceed to do inter-procedural analysis. Let F^* be the transitive closure of all the function calls invoked inside the critical section $C \subseteq R$ protected by a candidate LU-pair. LU-pair is discarded if (a) $\exists F \in F^* . s.t. F$'s summary contains HTM-unfriendly instructions or (b) $\exists F \in F^* . s.t. \mathcal{P} \cup (\mathcal{M}(L) \cup \mathcal{M}(U)) \neq \emptyset$. The former is simply the condition (4) expanded to all functions, and the latter is condition (4) expanded to all functions. We note that nested locks discussed in § 5.2.3 can be in different functions.

5.2.5 The defer Statement

The `defer` [49] statement in Go, introduced in § 2, needs special attention. Go defers the execution of functions prefixed with the `defer` keyword to the calling function's return point. The presence of `defer Unlock()` complicates our CFG-based dominance/post-dominance analysis. Deferred unlocks extend the critical sections till function exit points. Listing 7 shows a legal Go code, where the `defer m.Unlock()` appears even before the call to `m.Lock()`. Condition (2) in Feasible-HTM-Pair will treat this pair as an invalid candidate for transformation because the lock-point does not dominate the unlock-point.

We address this case by interpreting `defer m.Unlock()` in a CFG by (a) introducing a synthetic `m.Unlock()` statement at the end of each basic block that returns control from the function, and (b) discarding the presence of `m.Unlock()` in its original position during the analysis. This allows us to reuse the previously described dominance relationship. During transformation, however, GOCC simply replaces a `defer Unlock()` with a `defer FastUnlock()` in its original place, as shown in Listing 8.

Multiple `defer` calls are executed in a last-in first-out (LIFO) order of encountering the `defer` statement at runtime.

```
1 func DeferExample() {           1 func DeferExample() {
2                               2     l := OptiLock{}
3     m := &sync.Mutex{}         3     m := &sync.Mutex{}
4     defer m.Unlock()           4     defer l.FastUnlock(m)
5     m.Lock()                   5     l.FastLock(m)
6     // critical section        6     // inside HTM
7 }                               7 }
```

Listing 7: defer Unlock.

Listing 8: HTMized.

This complicates the dominance and post dominance relationship; for simplicity, we discard any function that contains multiple `defer Unlock()` statements. We found none in the packages used in our evaluation.

5.2.6 Profiles to Filter Hot Critical Sections

Profiling is a built-in feature in Go, which takes callstack samples via timer [48] or hardware performance counter [30] interrupts. One can take CPU profiles of a go program either at launch time by simply passing a `-cpuprofile` flag or from an already running program, for a specified duration, by accessing an exposed profiling port.

Go profiles are in the `pprof` format.

The `pprof` Go package [48] allows us to programmatically navigate the callstack samples presented as weighted call graphs, where the nodes represent functions and edges represent caller-callee relationships. The functions are annotated with their inclusive and exclusive execution times.

When profiles are available, we use them to filter the regions where negligible execution time is spent, even before applying the static analysis. In fact, this is the first filtering step we perform before making the aforementioned LU-pair identification. We treat any critical section (including the entry and exit) where the aggregated execution time is less than 1% of the total execution time as insignificant.

5.3 Transformer

Since our end product is a code patch, we perform the transformation on the AST form of the program. Go AST can be serialized into source code via `Go format` [8] package. To this end, the transformer maps the candidate set of LU-pair operations found during the SSA-based analysis phase (described in § 5.2) to AST nodes [6]. It then replaces the LU-pair operations with calls to `FastLock()/FastUnlock()` in `optiLib`. It also passes the original `Mutex` object as a pointer to the calls to `FastLock()/FastUnlock()` since the underlying lock object is necessary for lock elision (fastpath) as well as for slowpath. Figure 5 shows an example AST transformation. The transformation itself is mechanical but challenging. In the following sections, we discuss several Go features that pose special challenges in transforming the AST.

Go pointer vs. value: Go syntax does not distinguish accessing a field of a composite type (e.g., `struct`) via an object-pointer or an object-value; both use the same

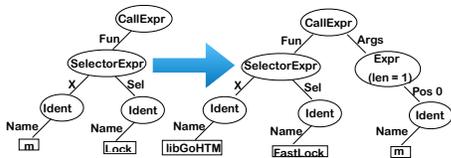

Figure 5: Example of AST transformation from `m.Lock()` to `optiLib.FastLock(m)`. Some AST nodes are omitted for brevity.

```

1 // pointer form
2 m := &sync.Mutex{}
3 m.Lock()
4 m.Unlock()
5
6 // value form
7 n := sync.Mutex{}
8 n.Lock()
9 n.Unlock()

```

Listing 9: Both Mutex pointer and Mutex value `n` invoke `Lock/Unlock` using the same `FastLock()/FastUnlock()` but dot dereferencing operator. `&n` to `FastLock()/FastUnlock()`.

AST dot operator as exemplified in Listing 9. However, `FastLock()` and `FastUnlock()` must receive a pointer to the Mutex object to perform the elision correctly. Hence, if the LU-pair uses a Mutex value, its address needs to be passed to `FastLock()/FastUnlock()`, and if the LU-pair uses a Mutex pointer, it should be passed as is.

We address this issue in the transformer by querying the type information [9] for each receiver object subject to transformation. If the receiver identifier is a Mutex value type, we insert the additional address-of operator before the Mutex identifier in the AST and pass it to `FastLock()/FastUnlock()`. If the receiver identifier is a pointer to a Mutex type, we pass it as is.

Go anonymous fields: Go allows programmers to define a struct that has fields without names. For instance, Listing 11 shows a struct `AStruct` that has an anonymous `*sync.Mutex` field. Operations on this anonymous mutex are performed by simply using the name of the enclosing struct variable as shown on Line 8. Hence, our transformation needs to be cognizant about whether the original LU-pair operations are performed on an anonymous mutex.

By inspecting the type information [9] of the *access path* [66] used to invoke the lock/unlock operation in the AST, we determine whether or not the operation is performed on an anonymous mutex field. Upon determining the operations to be on an anonymous mutex, we pass the address of the anonymous Mutex to `optiLib` by simply suffixing the operation access path with `Mutex` as shown in Listing 12, Line 8 (where access path simply consists of variable `a`). This transformation composes with the previously described pointer vs. value operations.

Anonymous goroutines: Go supports anonymous goroutines [2], which are nested inside other functions as

```

1 type AStruct struct {
2   x int //not anonymous
3   *sync.Mutex //anonymous
4 }
5 func main() {
6   a := AStruct{}
7   a.Lock()
8   a.Unlock()
9 }

```

Listing 11: Locking on an unnamed field of a struct.

```

1 m := &sync.Mutex{}
2 for i:=0;i<10;i++ {
3   go func() {
4     l := OptiLock{}
5     m.Lock()
6     // CS
7     m.Unlock()
8   }()
9 }
10 //wait all

```

Listing 13: Anonymous goroutines create concurrent units needed for the transformation of execution on anonymous should be placed in the innermost function scope.

Listing 14: The `OptiLock` outlines create concurrent units needed for the transformation of execution on anonymous should be placed in the innermost function scope.

shown in Listing 13; these goroutines run concurrently. Our transformation introduces a new `OptiLock` variable in transformed functions. `OptiLock`'s declaration should be in the scope that encloses both `Lock` and `Unlock` operations, but it should not be shared by other concurrent executions because it maintains goroutine-specific state. Hence, we make `OptiLock` a variable in the stack of each goroutine. We add the declaration to the innermost function body as shown on line 4 in Listing 14. A bottom-up AST walk from LU-pair to be transformed allows us to easily detect the innermost enclosing anonymous function scope.

5.4 Adaptive HTM Runtime: `optiLib`

`optiLib` implements all the intelligent runtime control needed to perform HTM in lieu of locks. It is in charge of starting and committing transactions in critical sections, as well as falling back to the lock when necessary. It is responsible for inter-operating with locking operations on the same mutex that may not be transformed to use HTM. In the event of aborts, it is responsible for determining the cause of the abort and deciding whether and how many times to retry. If, accidentally, the code rewriting matches lock-point with a programmer-unintended unlock-point, `optiLib` is responsible for detecting and recovering from the mistake. Finally, it is responsible for understanding and dynamically adjusting to changing contention.

We implement `optiLib` using TSX [5] for Intel platforms. `optiLib` is carefully implemented to ensure correctness under all circumstances. Equally important, it is implemented with the utmost attention to performance. Every instruction and its placement are carefully planned to minimize any overhead of its own. `optiLib` uses Intel RTM; it does not use the Hardware Lock Elision (HLE) [1] because it does not provide

the fine-grained control we need.

`optiLib` introduces a data structure: `OptiLock`, which has two fields: a boolean `slowPath` and a `*sync.Mutex lkMutex`. `slowPath` is set to `true` if the lock is not elided at runtime. `lkMutex` always holds the address of the fine-grained lock being elided. `OptiLock` supports `FastLock()/FastUnlock()` operations, both need a `*sync.Mutex` argument, which is the mutex receiver object being elided at the original call sites of `Lock()/Unlock()`. Try locks and timed locks [31, 78] are absent in Go; it is trivial to support them in `optiLib`.

The `FastLock()` implementation uses sophisticated mechanisms described previously by others [23, 32, 64] to interoperate slow and fast paths concurrently. Stated succinctly, the `FastLock()`, waits for the fine-grained lock to be available before starting the hardware transaction; on starting a transaction, it first checks if the fine-grained lock is already held and unconditionally aborts if it is already held; if it is not held, the act of checking adds the lock word to the transaction read-set, and hence, if a concurrent execution on the slowpath acquires the same lock during the transaction, the fastpath immediately aborts ensuring mutual exclusion. Any two threads in the fastpath can run concurrently as long as they do not conflict in their memory accesses.

Reading the internals of the original `sync.Mutex` object is straightforward and has no performance penalty; `FastLock()` simply de-references the first word of the `Mutex` pointer passed into the function, which contains the lock status.

The `FastUnlock()`, based on `slowPath` value, either commits the transaction or invokes the unlock on the mutex object. It also safeguards against accidental incorrect code patches by ensuring that the mutex object passed into `FastLock()` and stored in the `lkMutex` field of `OptiLock` matches the mutex object presented to `FastUnlock()`. In case of a mismatch, `FastUnlock()` restores safety by aborting the transaction (iff on fastpath), and subsequently enforces the slowpath.

5.4.1 Dynamic adjustment via perceptron

It would not be fruitful to attempt HTM if doing so has already proved to be unsuccessful for whatever reason. `GOCC` learns and adapts to HTM behavior and decides whether to use HTM for the already transformed LU-points, the fallback being the original lock. For this purpose, `GOCC` uses a featherlight, hardware-inspired “hashed perceptron” [84].

The hashed perceptron predictor hashes feature weights into one or more tables. Then at the prediction time, it uses indexes to access feature weights from the tables and adds up all the relevant weights. If the sum exceeds a threshold, the prediction will be regarded as positive (e.g., “HTM should be taken”). Otherwise, the result will be viewed as negative (e.g., “HTM should not be used”). The weights will be updated based on the correctness of the predictions.

If operations on a given `Mutex` have been HTM-friendly/unfriendly, we want to utilize this information.

Similarly, if a code location has been HTM-friendly/unfriendly irrespective of the `Mutex` used, we want to use this information as well. Hence, the two input features for the perceptron are the `Mutex` and the calling context [24, 50] of lock/unlock invocation. The address of the `Mutex` serves as the `Mutex` feature, and the address of `OptiLock` serves as a unique identifier for the calling context feature. Updating the same perceptron weight for the `Mutex` feature by different goroutines would create a conflict (and potentially a performance collapse). Hence, we instead XOR the `Mutex` address with the address of the `OptiLock` to produce a conflict-free feature input.

Our perceptron implementation creates two 4K-entry arrays as the global weight tables (GWT). The weights take an integer number ranging from -16 to 15. At runtime, `FastLock()` and `FastUnlock()` functions index into GWT by taking the lower-12 bits of the two features. Perceptron operations are done outside the transaction. The updates and reads from GWT are lock-free but racy — perfection is not required here, but high-performance is necessary. Experiment results from § 6.2 show the effectiveness of perceptron learning in protecting against poor HTM performance.

Perceptron weight update: Perceptron weight updates happen in the `FastUnlock()` function after successfully finishing the critical section, whether on fast and slow path.

If the perceptron decides that the lock should be used, there will be no update to the weights as the lock will always succeed. When the perceptron indicates to use the HTM and the execution finishes on the fastpath, the corresponding weight in the cell will be increased (because the perceptron makes a correct decision, it should be encouraged to use the HTM more frequently). On the other hand, if perceptron determines to use HTM, but HTM fails and falls back to slowpath, the weights will be decreased (because HTM does not work for the current call, perceptrons should be penalized for incorrect recommendation to improve future predictions).

Weight decay: We keep a counter, in each cell in GWT, to record the number of lock calls that go to the slowpath directly as a result of perceptron decision. If a lock has been used consecutively for a certain number of times and exceeds the threshold, we reset the weight of the perceptron cell and subsequently try HTM. Without this reset, perceptron would get stuck on the slowpath, preventing the benefits of the HTM execution in the future. We set this threshold to 1000 continuous decisions. Appendix D in the extended version of this paper [94] summarizes our `FastLock()/FastUnlock()` implementations including the perceptron logic.

5.4.2 Alleviating HTM overhead

HTM brings overhead for very short critical sections as described in § 2 above, even under single-core execution. `optiLib` avoids using HTM if it recognizes a single OS-thread in a Go process. `optiLib` employs `runtime.GOMAXPROCS(0)` API for this purpose.

repo	stars	contrib utors	com mits	LoC	Lock points	Unlock points	violates dominance	Candi date pairs	unfit for HTM	Nested alias locks	Transformed Pairs w/o profiles	Transformed Pairs w/ profiles

Table 1: Go package characteristics and their behavior using GOCC

6 GOCC Evaluation

We evaluate GOCC on an 8-core ($\times 2$ -way SMT [87]) Intel Coffee Lake CPU with a total 32GB memory, running Linux 5.4.0. The CPU has 32KB L1I and L1D cache, 256KB L2 cache, and 16MB L3 cache. The Go version is 1.15.2.

Table 1 shows the list of applications and libraries we employ. In the absence of standard benchmarking for Go, we selected packages that are popular open-source Go projects (column 2 in Table 1), focus on high performance, utilize lock-based Go concurrency, and provide thread-safe APIs. In particular, Zap and Tally are foundational logging and metrics collection packages used in production go programs by many organizations. Additionally, since we evaluate the projects using their own benchmark suites (more on this below), we only selected projects that feature concurrent benchmarks or whose benchmarks could be straightforwardly converted to be concurrent.

From a static analysis viewpoint, we see that all applications contain several locks. Defer unlocks are common (column 7). The “violates dominance” column shows how many LU-points were discarded since they did not meet the dominance relationship. The number is typically low except for `go-cache`, which has several functions with the repeating pattern of unlocks that do not post-dominate the candidate lock. The “candidate pairs” column shows how many LU-points remain for further analysis. Each column to the right progressively shows the reasons for which a candidate LU-pair was rejected. Rejection due to nested aliased locks is not found in these packages. The second-to-last column shows how many LU-pairs were finally rewritten to use `OptiLock`, including how many of them contain `defer Unlock()`. The last column shows the numbers after we retain only those locks where the functions contain at least 1% of execution time in execution profiles. Overall, GOCC transforms several LU-pairs in each application. Using profiles significantly reduces the number of transformed LU-pairs.

We run all the benchmarks within each repository five times and report the median. We believe the benchmarks accompanying the code best represent its desired characteristics. As some benchmarks are written for a single thread setting, we rewrite them to introduce concurrency to utilize HTM-enabled parallelism fully. We adopt the standard testing package from Go [16], which runs each benchmark for a certain amount of time and reports the throughput as nanoseconds per operation. We wrap the benchmark codes with `RunParallel` [4] helper

function to get parallel performance if it was not already done so. Using more CPU cores, ideally, increases throughput (i.e., reduces average nanoseconds per operation). Then we compare the throughput from locks vs. HTM — a positive percentage means GOCC’s rewrite did better, and a negative percentage means the baseline did better. We vary the number of CPU cores available for benchmarks from 1 to 8. Unlike HPC codes that run on all cores on a server, Go services often use 2-4 cores.

6.1 Results on Popular Go Programs

We categorize the benchmarks in each package into two groups:

1. **Concurrency non-sensitive** benchmarks either have no locks or do not spend much time in critical sections, or our transformation does not result in any performance difference. For these benchmarks, we only show the aggregate (geomean) results unless noted otherwise. They appear as “non sensitive” in our charts, and the number in the parenthesis indicates how many benchmarks are in this group.
2. **Concurrency sensitive** benchmarks exercise modified locks non-trivially. We might have impacted them positively or negatively. For these, we present data from each benchmark and also present an aggregate result (“sensitive” in our charts).

The “all” part of our charts is the geomean taken over all benchmarks. Sometimes this number looks small because of a large number of non-sensitive benchmarks.

In what follows, we provide details of performance evaluation on the aforementioned Go packages. The total number of benchmarks is large; hence, we dive deep only into benchmarks with surprisingly good speedups.

Tally [88] is a fast, buffered stats collection library and Figure 6 shows its results. For the `HistogramExists` benchmark, GOCC achieves more than 660% speedup on 8 cores reducing the original time per operation from 65 ns/ops down to around 8.47 ns/ops at 8 cores. Moreover, the HTM delivers scalable performance. This benchmark uses a `Mutex` lock on a read-only `Exists` operation, and hence, is a natural candidate to demonstrate speedup as HTM eliminates the unnecessary serialization. Conversely, the baseline has a scalability collapse, where the time per operation increases from 20.4 ns/ops to 65 ns/ops for 1 to 8 cores. `ScopeReporting1` holds three independent `RWMutexes` at different points in time and accesses read-

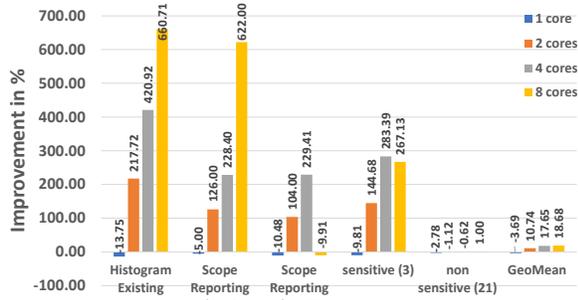

Figure 6: Results on Tally with different core numbers.

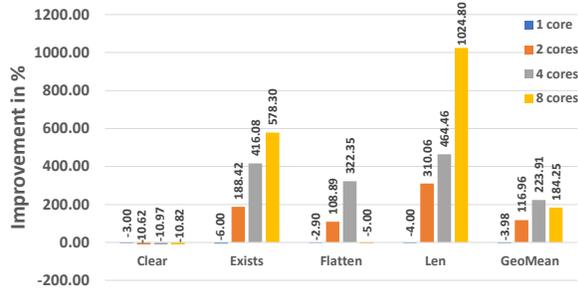

Figure 8: Results on concurrent set with different core numbers.

only data. However, since the `RWMutex` also involves a counter increment and a decrement, its overhead as a result of cache invalidation does not scale well. Thus, even eliding `RWMutex` proves highly beneficial. The speedup for `ScopeReporting10` is lower than that for `ScopeReporting1` because it performs 10x more work inside the critical section. Overall, in the sensitive group, we see a 10% performance drop with a single CPU but 145%, 283%, and 267% improvements with 2, 4, and 8 CPUs, respectively. In the non-sensitive group, the overall performance drop is within the margin of error. Among all the 27 benchmarks of tally, we see up to 18.7% speedup at 8-CPU.

`go-cache` [12] is an in-memory key-value store. It contains benchmarks that exercise repeatedly accessing the same item in a small map. The benchmarks contain both non-cached accesses, similar to how go programmers often use a map, and cached accesses provided by the `go-cache` layer to demonstrate the effectiveness of the library. All benchmarks employ `RWMutex`s for concurrent map read access. Unlike the rest of the use cases, the benchmark files themselves contain locks, which GOCC transforms into using HTM.

Figure 7 shows our empirical results. GOCC speeds up four benchmarks in `go-cache` that were directly accessing the map without the library-provided cache. In each case, we can see more than 100% speedup; the biggest speedup is 742%. The speedups come from eliminating contended atomic operations involved in entering and exiting from a reader lock. The performance scales well with increased parallelism because while the lock-based approach incurs more and more contention, the HTM approach remains conflict-free throughout. The other benchmarks, the majority of which employ the `go-cache`,

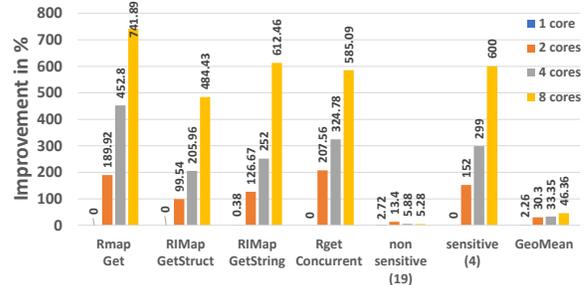

Figure 7: Results on go-cache with different core numbers. (benchmark names reflect abbreviated names of go-cache’s benchmark functions).

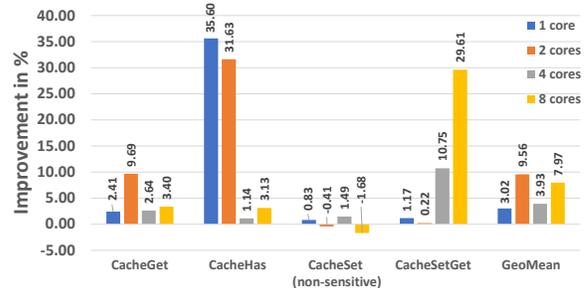

Figure 9: Results on fastcache with different core numbers.

are mildly improved, but more importantly, they were not degraded as a result of transformation via GOCC.

`go-datastructures` [21] is a collection of performant, thread-safe data structures. We apply GOCC on the `set` subdirectory, which contains concurrency benchmarks. The results are shown in Figure 8. The `Len` benchmark computes the length of the set, and it is sped up by $\sim 1000\%$ in the 8 cores setting. `Len` has a short critical section that has a higher entry and exit cost due to atomic operations when using `arWMutex`. HTM performance shows scalability since the HTM version remains conflict-free, whereas the lock-based version collapses with increased contention. The `Exists` benchmark is similar to `Len`, where each goroutine searches one item in a set containing only one item. It scales almost as well as `Len`, but more work is done in the critical section, which amortizes `RWMutex`’s overhead, and slightly reduces HTM’s advantage. The `Flatten` benchmark reads 50 elements from a shared map into a private array, with a layer of caching that eliminates repeated map scanning. It holds a `Mutex` to serialize concurrent accesses to the map/cache. The HTM version avoids the serialization and shows scalable performance for 1-4 cores. At 8 cores, the number of conflicts resulting from updating the cache rises, which makes perceptron not use the HTM, and hence there is no speedup. The `Clear` benchmark has true conflicts, and there is no speedup, but the HTM does not significantly degrade the performance. Overall, utilizing GOCC results in more than 100% geomean performance gain while introducing less than 4% slowdown in a single core setting.

`Zap` [17] is a library that implements fast and structured logging in Go. Being a logging library, it has several IO operations,

and hence GOCC rewrote fewer locks. Compared with other repositories, the improvement on zap is relatively mild. Due to arguably mild speedups on Zap, a large number of benchmarks, we omit a deeper analysis of Zap results. Slowdowns are rare, the biggest being 7%. Overall, we observed a mild $\sim 4\%$ geometric mean speedup with the best case 28% speedup.

Fastcache [18] is a fast, scalable, in-memory cache. The transformed code delivers a maximum of 35.60% speedup and a geomean of 15.65% speedup across all benchmarks.

In the **CacheGet** benchmark, goroutines repeatedly invoke the `Get` function, which uses an `RWMutex` to protect a shared map. `Get` has inter-procedural nested but non-conflicting locks, all of which are transformed into HTM. `Get` looks up a key in the map and returns a value blob. The critical section of `Get` contains a few atomic add instructions, which update shared variables. Transactional conflicts on the shared atomic adds are fewer at low core numbers, and the speedup is visible; however, at larger core counts, the conflicts increase, and the speedup vanishes. Fortunately, the perceptron kicks in and avoids any performance collapse.

The **CacheHas** benchmark is virtually the same as **CacheGet**, but its critical section is shorter since it does not return a populated value buffer. Hence, the speedups are higher due to fewer conflicts, but it follows the same performance pattern as **CacheGet**.

In the **CacheSetGet** benchmark, each goroutine has two loops: the first loop repeatedly invokes `Set` and the second loop repeatedly invokes `Get`. The `Set` function, which inserts a key-value pair into the map, may raise a `panic` if certain constraints are violated. Hence, GOCC does not modify a `Lock()` present in `Set`. The `Get` function is already described previously.

Since all goroutines first attempt `Set`, where Go's default locks are being used, the runtime recognizes it as a starved mutex and takes away the time slice of some of the goroutines. This runtime behavior reduces the number of lock contenders and, as a result, a few goroutines monopolize the lock. These goroutines quickly finish their series of `Set` operations and proceed into calling `Get` in a loop. The contention is lower on `Get` also since the load is now split between `Get` and `Set` with some goroutines on hold. The net effect is a high throughput for the whole benchmark.

It is worth noting that the only other benchmark which invokes the `Set` function is the non-sensitive benchmark **CacheSet**. Even though **CacheSet** exhibits no performance improvement, and **CacheGet** shows mild performance improvement, their composition in **CacheSetGet** leads to secondary effects causing much higher performance gain at higher core counts.

6.2 Perceptron Evaluation

We assess the effectiveness of perceptron using the **Tally** benchmarks. We compare the performance with and without the perceptron machinery. In the absence of the perceptron,

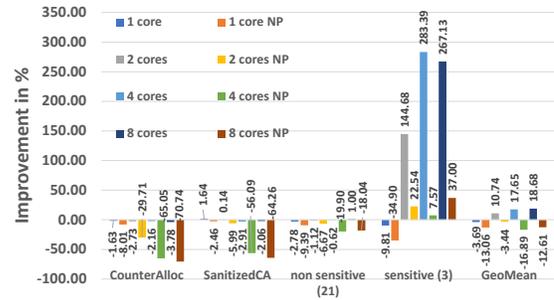

Figure 10: Results on **Tally** to show the effectiveness of perceptron. NP \Rightarrow No Perceptron.

we always attempt HTM. In the results presented in Figure 10, we can observe that the perceptron is effective in eliminating any performance loss. For example, **CounterAllocation** and **SanitizedCounterAllocation** are HTM-unfriendly benchmarks and cause aborts frequently. Perceptron quickly learns to move away from HTM and keeps using the slowpath. Therefore, there is minimal performance loss for the perceptron case.

Finally, we setup a synthetic benchmark — a conflict-free critical section with 1000 counter updates — to evaluate the overhead of the perceptron machinery. We measured the perceptron prediction overhead to be 0.65% and weight update overhead to be 0.73% for a total of only 1.38%.

7 Conclusions

GOCC is a source-to-source transformation tool to speed up lock-based pessimistic concurrency control in Go programs with Hardware Transactional Memory. GOCC combines thorough static analysis with intelligent runtime control to expose additional parallelism available in Go programs. GOCC keeps the developer in the loop, minimizes code changes via execution profiles, and targets only those critical sections that are likely to improve with HTM. The experimental results from real-world Go packages show that GOCC delivers significant (up to $10\times$), scalable performance for concurrent Go code that uses locks while exhibiting rare and relatively small slowdowns.

8 Availability

GOCC is available as an open-source tool [3].

Faastlane: Accelerating Function-as-a-Service Workflows

Swaroop Kotni*, Ajay Nayak, Vinod Ganapathy, Arkaprava Basu
Department of Computer Science and Automation
Indian Institute of Science, Bangalore

Abstract

In FaaS workflows, a set of functions implement application logic by interacting and exchanging data among themselves. Contemporary FaaS platforms execute each function of a workflow in separate containers. When functions in a workflow interact, the resulting latency slows execution.

Faastlane minimizes function interaction latency by striving to execute functions of a workflow as threads within a single process of a container instance, which eases data sharing via simple load/store instructions. For FaaS workflows that operate on sensitive data, *Faastlane* provides lightweight thread-level isolation domains using Intel Memory Protection Keys (MPK). While threads ease sharing, implementations of languages such as Python and Node.js (widely used in FaaS applications) disallow concurrent execution of threads. *Faastlane* dynamically identifies opportunities for parallelism in FaaS workflows and fork processes (instead of threads) or spawns new container instances to concurrently execute parallel functions of a workflow. We implemented *Faastlane* atop Apache OpenWhisk and show that it accelerates workflow instances by up to 15×, and reduces function interaction latency by up to 99.95% compared to OpenWhisk.

1 Introduction

Function-as-a-Service (FaaS) is emerging as a preferred cloud-based programming paradigm due to its simplicity, client-friendly cost model, and automatic scaling. The unit of computation on a FaaS platform is a developer-provided function. Contemporary FaaS applications typically comprise a set of functions expressed as a *workflow*. A workflow is a directed acyclic graph that specifies the order in which a set of functions must process the input to the application. When an external request such as a web request or a trigger (*e.g.*, timer) arrives for an application, an *instance* of its workflow takes life. AWS Step Functions (ASF) [9], IBM Action Sequences [28], and OpenWhisk Composers [43] enable developers to create and execute such workflows.

*Author is currently affiliated with Microsoft Research India. This work was performed when the author was at the Indian Institute of Science.

FaaS shifts the responsibility of managing compute resources from the developer to the cloud provider. The cloud provider charges the developer (*i.e.*, cloud client) only for the resources (*e.g.*, execution time) used to execute functions in the application (workflow). Scaling is automatic for the developer—as the workload (*i.e.*, number of requests) increases, the provider spawns more instances of the workflow.

In contemporary FaaS offerings, each function, even those that belong to the *same workflow instance*, is executed on a separate container. This setup is ill-suited for many FaaS applications (*e.g.*, image- or text-processing) in which a workflow consists of multiple interacting functions. A key performance bottleneck is *function interaction latency*—the latency of copying *transient* state (*e.g.*, partially-processed images) across functions within a workflow instance. The problem is exacerbated when FaaS platforms limit the size of the directly communicable state across functions. For example, ASF limits the size of arguments that can be passed across functions to 32KB [35]. However, many applications (*e.g.*, image processing) may need to share larger objects [2]. They are forced to pass state across functions of a workflow instance via cloud storage services (*e.g.*, Amazon S3), which typically takes hundreds of milliseconds. Consequently, the function interaction latency could account upto 95% of the execution time of a workflow instance on ASF and OpenWhisk (Figure 6).

Prior works [2, 11, 31, 52] have proposed reducing function interaction latency, but they are far from optimal. First, the proposed software layers to communicate state still incur significant, avoidable overhead. Second, they introduce programming and/or state management complexity. As examples, SAND orchestrates via global message queues for remote communication [2], while Crucial introduces a new programming API for managing distributed shared objects [11].

We observe that if functions of the *same workflow instance* were to execute on threads of a single process in a container, then functions could communicate amongst themselves through load/stores to the shared virtual address space of the encompassing process. The use of load/stores minimizes function interaction latency by avoiding any additional software

overhead and exposes the simplest form of communication possible—no new API is needed. The underlying hardware cache-coherence ensures strong consistency of the shared state at low overhead, without requiring elaborate software management of data consistency, unlike prior works [11, 52].

Faastlane strives to execute functions of a workflow instance on separate threads of a process to minimize function interaction latency. This choice is well-suited in light of a recent study on Azure Functions, which observed that 95% of FaaS workflows consisted of ten or fewer functions [50]. This observation limits the number of threads instantiated in a process. Faastlane retains the auto-scaling benefits of FaaS. Different instances of a workflow spawned in response for each trigger still run on separate containers, possibly on different machines.

While threaded execution of functions simplify state sharing within FaaS workflows, it introduces two new challenges: **① Isolated execution for sensitive data.** Several FaaS use-cases process sensitive data. In such cases, unrestricted sharing of data even within a *workflow instance* leads to privacy concerns. For example, a workflow that runs analytics on health records may contain functions that preprocess the records (*e.g.*, by adding differentially-private noise [19]), and subsequent functions run analytics queries on those records. Workflows are often composed using off-the-shelf functions (*e.g.*, from the AWS Lambda Application Repository [3] or Azure Serverless Community Library [40]). In the example above, raw health records are accessible to a trusted preprocessor function. However, they should not be available to untrusted analytics functions from a library.

Unfortunately, threads share an address space, eschewing the isolated execution of functions within a workflow instance. Thus Faastlane enables lightweight thread-level isolation of sensitive data by leveraging Intel Memory Protection Keys (MPK) [29].¹ MPK allows a group of virtual memory pages (*i.e.*, parts of process address space) to be assigned a specific protection key. Threads can have different protection keys and, thus, different access rights to the same region of the process's address space. The hardware then efficiently enforces the access-rights. Faastlane uses MPK to ensure that functions in a workflow instance, executing on separate threads, have different access rights to different parts of the address space. Simultaneously, it enables efficient sharing of non-sensitive data by placing it in pages shared across the functions.

② Concurrent function execution. Some workflow structures allow many functions within an instance to be executed in parallel. However, most FaaS applications (*e.g.*, 94%) are written in interpreted languages, like Python and Node.js [48], whose popular runtimes disallow concurrent execution of threads by acquiring a global interpreter lock (GIL) [12, 16].

Threaded-execution thus prevents concurrent execution of functions in a workflow instance even if the workflow and the

¹ARM [7] and IBM processors [27] also have MPK-like page-grouping support in their processors. AMD has announced MPK-like feature [6].

underlying hardware admit parallelism. Faastlane addresses this problem via its *adaptive workflow composer*, which analyzes the workflow's structure to identify opportunities for concurrent execution, and forks processes (within the same container) to execute parallel portions of the workflow. Specifically, Faastlane uses threads when the workflow structure dictates sequential execution of functions and processes when there is parallelism. Functions running on separate processes use pipes provided in the multiprocessing module of Python for sharing state. Python pipes internally use shared memory communication. Given that processors with 64-80 cores are commercially available ([46, 47]), while those with 128 cores are on the horizon [45], we expect that containers can be configured with enough vCPUs to allow most workflows to execute entirely within a single container instance. Thus, our key objective is to enable FaaS workflows to leverage efficient communication within a single server.

However, it is also possible for some workflow structures to allow hundreds and thousands of parallel functions. A single container may not have enough vCPUs to fully leverage the available parallelism within a workflow instance. Faastlane's adaptive workflow composer thus judges if the benefit from leveraging parallelism in function execution likely to outweigh the benefits of reduced function interaction latency due to execution of all functions of a workflow instance within one container. If so, the composer falls back on the traditional method of launching multiple containers, each of which would run the number of parallel functions that it can execute concurrently. Functions of a workflow instance executing in separate containers communicate state over the network as happens on contemporary FaaS platforms.

Designing for efficient function interactions also helped us significantly reduce the dollar-cost of executing FaaS applications. On FaaS platforms such as ASF, a developer is charged for **①** the cost of executing functions, **②** the cost of transitioning between nodes of a workflow across containers, and **③** the cost of storage services for transferring large transient states. Faastlane reduces the first two components and eliminates the last one.

To summarize, Faastlane makes the following advances:

- It reduces function interaction latency over OpenWhisk by up to 2307× by executing functions on threads. Consequently, it speeds up a set of example FaaS applications by up to 15×.
- It provides lightweight thread-level isolation using Intel MPK to support applications that process sensitive data.
- It leverages parallelism in workflows by adapting to execute functions as processes, when appropriate, to avoid serialization by GILs in popular FaaS language runtimes.
- Further, if the underlying container cannot fully leverage the available parallelism in a workflow instance, Faastlane falls back on using multiple containers as appropriate.

The source code for Faastlane and the applications are available at <https://github.com/csl-iisc/faastlane>.

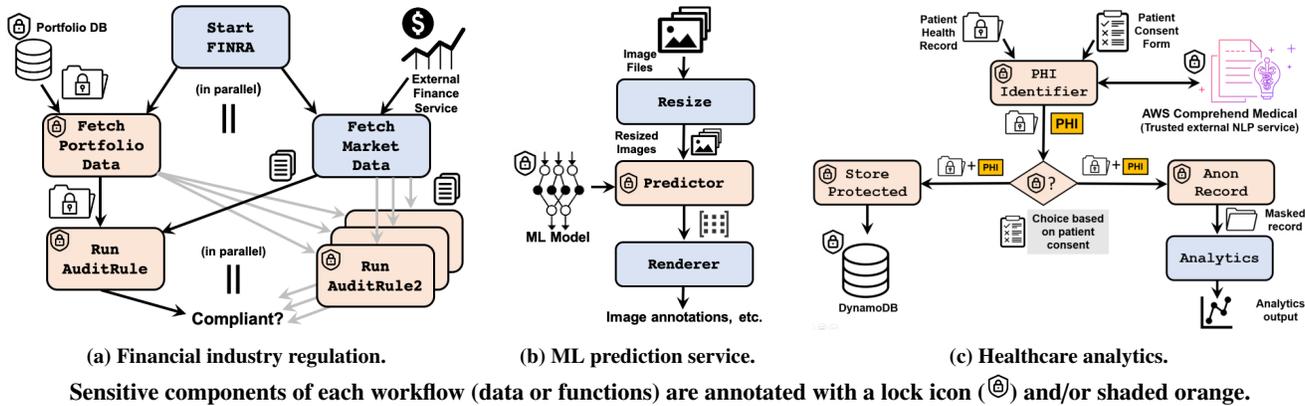

Figure 1: Examples of commercially-important FaaS workflows referenced in Section 2.

2 Function Interaction and State Isolation

We present three commercially-important FaaS workflows that illustrate the importance of minimizing function interaction latency and isolated execution of functions within a workflow instance. We also identify three key design patterns that suffice to express a wide variety of FaaS workflows.

2.1 Financial Industry Regulation

The US Financial Industry Regulatory Authority (FINRA) provides oversight on the operation of broker-dealers to detect malpractices [21]. FINRA requires every broker-dealer to periodically provide it an electronic record of its trades performed during that period. It then validates these trades against market data for about 200 pre-determined rules that check them against a variety of compliance criteria [20].

On average, FINRA validates about half a trillion trades daily [20]. However, this computation only needs to run for some time during the day, and the trade volume to be validated fluctuates daily. The pricing and auto-scaling models of FaaS make FINRA validation an ideal candidate for this platform.

Consider a FaaS workflow to validate a trade against an audit rule (Figure 1a). `StartFINRA` triggers this application’s workflow by invoking two functions. `FetchPortfolioData`, which is invoked on each hedge-fund’s trading portfolio, takes a portfolio ID as input and fetches highly-sensitive trade data, private to each hedge-fund. `FetchMarketData` fetches publicly-available market data based on portfolio type. This function accesses external services to access stock market trade data (e.g., Nasdaq). These functions can run concurrently in a given workflow instance.

The analyzer function (`RunAuditRule`) takes the sensitive output of `FetchPortfolioData` and the non-sensitive information obtained by `FetchMarketData` and validates the trades in each portfolio against the rules. Typically, the size of portfolio data (i.e., the state) shared between the functions runs in KBs, while the market data can be several MBs. Although we have discussed only one checker, FINRA checks compliance against about 200 rules [20]. The checker for each

such rule (e.g., `RunAuditRule2`, etc.) can execute in *parallel* with the other checkers, and each must obtain the outputs of `FetchPortfolioData` and `FetchMarketData`.

To protect sensitive portfolio data from accidental disclosure, `FetchPortfolioData` and `RunAuditRule` simply perform local computations, and do not access external sources. It is also important to ensure that `FetchMarketData` cannot access sensitive data of the other two functions, even though all three functions are part of the same workflow instance of the same application for the same external request.

Current FaaS platforms isolate functions by executing each function in a different container. However, the functions in a workflow may be data-dependent and need to share several MBs of state. Heavy-handed isolation via containers drives up the cost of sharing state and contributes to a significant component of the total workflow execution time (Section 5).

2.2 ML Prediction Service

ML prediction is a computationally-intensive task that takes input data (e.g., images or text), extract features, and provides domain-specific predictions (e.g., detecting objects or predicting sentiments) [17, 34, 52]. Real-world prediction services have real-time response requirements [24]. The workload of an ML prediction service can vary over time and, therefore, can benefit from auto-scaling as provided by FaaS.

Figure 1b presents an example workflow of an ML prediction service for image classification. The workflow has three data-dependent functions, and must, therefore, execute in *sequence*. `Resize` pre-processes an input image and passes the resized image to the main prediction function. `Predictor` consults an ML model and outputs a vector of probabilities that is then post-processed by `Renderer` and rendered suitably e.g., by identifying object boundaries, or suitably labeling objects in an image. The raw image is shared between `Resize` and `Predictor`, and can be 100s-1000s of KB in size, while the output of `Predictor` is in the order of 100s of bytes.

In a typical ML prediction service, the pre-trained ML model is usually the secret sauce, created using sensitive train-

ing data sets and/or at considerable expense. The service provider may not wish to release the model. However, other parts of the workflow may use functions developed by third-parties (e.g., [3, 40]). Here, it is crucial to ensure that `Resize` and `Renderer` do not have access to the state of `Predictor`, which loads the ML model in memory to performs its task.

2.3 Healthcare Analytics

Hospitals generate various health records that can be analyzed to create valuable information for population health management. Applications that process these health records need to meet strict compliance rules (e.g., HIPAA) regarding sensitive data in medical records, including patient details and doctors' notes, which we refer to as protected health information (PHI). Healthcare analytics applications are also a good fit for FaaS pricing and scaling models; AWS Lambda hosts many such applications [41]. Figure 1c depicts an example of healthcare analytics workflow. `PHIIdentifier` takes two inputs: a patient's health record, which may contain unstructured text or images, and a consent form. Using the consent form, the patient can choose to: ① store the medical record securely on a cloud-based service, e.g., DynamoDB in Figure 1c; and ② offer to make available an anonymized version of their medical record to analytics functions downstream. The workflow conditionally executes one or both of the subsequent steps (`StoreProtected` and `AnonRecord`) depending on the patient's consent—we call this design pattern a *choice*.

Both these subsequent steps require identifying PHI data in the unstructured text of the medical record. The `StoreProtected` function segregates PHI data from the medical record, and stores both the PHI data and the stripped medical record securely on a cloud server; the two parts can be combined later when the patient submits a request to retrieve the record. `AnonRecord` anonymizes the medical record by masking out the PHI data identified in the record.

The `PHIIdentifier` function securely communicates with a trusted, external service to identify PHI data in the medical record, e.g., a HIPAA-compliant NLP service like AWS Comprehend Medical [5] or a medical image analyzer like Amazon Rekognition [22]. The medical record and the PHI data are sensitive, and the untrusted `Analytics` function must not access them. The internal state of `PHIIdentifier`, `StoreProtected`, `AnonRecord` must also be protected from `Analytics`. As in the other two examples, this workflow also requires communication of a significant amount of state (e.g., medical records containing images) between functions.

2.4 Function Interaction Patterns in FaaS Workflows

The three workflows discussed thus far illustrate three design patterns for function interaction in FaaS workflows:

- The *parallel* pattern as seen in FINRA, in which functions that are not data-dependent can execute concurrently;
- The *sequence* pattern as seen in the ML prediction service, in which data-dependent functions must execute in sequence;

- The *choice* pattern as seen in Healthcare analytics, in which functions in the workflow are conditionally executed based on the user's input or the output of a function in the workflow.

With these design patterns, we can succinctly encode all constructs of Amazon States Language (ASL) [4, 8]. ASL is the format in which application developers specify workflows for ASF. Thus, it suffices for Faastlane to incorporate support for these three design patterns to express most of the workflows available on contemporary FaaS platforms.

2.5 Threat Model

As illustrated in our examples, functions in a FaaS workflow produce/consume sensitive and non-sensitive data. Even functions that belong to the same workflow instance of a FaaS application should not have unfettered access to each other's state. It is not uncommon for a single FaaS application to use untrusted functions from public repositories (e.g., [3, 40]) along with trusted functions and services that can access sensitive data. As we saw, functions do communicate a substantial amount of state, and the use of any heavy-handed mechanisms for isolation, e.g., executing function within separate containers, inevitably leads to performance bottlenecks.

Our goal is to enable efficient sharing of state across functions in a workflow with just the right amount of isolation. We assume that the cloud provider offers an MPK-based hardware platform and the operating system (OS) used to run FaaS processes includes standard, widely-deployed data-execution prevention features (e.g., $W\oplus X$). Additionally, Faastlane does not change the OS features that aid in defending against microarchitectural side-channel attacks. Best practices to defend against such attacks, such as those developed in Firecracker [1], can also be adapted for use with Faastlane. We implemented Faastlane's mechanisms as extensions to the language runtime (i.e., Python interpreter). We, therefore, assume that the runtime is part of the trusted computing base. Note that we strive to isolate sensitive data and *not* code. Thus, we cannot guard the confidentiality of proprietary functions in FaaS workflows.

3 Design Considerations

Faastlane's design has three objectives. First, we aim to *minimize function interaction latency without sacrificing concurrency in parallel workflows*. It leverages fast communication within a single server (machine) to share state across functions of a single workflow instance, wherever possible. Loads and stores to a shared address space are the lowest-latency options for sharing data. Faastlane thus strives to map functions in a workflow instance to threads sharing a process address space. While threads serve as a vehicle of concurrency in most settings, they do not in this case. Interpreters for popular languages used to write FaaS applications, such as Python and Node.js, use a global interpreter lock (GIL) that prevents concurrent execution of application threads. Faastlane thus has a workflow composer, a static tool that analyzes the workflow

structure, and forks processes instead of threads wherever the workflow allows parallelism. These processes run within the same container and communicate via Python pipes.

The workflow composer is also cognizant of the fact that a single container may not have enough vCPUs to run all functions concurrently (as processes) for workflows that admit massive parallelism. If all functions of an instance of such workflows are packed onto a single container, the performance loss from the lack of concurrency may outweigh the benefits of reducing function interaction latency. Therefore, the composer periodically (*e.g.*, once a day) profiles containers on the FaaS platform to ascertain the available parallelism. Wherever the composer encounters large parallelism in the workflow structure, it determines whether it would be beneficial to deploy instances of that workflow across multiple containers based on measurements from profiling. Each container itself concurrently runs multiple functions as processes, commensurate to that container’s vCPU allocation.

Second, Faastlane aims to *control the sharing of data within a workflow instance* when functions of a workflow instance run as threads. As motivated in Section 2, we discovered important workflows wherein sensitive data must be isolated and shared only with authorized functions. While there is a large literature on in-process isolation techniques [13, 15, 26, 36], recent work [25, 54] has shown that a hardware feature available on Intel server processors, called MPK, offers thread-granularity isolation at low overheads. Faastlane uses Intel MPK to provide thread-granularity memory isolation for FaaS functions that share a virtual address space.

Finally, Faastlane aims to meet the above two objectives *without needing FaaS application writers to modify their functions* and without requiring them to provide more information (than they already do) to FaaS platforms. It is also transparent to the cloud provider, except that Faastlane is most useful when the underlying hardware supports MPK or MPK-like features. Faastlane achieves this goal by designing a static client-side tool, the workflow composer, along with a profiler to achieve its objective of minimizing function interaction latency without sacrificing concurrency. A modified language runtime (here, Python), and the composer, ensure data isolation. Faastlane can be packaged in an enhanced container image. No new API is exposed to FaaS applications, and no additional information is required from developers. This differentiates Faastlane from many prior works (*e.g.*, [11]) that introduce new FaaS programming abstractions (*e.g.*, to specify data sharing). We demonstrate Faastlane’s adoptability by deploying it atop an unmodified OpenWhisk-based FaaS platform on a server equipped with MPK.

4 Implementation of Faastlane

Faastlane needs to accomplish two primary tasks. First, it must spawn threads and/or processes and/or multiple containers to execute functions of a workflow instance for minimizing function interaction latency without sacrificing concurrency that

42              args = [portfolioData, marketData])
43    T1.start(); T1.join()
44    T2.start(); T2.join()
45    return ruleOut

```

Figure 3: Workflow composer output for functions in Figure 2.

exists in the workflow structure. Second, when executing functions as threads, it must ensure the isolation of sensitive state across the functions. Faastlane’s workflow composer, aided by a simple profiler, accomplishes the first task. A modified language runtime and the composer accomplish the second.

4.1 Minimizing Function Interaction Latency

Current FaaS platforms take a workflow description (Figure 1a) and function definitions as inputs (Figure 2), as sepa-

rate entities. They create one container for each of the functions in each executing instance of a workflow. The platform uses the workflow description to suitably route function calls.

Faastlane does not demand any new information from the FaaS application developer or modifications to the code. Faastlane's workflow composer tailors the JSON workflow description and the function code for execution in Faastlane's runtime. The workflow composer first analyzes the workflow structure (JSON description) to identify if it allows for any concurrency in executing the functions of an instance. If the workflow is sequential, the composer packs all functions of the workflow within a unified function called `Orchestrator`. To schedulers on FaaS platforms, the unified workflow provides the *illusion* of an application with a single-function. The entire workflow is thus scheduled for execution in a single container. The workflow composer also creates *function wrappers*, which the `Orchestrator` invokes suitably to reflect the DAG specified in the workflow structure. The `Orchestrator` method's return value is the output of the FaaS application.

Function wrappers explicitly identify the input and output of the function. Wrappers have an associated built-in `start()` method that is implemented in Faastlane's runtime. Invoking a `start()` method spawns a new thread to execute the corresponding function (`join()` denotes the end of the thread). As will be described later in this section, wrappers also implement data isolation using MPK primitives. Each function wrapper begins by reading input from the (shared) process heap and places its output back on the heap. All the other data of a function, not explicitly specified in the wrapper's I/O interface, is considered private to that function and stored in that thread's heap partition (detailed shortly). The `Orchestrator` function specifies the order in which threads are invoked, thereby enforcing the workflow's data sharing policy. The functions of a workflow instance executing as threads minimizes function interaction latency by sharing data using load/stores to the shared process heap.

Language runtimes use a GIL that prevents threads from executing concurrently. This does not present any issues for sequential workflows but leads to loss of concurrency for workflows that contain parallelism. Faastlane launches functions of a workflow instance that can execute in parallel as separate processes instead of threads. Processes can run concurrently on vCPUs of the container deployed on the FaaS platform. These functions communicate via Python pipes.

For example, consider the functions `FetchMarketData` and `FetchPortfolioData` that can run in parallel. The workflow composer creates a parallel-execution wrapper (`PStateWrapper` in Figure 3) that identifies parts of the workflow that can execute concurrently (using the `Process` keyword). The subsequent `start()` method for `P1` and `P2` spawns new processes to execute those portions of the workflow. Each such forked process can itself be a sub-workflow and can further spawn threads or processes as required. The inputs to these functions need not be explicitly copied, as they are

already available in the address space before the `start()` method forks a new process. The output is copied back to the parent process using Python pipes (`queue1` and `queue2`). The `join()` methods in `Orchestrator` serve as barriers that prevent the workflow from progressing unless the corresponding function wrapper thread has completed execution.

Using processes eschews some of the benefits of sharing transient states via loads/stores. Moreover, the language runtime has to be set up in each process, resulting in extra page faults. Typically, functions in FaaS are short-running (<1 sec) [50]). Thus, the overheads due to page faults are non-negligible for these ephemeral processes (detailed in Section 5.2). However, the loss of concurrency with only threads justifies the use of processes for portions of a workflow that admit parallelism.

A container may not have enough vCPUs to run all functions for a parallel section of a workflow concurrently. The number of vCPUs exposed to a container may be smaller than the number of cores in the underlying hardware. Further, FaaS platform providers may not even expose the number of vCPUs on the container it deploys to run a workflow instance. Therefore, Faastlane deploys a simple compute-bound micro-benchmark on the FaaS platform and observes its scalability to infer the number vCPUs in the container deployed by the platform. Such profiling is needed only very infrequently (e.g., once a day) since the number of vCPUs in a container for a given class typically does not change [33].

On encountering a large, parallel workflow structure, the composer spawns multiple containers, each packed with the number of processes equal to the (inferred) number of vCPUs in the container. Networked communication across functions on different containers happens via a REST API [32].

To support cloud hardware that does not offer MPK (or MPK-like) support, the profiler checks for `pku` and `ospke` flags in `/proc/cpuinfo/` to ascertain if the FaaS platform supports MPK. If not, the workflow composer uses only processes to execute functions. This fallback option sacrifices the gains in lowering function interaction latency that threads offer, but adheres to Faastlane's principle of being transparent to both the application writer and the cloud provider.

4.2 Isolation for Sensitive Data

The use of threads for efficient state sharing among functions in a workflow fundamentally conflicts with the goal of protecting sensitive data in situations such as those illustrated in Section 2. Faastlane leverages an existing hardware feature to enforce thread-granularity isolation of data. Note that data isolation is not a concern when functions execute on separate processes. Each process has its own isolated address space, and the state-less nature of FaaS means that they cannot communicate amongst themselves via the local file system, even when they run on the same container.

Faastlane's runtime ensures that each thread gets a private, isolated portion of address space. There is also a shared parti-

tion of the address space that the threads use to communicate the transient state via load/store. Isolation is ensured efficiently using MPK hardware. The memory allocator of the language runtime is extended to ensure that each thread allocates its memory needs from its private partition by default.

Memory protection keys. Intel MPK provides hardware support for each page in a process's address space to be annotated with a 4-bit protection key. Logically, these keys allow us to partition the virtual address space into 16 sets of pages. MPK uses a 32-bit register, called the PKRU register, to specify access rights for each set of pages. Each key is mapped to 2 bits in the PKRU register, that specify access rights of the currently-executing thread to pages in each set. On a memory access, permissions are checked against the PKRU register. Thus, using MPK, it is possible to specify read/write accesses for a set of pages that share the same protection key.

When a process starts, all pages in its address space are assigned a default protection key, and the PKRU value allows both read and write access to all pages. A process assigns a protection key to a page using a system call (`pkey_alloc` in Linux), and the protection key is written into the page-table entry. To specify access rights for pages with that protection key, the process uses the `WRPKRU` instruction, which allows the process to modify the value of the PKRU register from user-space. Since the `WRPKRU` instruction can be executed from user-space, it is important to ensure that it is only invoked from trusted code (called *thread gates*). Faastlane uses binary inspection (as in ERIM [54]) to verify the absence of `WRPKRU` instructions in locations other than thread gates. Faastlane performs this inspection before the workflow is deployed in the FaaS environment. Therefore, it does not incur any run-time performance overheads.

Thread Gates. A thread gate is a sequence of instructions that contains MPK-specific instructions to modify the PKRU register or to assign protection keys to pages. A thread gate is classified as an entry gate or an exit gate, based upon whether it executes at the beginning or end of a thread. Faastlane modifies the Python runtime to implement the instruction sequence corresponding to entry and exit gates in the builtin `start()` and `join()` methods.

An entry gate accomplishes three tasks. First, it attaches a protection key to the thread, using the `pkey_alloc` system call. Second, it communicates this key to the memory manager in Faastlane's Python runtime. The memory manager ensures that all subsequent memory requests are satisfied from pages tagged with the thread's protection key. Finally, the gate uses the `WRPKRU` instruction to write to the PKRU register to ensure that only the current thread has read and write access to pages tagged with that protection key. In effect, this establishes a heap partition accessible only to that thread.

When the thread completes, the exit gate frees the protection key for further use using the `pkey_free` system call. It also zeroes-out the memory region allocated to serve memory for that protection key. Such cleanup allows Faastlane to reuse

protection keys for multiple threads without compromising the isolation guarantees. Without reuse, Faastlane's Python runtime would restrict the number of available protection domains to 16, thereby also restricting the number of functions in the workflow to 15.² One domain is reserved for the parent thread (Orchestrator). The shared heap is accessible to all threads and serves as the shared memory region to which all threads enjoy unfettered read/write access.

Thread Memory Management. Faastlane modifies Python's memory manager to map requests from different threads to different virtual address regions. Faastlane's modifications are packaged as a CPython module (tested for Python3.5). Faastlane modifies the default memory allocator to maintain separate arenas (contiguous regions of virtual address space; typically 256KB) for different threads and ensures that memory requests from one thread are always mapped to the thread's private arenas. After requesting an arena from `mmap`, Faastlane attaches a protection key to the arena using the `pkey_mprotect` system call, effectively reserving the arena for memory requests to the thread owning the protection key.

As discussed, the thread-entry gate associates a protection key for a thread executing a function in the workflow when it starts execution and maps all memory requests from the thread to that private arena. If the arena becomes full, it allocates another arena. When the wrapper finishes, it destroys all the arenas associated with that thread's protection key. The only exception is that of the main thread (Orchestrator), whose arenas are accessible to all threads in the process.

4.3 Putting It All Together

Figure 4 summarizes the lifecycle of a FaaS workflow in Faastlane. The lifecycle starts with the application developer supplying the functions and a workflow description connecting them. The client supplies these entities to Faastlane's workflow composer. The composer analyzes the workflow and produces a unified description using the design patterns discussed in Section 2.4, capturing the available parallelism in the workflow. Based on the available parallelism (if any) and the number of vCPUs in the container (determined via profiling), the workflow is deployed in the FaaS platform.

For workflows without or limited parallelism, the composer provides a single top-level function, called the `Orchestrator`, that encapsulates the entire workflow description. The client supplies this unified workflow description to the FaaS platform, which gives the platform the illusion of a single-function FaaS workflow. The platform schedules the entire FaaS application for execution within a single container. If the workflow contains parallelism that exceeds the estimated number of vCPUs in a container, the composer creates multiple `Orchestrator` functions. Each `Orchestrator` subsumes a sub-workflow with functions that can run concurrently within a single container. Each `Orchestrator` is scheduled on a dif-

²A vast majority of workflows contain fewer than 10 functions [50]. Previous work has also shown ways to virtualize MPK partitions [44].

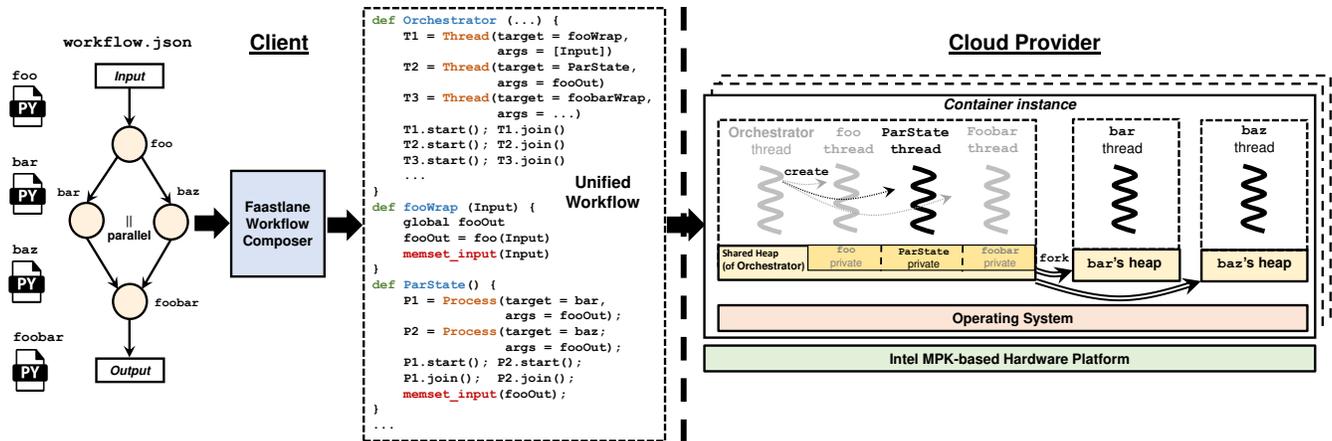

Figure 4: This picture shows a snapshot of the workflow when the functions bar and baz are executing concurrently. The threads shown in grey have either completed execution (foo), are currently paused (Orchestrator) or are yet to be created (foobar). ParState is the wrapper for the bar and baz functions in the parent process. Although not shown in this example, Faastlane allows child processes to be sub-workflows that can recursively spawn threads or processes. If the workflow is highly parallel, the workflow composer creates multiple top-level Orchestrator functions, each of which executes in a different container.

ferent container by the FaaS platform. Faastlane’s runtime component within the container accepts the unified workflow description and decomposes it to identify the functions within the workflow. Based on the Orchestrator, it either starts threads (one per function) or forks processes to execute functions of the workflow. When functions execute as threads, each thread executes instructions to identify a partition of the process heap accessible only to that thread (using MPK primitives). It uses this partition to store data private to the function. The functions running on the thread can share state via load/stores to a designated shared heap for the process. When a thread completes, the function’s output is made available (via the Orchestrator method) only to the functions in the workflow that consume that output. When Faastlane forks a process, it passes only the output of the last method from the parent process to the Orchestrator method of the child process via a Python pipe. For large parallel workflows, functions in different containers communicate over the network stack as in contemporary FaaS platforms.

Faastlane does not impact auto-scaling in FaaS. Different instances of a given workflow spawned in response to a trigger are scheduled on different containers, as is typical.

5 Evaluation

We evaluate Faastlane against four real-world applications that broadly capture popular FaaS function interaction patterns [39]. Besides the applications in Section 2, we include Sentiment analysis, which is another real-world use case [49]. Sentiment analysis evaluates user reviews for different products of a company. Its workflow contains two choice states. The first choice state chooses an analysis model based on the product. The second choice state publishes to a database versus a message queue (for manual analysis of negative reviews) based on review sentiments. Together, these applications en-

capsulate all the patterns discussed in Section 2.4. Table 1 shows the configuration of our experimental system, including the software stack. We measure how Faastlane improves function interaction latency, end-to-end latency, throughput, and reduces dollar-cost. We perform the experiments on a single machine where Faastlane can pack all functions of a workflow instance within a single container. However, in Section 5.4 we further show how Faastlane scales up to use multiple containers in face of large parallelism within a workflow structure.

We compare Faastlane’s performance against ASF, OpenWhisk and SAND [2]. SAND aims to reduce function interaction latency. It executes functions in a workflow as separate processes within a container and shares state using a hierarchical message queue. Our performance experiments with OpenWhisk, SAND and Faastlane were run on our local hardware platform, while ASF experiments were run on the AWS cloud infrastructure. We cannot control the AWS cloud hardware platform. Thus, the ASF measurements are not necessarily directly comparable to those of the other platforms.

5.1 Function Interaction Latency

Figure 5 reports the function interaction latency of the four applications under different FaaS platforms. The applications are as described in Section 2, with the only difference that the FINRA application checks portfolio data against 50 audit rules. We run each application at least 100 times and report the median. We observe that function interaction latency is

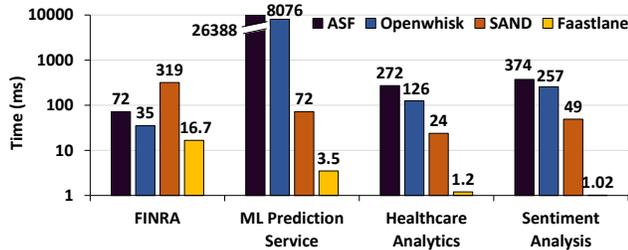

Figure 5: Median function interaction latency (in milliseconds)

lowest with Faastlane across all four applications, each with different function interaction patterns. Faastlane reduces the latency over its *closest* competitor by 52.3%, 95.1%, 95% and 98% for FINRA, ML prediction service, Healthcare analytics and Sentiment analysis, respectively.

SAND reduces the function interaction latency compared to current FaaS platforms, except for FINRA. FINRA runs 50 audit rules in parallel, where SAND’s hierarchical messaging queues serialize communication from concurrently executing functions. Consequently, SAND increases the function interaction latency to 319ms from 35ms on OpenWhisk. However, Faastlane reduces it to 16.7ms. For ML prediction service, SAND reduces the interaction latency to 72ms from thousands of milliseconds on OpenWhisk while Faastlane almost eliminates it. Similarly, for the remaining apps, the interaction latency is a mere 1-1.2ms with Faastlane.

Note that the ML prediction service has very high function interaction latencies (in thousands of milliseconds) on both ASF and OpenWhisk. This is because the ML prediction service transmits the largest state across functions—an image of about 1.6MB size from the Resize function to the Predictor function (Figure 1b). However, on ASF and OpenWhisk, functions in a workflow can directly transmit a maximum state of size 32KB [35] and 1MB, respectively. Consequently, the ML prediction service is forced to fall back upon a slow storage service like Amazon S3 for state sharing on these platforms. The other applications transmits tens of KBs of state across functions in a workflow (for the payloads we used).

Though Faastlane offers the lowest function interaction latency for FINRA, the latency of 16.7ms is higher than the latency observed for the other applications even if it transmits only tens of KBs of state across functions. This behavior is because FINRA’s workflow invokes 50 functions in parallel to audit the portfolios. Faastlane executes these functions as separate processes where the state is shared via Python pipes, instead of loads/stores within a process address space. While this helps end-to-end latency by leveraging concurrency (Section 5.2), the cost of sharing state increases compared to sharing state across threads of the same process.

5.2 End-to-End Application Performance

Latency. The end-to-end execution latency of an application’s workflow is the time that elapses between the start of the first function of the workflow and the completion of the final function in the workflow. We measure end-to-end latency by

executing each application at least 100 times and report both the median and tail (99%-ile) values.

We dissect the end-to-end latency as follows:

- ① The time spent in external service requests. An external service request is one that requires communication outside the FaaS platform. For example, the healthcare analytics application uses the AWS Comprehend Medical service to identify PHI in health records (Section 2.3). This component depends on several factors, including time over the network and the latency of processing the request at the external entity.
- ② The compute time, which is the time during which the workflow functions execute on the processor. It does not include the time spent on external service requests.
- ③ The function interaction latency on the FaaS platform.

Figure 6 presents the end-to-end latency broken down into the above components. For each application, we report median and 99%-ile latency on ASF, OpenWhisk, SAND, and Faastlane. The total height of each bar represents the end-to-end latency, and the stacks in the bar show the breakdown. In Figure 6a, we first note that the compute time is significantly more on ASF than on other platforms. While the FINRA application has 50 parallel functions, ASF never runs more than 10-12 of them concurrently. On other platforms, the compute time is much shorter because all the functions execute in parallel. Most of the time is spent on the external service request for retrieving the trade data. Overall, we find that Faastlane improves end-to-end latency by 40.5%, 23.7% over OpenWhisk and SAND, respectively.

In ML prediction service (Figure 6b), OpenWhisk’s and ASF’s end-to-end execution latency are dominated by the function interaction latency, as discussed earlier. In comparison, SAND significantly reduces function interaction latency, while Faastlane practically eliminates it. Consequently, even in comparison to SAND, Faastlane improves end-to-end latency by 22.3%. Over OpenWhisk, the improvement due to Faastlane is 15×. Note that the compute time on OpenWhisk is shorter (by about 100ms) than that on Faastlane and SAND, although we ran OpenWhisk, Faastlane, and SAND on the same hardware platform. This difference is because, on Faastlane and SAND, the ML prediction service application transmits data between functions using JSON (de)serialization methods, contributing to the compute time. In contrast, on OpenWhisk, the application is forced to use S3, and the application does not use JSON when communicating with S3.

In Healthcare analytics (Figure 6c), the time spent on external service request (AWS Comprehend Medical) is significant. The response latency from AWS Comprehend Medical depends on external factors and is orthogonal to our system design. We observed that the latency is much lower on ASF but similar on the FaaS platforms that were executed on our local hardware. In comparison to OpenWhisk and SAND, Faastlane improves end-to-end latency by 9.9% and 10.4%, respectively. Faastlane improves end-to-end latency of Sen-

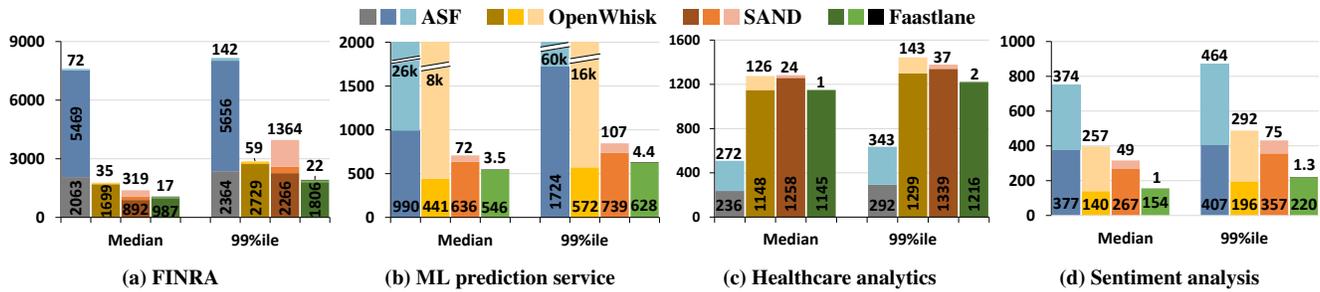

Figure 6: Application end-to-end latency (in ms). Legend shows external service time, compute time and function interaction latency for each platform in that order. Note that (b), (d) do not have external services and (c) has negligible compute time (2-4ms).

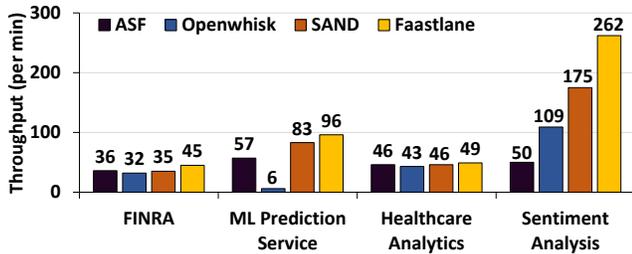

Figure 7: Measuring application throughput.

timent analysis (Figure 6d) by 61% over OpenWhisk and 51% over SAND. The tail (99%-ile) latency trends (Figure 6), mirror the above observations. In short, Faastlane provides the least end-to-end latency across platforms that are directly comparable, *i.e.*, run on the same hardware.

Throughput. Figure 7 shows the application throughput, measured as the number of application requests serviced per minute on different FaaS platforms. We use the time between the invocation of the first request and the response receipt for the last request. We repeat this experiment over several requests to measure throughput as the number of requests-per-minute. Unlike end-to-end execution latency, throughput measurement also accounts for initialization (*e.g.*, spawning containers), and post-processing time. Note that to compare throughput, we also need to ensure that all configurations run on the same hardware. The total number of cores on the hardware platform (and therefore, the available parallelism) has a *first-order* effect on throughput, unlike latency. While we present numbers from ASF for completeness, we forewarn the readers against directly comparing ASF's throughput numbers (run on hardware not in our control), with the numbers obtained on other FaaS platforms executed locally.

Figure 7 shows the throughput observed for each of our applications on ASF, OpenWhisk, SAND and Faastlane. In general, we observe that throughput follows the trends in the end-to-end latency. Faastlane provides the best throughput across all applications. For the FINRA application, Faastlane improves throughput by 28.6% over its nearest competitor (SAND). For ML prediction service and Sentiment analysis, Faastlane improves throughput by 15.6%, 49.7% over SAND and by 16 \times , 2.4 \times over OpenWhisk, respectively. For the healthcare analytics application, Faastlane provides a modest throughput improvement of 6% over SAND.

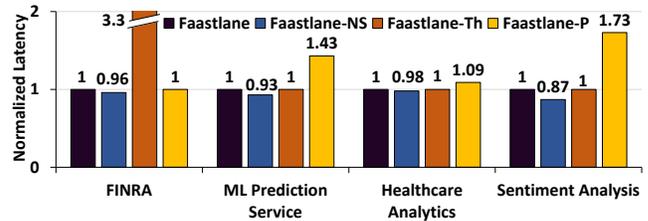

Figure 8: Analysis of the cost of isolation in Faastlane.

Cost of Isolation. For a deeper understanding of the design choices made in Faastlane, we create three variants of Faastlane. First, we turn off thread-level memory isolation in Faastlane by disabling its MPK-enabled memory manager and the zeroing-out of function's state in the shared domain (Faastlane-NS). The difference in performance between Faastlane-NS and Faastlane quantifies the performance cost of data isolation using MPK. Second, we constrain Faastlane to only use threads, and not a mix of processes and threads based on the workflow structure (Faastlane-Th). The performance difference between Faastlane-Th and Faastlane quantifies the usefulness of adapting between processes and threads. Third, we constrain Faastlane to use *only* processes, and share state via Python pipes (Faastlane-P). The performance difference between Faastlane-P and Faastlane quantifies the importance of employing threads when possible.

Figure 8 shows the normalized median end-to-end latency for Faastlane, Faastlane-NS, Faastlane-Th and Faastlane-P for all four applications. The height of each bar is normalized to latency under Faastlane. Comparing Faastlane-NS and Faastlane, we observe an increase of 1.9-14.9% in the end-to-end latency in Faastlane, which denotes the cost of MPK-based isolation mechanism. We argue that this performance cost is a reasonable price to pay for data isolation.

Next, we observe that the latency for Faastlane-Th is 3.3 \times of the Faastlane for FINRA. Recall that FINRA has 50 parallel functions in its workflow. Since the threads cannot execute concurrently in our Python implementation (due to the GIL), Faastlane-Th cannot execute these parallel functions concurrently. In contrast, Faastlane employs processes instead of threads and can leverage the underlying hardware resources for concurrency. For the rest of the applications, there is no difference between Faastlane-Th and Faastlane as they do not

Application	AWS Step Functions (ASF)				Faastlane Lambda
	Lambda	Step	Storage	Total	
FINRA	31.17	1325	0	1356.17	10.2
ML Prediction Service	21.75	125	27.85	174.6	11.87
Healthcare Analytics	1.65	150	0	151.65	0.83
Sentiment Analysis	1.85	175	0	176.85	1.03

Table 2: Cost (in USD) per 1 million application requests

contain any parallel functions. This experiment shows the importance of analyzing the workflow structure and using processes instead of threads in the presence of GIL.

Finally, the latency for Faastlane-P is 9-73% higher than Faastlane in applications except FINRA. Lifetimes of FaaS functions are short, *e.g.*, 50% of the functions execute in less than 1s [50]. Thus, processes running these functions in Faastlane-P are ephemeral and we found the page-fault latency in setting up language runtime in each process dominates their execution times. Faastlane reduces page-faults by 1.43-3.95 \times using threads over processes. For FINRA, Faastlane uses processes to leverage parallelism. Thus, there is no difference between Faastlane-P and Faastlane.

5.3 Dollar-cost of Application Execution

We now discuss the dollar-cost implications to developers for executing applications on Faastlane versus atop ASF. The cost of executing applications on ASF includes: ① *Lambda* costs, which is the cost of executing the functions of a workflow, ② *Step* costs, which is the cost of transitioning from one node to another in an ASF workflow across containers, and ③ *Storage* costs, for transferring large transient state [53]. We noticed that execution times of functions on ASF varies run-to-run. We used the smallest execution time to estimate the least cost of running an application on ASF.

Unlike with ASF, the dollar-cost of running on Faastlane *only* includes the *Lambda* cost. The *Step* cost of transitioning across containers is zero because Faastlane executes an entire workflow instance within a container. Faastlane does not need a storage service to transfer state and therefore incurs no *Storage* cost. To measure the *Lambda* cost on Faastlane, we deployed applications with Faastlane-enhanced virtual environments on AWS Lambda. We disabled MPK instructions because AWS machines may not have MPK-enabled today. However, we adjusted the billed-duration and maximum memory of each application with MPK overheads (1.9-14.9%). We exclude the cost of any external service that a function uses for its execution (*e.g.*, AWS Comprehend Medical).

Table 2 reports the total cost incurred for each application on ASF and Faastlane. Faastlane executes applications only at 0.6-6.8% of the cost of ASF. Faastlane eliminates expensive step costs and storage costs by designing for efficient function interactions. Despite running on containers with larger memory, Faastlane reduces Lambda costs, partly due to the reduction in runtime because of efficient function interactions and partly due to the current AWS Lambda pricing model.

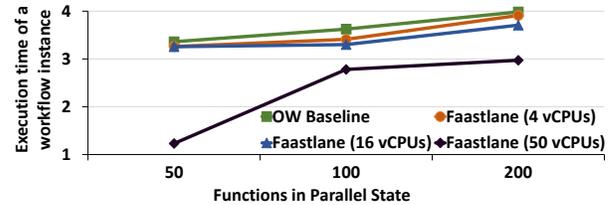

Figure 9: Scalability for FaaS Applications with parallelism.

5.4 Scalability with Multiple Containers

All experiments thus far were limited to one server, and the underlying container had sufficiently many vCPUs to run all parallel functions in applications like FINRA concurrently. We now explore how Faastlane would scale if the underlying container had a limited number of vCPUs and when multiple servers are to be deployed to cater to the parallelism available within a single workflow instance. For this purpose, we scaled up the number of functions in the parallel step in FINRA’s workflow from 50 to 200. We also varied the number of vCPUs in each container from 4 to 50.

When Faastlane detects that the parallelism in the workflow exceeds the parallelism serviceable by the vCPUs of a single container, it spawns multiple containers, possibly scheduled on multiple servers. Each container is packed with a number of processes commensurate with the vCPUs allotted to it.

Figure 9 shows how Faastlane performs under such circumstances vis-a-vis OpenWhisk baseline that runs every function in separate containers. The y-axis reports the average execution time of a workflow instance as the number of parallel functions are scaled (x-axis). We observe that when the number of vCPUs per container is limited, Faastlane offers limited uplift (2.46%). This is expected since Faastlane falls back on network-based communication across containers when spawning multiple containers. As we increase the number of vCPUs per container, Faastlane launches fewer containers, and performs much better. At 50 vCPUs per container, Faastlane speeds up by 2.73 \times over the baseline when there are 50 parallel functions. Even when there are 200 functions, Faastlane reduces execution time by 25.3%. In short, Faastlane is most effective when it can leverage fast communication within a container, particularly for sequential workflows and those with limited parallelism. However, even when faced with large parallelism in workflows, coupled with limited parallelism in underlying containers, Faastlane scales at least as well as the current offerings.

6 Related Work

Table 3 compares Faastlane against closely related systems using three criteria—function interaction latency, ability to support unmodified FaaS workflows (*e.g.*, those written for commodity FaaS offerings such as OpenWhisk and ASF), and whether the solution supports function interaction across machines. Commercial FaaS solutions satisfy the latter two criteria, but have high function interaction latencies [10, 23].

	Function Interaction Latency	Unmodified Application	Interaction Across Machines
OpenWhisk/ASF	High	✓	✓
SAND [2]	Medium	✓	✓
SONIC [37]	Medium	✓	✓
Crucial [11]	Medium	✗	✓
Cloudburst [52]	Medium	✗	✓
Faasm [51]	Low	✗	✗
Nightcore [30]	Low	✗	✗
Faastlane	Low	✓	✓

Table 3: Comparing Faastlane with related work.

SAND [2] reduces function interaction latency via hierarchical message queues, while allowing unmodified FaaS applications and workflows spanning multiple machines. However, as our evaluation showed, Faastlane’s approach of using memory load/store instructions reduces function interaction latency even further. SONIC [37] aims to reduce function interaction latency by jointly optimizing how data is shared (e.g., by sharing files within a VM or copying files across VMs) and the placement of functions in a workflow. However, SONIC uses files as the core data-sharing mechanism, leaving room for latency reduction in several cases.

Crucial [11] improves state-sharing in highly parallelizable functions using distributed shared objects (DSOs). DSOs are implemented atop a modified Infinispan in-memory data grid. Unfortunately, Crucial’s approach is not compatible with unmodified FaaS applications. Cloudburst [52] focuses on distributed consistency of shared data using Anna key-value stores [56]; other systems, like Pocket [31], use specialized distributed data stores for transient data. These systems improve function interaction latency, but leave significant headroom for improvement because of the overheads of accessing the remote data store.

While all the aforementioned systems support distributed FaaS applications, in which interacting functions execute on different machines, Faasm [51] and Nightcore [30] aim to reduce function interaction latency by executing workflows on a single machine. Faasm [51] uses threads and shared memory with software-fault isolation [55] (more heavy-weight) to provide thread-private memory partitions. Unfortunately, Faasm requires custom-written FaaS applications that are then compiled down to WebAssembly for execution. Nightcore [30] accelerates stateless microservices by co-locating them on the same physical machine and using shared memory to enable efficient data sharing. However, the FaaS applications must be modified to use Nightcore’s libraries to avail of these benefits. Faastlane’s function interaction latencies are comparable to Faasm and Nightcore, but it additionally supports unmodified FaaS workflows and distributed FaaS applications.

Aside from these systems that share Faastlane’s goal of reducing function interaction latency in FaaS workflows, there is prior work on reducing the memory footprint and performance overhead of other aspects of FaaS. Chief among these are methods that aim to reduce the memory footprint and performance overheads of containers by creating stripped-down containers [42], checkpointing [18], language-level iso-

lation [14], or create bare-bones VMs tailored to the application loaded in the VM [1, 38]. Faastlane’s lightweight sandboxing approach can be used in conjunction with prior work to improve the overall performance of FaaS applications.

Faastlane uses MPK to offer lightweight memory isolation between threads when they are used in the workflow. Recent works introduce new OS-level primitives for efficient in-process isolation [13, 15, 26, 36]. However, the overheads are still substantial compared to MPK which offers user-level instructions to switch memory domains. In contrast, the other solutions add new system calls, or introduce non-negligible runtime overheads. Prior studies have aimed to provide intra-process isolation using MPK. We borrow the ideas of thread gates and binary inspection from ERIM [54]. While Faastlane creates in-process thread-private memory domains, Hodor [25] creates protected libraries using MPK-backed protection domains. MPK offers 16 domains, which is sufficient for most current FaaS applications [50]. For larger workflows, Faastlane reuses thread domains wherever possible (Section 4.2). Libmpk [44] offers a software abstraction of MPK to create a larger number of domains. However, it adds non-negligible software overheads.

7 Conclusion

Developers structure FaaS applications as workflows consisting of functions that interact by passing transient state between each other. Commercial FaaS platforms execute functions of a workflow instance in different containers. The transient state must be copied across these containers or transmitted via cloud-based storage services, both of which contribute to the latency of function interaction.

Faastlane reduces function interaction latency by sharing data via memory load/store instructions. To accomplish this goal, it strives to execute functions of a workflow instance as threads within a shared virtual address space. However, this approach raises new challenges associated with isolating sensitive data and availing the parallelism afforded by the underlying hardware. Faastlane’s novel design uses Intel MPK for lightweight thread-level isolation and an adaptive mixture of threads and processes to leverage hardware parallelism. Our experiments show that Faastlane outperforms commercial FaaS offerings and also recent research systems designed to reduce function interaction latency.

Abstract

Data analytics applications are increasingly leveraging serverless execution environments for their ease-of-use and pay-as-you-go billing. The structure of such applications is usually composed of multiple functions that are chained together to form a workflow. The current approach of exchanging intermediate (ephemeral) data between functions is through a remote storage (such as S3), which introduces significant performance overhead. We compare three data-passing methods, which we call *VM-Storage*, *Direct-Passing*, and state-of-practice *Remote-Storage*. Crucially, we show that no single data-passing method prevails under all scenarios and the optimal choice depends on dynamic factors such as the size of input data, the size of intermediate data, the application’s degree of parallelism, and network bandwidth. We propose SONIC, a data-passing manager that optimizes application performance and cost, by transparently selecting the optimal data-passing method for each edge of a serverless workflow DAG and implementing communication-aware function placement. SONIC monitors application parameters and uses simple regression models to adapt its hybrid data passing accordingly. We integrate SONIC with OpenLambda and evaluate the system on Amazon EC2 with three analytics applications, popular in the serverless environment. SONIC provides lower latency (raw performance) and higher performance/\$ across diverse conditions, compared to four baselines: SAND, vanilla OpenLambda, OpenLambda with Pocket, and AWS Lambda.

1 Introduction

Serverless computing platforms provide on-demand scalability and fine-grained resource allocation. In this computing model, cloud providers run the servers and manage all administrative tasks (e.g., scaling, capacity planning, etc.), while users focus on the application logic. Due to its elasticity and ease-of-use advantages, serverless computing is becoming increasingly popular for advanced workflows such as data processing pipelines [35, 53], machine learning pipelines [11, 55], and video analytics [5, 22, 64]. Major cloud providers recently

introduced serverless workflow services such as AWS Step Functions [4], Azure Durable Functions [45], and Google Cloud Composer [24], which provide easier design and orchestration for serverless workflow applications. Serverless workflows are composed of a sequence of execution stages, which can be represented as a directed acyclic graph (DAG) [17, 53]. DAG nodes correspond to serverless functions (or λ s¹) and edges represent the flow of data between dependent λ s (e.g., our video analytics application DAG is shown in Fig. 1).

Exchanging intermediate data between serverless functions is a major challenge in serverless workflows [34, 36, 47]. By design, IP addresses and port numbers of individual λ s are not exposed to users, making direct point-to-point communication difficult. Moreover, serverless platforms provide no guarantees for the overlap in time between the executions of the parent (sending) and child (receiving) functions. Hence, the state-of-practice technique for data passing between serverless functions is saving and loading data through remote storage (e.g., S3). Although passing intermediate data through remote storage has the benefit of cleanly separating compute and storage resources, it adds significant performance overheads, especially for data-intensive applications [47]. For example, Pu *et al.* [53] show that running the CloudSort benchmark with 100TB of data on AWS Lambda with S3 remote storage can be up to 500 \times slower than running on a cluster of VMs. Our own experiment with a machine learning pipeline that has a simple linear workflow shows that passing data through remote storage takes over 75% of the computation time (Fig. 2, fanout = 1). Previous approaches reduce this overhead by implementing exchange operators optimized for object storage [47, 52], replacing disk-based object storage (e.g., S3) with memory-based storage (e.g., ElastiCache Redis), or combining different storage media (e.g., DRAM, SSD, NVMe) to match application needs [12, 37, 53]. However, these approaches still require passing data over the network multiple times, adding latency. Moreover, in-memory storage services are much more expensive than disk-based stor-

¹For simplicity, we denote a serverless function as lambda or λ .

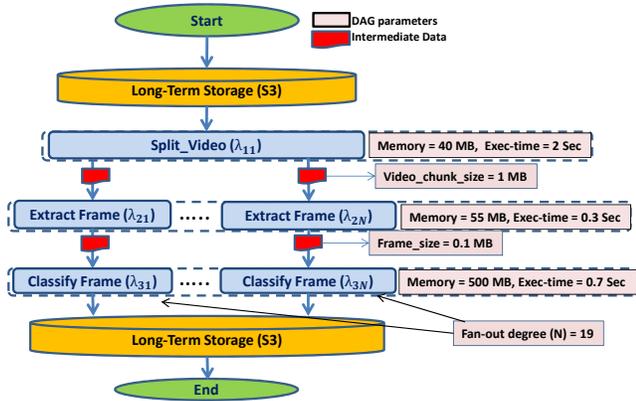

Figure 1: DAG overview (DAG definition provided by the user and our profiled DAG parameters) for Video Analytics application.

age (e.g., ElastiCache Redis costs 700× more than S3 per GB [53]).

We show how cloud providers can optimize data exchange between chained functions in a serverless DAG workflow with communication-aware placement of lambdas. For instance, the cloud provider can leverage data locality by scheduling the sending and receiving functions on the same VM, while preserving local disk state between the two invocations. This data passing mechanism, which we refer to as *VM-Storage*, minimizes data exchange latency but imposes constraints on where the lambdas can be scheduled. Alternatively, the cloud provider can enable data exchange between functions on different VMs by directly copying intermediate data between the VMs that host the sending and receiving lambdas. This data passing mechanism, which we refer to as *Direct-Passing*, requires one copy of the intermediate data elements, serving as a middle ground between *VM-Storage* (which requires no data copying) and *Remote storage* (which requires two copies of the data). Each data passing mechanism provides a trade-off between latency, cost, scalability, and scheduling flexibility. Crucially, we find that no single mechanism prevails across all serverless applications, which have different data dependencies. For example, while *Direct-Passing* does not impose strict scheduling constraints of receiving functions copy data simultaneously and saturate the VM’s outgoing network bandwidth. Hence, we need a hybrid, fine-grained data passing approach that optimizes data passing for every edge of an application DAG.

Our solution: We propose SONIC, a management layer for inter-lambda data exchange, which adopts a hybrid approach of the three data passing methods (*VM-Storage*, *Direct-Passing* and *Remote storage*) to optimize application performance and cost. SONIC exposes a unified API to application developers which selects the optimal data passing method for every edge in an application DAG to minimize data passing latency and cost. We show that this selection depends on parameters such as the size of input, the application’s degree of parallelism, and VM network bandwidth. SONIC adapts

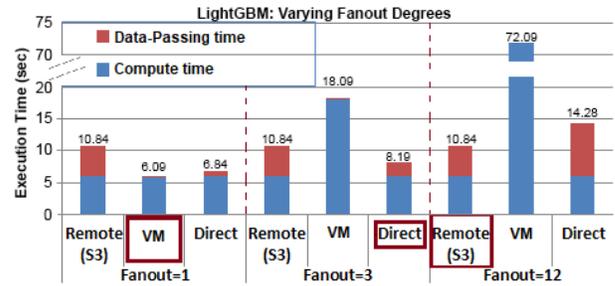

Figure 2: Execution time comparison with Remote storage, VM storage, and Direct-Passing for the LightGBM application with Fanout = 1, 3, 12. The best data passing method differs in every case.

its decision dynamically as these parameters change. Since locally optimizing data passing decisions at given stages in a DAG can be globally sub-optimal, SONIC applies a Viterbi-based algorithm to optimize latency and cost across the entire DAG. Fig. 3 shows the workflow of SONIC. SONIC abstracts its hybrid data passing selection and provides users with a simple file-based API, so users always read and write data as files to storage that appears local. SONIC is designed to be integrated with a cluster resource manager (e.g., Protean [29]) that assigns VM requests to the physical hardware and optimizes provider-centric metrics such as resource utilization and load balancing (Fig 4).

We integrate SONIC with the open-source OpenLambda [31] framework and compare performance to several baselines: AWS-Lambda, with S3 and ElastiCache-Redis (which can be taken to represent state-of-the-practice); SAND [2]; and OpenLambda with S3 and Pocket [37]. Our evaluation shows that SONIC outperforms all baselines for a variety of analytics applications. SONIC achieves between 34% and 158% higher performance/\$ (here performance is the inverse of latency) over OpenLambda+S3, between 59% and 2.3X over OpenLambda+Pocket, and between 1.9× and 5.6× over SAND, a serverless platform that leverages data locality to minimize execution time.

In summary, our contributions are as follows:

- (1) We analyze the trade-offs of three different intermediate data passing methods (Fig. 5) in serverless workflows and show that no single method prevails under all conditions in both latency and cost. This motivates the need for our hybrid and dynamic approach.
- (2) We propose SONIC, which automatically selects data passing methods between any two serverless functions in a workflow to minimize latency and cost. SONIC dynamically adapts to application changes.
- (3) We evaluate SONIC’s sensitivity to serverless-specific challenges such as the cold-start problem (set-up time for the application’s environment when it is invoked for the first time), the lack of point-to-point communication, and the provider’s lack of knowledge of lambda input data content. SONIC shows its benefit over all baselines with three common classes of serverless applications, with different input sizes and user-specified parameters.

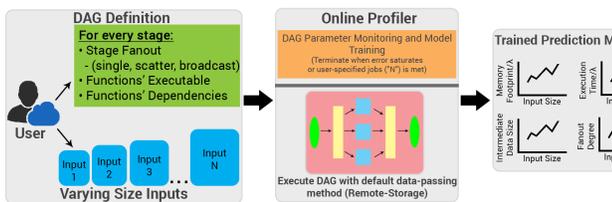

Figure 3: Workflow of SONIC: Users provide a DAG definition and input data files for profiling. SONIC’s online profiler executes the DAG and generates regression models that map the input size to the DAG’s parameters. For every new input, the online manager uses the regression models to identify the best placement for every λ and best data passing method for every pair of sending/receiving λ s in the DAG

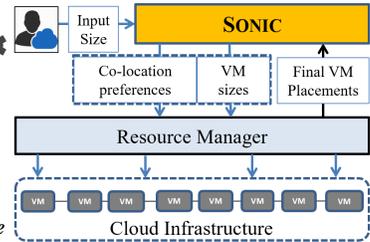

Figure 4: SONIC’s interaction with an existing Resource Manager in the system.

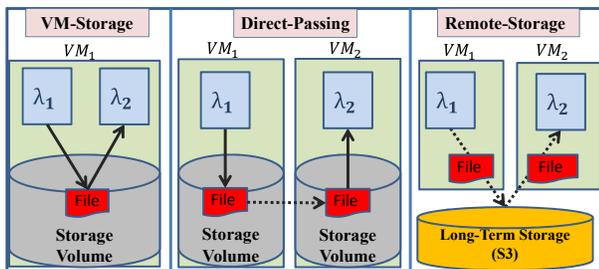

Figure 5: The three data passing options between two lambdas (λ_1 and λ_2). *VM-Storage* forces λ_2 to run on the same VM as λ_1 and avoids copying data. *Direct-Passing* stores the output file of λ_1 in the source VM’s storage, and then copies the file directly to the receiving VM’s storage. *Remote storage* uploads and downloads data through a remote storage (e.g., S3).

2 Rationale and Overview

We discuss the trade-offs of SONIC’s three data passing methods and motivate our hybrid and dynamic approach.

2.1 data passing Methods

SONIC chooses from among the three data passing options shown in Fig. 5 for *each* edge in the application DAG.

VM-Storage: This method saves the local state of the sending λ in the VM’s storage and schedules the receiving $\lambda(s)$ to execute on the same VM. This method leverages data locality to minimize latency, but imposes scheduling constraints. If the sending VM’s memory cannot fit all receiving λ s, this method forces the scheduler to run the receiving λ s serially or in batches, sacrificing parallelism in favor of data locality. This method is infeasible if the memory requirement of a single receiving λ exceeds the VM’s capacity, or when the receiving λ collects data from multiple λ s running on different VMs. Moreover, this data passing method may not be preferred by the resource manager in high load scenarios, where spreading the receiving functions over many servers is needed to avoid hot-spots and achieve better load balancing.

Direct-Passing: This data passing method saves the output of the sending λ on its VM storage and sends the λ ’s access information (IP address and File Path) to SONIC’s metadata manager. When one of the receiving λ s is scheduled to execute, the metadata manager uses the saved access information to copy the data file *directly* to the destination VM with the receiving λ . *Direct-Passing* allows higher degrees of paral-

lelism and poses no restrictions on λ placements compared to *VM-Storage*, but requires data to be sent over the network between source and destination VMs.

Remote-Storage: This data passing method involves uploading output files to a remote storage system and downloading them at destination $\lambda(s)$. This is the state-of-practice in commercial serverless platforms and has been optimized in several recent papers [12, 37, 53]. This method provides high scalability with no restrictions on λ placement. It also has the advantage of almost uniform data passing time with increasing fanout degrees as shown in Fig. 6 due to the high bandwidth of the storage layer. The disadvantage of *Remote-Storage* is having two serial data copies in the critical path — one from the source lambda to the remote storage and one from the remote storage to the destination lambda.

2.2 Dynamic Data Passing Method Selection

The optimal choice of data passing method for a job depends on the DAG’s parameters, which can vary due to dynamic conditions such as the input size, changes in network bandwidth, or changes in user-specified parameters (e.g., degree of parallelism). For example, we run the LightGBM application (application details are given in §5.3) with varying degrees of fanout and find that *VM-Storage* achieves optimal end-to-end execution time when the fanout is low (Fig. 2). However, when the maximum degree of parallelism across all stages is three, *VM-Storage* requires executing functions serially to fit on the same VM, making *Direct-Passing* superior. With a sufficiently high fanout, the sending VM faces a network bottleneck, making *Remote-Storage* the optimal data passing mechanism. Hence, no single data passing method prevails under all conditions.

SONIC prefers the *VM-Storage* method in cases where the receiving $\lambda(s)$ can be scheduled on the same VM as the sending λ while executing in parallel. However, in cases where *VM-Storage* is infeasible or sacrifices parallelism, SONIC selects between *Direct-Passing* or *Remote-Storage* methods. This selection depends on two factors: (1) VM’s network bandwidth (2) the fanout (i.e., parallelism) type and degree. To understand how these two parameters impact the selection between *Direct-Passing* and *Remote-Storage*, we show an experiment on the LightGBM application, which has a Broadcast Fanout stage (identical data from the sending λ is sent

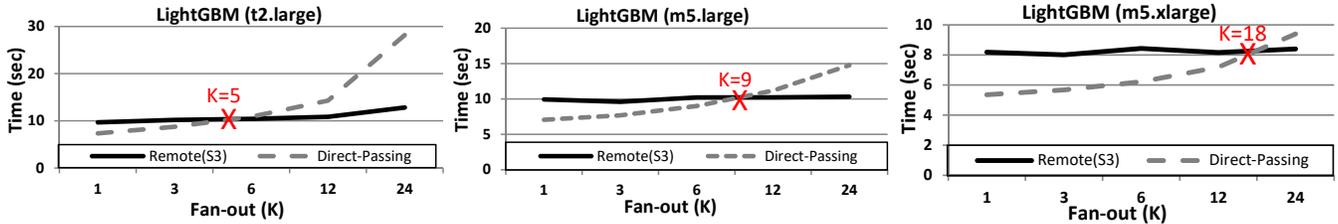

Figure 6: Comparison between Remote-Storage and Direct-Passing for LightGBM workload with varying fanout degrees. Typically, beyond a certain fanout, Remote has lower execution time than Direct-Passing. A more well-provisioned VM (m5.xlarge) will shift the crossover point to the right.

to all the receiving λ s). We vary the fanout degree (K) while using different VM types with varying network bandwidths in Fig. 6. With low degrees of parallelism (i.e., low values of K), *Direct-Passing* achieves lower latency than *Remote-Storage*. This is because copying the data directly across the two VMs is faster than copying the data twice over the network, to and from the remote storage. However, with increasing values of K , *Direct-Passing* suffers from the limited network bandwidth of the VM of the sending λ , which becomes the bottleneck as it tries to copy the intermediate data to K VMs simultaneously. In contrast, *Remote-Storage* can provide faster data passing in this case, since the sending λ saves its output file once to the remote storage and then every receiving λ downloads that file simultaneously. Thus, *Remote-Storage* provides better scalability over *Direct-Passing* in cases of large fanout degrees. The cross-over point shifts to the right as we go to more well-resourced VMs, from a network bandwidth standpoint (m5.xlarge > m5.large > t2.large). From this example, we see that selecting the best data passing method depends on the VM’s network bandwidth and DAG parameters.

We identify a number of trade-offs to be considered when performing this optimization. *First*, a trade-off between data locality and parallelism arises when the available VM’s compute and memory capacities are not sufficient to execute all receiving λ (s) in parallel. This preference of data locality over parallelism can be beneficial for lightweight functions communicating large volumes of data, while it can be harmful for compute-heavy functions with small volumes of data. *Second*, executing functions serially has the benefit of avoiding cold-start executions, which can significantly increase the execution time for functions that need to fetch many dependencies before execution [58]. *Finally*, we differentiate between two types of fanout stages: Scatter and Broadcast, depending on whether the output data is split equally among all outgoing edges (Scatter) or the same data is sent on all outgoing edges (Broadcast). With Scatter fanout, the intermediate data volume being sent is constant with the fanout degree while with Broadcast fanout, the intermediate data volume being sent increases linearly with the fanout degree. Therefore, the optimal data passing method also depends on the type of fanout and thus we cover both in our evaluation applications (video analytics and MapReduce sort for Scatter fanout and LightGBM for Broadcast fanout). In the next section, we describe the design of each component in SONIC.

3 Design

In § 3.1, we provide an overview of SONIC’s usage model. § 3.2 describes SONIC’s online profiling. § 3.3 discusses how SONIC estimates a job’s execution time for different input data sizes. § 3.4 shows how SONIC selects globally optimized data passing decisions. Finally, § 3.5 highlights further design considerations.

3.1 Usage Model

We discuss SONIC’s usage model from the perspective of application developers and the cloud provider’s resource manager.

Application DAG: As shown in Fig. 3, application developers provide SONIC with an application represented as a DAG. We assume users execute application DAGs multiple times with potentially different input data. Each such execution instance is referred to as a *job*. SONIC does not require the FaaS provider to have access to the source code for the serverless functions or hints about the resource utilization of these functions. The DAG definition from the user includes: (1) an executable for every λ ; (2) the dependencies between λ s; (3) the fanout type in every stage (i.e., single, scatter, or broadcast). Users can also provide an upper limit on the execution time or \$ budget for a single job or a batch of jobs. Notice, SONIC does not require users to specify the memory requirements for the functions in the DAG (this is a well-known pain point for users of serverless frameworks [20, 54, 57]). This is because SONIC predicts the memory footprint for every function, using our simple regression modeling (§ 3.2) and selects the right host VM size accordingly.

Data Passing Interface: SONIC abstracts the selection of data passing methods from application developers. λ functions write intermediate data to files using a standard file API (read and write), like writing to local storage. All λ s within a job share a file namespace and if an application DAG has an edge $\lambda_s \rightarrow \lambda_r$, SONIC ensures that λ_r reads from the same file path that λ_s wrote to. It also ensures that all of a λ_r ’s input files are present in its local storage before it starts execution.

Resource Manager: SONIC’s target is to minimize communication latency and cost, which are *user-centric* metrics. However, optimizing *provider-centric* metrics (e.g., load-balancing, resource utilization, and fairness) is also important. Fortunately, many resource management systems such

as Graphene [25], Protean [29], AlloX [38] and DRF [23] are designed to optimize *provider-centric* metrics efficiently, while respecting the dependencies between the functions (i.e., parent-child execution order). Hence, SONIC is designed to integrate with a system from this category (which we refer to as *Resource Manager*), as shown in Figure 4. First, the user executes the DAG with a new input. Second, SONIC uses the input size information to predict the memory footprints, execution times, and intermediate-data sizes for the DAG, which are key DAG parameters in selecting the best VM size for every function and the best data passing method for every edge in the DAG. Finally, the Resource Manager uses SONIC’s hints and decides which VMs to allocate on the available physical machines, and responds to SONIC with the final placement information, i.e., which functions go on which VMs. The Resource Manager may override SONIC’s hint to use *VM-Storage* whenever its scheduling constraint is not acceptable to the manager. Therefore, for that selection, SONIC always proposes the second-best option.

3.2 Online Profiling and Model Training

SONIC profiles jobs *online* to determine the impact of changes in input size to the following parameters: (1) each λ ’s memory footprint, (2) each λ ’s compute time, (3) intermediate data volume between any two communicating λ s, and (4) the fanout type and degree in every stage. Since the above parameters are *not* dependent on the data passing method, initially SONIC uses a default data passing policy (*Remote Storage*) while it collects DAG parameters for the first N runs of the job to train its models. N is either the number of jobs needed to reach convergence (default) or explicitly set by the user. Next, SONIC trains a set of prediction models that estimate the DAG parameter values for new inputs. SONIC develops polynomial regression models and splits the data collected into training and validation sets, then performs 5-fold cross validation to find the best model to avoid overfitting. We use polynomial regression models as they can learn from limited data points, are lightweight, and are interpretable [8].

"Online" profiling means that SONIC serves workloads while the models are being trained, which is important for practical adoption in production environments. In discussions with commercial cloud providers, we have repeatedly sensed an anathema to solutions that require offline training due to the concern that one will constantly be taking the system offline to (re-)train the models. However, if the system owner has ready access to representative input traces, she can feed SONIC with these representative traces *offline* to initialize the prediction models and reduce the online training burden.

SONIC measures the compute time for every λ under two conditions: cold execution (i.e., a new VM/container needs to be created) and hot execution (i.e., a warm VM/container with pre-loaded models/dependencies already exists). SONIC uses the difference between the two execution times in deciding

whether to queue λ s on the same VM and sacrifice parallelism (hot execute), or to execute the λ s on different VMs in parallel with the additional data passing cost and startup latency (cold execution).

3.3 Minimizing End-to-End Execution Time

We estimate the execution time τ of a stage S_i as follows:

$$\tau(S_i) = \text{DataPass}(S_{i-1}, S_i) + \text{Compute}(S_i) \quad (1)$$

When *VM-Storage* is selected, all λ s in a given stage are forced to run on the same VM. If only one λ can run at a time, the first λ incurs a cold execution time and all subsequent λ s experience hot executions. SONIC estimates τ_{VM} as follows:

$$\tau_{VM}(S_i) = 0 + \text{Cold}(\lambda_{i,1}) + \sum_{j=2}^K \text{Hot}(\lambda_{i,j}) \quad (2)$$

Here we set $\text{DataPass}(S_{i-1}, S_i)$ to zero since no additional latency is incurred by *VM-Storage* passing. For simplicity, we give here the upper bound, if all the λ s are serialized. In practice, we estimate based on batches that are serialized and all λ s within a batch can run concurrently. For *Direct-Passing* and *Remote Storage*, we take the nature of the fanout type into account. For *Direct-Passing*, with Broadcast-type fanout, the runtime is given by:

$$\tau_{\text{Direct}_B}(S_i) = \frac{F \times K}{\min(\text{BW}(VM_{i-1}), \text{BW}(VM_i))} + \text{Cold}(\lambda_{i,1}) \quad (3)$$

Where F is the intermediate data size, K the fanout, and $\text{BW}(VM_i)$, the bandwidth of the VM type hosting λ s in the i -th stage. Notice that the bandwidth is limited by the slowest of the sending and receiving VMs and that all execution times are *cold*, yet only one execution is accounted for, since they all run in parallel. For Scatter-type fanout, the equation becomes:

$$\begin{aligned} \tau_{\text{Direct}_S}(S_i) &= \frac{F/K}{\min(\text{BW}(VM_{i-1})/K, \text{BW}(VM_i))} + \text{Cold}(\lambda_{i,1}) \\ &= \frac{F}{\text{BW}(VM_{i-1})} + \text{Cold}(\lambda_{i,1}) \end{aligned} \quad (4)$$

Often cloud providers overprovision network bandwidth [14], hence we assume location of the source and destination VMs (intra- vs. inter-rack) does not affect the network bandwidth. Also, we find that the bandwidths are symmetric between VMs for all VM types; however, for remote storage, writing was faster than reading. Next, we show how we use the previous equations for our optimization.

3.4 Online VM and Data Passing Selection

A major challenge to optimize the Perf/\$ for the entire DAG is to do local selections for *each* stage to achieve the global optimum. Consider Fig. 1 for example: if we used *VM-Storage* passing between *Split_Video* and *Extract Frame*, all the extracted frames will reside in a single VM. Selecting *VM-Storage* between *Extract Frame* and *Classify Frame* will force *Classify Frame* to execute serially since that single VM does not have enough memory. However, if we select *Direct-Passing* or *Remote Storage* passing between

Split_Video and Extract Frame, every extracted frame will now reside in a separate VM. Therefore, we can use VM-Storage between Extract Frame and Classify Frame without sacrificing parallelism, lowering the DAG's execution time. Thus, greedily optimized decisions for individual stages can lead to sub-optimal global DAG performance.

To overcome the issue of sub-optimal greedy decisions, we apply the Viterbi algorithm [18] to find the globally optimized solution. SONIC uses a recursive scoring algorithm to generate all possible lambda assignments in every stage in the DAG based on the VM's compute and memory capacities, along with the λ s' predicted memory footprint. SONIC explores all possible λ -placement options under the constraints of VM resources (CPU and memory primarily) and selects the best data passing method for every pair of stages. Then, SONIC constructs a dynamic programming table with all the generated solutions. Finally, SONIC applies the Viterbi Algorithm to find the best sequence of options (i.e., the optimum Viterbi path) in the dynamic table. The selected solution is the one with the best Perf/\$ that also meets the user bounds on execution time and cost budget. This approach relies on the fact that the execution time up until stage i is equal to the execution time to stage $i - 1$ + data passing time between the two stages. This makes the Markovian assumption true (next state depends only on the current state) and makes the computation tractable.

We choose the Viterbi algorithm as it is guaranteed to find the true maximum a posteriori (MAP) solution [18, 19] unlike heuristic-based searching algorithms such as Genetic Algorithms or Simulated Annealing. The runtime complexity of the algorithm is $O(P^2 \times S)$, where P is the number of feasible λ placements on VMs for a given stage and S is the number of stages. P is upper bounded by the degree of parallelism of the stage (e.g., AWS sets a limit of 1,000) and in practice is much smaller considering many co-locations on VMs are infeasible. The runtime increases with the number of stages in the DAG, not the number of nodes or edges or fanout degree. This is desirable as the number of stages is small in practice, where a DAG of 8 stages is considered long for current serverless applications [53]. This reduction in complexity happens because SONIC applies the *same* data passing method to *all* the functions in a given stage.

3.5 Further Design Considerations

Fault tolerance. Most FaaS providers apply an automatic retry mechanism upon execution failure (e.g., AWS Lambda, Google Functions, and Azure Functions) to ensure that functions are executed *at-least-once*. For this retry mechanism to be successful, functions are required to be idempotent. To achieve idempotence, SONIC's file API assigns an ID to every intermediate file in the DAG that is used by the function that writes that file. Hence, a re-execution of this function simply overwrites the files from the previous execution. However,

as highlighted in RAMP [7] and AFT [60], idempotence in itself is not sufficient to achieve fault tolerance in serverless environments, since it does not guarantee *atomic visibility*. The problem happens when a sender λ generates only a subset of its output files, and then fails, triggering an incomplete subset of receiving λ s, resulting in a corrupted state. Therefore, SONIC applies the concept of *atomic visibility* by delaying the execution of *all* receiving λ s that belong to the same logical request until *all* their input files are successfully written to storage (either EBS in case of *Local-VM or Direct-Passing*, or S3 in case of *Remote Storage*). Although this delaying mechanism can potentially increase the E2E latency of the DAG, our evaluation shows that this additional latency is negligible: 6.3% for MapReduce, 3.3% for Video-Analytics, and 0.5% for LightGBM. All the SONIC results in the evaluation are with atomicity enabled.

DAGs with Content-Sensitive Structures. Our design assumes that the stages in the DAG are static and known, while the fanout degree in every stage can vary based on the input. This is analogous to state machines created by serverless orchestrators such as AWS Step-Functions [4]. Our video-analytics application is an example of an input-dependent fanout degree DAG and SONIC successfully predicts the fanout for new input sizes. If the structure of the DAG's stages depends on the input content, then our estimate of the DAG will be inaccurate. We evaluate the sensitivity of Sonic to prediction errors in Sec. 5.6.3.

Scalability of SONIC. For scalability, SONIC adopts a simple distributed design in which no state is shared across application jobs. When a new job arrives, SONIC's centralized component makes the decision whether to use an existing instance (if it is not overloaded) or to spin up a new instance to handle the new job. There is a central scoreboard maintained to keep track of the number of jobs being handled by each instance. The central component is lightweight in terms of its computational load and state. However, should it be necessary, this itself can be distributed through standard state machine replication (SMR) strategies [44].

4 Implementation

We implement SONIC as a data passing management layer and we use OpenLambda as our serverless platform [31]. OpenLambda is an open-source platform that relies on Linux containers for isolation and orchestration [51]. We choose OpenLambda for its flexibility—SONIC needs to control the lambda placement and needs IP addresses and administrative access to the hosting VMs. This level of control is infeasible to achieve on AWS Lambda or any other commercial offering. We implement SONIC in C# (482 LOC) and deploy it on EC2 instances, providing the same isolation guarantees as AWS Lambda across users [6]. In our setup of SONIC on OpenLambda, we use one separate container for each function (OpenLambda's design), while one VM can host multiple containers for the same application.

SONIC’s data manager consists of two parts: a centralized manager that stores IP addresses and file paths, and a distributed manager, deployed in every VM, executing the SONIC-optimized data passing method. The distributed manager also measures the actual DAG parameters during the online phase and sends them to the online manager, which updates the regression models in an incremental fashion. Moreover, since the network bandwidth can vary over time, we monitor it using Cloudwatch [13] (default of every 5 min). We use a weighted average of historic measures (as is common [56, 63]) when estimating data passing times. Thus SONIC adjusts its decisions based on bandwidth fluctuations. We use EBS storage as our storage for *VM-Storage* and *Direct-Passing* methods. EC2 EBS-optimized instances (e.g., our choice m5) have dedicated bandwidth for EBS I/O (minimizes network contention with other traffic), and can be rightsized for the predicted intermediate data volume.

5 Evaluation

5.1 Performance Metrics

Our primary performance metric is Perf/\$. Since we are minimizing end-to-end (E2E) execution time (i.e., latency), this is given by: $\frac{1}{\text{Latency}(\text{sec})} \times \frac{1}{\text{Price}(\$)}$. We also use raw latency as a secondary metric, to separate the \$-cost normalization effect. For the first metric, higher is better, and for the second, lower is better. When we refer simply to performance, we mean Perf/\$. When we refer to the secondary metric, we explicitly say (E2E) execution time or latency.

The different data passing methods considered by SONIC vary in their billing cost, which is sensitive to the selected configurations for each method. Hence, our solution should consider both latency **and** cost when selecting the best data passing method. Consequently, we use the Perf/\$ metric. We also empirically demonstrate that SONIC performs comparably to the baselines in terms of raw performance, and in many cases, outperforms the baselines (Figures 7, 8, 13, 14). Finally, there is precedence of prior work in cloud optimization using performance normalized by price [32, 40, 62]. SONIC’s *VM-Storage* and *Direct-Passing* methods add additional cost due to the extra local storage (e.g., EBS storage). However, this additional price is comparable to that of remote storage such as S3, and we include it in our evaluation.

5.2 Baselines and Methodology

We compare SONIC to the following baselines:

1. **OpenLambda + S3** [31]: This is the OpenLambda framework deployed on EC2 with S3 as its remote storage. A new VM is created to host each λ in the DAG. The smallest VM that has enough memory to execute the λ is selected.
2. **OpenLambda + Pocket** [37]: This is a variant of the OpenLambda framework with Pocket (deployed in EC2) as the remote storage. We use Pocket’s default storage tier

(DRAM) with *r5.large* instance types. The DRAM storage tier strikes the balance between performance and cost and provides the best Perf/\$ (Table 4 in [37]). Comparing the price for one DRAM node to one SSD node in Pocket, DRAM is also the cheapest tier. We vary the number of Pocket nodes for each application to reach the best Perf/\$. We include the price of the storage nodes only, excluding master and meta-data nodes. We use EC2’s per-second level pricing.

3. **SAND** [2]: This baseline leverages data locality by allocating all lambda functions on a single host with rich resources and performing data passing between chained functions through a local message bus.
4. **AWS- λ** : The commercial FaaS platform using two different remote storage systems: S3 and ElastiCache-Redis.
5. **Oracle SONIC**: This is SONIC with fully accurate estimation of DAG parameters and no data passing latency (mimicking local running of all functions). Although impractical, this serves as an upper-bound on performance for any of the three data-exchange techniques selected by SONIC.

Similar to prior OpenLambda evaluations [50], we deploy OpenLambda (and SONIC) on AWS EC2 General Purpose instances (*m5.large*, *m5.xlarge*, *m5.2xlarge*) for their balance between CPU, memory, and network bandwidth. We use the same EC2 family with SAND for fairness. *m5* instances have a network bandwidth of upto 10 Gbps, which we rely on for both *Direct-Passing* and *Remote-Storage*. All costs follow pricing by Amazon for 01/2021, N. California (Region).

5.3 Applications

We use three analytics applications popular as serverless applications and that span the variety of DAG structures.

Video Analytics: Fig. 1 shows the DAG for the Video Analytics application, which performs object classification for frames in a given video. It starts with a lambda that splits the input video into chunks of fixed length (10 sec in our case). Then, a second lambda is called for every chunk to extract a representative frame. Next, a third lambda uses a pre-trained deep learning model (MXNET [49]) to classify the extracted frame. It outputs a probability distribution across 1,000 classes over which MXNET is trained. Finally, all the classification results are written to long-term storage.

LightGBM: This application trains decision trees, combining them to form a random forest predictor using LightGBM Python library [39]). First, a λ reads the training examples and performs PCA. Second, a user-specified number of λ s train the decision trees in parallel (every λ randomly selects 90% for training, 10% for validation). A third λ collects and combines the trained models; then tests the combined model on held-out test data. Handwritten images’ databases: NIST (800K images); MNIST (60K images) used as inputs [15, 26]. **MapReduce Sort**: This application implements MapReduce sort with serverless functions. In the first stage, K parallel lambdas (i.e., mappers; K = user parameter) fetch the input

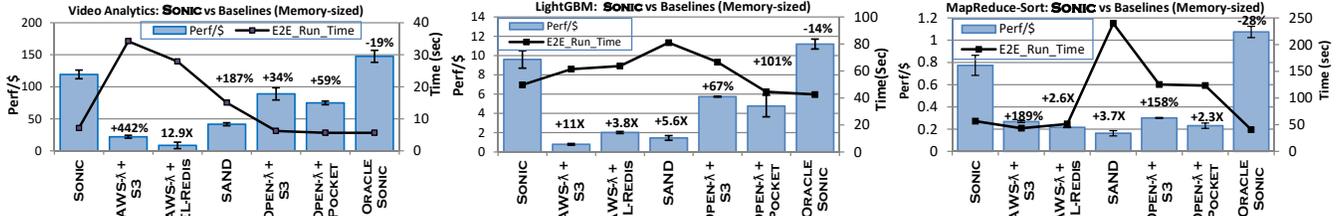

Figure 7: Performance of SONIC and the baselines for our three applications (memory-sized). Two performance metrics are shown: Perf/\$ (bars; left axis) and end-to-end execution time (lines; right axis). Relative improvements in Perf/\$ due to SONIC are at the top of each bar for the corresponding baseline.

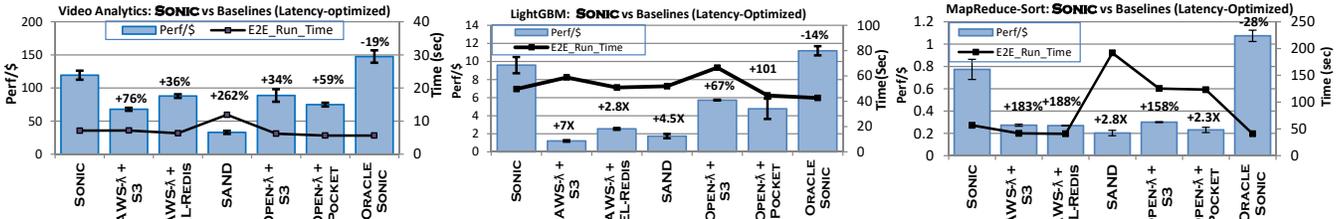

Figure 8: Performance of SONIC and the baselines for our three applications with the latency-optimized configuration.

file from a remote data store (e.g., S3) and then generate the intermediate files. Next, K parallel lambdas sort the intermediate files and write their sorted output back to storage.

5.4 End-to-End Evaluation

We compare the E2E Perf/\$ and latency of SONIC vs. other baselines for our three applications. For Video Analytics, we use a video of length 3 min and size of 15MB, which generates a fanout degree of 19 (we vary the video size in § 5.6.3). For LightGBM, we use an input size of 200MB and fanout degree of 6, generating a random forest of 6 trees (we vary the input size in § 5.5.2). For MapReduce Sort, we use an input size of 1.5GB and a fanout degree of 30. All the results of SONIC include its overheads (11ms for the DAG parameter inference phase; 120ms for the Viterbi optimization phase).

We perform online profiling and training with 35 jobs, by which we reach convergence for all applications with a low average Mean Absolute Percentage Error (MAPE) $\leq 15\%$. We show the accuracy of SONIC's predictions in Section. 5.6.1.

Memory configurations. SONIC infers memory requirements automatically from online profiling. Here, we describe how we select the memory allocation for each baseline. AWS Lambda and other serverless offerings scale compute resources relative to a user-specified memory allocation. We run the baselines under two different configurations, which we call "memory-sized" and "latency-optimized". These are respectively shown in Fig. 7 and Fig. 8. For the memory-sized configuration, we give each lambda just enough memory that it needs to execute. We determine each λ 's memory requirement by measuring the actual memory used when executing the DAG once with all λ s using the maximum memory limit (3GB for AWS- λ). For the latency-optimized configuration, we progressively increase the memory allocation as long as a reduction in latency is observed. We report the results for the run with the lowest latency. For OpenLambda, we use

SONIC's memory footprint predictor to select the cheapest VM that fits each lambda.

We draw several conclusions. First, although AWS- λ allows users to rightsize the allocated memory for their applications, it does not always lead to the best Perf/\$ or latency. For example, with Video Analytics and memory-sized configuration, SONIC achieves 442% and 12.9 \times better Perf/\$ over AWS- λ with S3 and ElastiCache-Redis respectively. However, with (memory) over-provisioning, the latency-optimized configuration improves AWS- λ performance significantly, reducing the gains of SONIC to 76% and 36% with S3 and ElastiCache-Redis respectively (similar observation is shown w.r.t. raw latency). The reason is that AWS- λ allocates all other resources (e.g., CPU capacity, network bandwidth, etc.) proportionally to the selected memory requirement [3]. Therefore, as the allocated memory is increased, the latency decreases and the cost also increases. But the latency decreases faster than the cost increases, thus Perf/\$ increases. However, beyond a certain point of over-provisioning, the latency does not decrease further, and thus the Perf/\$ begins to decrease.

For LightGBM and MapReduce Sort applications, we do not see a significant improvement in Perf/\$ for AWS- λ baselines with the latency-optimized configuration, since the memory footprint of these applications is close to the 3GB limit to begin with leaving very little room for over-provisioning. For AWS- λ , using ElastiCache-Redis as the remote storage achieves 18% lower latency than using S3. However, ElastiCache-Redis increases the cost significantly, causing a *reduction* of Perf/\$.

Compared to SAND, SONIC achieves 187% better Perf/\$ with 2 \times lower latency in the memory-sized case for Video Analytics application. The gain increases to 5.6 \times and 3.7 \times for LightGBM and MapReduce Sort applications, respectively. This is again due to the higher memory footprints of these two applications compared to Video Analytics. This reduces SAND's ability to run more λ s in parallel and forces a high

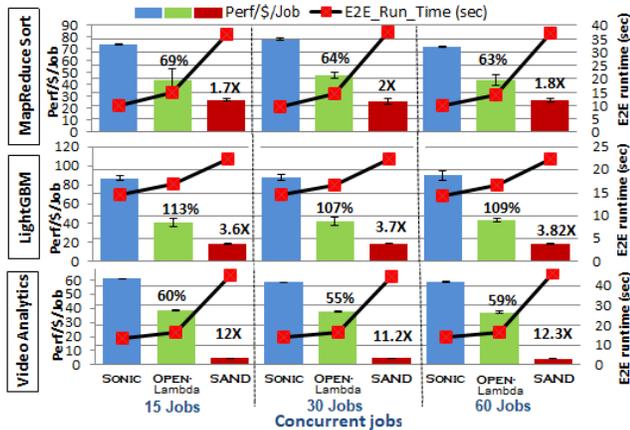

Figure 9: Scalability of SONIC, OpenLambda+S3, and SAND with equal portions of our three apps running concurrently. SONIC maintains its improvement over the entire scale, in both Perf/\$/job and raw latency.

degree of serialization. This explains the spike in latency for SAND in both applications.

Compared to OpenLambda, SONIC achieves 34% and 59% improvement in Perf/\$ with S3 and Pocket, respectively, for Video Analytics. The performance with Pocket suffers compared to vanilla OpenLambda (i.e., with S3) due to Pocket’s higher-cost storage (e.g., r5.large) without proportional benefit. Note that for OpenLambda, its performance turns out to be identical for the memory-sized and latency-optimized configurations as increasing the memory beyond SONIC’s predicted values for each function gives no latency benefit. Finally, Oracle-SONIC outperforms SONIC, as expected, but not hugely — within 19%-28% across all applications. Recall that Oracle-SONIC has perfectly accurate predictors and assumes no data passing latency.

5.5 Scalability

Here, we evaluate SONIC’s ability to scale to concurrent invocations of a mix of the applications and larger data sizes.

5.5.1 Varying Degree of Concurrency

We compare SONIC to SAND and OpenLambda+S3 serving a mixture workload of our three applications, with equal portions of invocations (jobs) per application. We use a cluster of 52 VMs of type *m5.large* with 2 compute cores per VM. We select SAND as it always prefers to keep data local, while OpenLambda+S3 always uses *Remote-Storage* data passing. OpenLambda+S3 is also the closest baseline to SONIC in terms of performance (Fig. 7 and 8). We vary the level of concurrent invocations from 15 (5 per app) to 60 (20 per app). With 60 concurrent app invocations, the cluster executes a total of 480 functions in parallel and all compute cores are fully utilized (except for SAND). We show the Perf/\$/job and E2E runtime for every app in Figure 9². We notice that the

²We normalize by the number of jobs because naturally the total cost increases with the number of jobs completed and the normalization brings out

gain of SONIC over both baselines is consistent across the different degrees of concurrency, which shows SONIC’s ability to seamlessly scale with the number of concurrent invocations. It is of course not surprising that the VM infrastructure scales up — the question was would SONIC scale up as well. This experiment answers that question in the affirmative (within the scales of the experiment), for SONIC as well as for the two baselines. This is expected from the design of SONIC where most of its components are stateless and different instances are spun up to handle more input jobs (Section 3.5). Since SAND schedules the entire job to execute on a single VM, it cannot utilize all the compute cores and hence suffers from very high latency. In contrast, OpenLambda uses *Remote-Storage* passing between functions, which allows scheduling functions on different VMs and utilizing the available compute resources. SONIC’s hybrid approach achieves both lower E2E execution time along with high resource utilization, and therefore, achieves better Perf/\$ and raw latency than all baselines.

5.5.2 Varying Intermediate Data Size

In Fig. 12, we show the impact of changing the intermediate data size on SONIC’s performance vis-à-vis two baselines. SONIC achieves lower E2E latency and higher Perf/\$ across all input sizes by predicting the corresponding DAG parameters and selecting the best co-location of lambdas and data passing methods. Second, the normalized Perf/\$ of SONIC and OpenLambda+S3 increases with higher input sizes. The reason is that the compute:data passing time ratio for this application increases with higher input sizes. This, in turn, is because the data passing time increases linearly with the input size, whereas its computation time grows faster than linear (PCA has quadratic compute complexity [65] and it dominates the total computation time). Recall that the Oracle assumes no data passing latency but it counts computation time. Accordingly, the higher the compute:data passing time ratio, the lower the gap between Oracle and the baselines (except SAND that has no data passing component).

5.6 Microbenchmarks

Here we evaluate SONIC’s online training accuracy, sensitivity to input content, prediction noise, and cold-start times.

5.6.1 Prediction Accuracy with Online Refinement

As discussed in Sec. 3.2, our solution profiles jobs to characterize the relation between input size and the data passing relevant parameters. This training phase is done online while serving production jobs, and we use remote storage data passing (SONIC’s default) until convergence is achieved. We show SONIC’s accuracy in prediction of execution parameters for new input sizes across the three applications. First, we execute the DAG of each application with jobs of varying input sizes while we measure the DAG’s execution parameters (i.e., λ ’s

the important trend that the metric is flat across the scales, implying perfect scalability.

memory footprint, λ 's compute time, data volume on every edge, and fanout degree in every stage). Next, we divide the collected data into train and test sets. We fix the test set size while we vary the number of jobs used for training to show the reduction in error w.r.t. training with more jobs for every application. In each training run, we generate the regression models for all execution parameters in the DAG. For example, PCA's runtime regression estimated equation is: $Y = 0.0024 X^2 + 12.764$, and PCA's estimated memory equation is: $Y = 16 X + 185.5$, where X is the input size in MBs .

For Video Analytics, we collect 60 YouTube videos with lengths that vary uniformly between 1 min and 1 hour and belong to 5 different categories with equal representation of each: News, Entertainment, Nature, Sports, and Cartoon. We similarly execute the LightGBM and MapReduce Sort applications with 60 jobs each. For LightGBM, we use the MNIST database of handwritten digits [15]. The data has 60,000 training images and 10,000 test images. To execute the DAG with varying input sizes, we sub-sample the training data and vary the sampling rate between 5% and 100% uniformly. For MapReduce Sort, we generate randomly shuffled data and vary the size of the data between 3M records (255MB) and 12M records (1.5GB). We also vary the number of Mappers and Reducers uniformly between 5 and 50.

Increasing the number of jobs used in training expectedly reduces the prediction error for all applications. With 35 jobs we reach convergence for all predictions with a low average Mean Absolute Percentage Error (MAPE) $\leq 15\%$ as shown in Figures 10 for Video-Analytics. This low prediction error is essential for SONIC to determine the best lambda placement information and data passing decisions for new jobs with new input sizes. Optionally, users can set a higher level of acceptable error to reduce the number of training jobs.

We notice that Video Analytics incurs the highest prediction error among the three applications. This is because our collected videos vary significantly in their bitrate, which impacts the relation between the input size and the video's length. Recall that SONIC is content-agnostic, it does not consider any information that is dependent on the content of the data when it makes its prediction. Although this negatively impacts the prediction accuracy for content-dependent applications, it allows SONIC to generalize to a wide range of applications without the need for special processing for each type of application. Furthermore, policies for public cloud providers often prohibit any visibility into the client applications. We evaluate SONIC's sensitivity to input content in § 5.6.3.

5.6.2 SONIC's Performance Improvement Root Causes

Here we highlight the root causes for SONIC's improved performance over baselines SAND and OpenLambda + S3. We show an example DAG for LightGBM application along with the data passing and lambda placement decisions made by each approach in Figure 11. We also show SONIC's selected optimum Viterbi path in the table at the bottom. We run

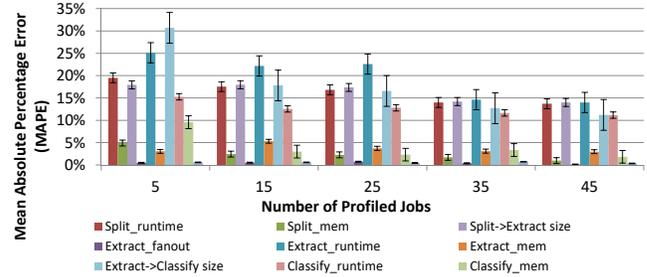

Figure 10: Error in parameter estimation for Video Analytics application. Convergence point is reached with e.g., 35 jobs. Split_mem, Extract_mem, and Classify_mem represent memory footprints for Split, Extract and Classify functions respectively. All parameters are predicted using polynomial regression models, which take the application's input size in MBs as input.

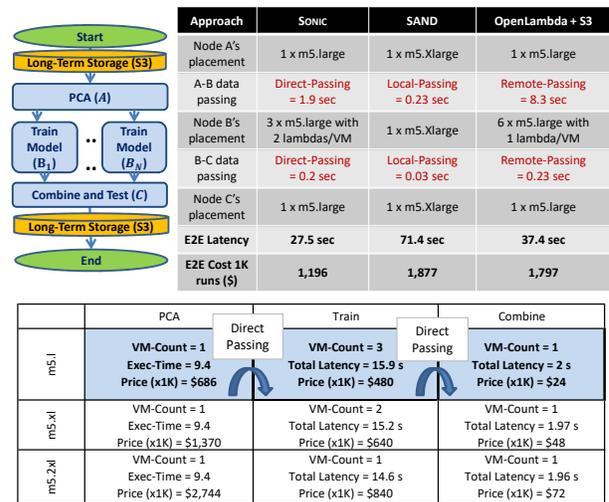

Figure 11: Example showing the benefits of SONIC over baselines. The table at the bottom shows possible λ placements for each stage in the LightGBM application and their corresponding latency and cost. We highlight the best sequence of decisions that achieves the best Perf/\$ for the entire DAG.

the LightGBM application with a fanout degree of 6 and show the E2E latency and Cost for all baselines. First, SAND leverages data locality between all stages and hence uses the same single VM of size m5.Xlarge for the entire application. This causes the fanout stage (TrainModel) to experience serialized execution as this single VM does not have enough resources to execute all invocations in parallel and hence increases the E2E latency to 71.4 sec. Compared to OpenLambda + S3, we notice that passing data between PCA and TrainModel is very slow with remote passing as it takes 8.3 sec. However, if direct passing is used (as done by SONIC), the data passing time becomes 1.9 sec only. We also notice that SONIC places each pair of lambdas in one VM using a total of 3 VMs. This makes direct passing faster as it only needs to transfer 3 copies of the transformed training data. Recall that this application has a broadcast fanout and all lambdas in TrainModel stage get the same copy of PCA's output file. In conclusion, with SONIC's optimized data passing and placement decisions, the

E2E latency is reduced by 27% over OpenLambda + S3 and by 62 % over SAND, and the Cost is reduced by 33% over OpenLambda + S3 and 36% over SAND.

5.6.3 Sensitivity to Input Content

SONIC uses only the input size information, as opposed to content awareness, to predict DAG parameters for a new job³. For example, for Video Analytics (Fig. 1) some of the parameters like the intermediate data size are sensitive to the video size (bytes), which depends on video bitrate specification. We want to examine how SONIC’s performance would be impacted on test videos different from training. In Fig. 13, we show the performance gain for three variants of SONIC, testing on a 396-sec video from the Sports category. First, we train SONIC on 60 videos from the same Sports category, which shows the best performance among the 3 variants. Second, we show SONIC’s performance with training videos from 5 different categories (60 in all, split equally), which shows an 8% performance reduction vis-à-vis the first. The third variant is trained with 60 videos from the *News* category, which has a 25% lower bitrate than the *Sports* category on average. This difference in categories causes a further performance reduction by 19% due to the error in predicting the fanout degree (40%) and intermediate data size between the `Split_Video` and `Extract_Frame` functions (21%). All three variants still show a significant gain over SAND and OpenLambda baselines. As expected, the higher the difference in critical features of the training and testing data (that can impact the DAG’s parameters), the lower is SONIC’s performance. Critical features are those that affect the compute time or the data passing volume, e.g., video bitrate. One solution to this limitation is to cluster the jobs based on the critical features and train a separate prediction model for each cluster.

5.6.4 Tolerance to Prediction Noise

We examine SONIC’s sensitivity to prediction noise. We use the MapReduce Sort application with 30 each of map and reduce functions and apply varying levels of synthetic noise to our memory footprint predictions. We show the impacts of over-predicting (i.e., the predicted memory footprint is *higher* than the actual), and under-predicting in Fig. 14. For calibration, the natural error of SONIC in prediction of memory parameters is 7%. We draw several conclusions. First, error levels of less than $\pm 20\%$ have little impact since with low levels of noise, the (categorical) decisions by SONIC for lambda-placement and data passing are unchanged. Second, under-predicting (the bars with -ve errors) has lesser impact on SONIC than over-predicting. Under-predicting causes SONIC to allocate fewer VMs (1 VM per 3 lambdas in this experiment) than without synthetic noise (1 VM per 2 lambdas). This causes the execution of only two lambdas in parallel while queuing the third lambda, increasing the job’s E2E exe-

³Although this hurts SONIC’s prediction accuracy for content-dependent DAGs, it allows generalizing without application-specific processing. Further, public cloud providers often are not allowed to look into client data.

cution time. On the other hand, over-estimation of the memory causes SONIC to allocate more VMs than what the job actually needs (1 VM per lambda). The increase in latency with under-prediction is partly compensated for by the reduction in the \$ cost, while with over-prediction, the increase in the \$ cost dominates over the reduction in latency.

5.6.5 Varying Cold-Start Overheads

In this experiment, we evaluate the effect of varying cold:hot execution times. We use a synthetic application of one stage containing 10 parallel functions and vary the function’s startup:steady state compute ratios. We compare SONIC to two static baselines, SAND and OpenLambda+S3, in Fig. 15. SAND always prefers data locality and hot execution over parallelism. We notice that this approach is beneficial for lambdas that have a gap of $5\times$ or more between cold and hot execution times. However, this solution is counter-productive when the gap between cold and hot executions is lower, unnecessarily forcing lambdas to run sequentially. The exact opposite happens with OpenLambda — it is competitive with SONIC for cold to hot execution ratios of $2\times$ or less but suffers increasingly as the ratios become higher as it always incurs cold-start costs. SONIC achieves close-to-optimal performance across the entire range of cold-to-hot execution ratios due to its ability to estimate the execution times under cold and hot executions and to select the best lambda placement and data passing approach dynamically. In practice, we find that the ratio varies in the range $[1, 3.6]$ (highest for Video Analytics’ Classify frame due to a heavy NN model); prior work has shown that the ratio can be as high as $9.6\times$ (Figure 21 in [50]). We also evaluate SONIC with varying fanout and ratios of compute time to total execution time (=compute time+data passing time). SONIC’s gain over OpenLambda is more significant at lower compute ratios as data exchange dominates, while it is more significant over SAND at higher fanouts (data locality hurts parallelism).

6 Related Work

Data-passing in serverless environments: We are not the first to identify data-passing latency as a key challenge for chained lambda execution [11, 12, 30, 31, 67]. Pocket [37] and Locus [53] implement multi-tier remote storage solutions to improve the performance and cost-efficiency of ephemeral data sharing in serverless jobs. SONIC can leverage these remote storage systems (e.g., we have evaluated SONIC with Pocket) while automatically optimizing data-passing performance with *VM-Storage* (as in SAND [2]) and *Direct-Passing* methods, which minimize data copying. Pocket also requires hints from the user about parameters of the DAG, which we infer using our modeling approach.

Prior systems have shown that serverless functions can communicate directly using NAT (network address translation) traversal techniques. ExCamera [22] uses a rendezvous server and a fleet of long-lived ephemeral workers to enable

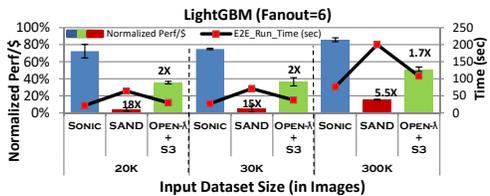

Figure 12: Normalized Perf/\$ of SONIC vs SAND and OpenLambda+S3 with varying input sizes. We fix the Fanout-degree=6 and change the number of images used in training the Random-Forest model.

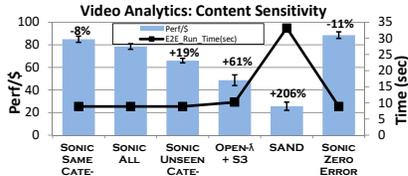

Figure 13: Effect of training SONIC on YouTube video categories similar or dissimilar to test. % over the bars represent the SONIC's (second bar from left) gain over that baseline.

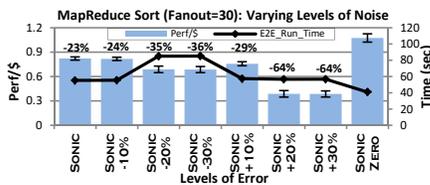

Figure 14: Impact of noise in SONIC's memory footprint predictions. Errors of less than $\pm 10\%$ have small effect and over-prediction has higher effect than under-prediction. The values over the bars are w.r.t. SONIC with zero error (rightmost).

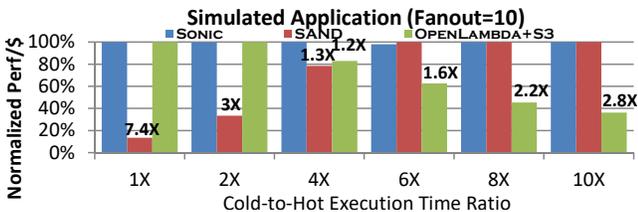

Figure 15: Effect of varying ratios of cold to hot execution times on SONIC, SAND, and OpenLambda+S3. Normalized Perf/\$ is calculated by dividing the Perf/\$ by the max across the three techniques.

direct communication. However, it needs both endpoint lambdas to be executing at the time of the data transfer, which SONIC does not. gg [21] is a framework for burst-parallel applications that supports multiple intermediate data storage engines, including direct communication between lambdas, which users can choose from. In contrast, SONIC abstracts and adaptively selects the optimal data-passing mechanism.

The need for processing state within serverless frameworks is being increasingly recognized [9, 46, 53, 59], e.g., for fine-grained state sharing or coordination among processes in ML workflows. This trend will emphasize the importance of efficient data passing among functions like SONIC provides. Automated tuning systems of clusters configurations have been proposed in [40–42]. However, these systems use black-box machine learning optimization and rely on hundreds of offline profiling runs to build accurate performance models. Cloudburst proposes using a cache on each lambda-hosting VM for fast retrieval of frequently accessed data in a remote key-value store [61], adding a modicum of statefulness to serverless workflows. SONIC does not cache data, but still exploits data locality with its lambda placement.

Efficiency of serverless executions. There is flourishing work to make serverless executions more efficient. One strategy optimizes cold-start latencies, which will influence SONIC's function placement decisions as in § 5.6.5 (e.g., SOCK [50], SEUSS [10], and Firecracker [1].) Another strategy optimizes in the isolation vs. agility spectrum (e.g., Firecracker [1], MVE [16] (supporting hugely concurrent services as in popular games), Spock [28], and Fifer [27] (hybrids of serverless and other cloud technologies for microservices). The data-passing selection in these works can benefit from SONIC. Costless [17] optimizes lambda fusion and placement, reducing the number of state transitions. This contribution is

orthogonal and beneficial to SONIC.

Cluster computing frameworks: Many distributed computing frameworks, such as Spark [66], Dryad [33], CIEL [48], and Decima [43] use DAGs of jobs to schedule tasks. With some engineering effort, SONIC can be used to support the data passing on these DAGs. However, SONIC stays close to the spirit of serverless in that it requires a minimal number of user hints or configuration options.

7 Conclusion

Optimizing the cost and performance of analytics jobs on serverless platforms requires minimizing the data passing latency between chained lambdas. The optimal data passing method depends on application-specific parameters, such as the input data size and the degree of parallelism. We presented SONIC, a system that *jointly* optimizes the inter-lambda data exchange method and lambda placement. SONIC performs online profiling to determine the relation between the application's input size and its DAG parameters. Afterward, SONIC applies an online Viterbi algorithm, to globally minimize the application's end-to-end latency, normalized by cost. SONIC achieves lower (\$ cost-normalized) latency against four competitive baselines for three popular serverless applications. Moreover, SONIC is able to adjust the best data passing method based on infrastructure changes such as network bandwidth fluctuations. In ongoing work, we are designing SONIC to handle conditional control flows in the application DAG through content-aware prediction.
