Current microservice applications always meet with load and call graph dynamics. These dynamics can easily lead to inappropriate resource allocation for microservices, and further lead to Quality-of-Service (QoS) violations of applications. However, current microservice management works are incapable to handle these dynamics, mainly due to the execution blocking effect among microservices. We therefore propose Nodens, a runtime system that enables fast QoS recovery of the dynamic microservice application, while maintaining the efficiency of the resource usage. Nodens comprises a *traffic-based load monitor*, a *blocking-aware load updater*, and a *resource-efficient query drainer*. The load monitor periodically checks microservices' network bandwidth usage and predicts the monitored loads based on it. The load updater updates the actual "to-be-processed" load of each microservice to enable fast resource adjustment. The query drainer allocates just-enough excessive resources for microservices to drain the queued queries, which can ensure the QoS recovery time target. Our experiments show that Nodens can reduce the QoS recovery time by 12.1X with only the excessive resource usage of 6.1% on average, compared to the state-of-the-art microservice management systems.

1 Introduction

User-facing applications are evolving towards the microservice architecture, with which the microservices communicate through the network [25, 41] and are able to scale independently [1, 5, 9]. The dependencies of the microservices can often be denoted by a Directed Acyclic Graph (DAG) [31, 32], each node represents a microservice and each edge represents the call dependency [24, 38]. Moreover, a production microservice application often has multiple call graphs [31, 32], as users have different query patterns. Figure 1 shows an example dependency graph and two call graphs that handle different user queries.

In these applications, the load of each microservice change dynamically, because 1) the load of the entire application may change over time due to the diurnal, irregular, and bursty load patterns (referred to be "load dynamic") [3, 19, 28, 40], and 2) the percentages of queries that go to different call graphs may change over time (referred to be "call graph dynamic") [34]. We analyze the open-sourced production traces [2, 8], and find that the load variation is 30% on average (up to 7.5X), and the percentages of queries that go to different call graphs also vary by 15% on average (up to 70%).

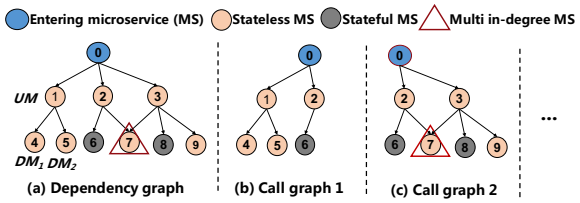

Figure 1: An example microservice dependency graph and two call graphs.

While it is crucial to ensure the required Quality-of-Service (QoS) of user-facing applications [20, 30, 39], prior works [22, 38, 41, 44] fail to handle these dynamic applications. Most prior works periodically check the load of each microservice, and adjust the resource allocation of each microservice based on the monitored load. They are incapable for the current dynamic microservice applications for two main reasons.

As for the first reason, the monitored load of a microservice may not be its real "to-be-processed" load due to the cascade call relationship. Many queries may be blocked by its upstream microservices. A microservice may not be allocated enough computation resources in this case. Worse, there is a lag in noticing the load increase. For instance, if the monitoring period is 1 second, the lag can be 1 second as well. However, the short lag may result in the long QoS violation, as a great many of queries may queue up at the microservice. A very long time is needed to adjust resources and drain up the query queue, when the microservice's resource is allocated based on the monitored load. Our experiments show that the QoS can be recovered in as long as 84.4 seconds.

Some other prior work [18, 23, 25, 45] predict the QoS and

adjust the resource allocation beforehand. They assume all the queries go through all the microservices, thus are not able to handle the dynamic loads due to the variation of call graphs.

An intuitive solution is calculating the actual "to-be-processed" queries of each microservice based on the dependency graph and the call graphs, and adjusting their resources accordingly. However, it does not work because we find that the queries of a microservice may also be blocked by other microservices besides of its upstream microservices in the dependency graph. For instance, microservice-2 in Figure 1 may be blocked by microservice-4 or microservice-5 that do not call it in the dependency graph. This happens when microservice-0 calls microservice-1 and microservice-2 in a fixed order and the resource allocation of microservice-4 or microservice-5 is insufficient.

An appropriate solution should be able to capture all the potential "blocking" relationships, and be able to drain up the query queues due to the monitoring lag. We therefore define an *execution blocking graph* that captures all the superior microservices that may block a microservice, based on which we further propose a runtime system named **Nodens**[1] that enables fast QoS recovery, if the loads of some microservices suddenly increase due to the two types of dynamics. Note that the execution blocking graph is not the same as the microservice dependency graph.

Nodens comprises a *traffic-based load monitor*, a *blocking-aware load updater*, and a *resource-efficient query drainer*. For each microservice, the load monitor periodically checks the input network traffics, and predicts the current monitored load of the microservice based on the traffics. This method is much faster than obtaining the load information from the microservices' interfaces, enabling earlier resource allocation adjustment. The load updater updates the execution blocking graph with the monitored load obtained from the monitor, and estimates the actual "to-be-processed" load of each microservice. The query drainer adjusts the CPU resource allocated to each microservice based on the actual loads of the microservices and the queued queries during the previous process, in order to quickly recover the QoS.

This paper makes three main contributions.

- **Comprehensive analysis of current methods to handle microservice dynamics.** The insights obtained from the analysis identify the opportunities to enable fast QoS recovery when dealing with microservice dynamics.
- **The design of a method to update actual loads of microservices under execution blocking effect.** We construct the execution blocking graph based on microservice dependencies, with which we can update actual loads of microservices under the blocking effect.
- **The design of a policy to drain the queued queries during the resource adjustment process.** The policy allocates excessive resources for microservices to satisfy the QoS recovery time target, while maintaining the resource efficiency.

We evaluate Nodens with our benchmarks on an eight-node cluster. The experimental results show that Nodens can reduce the QoS recovery time by 12.1X with only the over-provisioned resources of 6.1% on average, compared to the state-of-the-art microservice management systems.

[1]The source code is available at https://github.com/shijiuchen/Nodens.

2 Related Work

There has been some related work on ensuring the QoS of user-facing applications.

2.1 Reactive Microservice Management

Reactive microservice management systems periodically monitor the state (e.g., load or latency) of each microservice, and adjust the resource allocation of each microservice based on the state.

Heuristic methods: SHOWAR [17], PEMA [27], Astraea [44], and ATOM [26] designed heuristic approaches to conduct horizontal or vertical scaling for CPU or GPU microservices based on the resource utilization and response latency. These heuristic methods can determine the resource allocation for microservices in a quick way, but hard to achieve the near-optimal values.

Machine Learning (ML) based methods: Nautilus [22] used Reinforcement learning (RL) as feedback to tune microservices' resources based on the application's response latency. FIRM [38] identified the critical microservices which caused QoS violations, and used RL as feedback to adjust resources for each microservice based on tail latencies, to guarantee the QoS of the application. ELIS [41] utilized the bayesian optimization algorithm with tail latencies as input to recycle the over-provisioned resources and then allocate just-enough resources to critical microservices. These ML-based methods can allocate near-optimal resources for microservices, but are slower due to incremental training under microservice dynamics.

Moreover, above reactive methods all have long QoS recovery time when handling dynamics of microservices, which is caused by the long monitoring interval, and the load blocking under the cascade call relationship among microservices.

2.2 Proactive Microservice Management

Proactive microservice management systems predicted the performance and resource allocation for microservices based on historical data. Seer [25] and Sage [23] used ML-based methods to predict the microservices that cause QoS violations based on the latency metrics, and increase the allocated resources for them. Sinan [45] and DeepRest [18] utilized

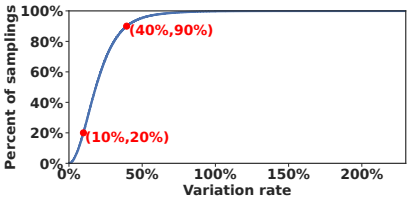

Figure 2: Load variation of top 20 microservice applications.

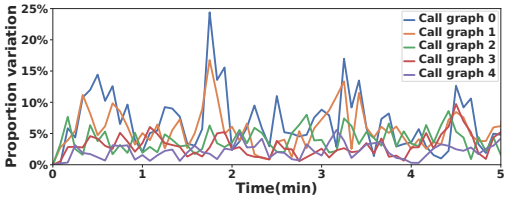

Figure 3: The call graph proportion variation of the largest microservice application in Alibaba Cloud.

the deep learning-driven methods to predict the end-to-end latency and estimate the resource allocation for different microservice stages, which can minimize the resource usage while ensuring the QoS target. These works only consider a unique dependency graph, which cannot handle the call graph dynamics of the microservice application. Moreover, Madu [34] predicted the load size for microservices based on time series prediction models with the consideration of dynamic call graphs into the loss function. However, it cannot handle the unpredictable dynamic load and call graph cases that commonly exist in production traces [2, 40].

3 Investigating Dynamic MS Applications

In this section, we first analyze the production trace in the current public cloud. Then, we introduce microservice benchmarks we make which have the dynamic call graph features. At last, we explore the challenges of the current microservice management systems in dealing with dynamics.

3.1 Dynamic Loads and Call Graphs

We analyze the open-sourced production-level microservice trace [2] that contains the microservice call dependencies across 3000+ applications in 12 hours to show the dynamics.

In the analysis, we record the loads of the microservices for every five seconds, and calculate the load variation. The load variation is defined to be the load changes in the adjacent samples. Figure 2 shows the cumulative distribution of the load variation of the microservices in the top 20 production-level microservice applications. The top-20 applications are selected according to the numbers of their queries. As observed, the load variation is from 10% to 40% for 70% of the samples. In the worst case, the load may increase by 2.3X.

From statistics, we find some of the top 20 microservice applications have a great many types of call graphs, with a maximum of 53761 types. All the microservices touched by a query form a call graph. Different queries may have the same call graph. Moreover, Figure 3 shows the call graph proportion variation over time of the top 5 call graphs in the largest microservice application. A call graph's proportion variation is defined to be its proportion changes in the adjacent samples. We can observe that the percentages of queries to the call graphs change dynamically with no oblivious pattern.

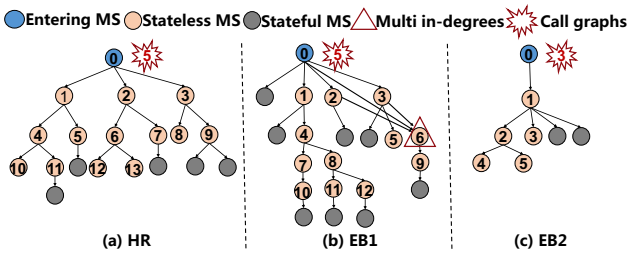

Figure 4: The dependency graphs of the benchmarks. Stateful microservices includes memcached and monogdb.

With the large number of call graphs and the unstable variation, it is non-trivial to profile the call graphs and their patterns, and define static optimal resource allocation beforehand.

3.2 The Investigation Benchmarks

While current microservice benchmarks do not support dynamic call graphs [24,42,46], and the traces [2] do not include the actual microservices (only the call traces), we build three benchmarks by integrating the call graph patterns of the trace and actual microservices in the benchmark suites.

Figure 4 shows the dependency graphs of the three benchmarks, and the number of call graphs. The *HR* benchmark is revised based on the popular HotelReservation benchmark [24]. It has five call graphs that respond to five types of user queries: nearest hotel search, highest rated hotel search, cheapest hotel recommend, comprehensive hotel recommend, and hotel reservation. The benchmarks *EB1* and *EB2* are created based on the dependency graphs of the top 2 applications with multiple call graphs in the trace. For *EB1* and *EB2*, similar to current benchmarks and related work [24,35,36,46], we use commonly-used workloads in microservices, i.e., Nearest Neighbor Searching [6], Word Stemming [13], Quick Sort [15], Float Calculation [43], and Page Rank [16] to be the stateless microservices.

3.3 The Long QoS Recovery Time

We show the QoS recovery time and 99%-ile latencies of the benchmarks with load and the call graph dynamics in this subsection. The QoS recovery time is the time needed to reduce the 99%-ile latency to be below a fixed latency target

Table 1: Experiment specifications

	Specifications
Hardware	Eight-node cluster, Intel(R) Xeon(R) CPU E5-2630 v4 @ 2.20GHz, 256GB Memory Capacity, 25 MiB L3 Cache Size (20-way set associative)
Software	Ubuntu 20.04.2 LTS with kernel 5.11.0-34-generic Docker version 20.10.18, Kubernetes version v1.20.4

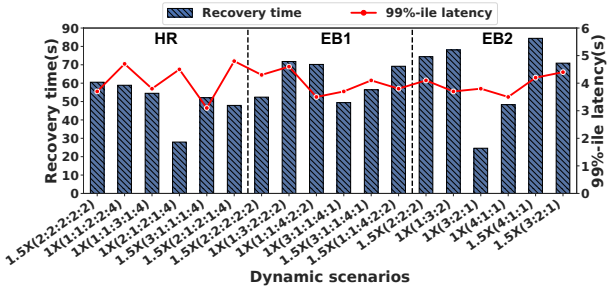

Figure 5: The QoS recovery time and 99%-ile latencies of benchmarks with ELIS.

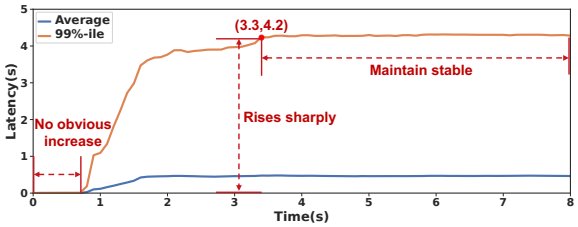

Figure 6: The exploration of latency monitoring intervals.

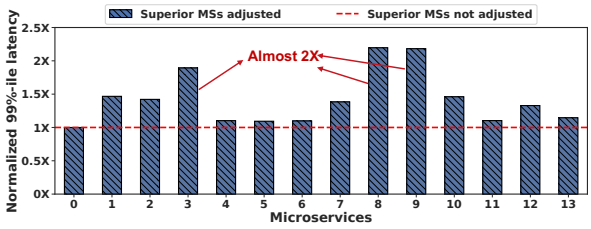

Figure 7: The 99%-ile latency of each microservice after its superior microservices have been allocated enough resources.

(e.g., 100ms) after microservice dynamics happen. Table 1 summarizes the detailed hardware and software configurations. ELIS [41] uses bayesian optimization to tune resource allocation for microservices. We use ELIS as the representative resource management system for microservices in this section. Other systems have similar results and we show them in the evaluation section.

In the experiments, each benchmark has 6 dynamic load and call graph scenarios. We run the experiments on three identical servers managed with Kubernetes [14]. We expand the evaluation on eight servers in Section 8. In each test, each microservice is allocated the hand-tuned enough resource, and the numbers of queries to different call graphs are the same. Figure 5 shows the QoS recovery time and 99%-ile latencies in all the test cases. The *x*-axis represents the dynamic scenarios. For instance, *1.5X(2:1:2:1:4)* means the load increases to 1.5*X*, and the proportions of the 5 call graphs change to 2/10, 1/10, 2/10, 1/10, and 4/10. As observed, the QoS recovery time ranges from 24.6 to 84.4 seconds, and the 99%-ile latencies range from 3.1 to 4.8 seconds, in all the test cases.

Both the two types of dynamics result in serious QoS violations and the QoS recovery time is long.

3.4 Causes of The Long Recovery Time

Our investigation shows the long QoS recovery time is caused by *long monitoring interval*, *execution blocking effect due to dynamcis*, and *slow query draining*.

3.4.1 Long Monitoring Interval

Current resource management systems monitor the realtime latencies of the microservices, and reallocate resources based on either heuristic methods [17, 27, 44] or machine learning based methods [23, 38, 45]. These systems often use seconds or tens of seconds to be the monitoring interval.

As an example, Figure 6 shows the 99%-ile latency and average latency of the benchmark *HR*, when we increase its load to 1.5X. The *x*-axis shows the time since we increase the load. As observed, the monitored 99%-ile latency has no obvious increase in the first second, even if the load already increases. The 99%-ile latency starts to increase sharply at about the first second, and becomes stable after 3.3 seconds. This is because the latencies of the newly arrived queries are not reported before they complete. In this case, the 99%-ile latency reported in the first second is actually the latency before the load actually increases.

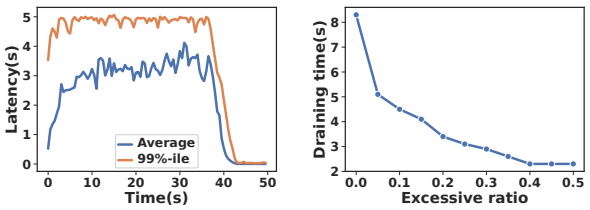
Long monitoring intervals are required for current systems that rely on the latencies of the microservices to adjust the resources. However, a great many of queries may already queue up at a microservice during the long monitoring interval.

3.4.2 Execution Blocking Effect

The second problem is that the monitored realtime load of a microservice may not be its actual "to-be-processed" load.

For instance, as shown in Figure 4(a), the load of microservice-3 may be blocked by microservice-0 if microservice-0 does not have enough computation resources. Similarly, the loads of microservice-8 and microservice-9 may also be blocked by microservice-3. There is more complex blocking effect, besides of the simple dependency relationship. The effect is referred to be *execution blocking effect* in this paper. We will analyze the effect in detail in Section 6.

Figure 7 shows the latencies of the microservices in the *HR* benchmark, when we allocated their superior microservices enough computation resources, normalized to their performance with the default resource allocation. The dynamic



(a) QoS recovery process. (b) Excessive resource ratio.

Figure 8: The results of queued query draining.

scenario of this experiment is *1.5X(2:1:2:1:4)*. As observed, the latencies of many microservices increase when their superior microservices get enough resources. This is because these microservices may get the real "to-be-processed" loads when the blocking effect is alleviated.

Due to the execution blocking effect, the monitored load of a microservice may be much smaller than its actual "to-be-processed" load. Current methods based on monitored load may not allocate enough resources for microservices, thus require to adjust the resource allocation for multiple times.

Similar to our conclusion, prior machine learning based and heuristic-based systems also notice that they require to adjust the resource allocation for multiple times [17, 22, 27, 38, 41]. For instance, the bayesian optimization based system, ELIS [41], needs to search for 4-15 samplings to find the final resource configuration for each microservice. Reinforcement learning-based system, FIRM [38], has to perform multiple incremental model updates, if the microservice application has dynamics. Each adjustment interval is also at least several seconds, incurring more queued queries.

Even if the optimal resource allocations can be determined directly, the long monitoring interval and the blocking effect already result in the long query queues. We also evaluate the optimal resource decision case in Section 8.

3.4.3 Slow Query Draining

The queued queries during the monitoring and the resource adjustment period can result in the long QoS recovery time.

As an example, Figure 8(a) shows the 99%-ile latency of the benchmark *HR* with ELIS, when we change the dynamic scenario to *1.5X(2:1:2:1:4)*. As observed, although appropriate resources are allocated to each microservice for its "to-be-processed" load, the 99%-ile latency gradually drops from time 39.6 seconds to 47.9 seconds instead of backing to normal immediately. This is because the resource allocation does not consider the queued queries at each microservice.

We further try to allocate excessive resources for microservices, and explore the impact of excessive ratio on queued query draining. The excessive ratio is the excessive resource allocation ratio for microservices after the resource adjustment process. Figure 8(b) shows the draining time under different excessive ratios. We can observe that the larger the excessive ratio, the shorter the draining time.

It is possible to reduce the queued query draining time through excessive resource allocation, so that can reduce the overall QoS recovery time. We should carefully determine the amount of excessive resources to ensure high resource efficiency, while minimizing the QoS recovery time.

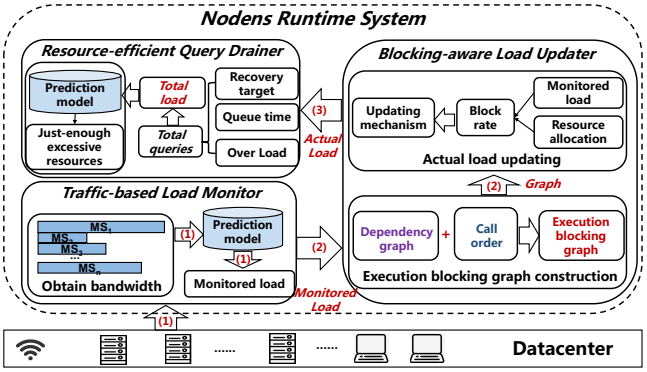


Figure 9: Design overview of Nodens.

4 Nodens Methodology

We design **Nodens** to enable the fast QoS recovery of dynamic microservice applications based on the above analysis.

Figure 9 shows the design overview of Nodens. It comprises a *traffic-based load monitor*, a *blocking-aware load updater*, and a *resource-efficient query drainer*. The monitor predicts the monitored load of a microservice based on the periodically obtained network bandwidth usage of the microservice. The load updater calculates the actual "to-be-processed" load of each microservice, based on the monitored loads of the microservices, the resource allocation of the microservices, and the execution blocking graph of the application. The query drainer allocates "just-enough" excessive resources for each microservice, to quickly drain the queued queries generated during the above process.

We use the network bandwidth usage to predict the load of a microservice for the short monitoring time. Section 5 shows that the incoming network bandwidth of a microservice is closely related to its realtime load. The monitored bandwidth is stable with the 1 second interval. With the short and stable monitoring interval, we can find the load variation quickly and tune the resource allocation as early as possible, reducing the number of queued queries at a microservice when the load increases.

The most challenging part is obtaining the actual "to-be-processed" load of each microservice, due to the execution blocking effect. We define an *execution blocking graph* for a microservice application. It reflects the blocking relationship among microservices, and is determined by the microservice dependency graph and microservice call order. A load updating mechanism is also required to capture the complex

realtime blocking actions due to the dynamics, based on the execution blocking graph (Section 6).

It is inevitable that some queries queue up at a microservice when its load increases, before the increase is noticed and the resource is adjusted. Without careful design, these queued queries result in serious QoS violations, or too much resource is allocated to handle the possible queued queries. The challenging part in the query drainer is to allocate just-enough excessive resources to ensure the QoS recovery time target while maintaining the resource efficiency (Section 7).

Specifically, Nodens manages the resource allocation of a microservice application in the following steps. 1) Nodens obtains the dependency graph and the possible call graphs of the application. Based on the obtained graphs, the *execution blocking graph* is built. 2) When serving the application, Nodens deploys a daemon process on each server to monitor the network usage of the microservices. 3) A server runs the load updater, and determines the resource allocation of each microservice with the query drainer. The load updater collects the bandwidth data of microservices on different servers, and calculates the actual "to-be-processed" load of every microservice. 4) The drainer updates the resource allocation accordingly, and sends back the allocation decision to each microservice. 5) The daemon process on each server then reallocates the resources based on the decision of the drainer.

Since the servers are in the same datacenter, we use gRPC [7] to collect the network usage of each microservice, and send back the allocation decision. The transfer latency is less than 5ms in our experiments. Nodens does not need to modify the source code of microservice applications, and can be implemented as a plug-in based on Kubernetes [14]. Moreover, Nodens does not focus on microservice deployment among distributed servers, and the initial deployment is determined by Kubernetes's random scheduling strategy.

Similar to prior works [29, 37, 41, 45], Nodens uses Linux cgroups [4] to adjust CPU resources, which can complete within 1ms. VPA [10] in Kubernetes also supports in-place pod vertical scaling with low overhead. After each allocation decision, if there are no resources available on some servers in the first place for vertical scale-up, Nodens utilizes the resource recycling idea [41] to deal with. Nodens will first recycle the resources from over-provisioned microservices on these servers, and then allocate them to microservices requiring scaling up. If some servers still lack sufficient resources for their deployed microservices after resource recycling, Nodens adopts current load balancing strategies [22, 33, 41] to migrate some microservices from busy servers to idle servers.

5 Traffic-based Load Monitor

5.1 The Speedup and Predictability

As discussed in Section 3.4.1, the latency monitoring can result in long resource adjustment time. Therefore, we use the upper network bandwidth usage for resource adjustment to reflect the load change of microservices. For microservice-6 of the *EB1* benchmark shown in Figure 4, its upper network bandwidth usage is the data communication amount per second from microservices 0, 2, and 3.

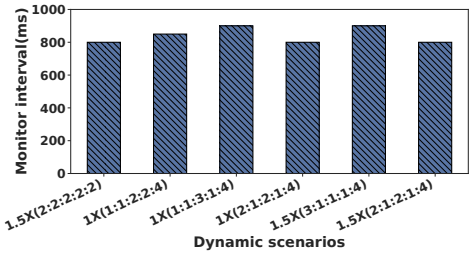

Figure 10: Network traffic monitoring intervals.

To explore the required interval of network traffic monitoring, we conduct 6 experiments on the *HR* benchmark, whose dynamic scenarios are the same as Section 3.3. For each dynamic scenario, we first run the benchmark and monitor all microservices for 10 seconds to obtain their stable network bandwidth usage (Mbits/s) as the baseline values. Then, we run the benchmark again and gradually increase the intervals (starting from 50ms) to find the minimum interval that may get stable monitoring data. We consider the monitoring data to be stable when the error between obtained microservices' bandwidth usage and corresponding baseline values are within 5%. Figure 10 shows that the obtained minimum monitoring intervals are less than 1000ms. Compared with the latency monitoring interval (3300ms) we test in Section 3.4.1, the required interval of monitoring network is 3X shorter.

In addition, we find the upper network bandwidth usage has a typical linear relationship with the load size (i.e., queries per second, QPS) for all microservices, and the relationship between load size and CPU core demand is the same. For a microservice application, we profile each call graph at 10 sets of loads (evenly from 0 to the peak supported load), and obtain the performance samples (i.e., the load, upper network bandwidth usage, and CPU core demand) of all microservices. The profiling can be done automatically and online. For long-running applications, call graphs can be known from history. Otherwise, we can trace the call graph and profile the new call graphs online. We use the profiled performance samples to train the linear models for microservices. We then use the performance samples at 10 other different sets of loads as the test dataset. Predicting the load size through the network bandwidth, and predicting the CPU core demand through the load size, the prediction accuracies are 97.0% and 97.9% on average for the 3 benchmarks, respectively. So, we can accurately predict the load size of each microservice through its upper network bandwidth, and further predict its CPU core demand. As prior works have shown that microservices are basically sensitive to CPU resources [31, 34, 45], Nodens primarily focuses on CPU core allocation. From our observations, the

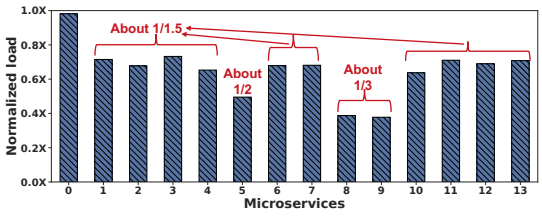

Figure 11: The monitored loads normalized to the actual loads of microservices.

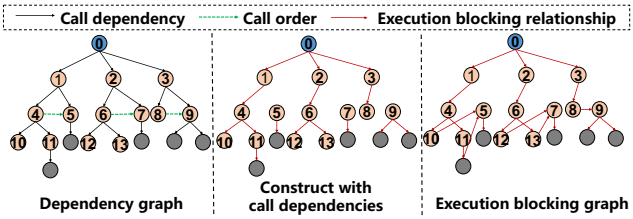

Figure 12: The dependency graph, and execution blocking graph of the *HR* benchmark.

memory usage of microservices is steady, and we pre-allocate enough memory capacity for microservices.

Compared with the ML-based methods [38,41], we can use these models to predict the CPU core demand from network bandwidth usage, whose overhead is usually less than 1ms.

5.2 Network Traffic Monitoring Methods

As the analysis of production microservice applications [31, 32], most of them have tree-like dependency graphs, while a few of them show graph-like structures. The in-degrees of some microservices in a graph-like structure are larger than 1.

For the tree-like dependency graph, we obtain the receive and transmit bytes of microservices' corresponding network interface during the monitoring interval by reading Linux file */proc/net/dev*, and then calculate the upper network bandwidth one by one based on the tree structure. The overhead of this method is less than 15ms, which includes reading the Linux file and calculations. For the graph-like dependency graph, we use Libpcap [12] to obtain network traffic between each pair of microservices directly, and then calculate the upper network bandwidth for each microservice. This method completes in 30ms. After obtaining the upper network bandwidth usage of microservices, the monitor uses linear regression models to predict the monitored loads of them as this module's output.

6 Blocking-aware Load Updater

6.1 Execution Blocking on Monitored Load

Since the effect of execution blocking under dynamics, the monitored loads may not equal to the actual "to-be-processed" loads of microservices. In this subsection, we explore the effect of execution blocking on monitored loads with the *HR* benchmark. We conduct an experiment from the initial state of *1X(2:2:2:2:2)* to the dynamic state of *1.5X(3:1:1:1:4)*. Figure 11 shows the normalized monitored loads to the actual loads of microservices. The left part of Figure 12 shows the dependency graph of *HR*.

As observed, since the load changes from 1X to 1.5X, we can find most microservices' monitored loads are about $\frac{1}{1.5}$ of their actual loads, as their superior microservices can only handle 1X load with current resource allocation. Microservices-8 and 9' monitored load is about $\frac{1}{3}$ of their actual loads, as the proportion of their located call graph also increases two times. Above observations prove that execution blocking effect can be caused by the **call dependencies among microservices**.

Moreover, microserivce-5's monitored load is about $\frac{1}{2}$ of its actual load, but not $\frac{1}{1.5}$. After looking into the dependency graph, we find since microservice-4 and microservice-5 are called by microservice-1 in a fixed order, the microservices in the subtree of microservice-4 can be the execution blocking microservices of microservice-5. In detail, since the load changes and the proportion of microservice-4's located call graphs also changes, microservice-4's subtree blocks $\frac{1}{2}$ of the actual load, which cannot be passed to microservice-5. Above observations prove that the execution blocking effect can be caused by the **call order among microservices**.

We give a simple example for Figure 12. Suppose queries pass through part of the microservices in following orders: 1) log in (microservice-3), 2) authentication (microservice-8), and 3) reservation (microservice-9). Suppose microservice-3's loads increase to 1500 queries per second but it only has just-enough resources to handle loads of 1000. At this point, the loads to its downstream microservices are blocked at 1000, which is 1/1.5 of 1500 (microservices-8 and 9's actual loads).

If we adjust resources only based on monitored loads, we need to adjust resources for microservices multiple times to deal with the execution blocking, which can greatly increase the QoS violation time. Therefore, a reasonable method is to combine the microservice dependency graph, monitored load, and resource allocation to update the actual loads of microservices in advance. During this process, we need to primarily consider the execution blocking effect caused by **call dependencies** and **call order** among microservices.

6.2 Execution Blocking Graph

Based on the observations in Section 6.1, we construct the **Execution Blocking Graph** for the microservice application.

Figure 13 shows the execution blocking graph construction based on the microservice dependency graph. The microservice dependency graph is obtained by using tracing tools (e.g., Jaeger [11]) after running the application online for one minute. Firstly, for the microservice in the dependency graph that has multiple in-degrees, we transform the subtree with it

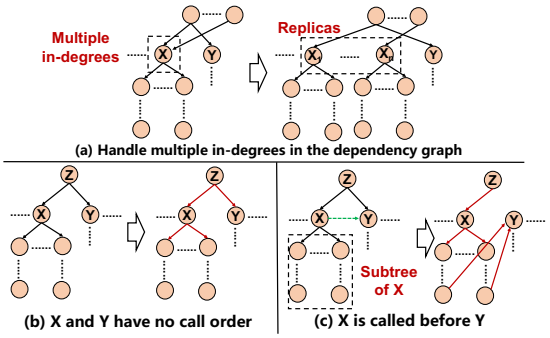

Figure 13: Execution blocking graph construction.

to multiple identical replicas, to maintain the tree structure of the dependency graph, as shown in Figure 13(a). The replicated overhead is low, because few microservices have multiple in-degrees in production microservice applications [31].

We then construct the execution blocking relationship for each sub structure. On the one hand, as shown in Figure 13(b), microservices X and Y have no fixed call order from their common superior microservice. In this case, the execution blocking relationship is equal to the call dependencies among microservices. On the other hand, as shown in Figure 13(c), X is called before Y by their common superior microservice. In this case, the execution blocking microservices of Y are the ones at the end of the execution blocking subtree with root X. The number of this kind of microservices can be one or more. We take an example for better explanations. Suppose X is the "authentication" microservice, Y is the "reservation" microservice, and Z is the "log in" microservice. As X is called before Y by Z, the resource insufficiency of X can block Y. By contrast, if X and Y are called by Z asynchronously, X cannot block Y.

Breaking down the microservice dependency graph into multiple sub structures, we iteratively build the execution blocking relationship from the root microservice. Then, we can obtain the execution blocking graph for the microservice application. Nodens does not need to replicate microservices with multiple in-degrees in the execution blocking graph.

We use the example of *HR* benchmark in Figure 12 to further explain the whole construction process. As microservices 1, 2, and 3 have no fixed call order, their execution blocking relationship is equal to their call dependencies. Some other microservices have similar construction, and the middle results are shown in the middle part of Figure 12. Moreover, microservice-5 is called after microservice-4 by their superior microservice-1. Therefore, its execution blocking microservices are the microservices at the end of the execution blocking subtree of microservice-4. Microservices 7 and 9 have similar construction process with considerations of the call order. The final execution blocking graph is shown in the right part of Figure 12.

The execution blocking graph differs from the execution graph in 2 ways. First, actually an execution graph is similar to a call graph, while the execution blocking graph is constructed once from the dependency graph and it captures all the possible blocking relationship. Second, we define the node and edge weights in the execution blocking graph for updating the actual loads for microservices (Section 6.3), while execution graphs do not have such information.

6.3 Actual Load Updating Mechanism

Based on the execution blocking graph, we then introduce the actual load updating mechanism.

We define the triple to record current state of each microservice i as $(MonitoredLoad_i, ActualLoad_i, HandleLoad_i)$. The $MonitoredLoad_i$ is obtained from the traffic-based load monitor. The $ActualLoad_i$ will be updated by the mechanism for each microservice, and is equal to the $MonitoredLoad_i$ at the beginning. The $HandleLoad_i$ represents the load that can be handled for each microservice. It is predicted by using the linear regression model from its corresponding microservice's resource allocation. For microservices i and j in the execution blocking graph, the edge weight EW_{ij} is defined as the load passing from i to j. The EW_{ij} is equal to the monitored load from i to j at the beginning, and will be updated during the updating mechanism.

Since microservices may block the load of their downstream microservices, we then define the blocking rate of the microservice j as:

$$rate_j = max(\frac{ActualLoad_j}{min(HandleLoad_j, MonitoredLoad_j)}, 1) \quad (1)$$

In this formula, the blocking rate is the $ActualLoad$ dividing the minimum of the $HandleLoad$ and $MonitoredLoad$, as the former may be larger than the latter since higher-level blocking. Moreover, as the loads of some microservices may decrease under dynamics, the blocking rate may be smaller than 1, and we set $rate_j = 1$ for these cases.

We mainly adopt the Breadth-First-Search (BFS) algorithm based on the execution blocking graph to calculate the blocking rate and update the actual loads of microservices layer by layer. Algorithm 1 shows the mechanism. We first initialize the load triple for microservices, the execution blocking graph, and a queue for the BFS process. We then put the root microservice into the queue, and then come into the major process of actual load updating. During this process, we first calculate the blocking rate of the head microservice j of the queue based on Eq.(1), whose $ActualLoad$ has been updated correctly, as shown in the lines of 6-8. Then, we start to handle the downstream microservices of j, as shown in the lines of 9-14. For each downstream microservice k, we first update the actual load from j to k with the blocking rate of j. If k's all entry edges are all updated, we then put it into the queue to follow the process of the BFS algorithm. The updating process is ended when the queue is empty, which represents the

Algorithm 1: Actual Load Updating Mechanism

```
Initialize (MonitoredLoad_i, ActualLoad_i, HandleLoad_i)
Initialize execution blocking graph EBG with edge weights EW_ij
Initialize a queue q for the BFS process
q.put(EBG.root)
while q ≠ ∅ do
    j = q.get()
    ActualLoad_j = Σ_{i→j} EW_ij
    rate_j = max(ActualLoad_j / min(HandleLoad_j, MonitoredLoad_j), 1)
    for each downstream microservice k of j do
        EW_jk = EW_jk × rate_j
        if all entry edges of k are updated then
            q.put(k)
        end if
    end for
end while
return ActualLoads for all microserivces
```

actual loads of all microservices have been updated. Lastly, we return the actual loads of microservices.

7 Resource-efficient Query Drainer

Although the resource adjustment time of Nodens is greatly decreased compared to the latency based resource adjustment methods, the queued query draining is non-negligible, as just-enough resources can lead to the queued queries being unable to be drained for a long time. As discussed in Section 3.4.3, the larger amount of excessive resources can accelerate the draining process, but obviously sacrifice the resource efficiency. We define the QoS recovery time as the time needed to reduce the 99%-ile latency to be below a fixed latency target (e.g., 100ms) after microservice dynamics happen. Same to prior work [21, 38, 41, 45], the QoS is often defined to be latency. Nodens can also support other QoS definitions (e.g., throughput) through simple adaption. We set the QoS recovery time target for the microservice application, e.g., the QoS recovery time is within 3 seconds after microservice dynamics happen. Therefore, the excessive resource allocation of the microservice application can be described as *minimizing the excessive resource allocation on the premise of guaranteeing the recovery time target*.

To allocate just-enough excessive resources for each microservice, we try to drain the queued queries for each microservice exactly within the recovery time target. Therefore, our goal is to calculate the total queries to be processed for each microservice during the residual recovery time, and then allocate just-enough excessive resources correspondingly.

We first calculate the overload of each microservice i during the resource adjustment process as:

$$OverLoad_i = ActualLoad_i - min(MonitoredLoad_i, HandleLoad_i) \quad (2)$$

where the $ActualLoad_i$, $MonitoredLoad_i$, and $HandleLoad_i$ have the same definition to Section 6. For some microservices, their actual loads may be less than or equal to their monitored and handle loads under microservice dynamics. For these cases, we set $OverLoad_i = 0$ for them.

After calculating the $OverLoad_i$, we can further calculate the total queries to be processed for each microservice during the residual recovery time as:

$$TotQuery_i = OverLoad_i \times T_i + ActualLoad_i \times (QT - T_i) \quad (3)$$

where T_i is the resource adjustment time which causes query queuing, and QT is the recovery time target. In this formula, the first item represents the total amount of queued queries, while the second represents the total amount of normal queries that need to be processed during the residual recovery time.

At last, we can calculate the total load (i.e., queries per second) that needs to be handled during the residual QoS recovery time for each microservice i as:

$$TotLoad_i = \frac{TotQuery_i}{(QT - T_i)} \quad (4)$$

Obtaining the $TotLoad$, we can use the linear model mentioned in Section 5.1 to predict the total CPU core demand of each microservice, and then tune the allocated resources accordingly. The total CPU core demand includes the just-enough resources under the corresponding dynamic scenario and excessive resources for queued query draining. After QoS is recovered, the excessive resources will be recycled to maintain high resource efficiency.

8 Evaluation of Nodens

In this section, we first evaluate the performance of Nodens in recovering the QoS while achieving resource efficiency. Then, we show the effectiveness of the blocking-aware load updater, and the resource-efficient query drainer.

8.1 Evaluation Setup

Table 1 already shows the configurations of the experimental platform. We evaluate all the three benchmarks *HR*, *EB1*, and *EB2* on the eight-node cluster in the experiments. For each benchmark, we evaluate Nodens with six dynamic scenarios, including load dynamic, call graph dynamic, and the mix of the two types of dynamics.

We compare Nodens with two state-of-the-art microservice management systems FIRM [38] and ELIS [41]. FIRM monitors the latencies of microservices periodically, identifies the critical path and critical microservices, and increases their resources to the optimal resource allocations using reinforcement learning. ELIS first recycles the over-provisioned resources of non-critical microservices before reallocating the resources. It uses bayesian optimization to reallocate resources. For FIRM and ELIS, the latency monitoring periods

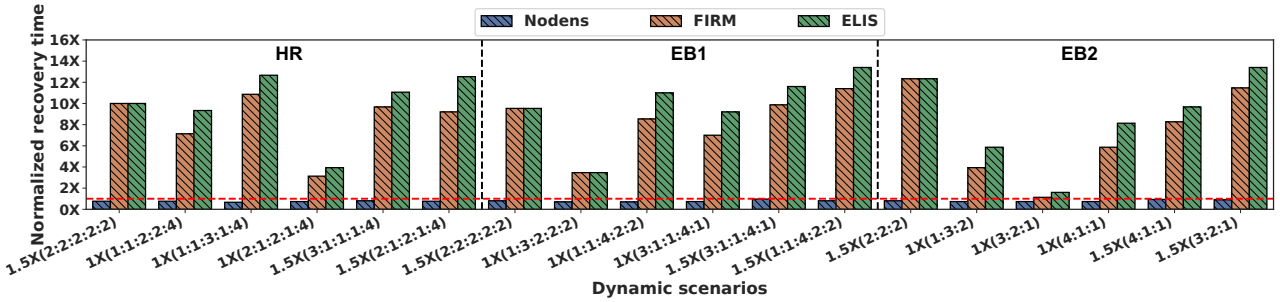

Figure 14: The normalized QoS recovery time relative to the recovery time target of benchmarks with Nodens, FIRM, and ELIS.

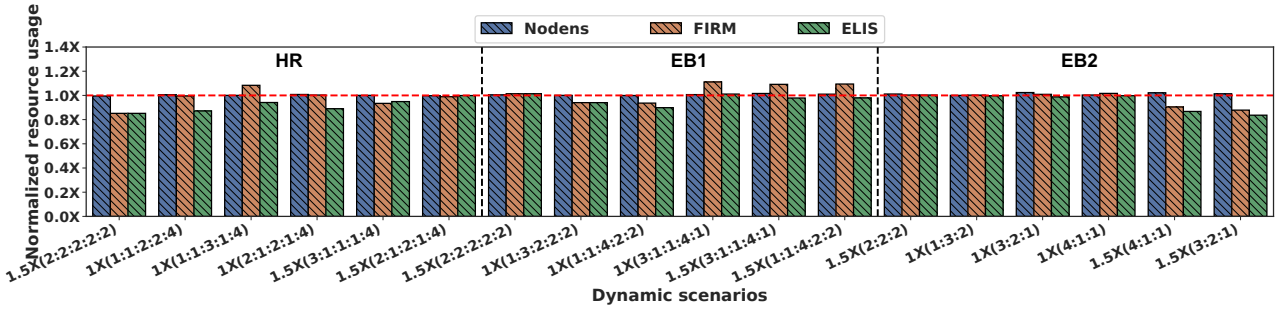

Figure 15: The normalized resource usage relative to the just-enough resources of benchmarks with Nodens, FIRM, and ELIS.

are set to be the minimum time with which the latency is stabilized (i.e., the subsequent latency increase is less than 5%). In Nodens, we use 1 second to be the network traffic monitoring interval as analyzed in Figure 10.

In our experiments, we already optimize FIRM and ELIS through offline profiling. While ML-based resource adjustment requires multiple iterations to find the optimal resource configuration, we optimize them to be able to directly allocate the optimal resources for microservices. Moreover, we also give each microservice excessive resources according to the recommendation of Nodens's query drainer. The native FIRM and ELIS perform worse than the ones we used here.

In the following experiments, we use 3 seconds to be the recovery time target. In other words, Nodens will adjust the resource allocation, in order to make sure that the QoS violation is eliminated in 3 seconds.

8.2 QoS Recovery and Resource Efficiency

In all test cases, microservices are initially allocated the just-enough resources when the load is 1X and the percentages of queries that go to different call graphs are identical. Then, we change the loads of the entire benchmark and the percentages of queries go to different call graphs, and evaluate the performance of Nodens in recovering the QoS before the given QoS recovery target.

Figure 14 shows the QoS recovery time of all the $3 \times 6 = 18$ test cases with FIRM, ELIS, and Nodens, respectively. The time is normalized to the recovery time target (3 seconds). In the figure, "1.5X(2:2:2:2:2)" represents the case that the application's load increases to 1.5X, and the percentages of queries to the five call graphs are identical. As observed from the figure, Nodens successfully eliminates the QoS violation in the given recovery time target. By contrast, the QoS recovery time with FIRM and ELIS is 7.9X and 9.4X of the recovery time target, and 10.2X and 12.1X of Nodens's.

Nodens has shorter QoS recovery time because it has shorter but stable load monitoring interval, and calculates the actual "to-be-processed" load of each microservice. It is able to reduce the queued queries during the monitoring interval, and allocate enough resources for each microservice beforehand. We can also find that the QoS recovery time is longer with ELIS than with FIRM. This is because ELIS first recycles the over-provisioned resources, which can spend some extra time. Moreover, the QoS recovery time is also short with ELIS and FIRM in some cases (e.g., the scenario *1X(3:2:1) with EB2*). It happens when there are only a few microservices' resources are insufficient.

Figure 15 shows the corresponding total resource usage (*cores* $\times$ *hours*) of the test cases during the QoS recovery process. The resource usage is normalized to the case that all the microservices have "just-enough" resources for the new load since the dynamic happens. We use the longest QoS recovery time (i.e., ELIS's) to calculate the total resource usage for the fair comparison. As observed, Nodens uses 1.5% and 6.1% more resources on average than FIRM and ELIS, respectively.

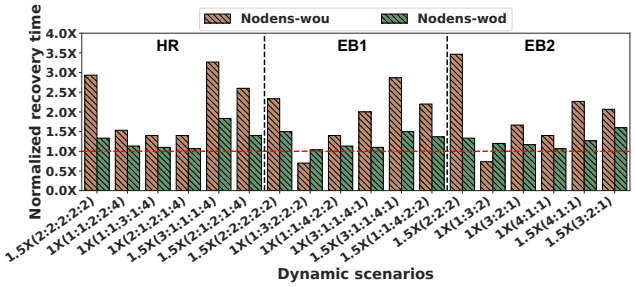

Figure 16: The QoS recovery time with Nodens-wou and Nodens-wod normalized to the recovery time target.

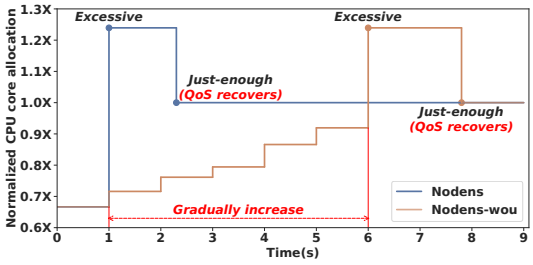

Figure 17: The CPU core allocation timeline of Nodens and Nodens-wou in an example dynamic scenario.

FIRM also uses more resources than ELIS. This is because FIRM only increases the resources of critical microservices without recycling the over-provisioned resource.

Therefore, Nodens is resource efficient while realizing the fast QoS recovery.

8.3 Effectiveness of the Load Updater

In this experiment, we show the performance of *Nodens-wou*, a variant of Nodens that disables the blocking-aware load updater. With Nodens-wou, the query drainer still allocates excessive resources for the microservices.

The orange bars of Figure 16 show the QoS recovery time of all the test cases with Nodens-wou normalized to the QoS recovery time target. As observed, Nodens-wou recovers the QoS before the recovery time target in only two cases. Compared with Nodens, Nodens-wou requires 2.6X time on average to recover the QoS.

As an example, Figure 17 shows the normalized resource allocation timeline of Nodens and Nodens-wou in the test case *1.5X(2:1:2:1:4)* of the *HR* benchmark. Other test cases show similar conclusions. As shown in the figure, Nodens allocates excessive resources to the microservices at an early time, and returns to the "just-enough" resource allocation once the QoS violation is eliminated. On the contrary, Nodens-wou gradually increases the resource allocated to the microservices after each monitoring interval. This is because the execution blocking effect makes Nodens-wou cannot obtain the actual "to-be-processed" loads of the microservices. For a microservice, its load pressure is released layer by layer from its superior microservices.

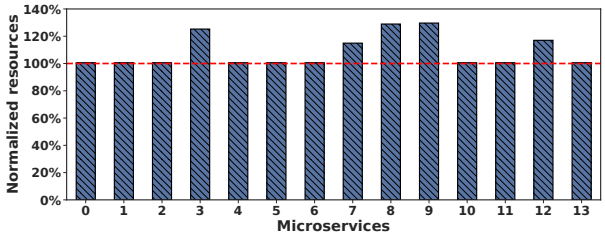

Figure 18: The resource allocation of microservices normalized to the just-enough resources for an example experiment.

The blocking-aware load updater is necessary for Nodens. It avoids the execution blocking effect by updating the actual "to-be-processed" loads of microservices in advance.

8.4 Effectiveness of the Query Drainer

In this experiment, we show the performance of *Nodens-wod*, a variant of Nodens that disables the query drainer. The blocking-aware load updater still works in Nodens-wod.

The green bars of Figure 16 show the QoS recovery time of all the test cases with Nodens-wod normalized to the QoS recovery time target. As observed, Nodens-wod fails to recover the QoS before the recovery time target in all the cases. Compared with Nodens, Nodens-wod requires 1.6X time on average to recover the QoS. This is because the queued queries generated during the resource adjustment cannot be drained up quickly without the excessive resources allocated by the query drainer. Moreover, we can find that Nodens-wod performs better than Nodens-wou in most cases. This is because Nodens-wod can eliminate the execution blocking effect which is the most important influence factor that causes long-time QoS violations.

As an example, Figure 18 shows the actual resources allocated of microservices normalized to the just-enough resources in the test case *1X(1:1:3:1:4)* of the *HR* benchmark with Nodens. As observed, Nodens allocates excessive resources for 5 of the 14 microservices in the test case. Specifically, microservices 3, 8, and 9 belong to the same call graph and are affected by the same degree of execution blocking, so they have almost the same ratio of excessive resources. Microservices 7 and 12 belong to another call graph, and their resource shortage is smaller than the previous 3 microservices, so Nodens's drainer allocates them less excessive resources.

8.5 The Impacts of Dynamics

Since there are load dynamics, call graph dynamics, and load+call graph dynamics when serving a microservice application, we evaluate their impacts on the query drainer.

Figure 19 shows the ratio of total excessive resource allocation for all dynamic scenarios of the 3 benchmarks with

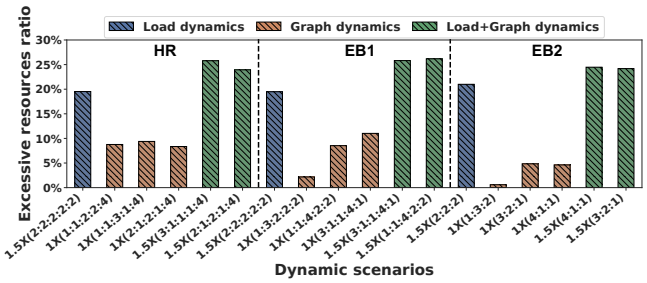

Figure 19: The ratio of total excessive resource allocation for all dynamic scenarios of the three benchmarks.

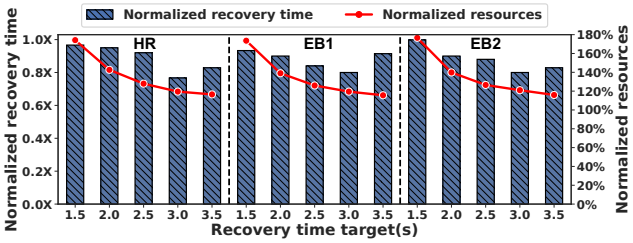

Figure 20: The QoS recovery time and resource allocation under different recovery time targets.

Nodens. As observed, the excessive resource ratio is smallest with only call graph dynamics, larger with only load dynamics, and the largest with both load and call graph dynamics.

This is because dynamic call graph scenarios only cause a few microservices' resources to be insufficient and dynamic load scenarios cause more, while the simultaneous dynamic load and call graph scenarios cause the most. As the resource shortage of more microservices can cause more queries queued, Nodens' drainer will allocate more excessive resources for these scenarios.

8.6 Handling Different Recovery Time Targets

In this experiment, we show Nodens's performance in handling different recovery time targets. We use one dynamic case of each benchmark to conduct the experiment, i.e., 1.5X load with identical call graph percentages.

Figure 20 shows the QoS recovery time and the actual resource allocation for all the cases. The QoS recovery time and the actual resource allocation are normalized to the recovery time target and just-enough resources in each case, respectively. As observed, Nodens successfully eliminates the QoS violation in different given recovery time targets for all the cases. Moreover, Nodens allocates more/fewer resources for the case with the smaller/larger recovery time target, which proves Nodens's resource efficiency.

Therefore, Nodens can ensure different QoS recovery time targets, while maintaining resource efficiency.

8.7 Overhead of Nodens

Offline Overhead. To train the prediction models for CPU core allocation, Nodens needs to profile the bandwidth and performance data for different microservices at different loads in advance. The offline profile time is about 25 minutes for each benchmark. The offline training time of the linear regression models for each benchmark is less than 150 ms.

Online Overhead. After deploying Nodens online, the execution time of the load monitor to get network traffic is less than 30ms. Moreover, the execution time for the load updater and query drainer are both less than 5ms. The prediction time and CPU core allocation time are all less than 1ms. The data transfer latency between servers is less than 5ms. Therefore, the total online overhead is about 50ms. The overhead is acceptable as it is far less than the monitoring interval in our experiments (i.e., 1 second).

We also evaluate Nodens's overhead using a simulated large-scale application with 200 microservices and 10 call graphs based on production-level microservice traces [31]. The online overhead is 126.6ms (59.4ms, 31.6ms, and 35.6ms for the network monitor, load updater, and query drainer, respectively), the offline profiling overhead is 50 minutes, and models can be trained in 2s.

9 Conclusion

In this paper, we propose Nodens to enable fast QoS recovery of dynamic microservice applications, while maintaining the efficiency of resource usage. Nodens's traffic-based load monitor predicts the monitored loads for microservices based on their network bandwidth usage. Nodens's blocking-aware load updater calculates the actual "to-be-processed" loads of microservices based on the execution blocking graph. It can eliminate the execution blocking effect, so that can reduce the total resource adjustment time. The query drainer allocates excessive resources for microservices to drain the queued queries, ensuring the QoS recovery time target. We have implemented Nodens and the experimental results show that, compared to the state-of-the-art microservice management systems, Nodens reduces the QoS recovery time by 12.1X.

Lifting the veil on Meta's microservice architecture: Analyses of topology and request workflows

Darby Huye

Yuri Shkuro
Meta

Raja R. Sambasivan
Tufts University

Abstract

The microservice architecture is a novel paradigm for building and operating distributed applications in many organizations. This paradigm changes many aspects of how distributed applications are built, managed, and operated in contrast to monolithic applications. It introduces new challenges to solve and requires changing assumptions about previously well-known ones. But, today, the characteristics of large-scale microservice architectures are invisible outside their organizations, depressing opportunities for research. Recent studies provide only partial glimpses and represent only single design points. This paper enriches our understanding of large-scale microservices by characterizing Meta's microservice architecture. It focuses on previously unreported (or underreported) aspects important to developing and researching tools that use the microservice topology or traces of request workflows. We find that the topology is extremely heterogeneous, is in constant flux, and includes software entities that do not cleanly fit in the microservice architecture. Request workflows are highly dynamic, but local properties can be predicted using service and endpoint names. We quantify the impact of obfuscating factors in microservice measurement and conclude with implications for tools and future-work opportunities.

1 Introduction

Microservice architectures are the de-facto method for building distributed systems in large-scale organizations [8, 13]. The basic tenants of this architectural style are well-known—monolithic applications are decomposed into smaller software services that communicate with one another over well-defined APIs, facilitating independence of different development teams, increased deployment velocity, and fine-grained scaling [11, 22]. But, outside of this basic understanding, there is a lack of clarity about industrial microservice architectures' design choices and their resulting characteristics. This ambiguity curtails the impact of microservices research. It is impossible to identify the microservice designs to which improvements suggested in the literature are best suited or which assumptions about microservices' characteristics are valid.

There has been a plethora of research seeking to improve the community's understanding of microservices. Many are qualitative, focusing on reasons for deploying microservice architectures [18, 24, 39], methods for decomposing monolithic applications to microservice architectures with many smaller services [9, 17, 36], and difficulties introduced by microservice architectures [39]. Though useful, they do not provide quantitative data about different organizations' microservice architectures, such as (but not limited to) their scale, topologies, or communication methods, all of which are critical to inform future research.

The community has also created many open-source testbeds built with the microservices design philosophy [1, 13, 46]. But, their scale and complexity do not match that of large-scale organizations' microservice architectures. Past research has shown that these testbeds exhibit much simpler behaviors than industrial architectures [31]. As a result, quantitative data about microservices obtained from these testbeds are not representative of industrial microservice architectures where the microservice architectural style is perhaps most valuable. This is concerning due to the number of research papers that rely on these testbeds [12, 14, 23, 25, 37, 38, 40, 43, 44]. For example, Sage [12] assumes synchronous RPCs. Tprof's [14] layer 4 grouping assumes non-combinatorial explosion when grouping requests by visited services' execution order. Both assumptions are invalid at Meta.

Recent publications from other large cloud companies provide quantitative data about their microservice architectures [20, 41]. But, they represent only partial views of single design points. Additional quantitative studies—both confirming existing findings and focusing on unexplored dimensions— are needed to enrich the community's understanding of large-scale microservices. We envision that these studies will collectively inform robust assumptions for use in microservice research and development.

We present a top-down analysis of Meta's microservice architecture, starting from its service-level topology and descending into individual request workflows. (Request workflows describe the order and timing of services visited by requests when executing.) Our focus is on underreported characteristics of microservice architectures important for developing microservice tools and artificially modeling microservice topologies. Specifically, we describe growth and churn of the microservice topology (to inform tools that learn models of the topology [12, 25, 44]), whether elements of the topology fit power-law distributions common to large graphs (to inform potential artificial topology generators), and the predictability of individual request workflows (to inform the vast number of tools that work by aggregating trace data [14, 29, 45]). We report on characteristics described in previous studies, such as workflows' sizes and shape, to enable qualitative comparisons.

We perform our study using production datasets[1] describing Meta's microservice topology and request workflows within it.

[1] https://github.com/facebookresearch/distributed_traces

Our datasets for topological analyses span a 22-month period (the entire amount of time historical data about the topology has been maintained). We focus on 1-day of distributed traces [16] (totaling 6.5 million) for our analyses of request workflows, which allows us to focus on predictability of specific request behaviors.

We present our main findings below and conclude this paper with their implications along with a discussion of future research opportunities.

(1) Topological characteristics: The topology is very diverse containing many types of software entities that are deployed as services. The topology is constantly growing, sees daily churn in deployed and deprecated services, and (mostly) does not exhibit power-law relationships.

(2) Workflow characteristics: Traces of request workflows vary in size depending on the high-level functionalities they represent. Similar to previous studies [20, 41], we find that traces are small in size and wide in number of communication calls. Service and endpoint names do not predict number of communication calls or their concurrency. But, they reduce uncertainty in the set of services they will call (callers and callees are specified as services + ingress endpoint). Adding knowledge of the children service set better predicts concurrency.

(3) Obfuscating factors preventing quantitative comparisons between architectures: Scale and complexity analyses are hindered because the term "service" is ill-defined for microservices and previous studies do not report their definitions. Different organizations use different tracing platforms with unspecified assumptions about how workflows are sampled and what sampling policies are used. We find that these factors have non-negligible effects on our results.

2 Toward characterizing Meta's microservices

Figure 1 illustrates Meta's microservice architecture. It is similar to other large-scale microservice architectures [11, 20, 22, 31, 41], consisting of ① (in Figure 1) a topology of interconnected, replicated software services running in dozens of datacenters; ② load balancers for distributing requests amongst service replicas; ③ an observability framework for monitoring the topology and creating traces (graphs) of a sampled set of request workflows; and ④ a globally-federated scheduler for running services on host machines within containers. A basic assumption of Meta's architecture (which may or may not be true for other organizations' architectures) is that *business use case* is a sufficient partitioning by which to define services, scale functionality, and observe behaviors.

The rest of this section motivates the value of studying the topology and request workflows, discusses limitations of previous studies, and fills in important details about Meta's architecture relevant to our analyses. We conclude by discussing the observability framework and the datasets generated from it that we use in our analyses. Given the sparsity of information

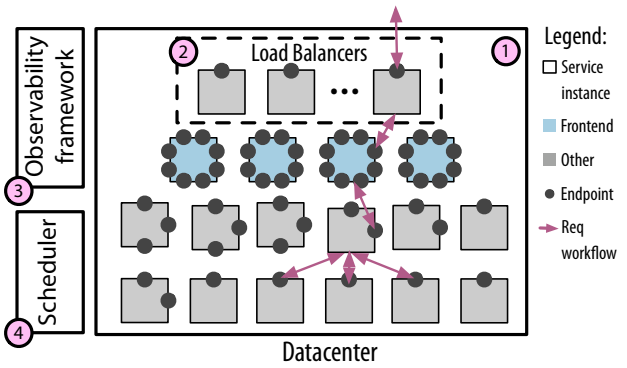

Figure 1: **Meta's microservice architecture and an example request workflow.** The architecture consists of many service instances distributed across many datacenters.

available about Meta's microservice architecture, we err on the side of providing more information than strictly needed.

How do applications use Meta's microservice architecture? Customer applications, such as Instagram or Facebook mobile, issue requests that are load balanced by DNS to specific datacenters and processed by a subset of the architecture's software services. Example requests include those to save photos or record reactions to posts. Applications internal to Meta, such as dashboard or internal tools, use the architecture similarly. But, their requests are load balanced via internal mechanisms, not DNS.

2.1 Topology: services & communication

Why study microservice topologies? We need to understand their complexity, factors that influence their complexity, heterogeneity of constituent services, and the speed at which the topology changes. These characteristics are important to inform tools that visualize the topology, learn models based on the topology, or make assumptions about services' homogeneity [12, 14, 25, 44].

Limitations of existing studies: Only Wen et al. [41] focuses on the microservice topology. The scale they report for number of services is based on a sampled dataset of request workflows, which may not reflect the true scale of their architecture. No existing study defines what constitutes a service or how their definition impacts analyses of the topology (e.g., number of services and communication edges). Existing studies do not report on how the topology evolves or the velocity of change [20, 45].

Meta's microservice topology: The topology is formed by many replicated software services (☐ in Figure 1) deployed across dozens of geographically-distributed datacenters along with their communication to process application requests. (Replicas are typically called *instances*). We note that within the topology, the notion of an application is ill-defined. Individual service instances may process work on behalf of multiple applications. They may also issue requests with batched data from multiple applications to other service instances. The topology evolves *organically* with no central coordination

because development teams responsible for services have complete control over how they are built and maintained.

Services: Services are defined as units of software with well-defined API interfaces, called endpoints (● in Figure 1). Each service satisfies a specific *business use case* (e.g., caching a photo feed). There is significant room for interpretation in defining the scope of a business use case. Additionally, software that pre-dates the microservice architecture may serve multiple business use cases, but be deployed as a single service. Both services and endpoints are named by respective services' developers. (We use *Service ID* and service name interchangeably in latter sections to refer to services' names.)

Services can be stateful or stateless [11]. Stateful services, such as databases, persist state for callers whereas stateless ones, such as search frontends, call other services and integrate their results. A variety of programming languages are used to write services depending on fit for the business use case and societal pressures within the organization.

Load-balancing & Communication: Requests to services are load balanced across their instances. Initially, a datacenter load balancer, itself a service, load balances incoming application requests. Afterward, requests between service instances are load balanced by a service-routing library [30] either linked to applications or to outbound sidecar proxies. (Only some services use sidecars, e.g., when their runtimes do not support linking the routing library directly). The routing library periodically communicates with a global service registry to discover services and routes for their instances. Requests can be load balanced to instances within the same datacenter or to instances in different datacenters. Only the datacenter load balancer is depicted in Figure 1.

Most services at Meta use two-way Thrift RPCs [35] for communication, with payloads serialized in Thrift binary format. Many frontend and some backend services also expose numerous HTTP (REST and GraphQL) endpoints; however, they do not have canonical names that we can use for our analyses. For this reason, we limit the endpoint analysis only to Thrift RPCs reported in the dataset from the routing library.

2.2 Individual request workflows

Why study request workflows: We need to understand the dynamic nature of request workflows. Given a single request execution, what will vary in subsequent executions versus what will remain stable? How much of a statement can we make about other request executions after seeing one or a limited number of samples? Such information is important to inform tools that predict performance, extract critical paths, and present aggregate analyses of request workflows.

Limitations of existing studies: Luo et al. [20] present a way to predict the total number of services that will be called at any hierarchical level of a request workflow. But, they do not discuss whether the number, set, or concurrency level of services called by a specific parent can be predicted. Wen et al. [41] present the amount of time children execute concurrently. Zhang, et al. [45] present distributions of the maximum number of concurrent services observed in workflows. But, neither discuss if information in request workflows can predict concurrency or other workflow characteristics.

Request workflows at Meta: Requests from external applications originate at a datacenter load balancer. This load balancer sends requests to instances of *frontend services*, which are entry points for executing request business logic. There are several frontends at Meta serving different subsets of applications and each has many instances. Frontends may call many services, which in turn may call other services. The resulting hierarchy can be described as forming parent/child relationships. Request workflows for requests originating from internal applications are similar, but originate at the first service that executes business logic on behalf of them.

The set of services involved in a request workflow depends on a number of factors including (but not limited to) the business logic that must be executed on behalf of application requests and whether any requested data is cached. On the other hand, the specific set of instances involved in a request workflow depends on the current load and the load-balancing policy in use.

Concurrency & latent work: Within request workflows, parent services may call all or a subset of children services sequentially or concurrently. The former will be the case if parents are blocking (e.g., single threaded so cannot do work while there is an outstanding call). It may also be the case if there are data dependencies between subsequent calls to children, such as an authentication token that must be returned from one service and passed as input to others. The critical path of concurrently-called children services includes only the slowest one, whereas that of sequentially-called ones includes all of them. Children may perform additional, *latent* work after replying to the parent (e.g., for garbage collection or data replication).

Sample request workflow: The arrows (↔) in Figure 1 show a request traversing a single datacenter. The request first arrives to an instance of the datacenter load balancer, which routes it to an instance of a frontend service, such as `www`. The request then traverses deeper into the topology to backend services.

2.3 Observability framework & datasets

Meta's observability framework includes monitoring mechanisms for recording metrics, logging mechanisms for recording various events, and a distributed-tracing infrastructure, Canopy [16], for recording graphs (called traces) of request workflows. Data generated by the framework is retained for a limited time period to reduce storage volume and due to policy. We describe Canopy in more detail below due to its criticality to observability of microservices. We conclude with a description of the log-based and trace-based datasets we use for our analyses.

Canopy for recording request workflows: Canopy works similarly to most existing distributed-tracing infrastructures [27]. It provides APIs that developers use to define

a request workflow and capture important information about the workflow that should be recorded in traces. The former involves modifying services' code to propagate per-request context—e.g., request IDs and happens-before relationships—within and among the services involved in request execution. The latter involves adding *trace points*, similar to log messages, within source code. During runtime, records of trace points executed by requests are annotated with request context and timestamps. Off of the critical path of request execution, records with identical trace IDs are ordered by happens-before relationships to create traces.

Under the hood, Canopy's implementation is similar to *event-based* tracing infrastructures [10, 26, 29]. However, the way developers instrument services and use the resulting traces is similar to *span-based* tracing infrastructures [4, 32, 34]. *Implementation*: *(1)* Trace points are single events. Higher-level blocks demarcating various intervals (e.g., service executions, queuing time, or function executions) are constructed via annotations added to them. *(2)* context is propagated on both request (forward) and response (reverse) paths, allowing points to be ordered globally within and across services. *Usage*: *(1)* developers (typically) only add blocks denoting service executions; *(2)* happens-before relationships are only established in the forward direction of context propagation, meaning they identify parent/child relationships between blocks and not ordering between siblings; (3) causality between sibling blocks is not explicitly captured via alternate mechanisms. It is impossible to tell whether siblings that execute sequentially as per timestamps in one trace must execute sequentially in other traces.

We describe aspects of Canopy relevant to our workflow analyses. A key observation is that traces created with Canopy may—*by design*—not capture all of a request's workflow.

Effective trace model: Traces are graphs. Nodes are blocks (spans) indicating service execution and hierarchical levels indicate parent/child relationships. Blocks include trace points indicating message send and receives. They may contain additional points indicating other events of interest. Edges between points represent network communication. Latent work started on behalf of a request after the response is returned to the client, such as data replication or asynchronous notifications, may be recorded as additional points on the service block, or as a separate trace with a link back to the originating request's trace (similar to OpenTelemetry's *span links* [5]). Service blocks automatically record *Service ID*s and endpoint names for communication using Thrift RPCs [35]. Developers must manually provide names for services that use custom communication methods. Figure 2 shows an example Canopy trace originating at the *www* service. It has two children services. One of the children (Service B) also has a child (DB).

Streaming model for trace creation with timeout: A stream-processing framework [21] is used to construct traces from trace-point records for subsequent post-processing, such as computing critical path or generating end-to-end latency metrics. The framework accumulates trace events using a

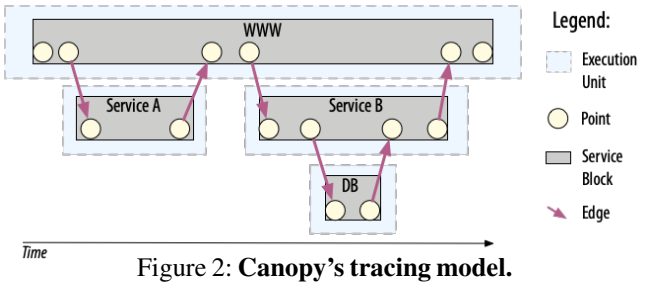

Figure 2: **Canopy's tracing model.**

session window with a fixed gap of inactivity [6]. Traces whose events have a gap in the arrival time larger than the session window would be accumulated in more than one session, but only the first one would be used to trigger post-processing, which may result in processing of partial traces.

Per-service sampling profiles (policies) with rate limiting: Sampling profiles are unique to Canopy. They can be attached to any service and indicate sampling policies to apply based on specific attributes of incoming requests. Traces reflect the union of all sampling profiles that their corresponding requests encounter while executing. This means that a request's trace may start at a service deep in the topology, not recording prior services executed by the request. Trace branches may end prematurely at services whose profiles chose to stop recording the rest of the request's workflow.

A policy specifies: *(1)* a set of conditions for when it is applicable, such as group of endpoints, *(2)* a sampling method, *(3)* a maximum rate of trace data, measured over a sliding time window, beyond which additional traces will not be captured, and *(4)* a verbosity level to decide which instrumentation to execute for requests. Sampling methods may be random head-based sampling [34], in which requests are traced with a random probability, or adaptive sampling [33], in which the sampling probability is periodically changed to achieve a target rate of trace throughput.

Inferred service blocks: These blocks represent services that prematurely ended trace branches, either because of rate limiting or because they lacked tracing instrumentation. Inferred blocks are created during trace construction using information in parent services' message-send points. Inferred blocks may be named or unnamed. The former will be the case when parent points contain the necessary naming information.

Datasets used for this paper: Table 1 shows the datasets we use. For our topological analyses, we use logs describing service activity: history of deployments and deprecation, endpoints exposed by deployed services, and calls made from/to deployed services. For the workflow analyses, we use distributed traces collected by Canopy. The log data describes every deployed service, whereas traces are sampled using methods unique to Canopy, described above.

3 Topological Characteristics

We characterize Meta's current microservice topology as well as how it has evolved. Our analyses of the current topology uses the last (most recent) day of the *Service History* and

Dataset	Description	Format	Retention	Size	Period Used
Service History	Service deployment, lifetimes & interservice communication	*Service ID*s deployed each day	22 months	17 MB	All
Service Endpoints	Endpoints exposed by services	*Service ID* endpoints accessed each day	30 days	18.8 MB	1 day
Traces	Distributed traces	Canopy Trace Objects	30 days	13.1 PB	1 day (4.6 TB)

Table 1: **Datasets used for analyses.**

Endpoints datasets (2022/12/21). Our historical analyses use all 22-months of data available to us (2021/03/01 to 2022/12/21). We also use various dashboards w/statistics about services. The main findings are summarized below.

Finding F1 (All subsections): Meta's microservice topology contains three types of software entities that communicate within and amongst one another: *(1)* Those that represent a single, well-scoped business use case. *(2)* Those that serve many different business cases, but which are deployed as a single service (often from a single binary); *(3)* Those that are ill-suited to the microservice architecture's expectations that business use case is a sufficient partitioning on which to base scheduling, scaling, and routing decisions and to provide observability. These latter entities use *Service ID*s in custom ways, obfuscating their true complexity.

Finding F2 (§3.2): The topology is very complex in its current state, containing over 12 million service instances and over 180,000 communication edges between services. Individual services are mostly simple, exposing just a few endpoints, but some are very complex, exposing 1000s or more endpoints. The overall topology of connected services does not exhibit a power-law relationship typical of many large-scale networks. However, the number of endpoints services expose does show a power-law relationship.

Finding F3 (§3.3): The topology has scaled rapidly, doubling in number of instances over the past 22 months. The rate of increase is driven by an increase in number of services (i.e., new functionality) rather than increased replication of existing ones (i.e., additional instances). The topology sees daily fluctuations due to service creations and deprecations.

3.1 Existence of ill-fitting software entities

We discovered several anomalous patterns in the structure of service IDs within both datasets. For example, we found that on average, 60% of services observed on any single day of the 22-month period have *Service ID*s of the form `inference_platform/model_type_{random_number}`. We found that these services all expose a small number of endpoints with identical names. Meta's engineers informed us that these *Service ID*s are generated by a general-purpose platform for hosting per-tenant machine-learning models (called the Inference Platform). The platform serves a single business use case—i.e., serving ML models—but many per-tenant use cases. Platform engineers chose to deploy each tenant's model under a separate *Service ID* so that each can be deployed and scaled independently per the tenant's requirements by the scheduler.

Following our discovery of the Inference Platform, we investigated the most frequent *Service ID*s and those with the greatest number of service instances. We found two types of software entities that use *Service ID*s in custom ways: *(1)* platforms, such as the Inference Platform, for which multi-tenancy is an additional dimension that must be considered for scheduling, scaling, routing, or observability; *(2)* storage systems, which must take into account data placement in addition to their business use case(s).

We found that some entities, such as the Inference Platform, appear as many services where each service is a combination of the business use case and the additional dimension(s) of partitioning required. Other entities, such as databases and other platforms, appear as a single service and provide their own scheduling and observability mechanisms. Both types of entities' unique use of *Service ID*s masks their true complexity and skews service- and endpoint-based analyses of microservice topologies (ours and likely previous studies [20, 41]).

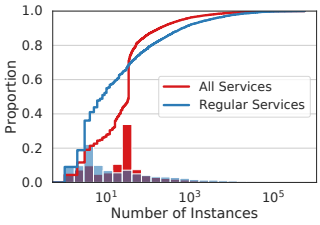
There is no systematic way to identify these ill-fitting software entities at Meta. To illustrate how they may affect *Service ID*-based analyses, we call out contributions by two entities that affect our results significantly. The first is the Inference Platform, which inflates the number of services observed. The second is the ML Scheduler, a scheduling platform for ML training jobs which chooses to appear as a single service and so inflates instance counts. We collectively refer to them and their services as *Ill-fitting services* and all other services as *Regular services*.

3.2 Analysis of the current topology

Scale is measured in millions of instances: On 2022/12/21, the microservice topology contained 18,500 active services and over 12 million service instances. Excluding the ill-fitting services, there are 7,400 services and 11.2 million instances.

The instance count is due to a few highly-replicated services: Figure 3 shows that the ill-fitting services greatly skew instance counts. Notably, the `ML scheduler` is replicated over 270,000 times, 2.2% of all instances. When these services are excluded, the median service's replication factor is only eight and the 99th percentile is 31,306. Frontend service `www` is the most replicated service (557,000 instances, 4.6% of all instances) as it handles most incoming requests.

Services are sparsely interconnected: We construct the service dependency diagram by connecting services that communicate with each other at least once with an edge. (Our dependency diagram is similar to that constructed by OpenTelemetry or Jaeger, except that it is constructed from a portion of the *Service History* dataset that captures commu-



(a) CDF

	# Instances	# Instances (Regular)
Min	1	1
Med	34	8
Avg	668	1,504

P99	86	101	324	158
Max	14,084	5,865	2,968	1,069

(c) Statistics

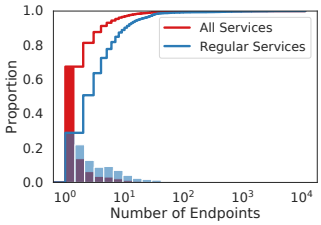
Figure 4: **Service fan-in and fan-out.**

nication between services, not raw traces.) There are 393,622 edges that connect services, which is much smaller than a fully connected topology (18,500^2 or 342 million edges).

Services are called by services more than they call other services: Continuing with the dependency diagram, Figure 4 shows CDFs and statistics about services fan-in (# of services that call them) and fan-out (# of services that they call) degrees. The median fan-in and fan-out are the same, but average and maximum fan-in is larger than fan-outs (14 vs 12 and 14,084 vs 5,865). Excluding the ill-fitting services, by removing all edges connected to ill-fitting services, decreases the median fan-in but increases the median fan-out. Excluding the ill-fitting services also increases the 99.9 percentile and decreases the maximum fan-in and fan-out values.

We investigated the services that have the highest fan-in and fan-out degrees. The former is a vault server storing credentials for use by other services. The latter is a service for querying hosts for arbitrary statistics. Both are used heavily by ill-fitting services, constituting 78% and 91% of the vault service's callers and the services called by the stats service respectively. When ill-fitting services are excluded, two other services rise to the highest fan-in and fan-out degrees respectively: a generic counting service used for various rate limiting mechanisms and a frontend service for internal applications.

Most services are simple, exposing only a few endpoints:



(a) CDF

	# Endpts	# Endpts (Regular)
Min	1	1
Med	1	2
Avg	5	14
P99	26	61
Max	11,359	11,359

(b) Statistics

Figure 5: **Number of endpoints exposed by services.**

Figure 5 shows a CDF and statistics of services' endpoints. Most services do not expose many endpoints (median: 1, P99: 26) and excluding ill-fitting services does not shift the statistics much. The service that exposes 11,359 endpoints is `www`, a frontend service which is used for many business use cases. It is deployed as a single binary from a large, well-engineered codebase that predates the microservice architecture.

Service complexity follows a power-law distribution: Service complexity, measured by number of unique endpoints in a service, follows a power law distribution ($\alpha = 2.23$, $R^2 = 0.99$), indicating that most services are simple with a long tail of more complex services. The power law does not hold for other measures of complexity. Despite there being a long tail of more complex services, the service dependency diagram does not follow a power law distribution ($R^2 = 0.62$). This means the services with more endpoints are not proportionally more connected to the topology than services with fewer endpoints. While there are some highly replicated services, the overall trend of instance counts does not follow a power law distribution either ($R^2 = 0.25$).

Sixteen different languages used to write services: Services can be written in many programming languages. There are currently 16 different programming languages in use at Meta, with the most popular being Hack (a version of PHP), measured by lines of code. Other popular languages include: C++, Python, and Java, with the rest forming a long tail.

3.3 Past growth & dynamism

The number of deployed service instances has almost doubled over the past 22 months: Figure 6 shows the percentage of deployed service instances each day as a percentage of the maximum value observed on 2022/12/21. We show different series for when all services are included, just the ill-fitting services, and only regular services. The slope when all services are considered is $s = 0.052\%$ per day (linear regression $R^2 = 0.95$). The slope when ill-fitting services are excluded is $s = 0.046\%$ per day ($R^2 = 0.95$).

The steady increase in instance counts reflects either an increase in hardware capacity over the time period or an increase in utilization of existing hardware. It cannot be explained by changes in instance sizes as they have remained mostly static.

Instances' rate of increase is due to new business use cases rather than increased scale: Figure 7 shows unique services deployed each day as a fraction of the maximum value

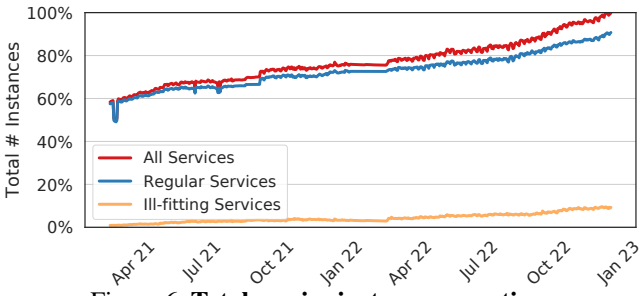


Figure 6: **Total service instances over time.**

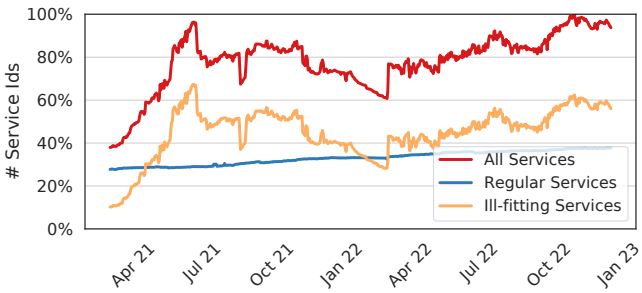

Figure 7: ***Service ID*s over time.**

observed on 2022/11/03. Note that the day with the maximum number of *Service ID*s is different from the day with the most instances. Almost all variability is explained by the ill-fitting services, specifically the Inference Platform, which launches and terminates services as per tenants' demands. The daily increase in services when ill-fitting services are excluded (slope of *Regular Services* series) is $s = 0.043\%$ ($R^2 = 0.98$). It is almost identical to the daily increase in instance counts when ill-fitting services are excluded, which was $s = 0.046\%$ (slope of the *Regular Services* series in Figure 6).

Lots of churn in services, with both long-lived and ephemeral ones: Over the 22-month time period, 180,000 new *Service ID*s were deployed, 89.7% of which were deprecated at some point. Figure 8 shows the number of services created and deprecated each day. Newly-created services are ones whose *Service ID*s were not observed previously during the 22-month period, whereas deprecated ones are services whose *Service ID*s are never observed again. For regular services, creation rates are slightly higher than deprecation rates. As expected, ill-fitting services have high churn.

We also computed the percentage of services observed over the entire period that were deprecated in less than one week (54% of ill-fitting Services, 7.7% of regular services) and the percentage that existed throughout the 22-month period (0% of ill-fitting services, 40% of regular services).

4 Request-workflow characteristics

We now analyze service-level properties of individual request workflows using traces collected by different profiles. We first discuss traces' general characteristics, such as size and width (§4.2). We then analyze whether specific elements of a single trace predict properties of other traces representing the same high-level behavior(s) (§4.3-§4.4). As with any large-scale

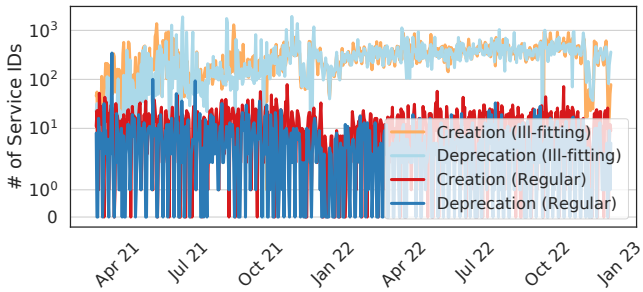

Figure 8: ***Service ID* creation & deprecation.**

tracing infrastructure, traces' visibility into request workflows may be limited due to dropped records, rate limiting, and non-instrumented services. We quantify the extent to which visibility into traces is obscured as a result of these factors in §4.5.

Methodology: For all experiments, we use traces collected on 2022/12/21 from three profiles monitoring important high-level business functionalities. Using a few profiles and a single day avoids factors that would otherwise obscure the interpretability of our results: the effects of analyzing traces using many sampling policies and code updates that change service behaviors. Focusing on important profiles increases the likelihood that traces are representative of their workflows: the services they access are likely to propagate context accurately and use descriptive *Service ID*s and endpoint names. Overall, we analyze 6.5 million traces representing 0.5% of traces collected on 2022/12/21 by all Canopy profiles. Though we do not report them, we observed similar trends to our results on different neighboring days to 2022/12/21 while refining our experiments.

For our predictability experiments, we conduct an ex-post-facto analysis of whether *Ingress ID*s, defined as a combination of *Service ID* and ingress endpoint name, predict properties of their children across many traces. We choose to use *Ingress ID*s because they are readily available in traces, are usually the primary means of understanding trace behaviors, and are location-independent so do not require alignment of traces starting at different (unknown) depths in the topology. We do not consider global characteristics of traces, such as size or width, for prediction experiments as they are not guaranteed to be comparable due to rate limiting or dropped trace records. In our predictability sections, we mean *Ingress ID*s when we refer to parents and children, as in "unique children."

We omit inferred calls (§2.3) from experiments that consider service names since names of inferred services are often unknown. Also, we omit *Ingress ID*s found fewer than 30 times within a profile to allow meaningful statistics to be calculated for the rest of the endpoints.

Our main findings are summarized below; we introduce the profiles afterward. Figure 9 describes the trace properties we analyze and predict.

Finding F4 (§4.2): We measure traces with regard to the number of service blocks they contain (recall from § 2.3 that a service block represents the time interval a service was executed; repeated invocations of the same service appear

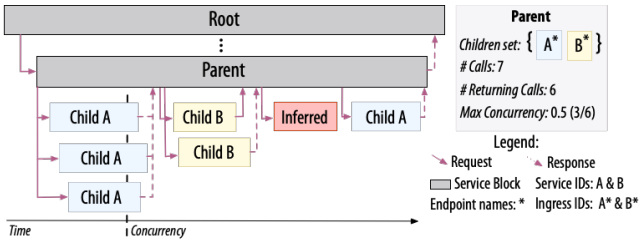

Figure 9: **Trace Characteristics.** Generic example trace showing attributes for a parent *Ingress ID*. Root service is either *www* or *RaaS*. *Inferred* services are represented as blocks of a fixed length since they do not contain notions of time or return edges. They are omitted from concurrency calculations.

as multiple service blocks.) Trace sizes vary depending on workflows' high-level behaviors, but most are small (containing only a few service blocks). Traces are generally wide (services call many other services), and shallow in depth (length of caller/callee branches).

Finding F5 (§4.3-§4.4): Root *Ingress ID*s do not predict trace properties. At the level of parent/child relationships, parents' *Ingress ID*s are predictive of the set of children *Ingress ID*s the parent will call in at least 50% of executions. But, it is not very predictive of parents' total number of RPC calls or concurrency among RPC calls. Adding children sets' *Ingress ID*s to parent *Ingress ID*s more accurately predicts concurrency of RPC calls.

Finding F6 (§4.5): We observe that many call paths in the traces are prematurely terminated due to rate limiting, dropped records, or non-instrumented services. Few of these call paths can be reconstructed (those known to terminate at databases) while the majority are unrecoverable. Deeper call paths are disproportionately terminated.

4.1 Profile details

Ads: This profile represents a traditional CRUD web application focusing on managing customers' advertisements, such as getting all advertisements belonging to a customer or updating ad campaign parameters. The profile captures traces from 56-related endpoints exposed by the `www` frontend service. There are 3.2 million traces over the single-day period. This profile's sampling policy is random at 0.01% capped at 65 traces per second or 160 MB of trace data per minute.

Fetch: This profile represents deferred (asynchronous) work triggered by opening the notifications tab in Meta's client applications. Examples of work include updating the total tab badge count or retrieving the set of notifications shown on the first page of the tab. It captures traces from 91-related endpoints exposed by the `www` frontend service. There are 87,000 traces over the one-day period. This profile uses adaptive sampling with a target rate of 1 trace per second, capped at 20 MB of data per minute.

RaaS (Ranking-as-a-Service): This profile represents ranking of items, such as posts in a user's feed. The RaaS sampling policy is applied to the `RaaS` service, a non-frontend service

that is called by other services. As a result, traces from this profile always represent only portions of request workflows. Of the workflows we analyze, only those captured by Fetch call `RaaS`. Occasionally, a RaaS trace will be a portion of a Fetch trace, but such occurrences are rare because both Fetch and RaaS profiles use low sampling probabilities that are independent of each other. There are 3.3 million traces over the single-day period, from 4 different endpoints in `RaaS`. This profile uses adaptive sampling with a target rate of 25 traces per second.

4.2 General trace characteristics

There is significant diversity in trace sizes: Figure 10 shows CDFs and statistics of the number of service blocks in our traces. Traces collected by the Fetch profile are significantly larger than Ads and RaaS except at the tail, where Ads traces are largest.

Traces are shallow and wide: Figure 11 shows the maximum call depth in service blocks of our traces starting from trace roots (root is call depth 1). Figure 12 shows maximum trace width, which is the maximum number of calls made by all services at any depth level. (For example, 3 service blocks at one depth making 3 calls each results in a width of 9). We see that across all profiles, traces are much wider than deep: in Fetch profile the median depth is 4 vs. median width of 472, and P99 depth is 6 vs. P99 width of 7,400. We conclude that large traces are a result of the number of calls made by services, not depth of calls. This can be partially explained by the widespread use of data sharding where retrieving a collection of items requires fanning out requests across many storage service instances.

Service reuse within traces is high and occurs at many different call depths: Figure 13 shows CDFs and statistics of the number of services visited within individual traces. Comparing with trace sizes (Figure 10), traces generally contain more service blocks than unique services. At the median, traces visit be-

Variable relay	195 (46.3%)	43 (33.9%)	20 (27.8%)

Table 2: **Parent types.** The distribution of parents of each type within each profile.

tween 1x (2/2), 38x (498/13), and 2x (4/2) more service blocks than unique services across Ads, Fetch, and RaaS respectively; at P99 these ratios are 71x, 21x, and 810x respectively.

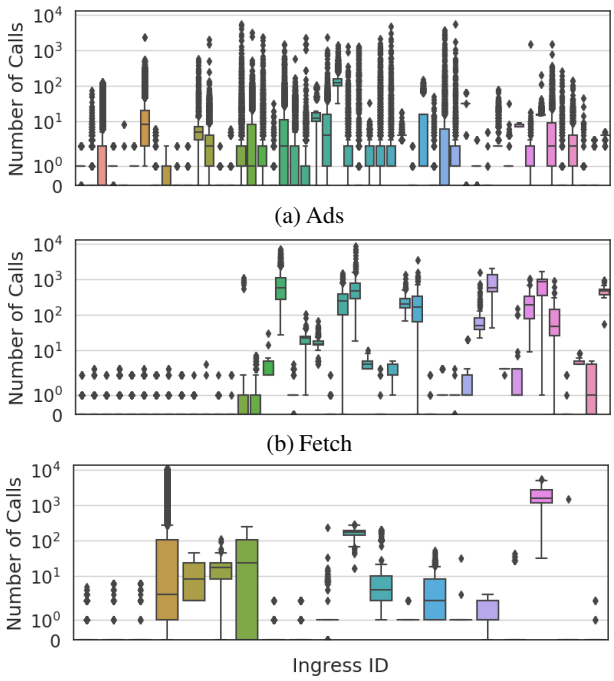
Most services are observed at more than one call depth in our profiles. We measured the number of call depths at which each service was observed. The services in Ads traces have high rates of appearing at multiple depths (median: 6, average: 7.3). Approximately 60% of Fetch and RaaS services are observed at multiple levels (median: 2, average: 2.6 for both profiles).

4.3 Predicting parent/child relationships

Parent *Ingress ID*s strongly predict whether services will have no children or only one child: Table 2 shows that such services, defined as *leaves* and *single relays*, make up from 53 to 73 percent of service executions in our profiles. We find that they are always databases or calls to databases.

***Ingress ID*s do not predict number of downstream calls**: Parents that make one or more downstream calls to children are called *variable relays* in Table 2, making up from 27 to 47 percent of *Ingress ID*s in our profiles. Figure 14 shows that variable relays exhibit a wide distribution in the number of children calls they make. Some *Ingress ID*s exhibit high variance in the number of children they call across different executions whereas others have very little variance (but it is always non-zero).

Variability in number of children calls is due to database calls for Fetch and RaaS: We find that at least 61.1% and



(a) Ads

(b) Fetch

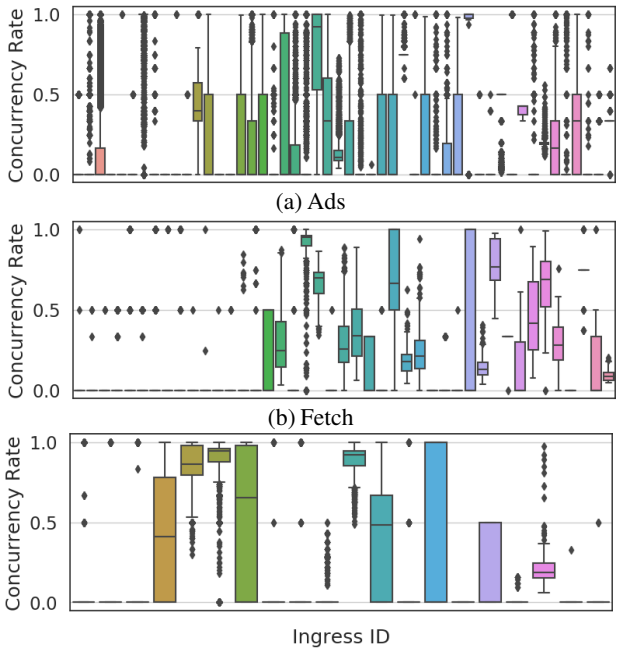
(c) RaaS

Figure 14: **Calls per parent.** Boxplots are shown for every Fetch and RaaS variable relay. Due to limited space, only the 50 variable relays with the greatest number of invocations are shown for Ads. Parent *Ingress ID*s are sorted in descending order by total number of invocations. Boxplot boundaries indicate P25-P75 and the horizontal line within boxes indicate medians. Lower and upper whiskers indicate the smallest/largest data values within 1.5 IQR below/above P25/P75 and dots are outliers.

72.1% of these variable relays' children calls are database accesses in Fetch and RaaS traces respectively. For Ads traces, only 35.7% of children calls are database accesses.

There is a dominant set of unique children per parent: When we ignore number of calls, we find that most single and variable relay parents call only a few *children sets*, where each set is defined as a combination of unique children *Ingress ID*s within a given invocation of the parent *Ingress ID*. For example, one children set may contain `memcache+read` and `database+write`, whereas another may contain `key_service+retrieve` and `database+write`. The average number of children sets called by a relay parent is 28 for Fetch & Ads and 12 for RaaS parents. Most parents have a *dominant children set* that they call in more than 50% of executions. Specifically, 71.9%, 80.2%, and 81.6% of Fetch, Ads, and RaaS relays have dominant children sets.

Non-dominant children sets contain mainly one off children *Ingress ID*s and are not a superset of the parent's dominant children set. On average, only 27% of children *Ingress ID*s called by a parent are in most (>50%) of the parent's children sets.



(a) Ads
(b) Fetch
(c) RaaS

Figure 15: **Parent concurrency.** Concurrency distribution for all invocations of a parent *Ingress ID*. Shows all variable relays for Fetch & RaaS, and the top 50 in Ads by invocation count. Boxplots are interpreted identically to figure 14.

4.4 Predicting children's concurrency

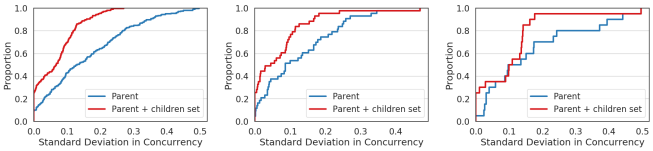
We define *maximum concurrency* as the maximum number of children calls executing concurrently by a parent at any point in time in its execution. More formally, a set of concurrent calls S_t at time t is all children calls with $t_{start} \leq t < t_{end}$, where all timestamps are measured at the parent, and the maximum concurrency C is computed as:

$$C = max(|S_t|), \forall t : t_{start}^{parent} \leq t < t_{end}^{parent} \quad (1)$$

We use a normalized measure of maximum concurrency, the *concurrency rate*, calculated as $C/num\_children$, to allow comparisons across different executions of the same parent (different numbers of children may be called in each execution) and to allow comparisons between different parents. *num_children* refers to children that have return edges and well-defined durations. We only consider variable relays since concurrency is ill-defined for leaves and single relays.

Parent *Ingress ID* does not predict whether children will execute concurrently or sequentially: Figure 15 shows boxplots of concurrency rates across executions for each parent *Ingress ID* observed in our traces. We see that there is a mix of high and low variation in concurrency rate across *Ingress ID*s.

The combination of parent *Ingress ID* and children set more accurately predicts concurrency rate: Figure 16 shows a CDF of the standard deviation in concurrency rate across all executions of parent *Ingress ID*s. To understand if children set adds predictability value, we calculate the standard deviation for each parent's children set and average them to obtain a



(a) Ads (b) Fetch (c) RaaS

Figure 16: **Standard deviation in concurrency rate.** *Parent* shows a CDF the standard deviation in concurrency rates for all executions of a parent. *Per-parent avg. children set* shows the average standard deviation per children set for each parent.

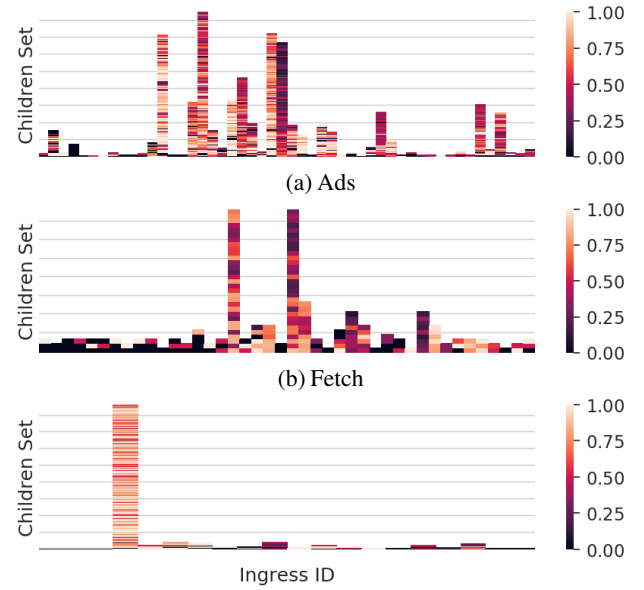
per-parent average. We plot this CDF of per-parent average. Intuitively, if children sets provide value, the per-parent average should decrease whereas if they do not, the data points will be randomly distributed and standard deviation will not decrease. Overall, we find that including children sets shifts the distributions to the left. The shift is most pronounced at the median for Ads and Fetch: 0.13, 0.09 vs. 0.04 and 0.02. Adding children set does not provide value in the tail for Fetch and RaaS.

We speculate the reduction in standard deviation is because children belonging to the same children set likely have well-defined control or data dependencies between each other. Reduction in variation due to control dependencies may be a result of custom threading models for different code logic blocks in parents (each responsible for a different behavior and thus children set). For data dependencies, consider the following examples. Children sets containing different cache services may have no dependencies and thus may be able to execute concurrently. In contrast, children sets comprised of a key server and a database service may have to execute sequentially: credentials may be required to access the database.

***Ingress ID* + children set calls display a range of dependency relationships**: We now quantify the strength of dependencies within *Ingress ID* + children set's calls. We use the maximum concurrency rate observed across *Ingress ID* + children set executions as a indicator of dependency. A maximum concurrency rate of 1 implies that there are no dependencies among children calls. A maximum observed concurrency rate of 0 builds confidence that the children calls are dependent and must execute sequentially. Figure 17 shows the results. Overall, we find that most *Ingress ID* + children set executions display weak dependencies (some concurrency) and there are a few strongly dependent (sequential) children sets.

4.5 Quantifying traces' observability loss

Most prematurely terminated call paths are unrecoverable: We plot the percent of branches that terminate prematurely (at an *inferred* service) at each call depth in our traces (Figure 18). Some branches terminate prematurely due to internal rate-limiting at databases, which are usually leaves in the traces. The shaded area in Figure 18 is the portion of inferred services that represent known databases. The distance between the curves are unknown inferred services, which make up the majority of inferred services. Using trace data alone, we cannot know what the unknown inferred services are



(a) Ads

(b) Fetch

(c) RaaS

Figure 17: **Parent *Ingress ID* + children set max concurrency rate.**

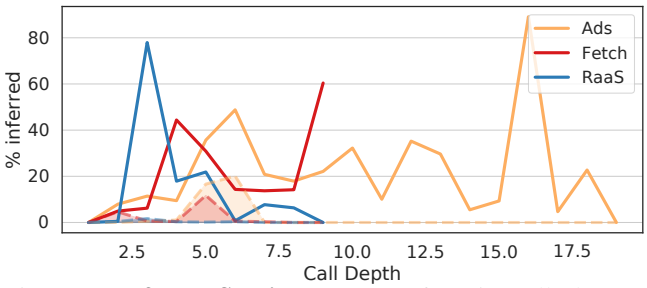


Figure 18: **Inferred Services.** Percent of service calls that are inferred at each call depth. The shaded region is the percent of inferred services that are known to be database calls.

(some may still be other databases we were not able to identify reliably) or the shape of the workflow from that point on.

Non-uniform probability a branch is terminated: Deep branches are disproportionately prematurely terminated. For RaaS traces, 80% of call paths that reach depth 3 are terminated with inferred nodes, none of which were identified as databases. However, as the average trace depth for RaaS is only 2.3 (Figure 11), the majority of RaaS traces are not affected by premature branch terminations. Similarly, Fetch and Ads traces are shallow and prematurely terminated branches mainly occur beyond the average trace depth.

5 Implications and opportunities

Implications for microservice testbeds: Existing testbeds [1, 13, 46] represent only single applications, whereas microservices within Meta serve many applications (§2.1). Previous studies state that existing open-source testbeds' topologies are lacking in scale compared to industrial microservices [20, 41]. Our results confirm these results (Finding F2) and add the following dimensions to consider in future testbeds: heterogeneity of services, churn, and growth. Specifically, we find that Meta's microservice architecture contains a mix of software entities that are deployed as services: complex ones that expose many endpoints and are likely more monolithic in nature, simple ones that expose just a few, and ill-fitting ones that require support beyond which the microservice architecture provides by default (Finding F1). We find that services are deployed and deprecated (at least) daily and that the shape of the communication topology is constantly growing and changing (Finding F3).

Luo et al. [20] state that request workflows within existing testbeds are too static. Many service-level workflow properties can be predicted from root endpoint alone. Our analyses show that future testbeds should include concurrency, number of children, and set of children that are executed as dimensions of variability in request workflows representing the same or similar high-level behaviors (Finding F5).

Implications for microservice tooling: Tools that use models of microservice topologies [12, 25, 44] should assume that its constituent services are always changing and that the topology itself is highly-dynamic (Finding F3). Periodic retraining may be necessary; mechanisms are needed to identify when predictions diverge from the ground truth due to stale topological information.

Tools that aggregate request-workflow traces for performance predictions, diagnosis, or capacity planning [7, 14, 28, 29, 45] must assume that there is significant diversity in workflows originating from the same root endpoints or groups of related root endpoints (Finding F5). Our studies show that many workflow properties can be predicted when they are broken down into fundamental building blocks (parent/child relationships) (Finding F5), perhaps a promising starting point for aggregation-based tools. However, capturing total orderings for entire traces [14] or even individual services may not scale due to parent *Ingress ID*s initiating large number of RPCs with high concurrency (§4.4).

Need for artificial microservice topology & workflow generators: Such generators are a necessity given the infeasibility of creating microservice deployments outside of industrial settings. The sole existing workflow generator [20] may be too specific to a single organizations' microservice design (that number of children depends on depth in trace) and generates stochastic workflows that do not represent any single request. Research is needed to identify: *(1)* which dimensions of microservice architectures are best explored in testbeds versus artificial topology or workflow generators; *(2)* how to ensure these dimensions are representative of a variety of large-scale organizations' characteristics. Our analysis shows that assuming topologies follow power-law relationships is insufficient for modeling microservice topologies (Finding F2).

How to better incorporate ill-fitting software entities into microservice architecture? Ill-fitting entities constitute a significant portion of Meta's microservice topology. Key questions include: *(1)* Should infrastructure platforms provide richer interfaces to allow scheduling, scaling, and observability based on additional dimensions rather than only one? *(2)* In

cases where ill-fitting-entities use custom techniques, what mechanisms are necessary to allow mapping them to standard service-level operations?

Naming & predicting missing elements of workflows: Our predictability results (Finding F5) indicate that well-defined service and endpoint names are important for predicting local workflow properties. Almost all tools that use distributed traces [7, 12, 14, 25, 28, 29, 42, 44, 45] assume descriptive names. But, naming quality can vary considerably, especially for services that satisfy many business use cases and for microservice architectures in which all instrumentation is done within proxies surrounding services [3]. Research into naming schemas that allow different parts of service behaviors to be differentiated based on parts of the name (or attached attributes) is needed. Research is also needed into how to automatically identify meaningful names and/or attributes that differentiate important within-service behaviors, and whether missing observability data (Finding F6) can be predicted based on other data already available.

Need for standardized methods to contrast different organizations' microservice architectures: Our original goal for this research was to compare characteristics of Meta's microservice architecture with previous studies of industrial microservice architectures. At 30,000 ft, we find that organizations' architectures have similar architectural diagrams (Figure 1) and use custom versions of the same architectural components or open-source versions [4, 19, 35]. Furthermore, similar to Meta, the traces used in Luo et al. [20] and Wen et al. [41] tend to be small. Large traces are wider than deep, indicating common use of data sharding. We also find some differences. Traces used in Zhang et al. [45] seem to be much deeper than those used in our analyses, perhaps due to their domain-oriented microservice strategy [15].

Unfortunately, we found more detailed quantitative comparisons to be impossible due to divergent (or ill-specified) definitions in previous studies and because different studies use custom measurement techniques specific to their observability frameworks. With regard to comparing scale and complexity, previous studies do not define the term *service*, describe individual service's complexity, or describe number of communication edges between services, or service instances. For request-workflow-based analyses, these studies do not identify tracing sampling rates and mechanisms, whether traces capture all of request workflows or only parts or whether dropped records or rate limiting impact their analyses. Similar to rich research into Internet measurement [2], we need to develop rich, well-accepted methodologies for collecting data about microservice architectures to understand and systematize similarities and differences across them.

6 Summary

The characteristics of large-scale microservice architectures are largely invisible outside of industrial organizations. We presented an analysis of Meta's microservice architecture to inform more robust assumptions for future microservices research and development.

7 Acknowledgments

We thank our shepherd, Jan Rellermeyer, the anonymous USENIX ATC conference reviewers, Lenni Kuff, Alex Knott, and members of Meta's observability team for their insightful feedback and support. We thank Theo Benson for suggesting examplars on which we could base this paper's structure.

Abstract

Tectonic-Shift is the storage fabric for Meta's production machine learning (ML) training infrastructure. Industrial storage fabrics for ML need to meet both the intensive IO and high-capacity storage demands of training jobs. Our prior storage fabric, *Tectonic*, used hard disk drives (HDDs) to store training data. However, HDDs provide poor IO-per-watt performance. This inefficiency hindered the scalability of our storage fabric, and thus limited our ability to keep pace with rapidly growing training IO demands.

This paper describes our journey to build and deploy *Tectonic-Shift*, a composite storage fabric that efficiently serves the needs of our training infrastructure. We begin with a deep workload characterization that guided an extensive hardware and software design space exploration. We then present the principled design of *Tectonic-Shift*, which maximizes storage power efficiency by combining *Shift*, a flash storage tier, with *Tectonic*. *Shift* improves efficiency by absorbing reads using IO-efficient flash, reducing required HDD capacity. *Shift* maximizes IO absorption via novel application-aware cache policies that infer future access patterns from training dataset specifications. *Shift* absorbs $1.51-3.28\times$ more IO than an LRU flash cache and reduces power demand in a petabyte-scale production *Tectonic-Shift* cluster by 29%.

1 Introduction

The success of industrial machine learning (ML) training is enabled by highly efficient and scalable infrastructures that store and feed massive amounts of training data to datacenter-scale training clusters [27, 31, 44, 46, 68]. At Meta, we deploy training clusters, each with of thousands of GPUs, across many datacenters in order to meet our ML training demands [42]. Each cluster requires a storage fabric capable of storing exabytes of data and serving reads at tens of terabytes per second.

Our prior storage fabric was *Tectonic*, Meta's exabyte-scale distributed file system [50]. Each *Tectonic* instance is backed by a cluster of disaggregated hard disk (HDD) storage nodes. To feed trainers, we needed to provision each *Tectonic* cluster with HDDs to provide *both* sufficient storage capacity for training datasets and enough IO capacity to meet the read bandwidth demands of all trainers in the datacenter. The significant and increasing IO requirements of training accelerators resulted in a large imbalance between IO and storage demands compared to what is afforded by modern HDDs. We needed to provision an order of magnitude more storage capacity to meet trainers' IO demands than to store datasets. This storage inefficiency expended a large portion of each datacenter's power budget — *modern ML storage fabrics often require more power than trainers themselves* [68] — which constrained the scalability of our training infrastructure.

This paper chronicles our journey to improve the power efficiency of our production storage fabric for IO-bound ML training workloads. We begin with a hardware design space exploration and show that traditional homogeneous storage fabrics (HDD or otherwise) cannot meet the imbalanced storage and IO demands of ML training without resource over-provisioning. An ideal storage solution should combine multiple storage media in a *composite storage fabric* to balance storage and IO capacity. It can efficiently meet IO demands by serving most IOPS from IO-efficient (high bytes/s per watt) devices, e.g., flash, while relying on storage-efficient (high bytes per watt) devices, e.g., HDDs, to meet storage demands.

However, simply deploying a composite storage fabric does not beget high efficiency. It must hold the *right data* in IO-efficient devices at the *right time* — exploiting data locality via caching. We present a software design space exploration, guided by a deep characterization of our production ML training workloads, showing that current cache systems do not capture the data reuse characteristics of these workloads. General-purpose software flash and DRAM caches are designed for web-based workloads with trillions of small requests such as content delivery networks, social graphs, key-value stores, and databases [1, 6, 7, 9, 13, 38, 43, 45, 55, 56, 66]. Meanwhile, ML training jobs issue a small number of massive scans over petabytes of data, resulting in scan and churn patterns that easily thrash an LRU cache [52]. Alternatively, current ML-

specific storage systems [16, 23, 30, 32, 41, 61, 71] are ineffective because existing solutions have been designed for small-scale deployments with highly-synchronized training jobs reading multiple epochs of the same static data. Meanwhile, large-scale production training environments consist of highly asynchronous, single-epoch training jobs reading varying subsets of continuously-updated datasets.

While cache systems leveraging composite storage have been widely studied and deployed, our hardware and software design space exploration elucidates the need for a unique combination of techniques tailored to our ML workloads. To this end, we built *Tectonic-Shift*, a composite storage fabric that improves storage efficiency by balancing storage and IO capacity across HDDs and flash. We present *Tectonic-Shift* and several guiding design principles that make it deployable and effective across our datacenters: a) *Transparent. Tectonic-Shift* presents the same APIs as the *Tectonic* File System, requiring no user knowledge or application changes. *Tectonic-Shift* combines *Shift*, a flash storage tier that aims to maximize IO absorption, with each HDD *Tectonic* cluster. b) *Simple. Shift* is built on top of CacheLib [6], and deploying *Shift* requires no changes to other storage services such as *Tectonic*'s Metadata Layer. c) *Scalable. Shift* is fully decentralized, consisting only of disaggregated flash storage nodes, each using local dynamic cache policies that adjust to observed load. d) *Intelligent.* While *Tectonic-Shift* is transparent to users, it understands application information from training job specifications, such as the list of table partitions that comprise the job's dataset. We present novel cache mechanisms that leverage this information to improve the performance of *Shift* by inferring training jobs' future data access patterns.

We demonstrate how these principles allow *Shift* to absorb $1.51-3.28\times$ IO than an LRU-based flash cache on a mix of representative training workloads, all while managing flash endurance limits. Furthermore, we present results on our petabyte-scale production tiers, serving real ML training jobs, showing how *Tectonic-Shift* can save 29% of power relative to using HDDs alone for training data. We close with a discussion of lessons learned in deploying *Tectonic-Shift* and several promising areas of future exploration. In summary, we make the following contributions.

- We provide an in-depth hardware and software design space exploration of storage systems for ML training jobs, guided by a characterization of our production workloads.
- We present the principled design of *Tectonic-Shift*, which combines *Shift*, a flash storage tier, with each *Tectonic* cluster to improve the overall efficiency of Meta's storage fabric.
- We describe novel cache policies employed by *Shift* that predict and optimize for future data access patterns derived from training job specifications.
- We show detailed production evaluation results. *Shift* absorbs $1.51-3.28\times$ more IO than LRU. *Tectonic-Shift* improves the power efficiency of our storage fabric by 29%.

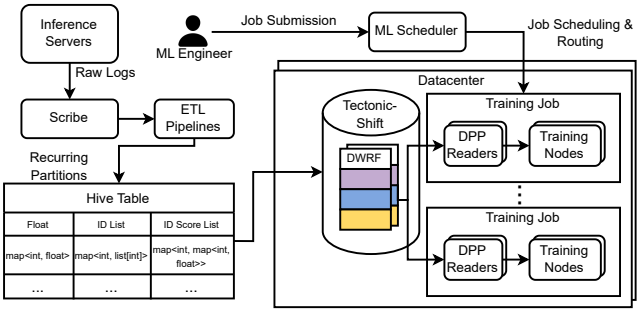

Figure 1: Overview of Meta's data storage and ingestion (DSI) pipeline. *Tectonic-Shift* is the durable storage fabric for training data in each datacenter.

2 ML Data Storage and Ingestion Background

Deep learning recommendation model (DLRM) training dominates our ML infrastructure demands [2], requiring significant data storage and ingestion (DSI) capacities to manage structured datasets [68]. Thus, we primarily focus on DLRM workloads in this paper, and we discuss extending *Tectonic-Shift* to other ML domains and non-ML workloads in Section 7. Figure 1 shows how the DSI pipeline continuously generates, stores, and ingests DLRM training data.

Data Generation. Fresh data is needed to ensure model accuracy [18]. We continuously generate training samples from inference requests served by our production fleet. When a given host serves an inference request, it logs a snapshot of the relevant *features* of the requester (e.g., a user's set of liked pages) and the outcome of the *event* corresponding to the inference request (e.g., if a user likes the recommendation). These logs are continuously published to Scribe [26], Meta's global distributed messaging system. A training data pipeline, corresponding to a set of extract-transform-load (ETL) jobs (e.g., Spark [67]), consume these logs by joining and labeling them to form structured training samples.

Dataset Storage. Each pipeline's training samples are stored in a corresponding Hive [57] table. Tables are constantly updated with new time-based partitions of fresh data, generated by each pipeline with a regular cadence (e.g., hourly). Old partitions regularly expire and are deleted. Each table is replicated to all datacenters with training clusters, and each partition is stored as columnar DWRF [21] files (similar in format to ORC [14]) in a new directory in each respective datacenter's *Tectonic* File System. Training jobs read from their local *Tectonic* instance.

We adopt a common schema across our training tables to ensure interoperability across models [68]. Specifically, all features are stored in a small number of map columns and comprise the majority of each row ($>99\%$ of bytes). Each column maps multiple integer feature IDs to the row's corresponding value for that feature (e.g., a float for a dense feature column or lists/maps for a categorical feature column).

Data Ingestion. Training jobs are submitted to a global queue

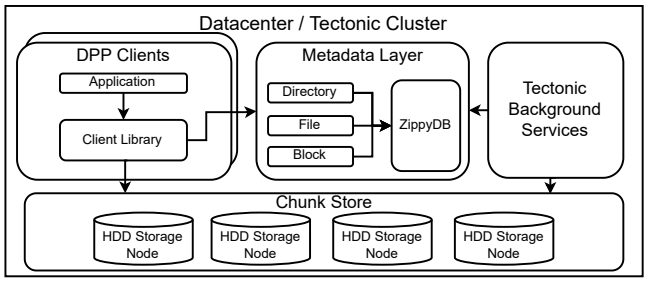

Figure 2: Overview of the *Tectonic* File System. Directory, file, and block metadata operations are served by a Metadata Layer. Clients directly read chunks from HDD-based Chunk Store nodes.

by ML engineers and are scheduled and routed to a specific datacenter when capacity allows. When each job is scheduled, it allocates a set of training nodes (Trainers) [42] and a set of Data PreProcessing (DPP) Readers [68] from the datacenter's training cluster. Trainers are equipped with GPUs and perform the actual training, continuously ingesting tensors from Readers. Readers are general-purpose CPU nodes that continuously read raw bytes from the *Tectonic* File System, reconstruct minibatches of samples from the bytes, and preprocess each minibatch into tensors.

Specifically, Readers read data based on a training job's *dataset*, specified by an ML engineer. The dataset contains a *list of table partitions* and a *list of feature IDs*. Throughout the lifetime of the training job, Readers will continuously ingest (disjoint) minibatches of samples, filtering out unused features in each sample, until the Readers have collectively read all samples from the specified partitions. To read the appropriate bytes from *Tectonic*, Readers map each partition to a set of *Tectonic* files by querying the Hive Metastore [57,58]. Readers then scan each file and progressively read samples by issuing *Tectonic* reads. Readers push filtering to storage, referencing metadata within footers of the file to selectively read bytes corresponding to features specified by the dataset [68].

***Tectonic* File System.** Figure 2 shows the architecture of the *Tectonic* cluster (sans *Shift*) backing each *Tectonic* File System instance. Files are divided into *blocks* (typically 72 MiB) representing a logical array of bytes. *Tectonic* further divides blocks into smaller *chunks* (typically 8 MiB) and durably encodes each via replication or Reed-Solomon (RS) encoding [51]. Chunks are distributed across the cluster's Chunk Store, backed by a number of HDD storage nodes.

Readers directly read data from storage nodes using the *Tectonic* Client Library. The Client Library exposes a file `pread` interface to clients. For each read, the Client Library issues requests to specific chunks on storage nodes and performs reconstructions if necessary. The Client Library obtains chunk mappings and any directory and file metadata (e.g., directory `ls`) via queries to a hash-sharded Metadata Layer built on ZippyDB [37]. DPP Readers optimize for HDD seeks and coalesce reads into large $O(1MB)$-sized IOs [68].

Table 1: Storage power requirements for an HDD, flash, and ideal composite cluster, assuming 100 PB and 10 TB/s storage and IO demand. We show required power to meet storage-only, bandwidth-only, and both requirements, normalized to HDD storage-only.

	Storage Req.	IO Req.	Storage & IO Req.
HDD Cluster	1.00	9.92	9.92
Flash Cluster	6.53	1.88	6.53
HDD + Flash	1.00	1.88	2.69

3 Production ML Storage Design Space

This section explores why we could not efficiently scale *Tectonic* to meet the IO bandwidth that our training clusters increasingly demand. We present various hardware and software design space explorations that led us to *Tectonic-Shift*, guided by a characterization of our production ML training jobs.

3.1 Hardware Design Space

We first evaluated different storage hardware options, summarized in Table 1. Specifically, we used our HDD [3] and flash [8] server specifications to calculate the power (watts) required by the number of HDD, flash, or HDD + flash servers (rows) to supply 100 PB of storage, 10 TB/s of read bandwidth, or both (columns). These demands are representative of our workloads [42,68], and we must provide both sufficient storage *and* IO capacity. The HDD + flash analysis used only HDDs to supply 100 PB of storage and only flash to supply 10 TB/s of IO. In the storage and IO case, we used HDDs to supply storage capacity and flash to supply IO capacity, discounting the IO capacity supplied by the HDDs. We focused on power because it is the primary budget and optimization metric for services across our fleet [68]. We normalized results to the HDD, storage-only case.

Option 1: HDD-Only (Status Quo). Our first option to meet IO demand was to continue provisioning more HDD storage nodes into each *Tectonic* cluster. This would linearly scale IO capacity as chunks are distributed across HDDs evenly. Unfortunately, this option would require us to provision 9.92× more storage capacity than necessary — $1.6EB$ of disks assuming $RS(9,6)$! Furthermore, since our IO demand is growing 2× as fast as storage demand [68], this option is unsustainable.

Option 2: Flash-Only. We also considered using a flash storage tier [28] for our training datasets. Flash trades off storage-efficiency for IO-efficiency. Compared to HDDs, A flash cluster would need 5.28× less power to meet IO demand, but 6.53× more power to meet storage demand. Meeting both demands is more efficient using flash, but there is a significant over-provisioning of IO capacity, making this sub-optimal.

Option 3: Composite Storage. Relying on a single storage hardware inherently precludes us from balancing storage and IO capacity. An ideal cluster would use *both* a storage-efficient device and IO-efficient device together, provisioning enough of each to meet their respective demands. HDDs are

Figure 3: IO bandwidth demand across 85 tables over the course of one day. Training tables exhibit a power law in popularity.

an ideal storage-efficient device due to their density. We considered DRAM and flash for our IO-efficient device.

Option 3.1: HDD + DRAM. We decided against using only DRAM, as a DRAM storage node would be bound by the NIC throughput (e.g., 100 Gbps) as opposed to DRAM throughput. Modern SSDs can provide $O(1GB/s)$ of read bandwidth at $O(1W)$ of power [11], allowing a flash storage node to provide the same IO capacity in roughly the same power footprint as a DRAM storage node. Meanwhile, flash storage nodes have significantly higher storage capacities ($O(10TB)$), greatly improving cache performance.

Option 3.2: HDD + Flash. We opted to use flash as our underlying IO-efficient device. Table 1 shows how an ideal composite cluster would allow us to provision only 1.69× flash-based power to meet IO demand plus 1.00× HDD-based power to meet storage demand, reducing the power footprint of our storage tier by 3.69× compared to Option 1.

However, Option 3.2 assumes that flash servers are able to meet the bulk of IO demand by holding a popular subset of bytes. Our next challenge was designing a system that could intelligently manage the contents of each flash server to maximize its IO absorption. Our first option was to create both a flash and HDD Chunk Store within the same durable storage fabric. The *Tectonic* Metadata Layer would move blocks between flash and HDD based on read demand. This option has several drawbacks. It a) requires extra RS encoding overheads on flash, b) adds metadata overheads due to block location updates, and c) requires significant changes to the Metadata Layer to support sub-block granularities (due to byte-range popularities, to be discussed in Section 3.2.1). For these reasons, we decided to use flash as the foundation for a metadata-less, non-durable cache. We present the design space exploration of this software cache next.

3.2 Software Design Space

3.2.1 Production ML Workload Characterization

We begin by characterizing our production ML training jobs, which present a uniquely challenging cache workload.

Row-wise Reuse. Training samples (rows) exhibit a skewed popularity across training jobs. Figure 3 shows the IO demand targeting 85 tables over the course of one day. We run many ML model types in production, and ML engineers continuously train and experiment on each model type with varying

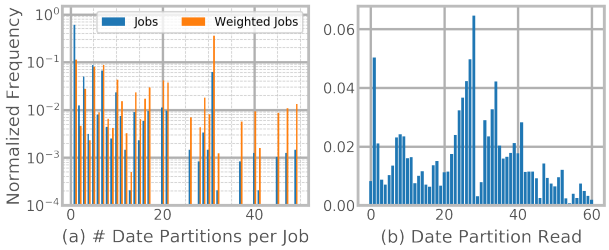

Figure 4: (a) Normalized histogram showing # of date partitions read by each training job, with orange bars weighing jobs by the number of partitions read. (b) IO demand across date partitions over a one-day period, with day 0 being the most recent partition.

popularities. Since each model type typically uses a distinct table, this variation manifests in tables' IO demands. There is a distinct power-law in table popularity with a long tail.

Furthermore, training jobs typically read a subset of table partitions, as models can typically reach convergence before all rows are exhausted. For a similar reason, each training job only reads its specified rows once (i.e., one epoch). Figure 4(a) shows a distribution for a popular table[1] of the number of date partitions[2] read by training jobs in one day. Most jobs read only a few partitions. However, when we consider IO demand by weighing the impact of each job by the number of date partitions it reads (the orange bars), we see that the majority of IO demand comes from jobs that read 20 or more partitions.

It is also important to understand *which* partitions training jobs typically read. Figure 4 shows a normalized histogram of IO demand over the popular table's date partitions over the course of one day. Partitions do not exhibit flat popularity, but instead show multiple modalities. A large fraction of traffic reads the most recent date partition. This is typical of "recurring" jobs that keep the model up-to-date and exploratory jobs that use the freshest data. There also exist multiple groups of popular date partitions, where multiple larger-scale training jobs use similar date ranges to ensure comparable results.

The above graphs show multiple important characteristics. a) Row reuse is solely across single-epoch training jobs. b) The active working set size of all training jobs is massive. There are over 85 active tables, each containing $O(1-10PB)$ of samples [68]. c) Most IO demand comes from jobs that read tens of date partitions. These jobs have PB-scale working sets due to $O(100TB)$-sized date partitions [68]. There are also many smaller jobs that read a few date partitions. d) Date partitions exhibit varying popularity, with popularity changing over time as date partitions are generated and deleted.

Column-wise Reuse. Columns (i.e., features) also exhibit a distribution in popularity, as training jobs typically use a subset of all features due to hardware (e.g., GPU memory) constraints. Figure 5(a) shows an analysis of 1265 production training jobs that read a specific date partition of the popular

[1]Where relevant, we characterize this same table throughout this section.
[2]A date partition consists of all training samples generated in a given day.

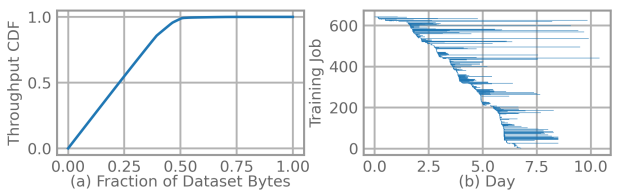

Figure 5: (a) CDF showing distribution of stored feature bytes to IO served to 1265 training jobs reading a single date partition. (b) Time-series of training jobs reading a popular table over one week.

table. The x axis shows a distribution of the stored bytes, ordered by read popularity. The y axis shows the fraction of total IO bandwidth served by most popular x fraction of bytes. Over 75% of bytes are read at least once. However, roughly half of all bytes, corresponding to popular features, serve almost all IO demand.

This has important implications for a cache system, as features are stored into columnar byte streams within large DWRF files. Specifically, row-wise popularity corresponds to *file-popularity*, and column-wise popularity corresponds to *byte-range popularity* within each file. A cache system must effectively capture both dimensions.

Temporal Behavior. Cache systems must also account for the unique temporal characteristics of training jobs. Figure 5(b) shows a time-series plot of 642 jobs, launched over one week, that read the popular table. Each horizontal bar reflects the lifetime of each job, during which it reads the samples and features specified in its dataset. We observe that first, training jobs are largely asynchronous. Cache systems cannot solely optimize for highly synchronized jobs (e.g., hyperparameter tuning) and assume high temporal locality. Secondly, data reuse is expressed across a small number of training jobs, unlike the billions of requests common to web-based workloads [6]. Finally, each training job can run from hours to days, requiring a large storage and temporal footprint.

3.2.2 Cache Software Design Space Exploration

With our workload characteristics in mind, we evaluated various system architectures to manage our flash storage tier.

Option 1: General-purpose Software Caches. We built CacheLib at Meta as a general-purpose cache engine to support caches for datacenter applications such as key-value stores, databases, CDNs, and social graphs [6]. CacheLib offers LRU and FIFO eviction policies over flash, and random and reject first admission policies to manage flash endurance. Our first option was to simply deploy a cluster of flash storage nodes, each managed by CacheLib, to cache file byte ranges.

Unfortunately, ML training workloads exhibit patterns that general-purpose cache policies fail to handle. Our characterization showed a long tail of jobs that read unpopular tables and partitions. However, each job can still have working sets up to tens of petabytes, potentially larger than the entire cache itself. These massive and long-running *scans* can easily evict the entire cache, reducing hits on popular items. Furthermore, even popular training samples are susceptible to *churn*, where each sample is repeatedly evicted and inserted into cache. Churn occurs because a) there are relatively few training jobs in each datacenter, b) data reuse occurs with a relatively long duration between jobs (Figure 5), and c) working set sizes exceed our cache capacities. Scans and churns are well-known antagonist cache patterns [52], motivating the need for specialized and domain-specific admission and eviction policies.

Option 2: ML-specific Caches. We also considered techniques for building an ML-specific cache, inspired by recent work [16, 23, 30, 32, 41, 61, 71], that allows applications to explicitly cache samples in high-bandwidth storage. While such caches can optimize policies for ML workloads, they face several disadvantages. First, current ML caches employ techniques that require assumptions not representative of our workloads, limiting their effectiveness. For example, they cache entire files (e.g., images), and they rely on a large amount of intra-job data reuse across multiple epochs and inter-job data reuse across highly concurrent hyperparameter tuning jobs. Meanwhile, feature popularity requires our cache to store byte ranges within files, and our workloads only exhibit inter-job data reuse with highly asynchronous workloads. Secondly, an application-controlled cache introduces security concerns due to the need to handle access to and deletion of multiple copies of data. Finally, ML caches require end-user efforts to adopt, hindering both our deployment velocity, and more importantly, the productivity of ML engineers.

Option 3: A Transparent, Application-aware Cache. Our final cache design combined benefits from both software and ML caches. We focused on policies that provide the transparency and generalizability of software caches and the application-level awareness of ML caches. Our characterization highlighted key opportunities. Specifically, not only do training jobs tend to favor specific rows and columns, their dataset specifies *which* features, tables, and partitions the job will deterministically read throughout its lifetime.

We next explore how our entire design space exploration yielded a principled design of *Tectonic-Shift*. Section 5 then describes how we leverage policies that infer future access patterns from dataset specifications to minimize cache contention and to maximize the read IO absorbed by the cache.

4 *Tectonic-Shift* Architecture

4.1 *Tectonic-Shift* Design Principles

Figure 6 shows the architecture of *Tectonic-Shift*. We designed *Tectonic-Shift* around four key design principles.

Transparency: Tectonic-Shift combines *Shift*, a flash storage tier, in front of each HDD *Tectonic* cluster transparently. Each *Tectonic-Shift* cluster serves read requests for all training workloads in its respective datacenter. It exposes the same

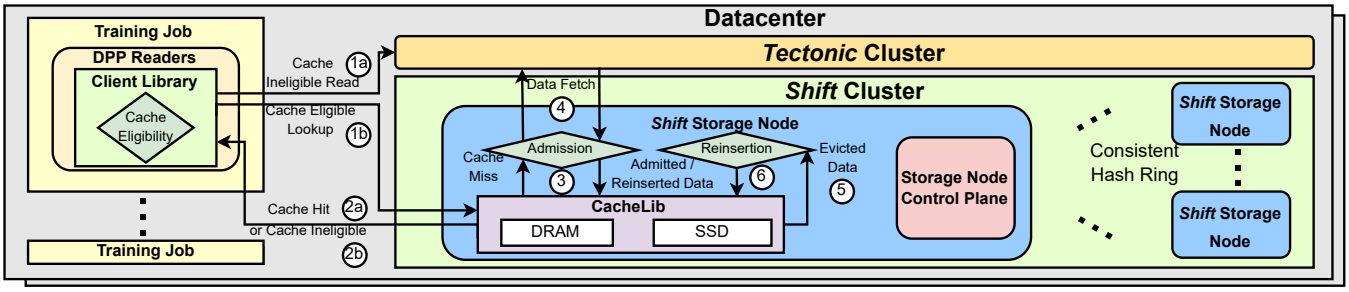

Figure 6: The block diagram of *Tectonic-Shift*, with numbered arrows depicting the path of each read request.

APIs and semantics as our current *Tectonic* File System. Transparency was important for two reasons. First, we avoided exposing storage decisions to ML engineers, as doing so may lead to inefficient configurations and hinder their productivity. It also eased deployment, allowing us to progressively roll out *Shift* and re-balance *Tectonic* clusters under the hood. Secondly, because most of Meta's storage services rely on *Tectonic*, a general API would allow us extend *Shift* to new customers that could become IO-bound (see Section 7).

Simplicity: We kept *Shift* simple and robust by reusing as much infrastructure as possible. *Shift* can only be accessed via the Client Library, which uses *Tectonic*'s Metadata Layer. This simplifies security since all access controls are validated before reaching *Shift*. *Shift* also uses the fact that training data is stored in immutable, *sealed* blocks [50] to avoid managing cache invalidations or mutations. Each *Shift* node uses CacheLib as its internal caching engine, allowing us to harness resources from the myriad teams that rely on CacheLib.

Scalability: We built *Shift* to be effective at any deployment size, quickly deployable, and easily scalable to meet the demands of each datacenter. *Shift* is fully decentralized, consisting of only flash storage nodes placed in a consistent hash ring. Cache decisions are only made locally to each storage node and dynamically adjust based on observed load.

Intelligence: Finally, based on Section 3, *Shift* must adapt to the unique workload characteristics of ML training jobs. Section 5 explores how we built intelligent cache policies on top of CacheLib. These policies infer each training job's data access pattern based on its initial dataset specification, allowing each *Shift* node to maximize IO absorption based on both historic and expected future data access patterns.

4.2 The Life of a *Tectonic-Shift* Read

Client Library. As discussed in Section 2, for each training job, DPP Readers collectively scan through the specified partitions, with each Reader individually reading separate splits of rows. Each partition is mapped to a distinct file system directory, and Readers directly read data corresponding to used features from files in the respective directories. Readers obtain file handles by querying the *Tectonic* Metadata Layer (Figure 2). Mappings from features and rows to file byte ranges are decoded by Readers from file footers. Each Reader issues reads via a `pread` Client Library API call, which returns `count` bytes starting at `offset` within a file.

Figure 6 shows how the Client Library handles each `pread`. It first decomposes the `pread` into a set of block reads by querying the *Tectonic* File Layer. The Client Library then checks if each block read is cache eligible. Cache *in*eligible reads directly read each block range from the *Tectonic* Chunk Store (1a). Cache eligible reads directly issue a `get(blockId, offset, length)` for each block to the *Shift* cluster (1b). We piggyback a number of *tags* with each `get` request that associate each request with relevant metadata, such as the file path and training job ID, to be used by *Shift* policies. The *Shift* cluster consists of a number of flash *Shift* Storage Nodes (SNs) placed in a consistent hash ring [25]. The Client Library maps each `get` request to a *Shift* SN based on `hash(blockId)`. `get` requests either return data for the corresponding block (2a), or return a cache miss (2b). The Client Library reads missed blocks from the *Tectonic* cluster (1a). Once all blocks are fetched, the Client Library returns the results of the `pread` to the caller.

***Shift* Storage Node Data Plane.** *Shift* uses CacheLib [6] within each SN to manage both DRAM and flash. We break up each *Tectonic* block into fixed-size *segments*, which are the objects that we place into CacheLib. Blocks are typically 72 MiB; we discuss segment sizes in Section 5.2.

The SN breaks up each `get` request's range into segments. If all segments are present in cache, the SN simply returns the requested data (2a). Otherwise, *Shift* implements two critical policies on top of CacheLib. First, if any segments are missing, the SN decides if the segment is *admitted* (i.e., allowed) into cache (3). If any segment is not admitted, the SN returns a cache ineligible miss to the Client (2b). Otherwise, the SN will fetch admitted segments from the *Tectonic* cluster and insert them into cache (4). The SN then returns data corresponding to the `get` request (2a). Secondly, any cache insertions will potentially result in segments being evicted from the cache (5). For each evicted segment, the SN can optionally *reinsert* the segment into cache (6), potentially avoiding a cache miss if the evicted segment is accessed in the near future.

***Shift* Abstractions and Guarantees.** The primary goal of

Shift is to serve IO bandwidth corresponding to popular bytes, reducing IO to *Tectonic*'s Chunk Store. We rely on and do not change the semantics of the *Tectonic* File System.

Specifically, the *Tectonic* File System provides append-only semantics. Data pipelines will *seal* blocks; we do not have to handle modifications in *Shift*. *Shift* SNs act only as a part of the data plane. To keep file system operations centralized and scalable, we rely on the *Tectonic* cluster's Metadata Layer for all metadata operations. Thus, *Shift* does not expose a `put` API. Inserts into cache are only made for missed `get` requests. Accesses to blocks are consistent since *Shift* SNs can only be accessed by the *Tectonic* Client Library, which first references the Metadata Layer for file-to-block mappings, preventing reads to renamed or deleted files. Similarly, unauthorized reads are prevented as any the Client Library performs ACL checks for each block before issuing reads to *Shift*.

Our proposed design also allows *Shift* to be inherently fault tolerant. *Shift* contains no centralized state. *Shift* relies on the fault tolerant *Tectonic* Metadata Layer [50] for metadata operations. Cache policies are made local to each SN, allowing other SNs to proceed unhindered in the event of a SN failure. Furthermore, *Shift* serves only reads, and Clients will default to *Tectonic* reads (e.g., after a timeout) if a given SN fails.

5 Application-Aware Cache Policies

Building on our design principles, our key insight is to instrument *Shift* with intelligent policies that maximize the IO absorbed from *Tectonic*. These policies transparently adapt to workloads by leveraging both historic and application information, ensuring that only segments with high reuse across training jobs are kept in each SN. Specifically, each *Shift* SN contains a Control Plane that implements an **admission** and **reinsertion** policy. We incorporate a **cache eligibility** policy in the Client Library to reduce RPC pressure and avoid requests to *Shift* from "uncacheable" workloads.

We focused on building a flexible SN Control Plane that aggregates the necessary metadata (including application information) to define and inform highly configurable policies, allowing us to constantly tune and improve performance. We prioritized admission and reinsertion policies as opposed to eviction policies such as LRU because a) we can prevent significant thrashing due to the scan and churn (Section 3) patterns common in our workloads, and b) we can control write rates to flash in order to manage flash endurance constraints. Meanwhile, our policies are built on top of CacheLib, and we use CacheLib's provided eviction policies (LRU or FIFO) after admission into cache.

As discussed in Section 4, each *Shift* SN acts as an independent entity, serving only requests on its portion of a consistent hash ring. Thus, the overall goal of *each Shift* SN is to maximize the absorbed IO locally — doing so maximizes the aggregate IO absorbed by the entire *Shift* cluster. We define the absorbed IO at each SN as the bandwidth of successful

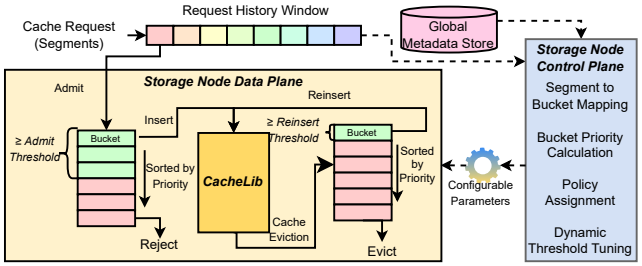

Figure 7: Overview of *Shift* SN Control and Data Plane. The Control Plane dynamically tunes Data Plane cache policies.

Table 2: Table listing configurable parameters in *Shift*.

Configurable Parameter	Meaning
$MapSegment(s)$	Mapping function from segment to bucket.
$BucketPriority(b)$	Function to calculate priority of bucket b.
$AdmitThreshold$	Dynamic scalar threshold to admit buckets.
$ReinsertThreshold$	Dynamic scalar threshold to reinsert buckets.
$BucketRefreshTime$	Update period for bucket policies.
$RHWSize$	Size of request history window logs to keep.

`get` requests returned to clients, minus the bandwidth of data fetches to the *Tectonic* cluster due to data misses. Importantly, non-admitted cache requests do not impact absorbed IO, and reinserted segments do not contribute to fetches to *Tectonic*.

5.1 Admission and Reinsertion

Figure 7 shows an overview of the Control and Data Plane running in each SN. The Control Plane dynamically directs the Data Plane to admit or reinsert segments into the cache upon a cache miss or eviction, respectively, using *historical* and *application* metadata. These decisions are made based on the configurable parameters summarized in Table 2.

Mapping a Segment to a Bucket. The Control Plane statically maps each segment s to a *bucket* b using the tags attached to each read request, based on a configurable function $MapSegment(s)$. Intuitively, each bucket represents a collection of segments that will likely be accessed together and connects to a logical grouping within the application.

For example, we typically use a segment's corresponding directory as its default bucket mapping, as each training job specifies a set of partitions to read and will scan through files within each partition's directory. Furthermore, we can correlate data reuse across multiple jobs based on their dataset partitions (and thus directories). While finer-grained bucket mappings such as files or features (i.e., file byte ranges) are possible, directories provide sufficient granularity since jobs mostly read similar features within each file (Section 3).

Assigning a Policy to Each Bucket. Each bucket is assigned a binary admission and reinsertion policy. The Data Plane simply admits/rejects (on miss) or reinserts/evicts (on eviction) each segment depending on its bucket's current policy. The Control Plane will admit or reinsert a bucket if the bucket's current *BucketPriority(b)* is greater than *AdmitThreshold* or

ReinsertThreshold, respectively. Bucket policy assignments are updated every *BucketRefreshTime*, a configurable parameter. Buckets should be updated frequently enough to react to changes in reading patterns; we use a default of 10 seconds.

Deriving a Bucket's Priority. *BucketPriority(b)* directly determines b's admission/reinsertion policy. Intuitively, we interpret b's priority as *the number of times we expect each segment in the bucket to be read in the near future*. Higher priority buckets will be placed into the cache (via admission/reinsertion) over lower-priority buckets and thus absorb more IO in total. Our key insight is to calculate buckets' priorities using both *historical* and *future* information derived from the Request History Window (RHW) and Global Metadata Store (GMS), respectively.

Historic Priority. The RHW tracks recently observed requests (regardless of admission) over a past time period, $RHWSize$. The RHW reports the number of *unique* segments and *total* segments requested for each bucket. A *historic priority* for bucket b can be calculated as $BucketPriority(b) = TotalBytes(b)/UniqueBytes(b)$, providing the traditional cache signal which assumes that past access patterns are indicative of the future. $RHWSize$ is a configurable parameter. We tune it to capture sufficient historical data without exceeding memory capacity limits; we use a default of 6 hours.

Future Priority. The RHW also records the set of active training jobs and the set of buckets read by each training job using the job ID tag piggybacked with each request. The GMS is a set of databases which contains real-time information about the dataset specification of each training job. By combining the RHW and GMS, *we can directly derive future accesses for each training job* and thus bucket priorities. The Control Plane queries the RHW for all active training jobs and pulls each job's dataset specification from the GMS. For example, for directory-based buckets, the Control Plane derives a bucket's *future priority* as equal to the number of jobs that include the corresponding partition in its dataset, discounting any jobs that have finished reading the bucket.

In summary, the RHW captures historic access patterns and active training jobs, while the GMS associates each training job with application information about its dataset. While we presented potential historic and future policies, variations can easily be created using the RHW and GMS. For example, a potential future policy can further prioritize directories earlier in read order (and thus read sooner). Section 6 explores a *hybrid* policy combining historic and future priorities.

Threshold Tuning. The Control Plane continuously tunes the $AdmitThreshold$ and $ReinsertThreshold$ based on two factors. First, a *minimum threshold* avoids admitting unpopular workloads that can evict the entire cache. We use a minimum value that is strictly greater than 1, and we constantly tune it based on observed performance. Secondly, we implement a PID-controlled *feedback loop* to ensure that the cache admit plus reinsert rates (reported by the RHW) is strictly less than our flash endurance limits (defined by a maximum average write rate). This allows the threshold to increase beyond the minimum in response to high flash write rates, thereby admitting/reinserting fewer segments. We only tune the $AdmitThreshold$ and tie the $ReinsertThreshold$ to be a fixed offset (e.g., $AdmitThreshold + 1$) to prioritize admits over reinserts to limit write amplification due to reinserts.

An additional benefit in building an admission policy *above* CacheLib is to rate limit prior to *Tectonic* reads. While CacheLib provides a rate limiter, which selectively admits segments to flash upon DRAM eviction, it inherently requires first inserting data into DRAM. This results in unnecessary *Tectonic* reads if the data is soon to be evicted due to write endurance limits. *Shift*'s admission policy acts prior to *Tectonic* fetches, avoiding unnecessary HDD reads for rate limited data.

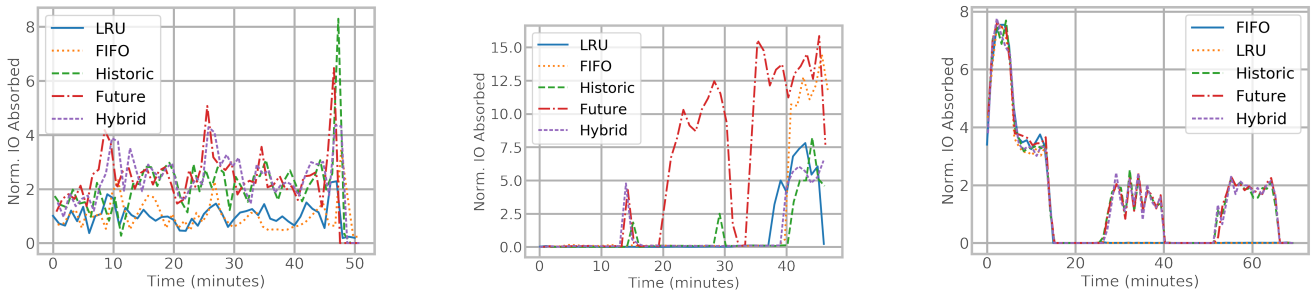
5.2 CacheLib Tuning

CacheLib offers a suite of configurable parameters that we continuously tune via a host of stress, release validation, and production tests. While prior flash caches focused on addressing write amplification caused by small objects (e.g., <1KB messages) [6, 13, 38, 56], a key difference and advantage in *Shift* is the ability to configure segment sizes. Too large segments, relative to request sizes, result in overheads since we fetch and store data in segment-granularity. On the other hand, too small segment sizes constrain both DRAM and flash due to metadata and write amplification overheads. We found that 256 KB was a good balance for our workloads. We also rely on CacheLib to optimize underlying data layouts on flash [6] to further improve flash endurance. Finally, we evaluated the available eviction policies for DRAM and flash and found that LRU works well (when combined with *Shift*'s policies); we provide further exploration in Section 6.

5.3 Client Cache Eligibility

We also incorporate a *Shift* eligibility policy at the *Tectonic* Client Library. *Tectonic* serves a diverse set of training and non-ML workloads across Meta. The primary purpose of the cache eligibility policy is to prevent customers that are not onboarded to *Shift*, as well as low-priority and uncommon (and less-cacheable) tables, from issuing lookups to *Shift*. While these read requests would likely be rejected by the SN's cache admission policy, applying a first filter significantly reduces the RPC load and memory pressure at each SN.

We currently filter out all non-ML traffic to bolster ML training capacity. Furthermore, Figure 3 shows that tables are disproportionately popular. Filtering out rarely-used tables adds another layer of protection against cache contention, since all IO can be sufficiently served from *Tectonic* HDDs. As a baseline heuristic, we filter out tables whose IO demand can be sufficiently served by the HDD capacity needed to store it. We continuously tune our filters based on demand.



(a) Synchronized workload (b) Pipelined workload (c) Sequential workload

Figure 8: IO absorbed by different policies across benchmarks, normalized to the average IO absorbed by *LRU* eviction.

Table 3: Benchmark DLRM training job workloads used for evaluation. Each job j is denoted as $\{\}_j$ and reads each partition P in specified order. Each partition P has a $\approx$ 5 TB working set.

Workload	Jobs & Partitions Read	Description
Synchronized	$\{P_1,P_2,P_3\}_1$, $\{P_4,P_5,P_6\}_2$, $\{P_1,P_2,P_3\}_3$, $\{P_7,P_8,P_9\}_4$, $\{P_1,P_2,P_3\}_5$	Multi-tenant HP tuning or exploratory jobs. Jobs are launched synchronously.
Pipelined	$\{P_1,P_2,P_3\}_1$, $\{P_2,P_3\}_2$, $\{P_3\}_3$	Long-running, pipelined jobs. Jobs are launched synchronously.
Sequential	$\{P_1\}_1$, $\{P_1\}_2$, $\{P_1\}_3$, $\{P_1\}_4$, $\{P_2\}_5$, $\{P_3\}_6$, $\{P_1\}_7$, $\{P_4\}_8$, $\{P_5\}_9$	Queued jobs that launch when training capacity is available. Jobs 1-3, 4-6, and 7-9 launch together.

6 *Tectonic-Shift* Deployment and Evaluation

Tectonic is Meta's durable storage system. It has been in production since 2015 and stores exabytes of data. *Shift* has been in production since early 2022 and is deployed at petabyte-scale alongside multiple *Tectonic* clusters serving DLRM training workloads. In this section, we evaluate *Shift*'s various caching policies compared to state of the art using a series of representative workloads, and we present results of *Shift* in production. We focus on and report absorbed IO because it is *Shift*'s top-line metric and optimization goal. A comparison of hit rates would yield analogous results since requests rates are equally distributed across SNs due to consistent hashing.

6.1 *Shift* Policy Evaluation

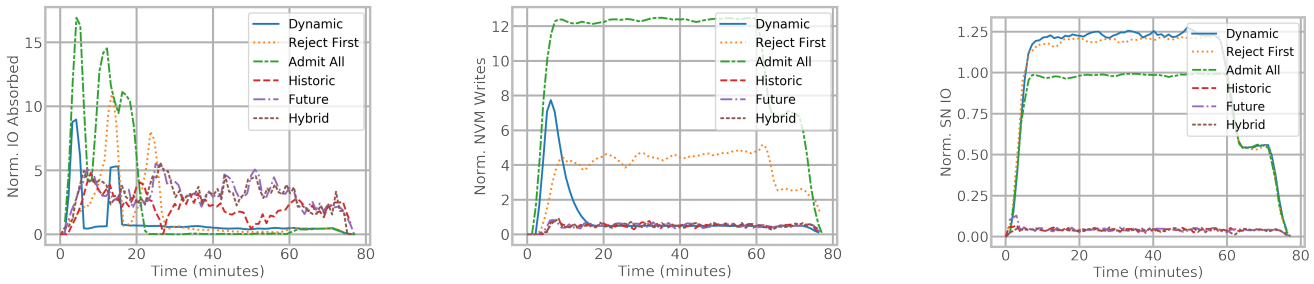
To better understand how *Shift* policies perform, we used a set of representative workload patterns shown in Table 3. Each pattern was derived from production DLRM training job traces and downsized to scale to our evaluation cluster. The *Synchronized* pattern represents a case where multiple training jobs reading the same partitions are launched at the same time (e.g., for hyperparameter tuning jobs), with training jobs reading other partitions interleaved due to the multi-tenancy of our training clusters. The *Pipelined* pattern frequently occurs in long-running jobs when users kill an under-performing job and replace it with a new model using the same dataset. The *Sequential* pattern occurs due to limited training resources, where jobs will run in separate batches as jobs finish and resources become available. For each workload, we used a set of Readers that each read from *Tectonic-Shift* at $\approx$ 1.5 GB/s.

We evaluated on a 6-node *Shift* cluster deployed with our production configuration. In each experiment, we configured nodes with different policies and evaluated each policy concurrently to ensure equal read locality; consistent hashing evenly spread requests across nodes. We used 16 GB of DRAM cache for each node. The Synchronized, Pipelined, and Sequential patterns used (1.28 TB, 5 TB, and 5 TB), and (4, 5, and 5) of total flash cache and Readers per job, respectively. Unless otherwise stated, we used directory bucket mappings and disabled reinsertion and write rate limits.

Do admission policies improve IO absorption? First, we evaluated if various *Shift* admission policies improved IO absorption across all workloads. We used the *Historic* and *Future* admission policies presented in Section 5.1, which use historic and future metadata, respectively, from the RHW and GMS to calculate a priority equal to the number of expected reads per segment. We also used a *Hybrid* admission that uses $BucketPriority_{Hybrid}(b) = max(BucketPriority_{Historic}(b), BucketPriority_{Future}(b))$. We set a minimum admit threshold of 1.1 for each policy, implementing a "reject first" policy. We used LRU eviction for each admission policy, and we compared to two baselines that only used CacheLib's *FIFO* and *LRU* eviction policies.

Figure 8 shows the IO (bandwidth) absorbed by each policy, normalized to the average IO absorbed by *LRU*. A higher IO absorption directly translates to higher *Shift* efficiency. In the Synchronized workload, *FIFO* absorbed an equal amount of IO (1.01×) as *LRU*. The *Historic* policy absorbed 2.01× more IO than *LRU*, since it was able to avoid cache thrashing induced by P_{4-9} (see Table 3) by not admitting them. The *Future* and *Hybrid* policies absorbed 2.27× and 2.32× more IO, out-performing *Historic* admission since they were also able to immediately cache $P_{1,2,3}$ without rejecting initial reads waiting for the Request History Window to populate.

For the Pipelined workload, *FIFO* was able to absorb 1.86× more IO than *LRU*, since churn caused *LRU* to evict more objects in P_3 before job 1 read P_3. *Historic* admission performed worse than *LRU*, absorbing only 0.80× IO, as it did not admit any bytes from P_3 until job 2. Since the *Future* admission policy immediately knew of P_2 and P_3's popularity,



(a) IO Absorbed (b) NVM Write Rate (c) HDD Read / Cache Fill Rate

Figure 9: Policy performance using the Synchronized workload, normalized to *Dynamic*. *Dynamic* and *Shift* write limits are set to 100 MB/s.

it was able to maximize and absorb 5.84× more IO than *LRU* by admitting them to both to cache on the first read by jobs 2 and 3. *Hybrid* admission equalled *LRU* (0.99×), since it kept admitting P_2 during job 1, expecting future reads due to historic popularity and thrashing P_3's data in cache.

Finally, we observe that for the Sequential workload, *FIFO* performed on-par (1.06× IO absorbed) with *LRU*, while *Historic*, *Future*, and *Hybrid* outperformed *LRU* equally (1.71×, 1.74× and 1.69× respectively). Specifically, for the first set of jobs (1-3), all policies saw high hit rates since only P_1 was actively read. However, for the second (4-6) and third (7-9) sets of jobs, the *Shift* policies rejected reads from P_{2-5}, avoiding contention and improving IO absorbed by P_1.

On average across all workloads, *FIFO*, *Historic*, *Future*, and *Hybrid* respectively absorbed 1.31×, 1.51×, 3.28×, and 1.67× more IO compared to *LRU*.

Can admission policies manage flash endurance? We need to limit the write rate to SSDs in order to preserve their lifetime. To study how well *Shift* policies perform under constrained write limits, we repeated the Synchronized workload while limiting each *Shift* node with an flash write limit. We compared to two state-of-the-art admission policies provided by CacheLib: a *Dynamic* flash admission policy randomly rejects writes to flash in order to maintain the specified write limit, and a *Reject First* flash admission policy rejects objects' first write to flash. We also evaluated no admission policy (*Admit All*). We used LRU eviction for all admission policies, and we configured *Shift* policies and the *Dynamic* policy to write only 100 MB/s per node. To fully evaluate the *Shift* threshold tuner, we did not set a minimum admit threshold.

Figure 9 shows the IO absorbed, flash write rate, and *Tectonic* HDD read rate for each admission policy, with each metric normalized to the average for the *Dynamic* admission policy. All admission policies absorb more IO than *Dynamic*. *Reject First* and *Admit All* absorb 1.51× and 2.66× more IO, respectively; the *Historic*, *Future*, and *Hybrid* policies absorb 2.14×, 3.07×, and 2.99× more IO, respectively.

While *Shift*'s *Future* and *Hybrid* policies performed similarly to *Admit All*, Figure 9b shows how *Admit All* required significantly more (10.38×) flash writes than *Dynamic*, exceeding our write limit. *Reject First* was similarly ineffective, requiring 3.78× more flash writes. Meanwhile, all of *Shift*'s policies matched CacheLib's write rate (within 5%, even discounting CacheLib's increased writes initially due to its counter warm-up) while outperforming its IO absorption.

Table 4: Hit rate and HDD IO (cache fills) using *Hybrid* admission with dynamically-tuned reinsertion, normalized to *Hybrid* admission without reinsertion. Write rate is limited to 1 GB/s.

	Normalized Hit Rate	Normalized HDD IO
Hybrid with Reinsertion	1.03	0.82

Furthermore, *Shift* has the advantage of avoiding excess reads from *Tectonic* HDD nodes for rejected objects, compared to CacheLib's *Dynamic* policy which always admits objects to DRAM first (and thus incurring an HDD read) before rejecting it from flash. Figure 9c shows this benefit; each of *Shift*'s policies avoids an HDD read upon rejection, significantly reducing the amount of cache fills (96% less than *Dynamic*) compared to CacheLib's baseline policies.

These results show that *Shift*'s threshold tuning mechanism is effective at maximizing IO absorption given a write constraint, without incurring excess *Tectonic* cluster reads.

How effective is reinsertion? We evaluated if reinsertion was effective at reducing HDD reads compared to admission only. We repeated the Synchronized workload with a write limit of 1 GB/s and a reinsertion threshold 1.0 greater than the dynamic admission threshold with a minimum admit of 1.1. We compared a *Hybrid* admission policy with reinsertion against a baseline *Hybrid* policy without reinsertion.

Table 4 shows the hit rate and HDD IO with reinsertion enabled, normalized to the baseline without reinsertion. We observe that enabling reinsertion resulted in similar hit rates (3% increase), while reducing HDD reads by 18%. However, compared to the limited flash write rate of the baseline (≈ 300 MB/s), enabling reinsertion with dynamic threshold tuning resulted in *Shift* always hitting the write limit, since reinsertions caused more reinsertions until the limit was exceeded. Our takeaway is that currently, reinsertions may be effective when reducing HDD reads are prioritized over reducing flash writes. However, potential future optimizations in CacheLib (see Section 7) can harness reinsertion's benefits while eliminating the write overheads caused by continued reinsertions.

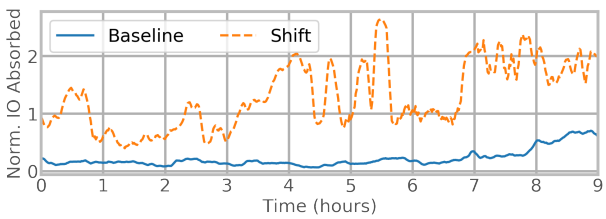


Figure 10: Production results comparing *Shift* to an expert manual-tuned policy that admits only IO-heavy tables.

6.2 Production Results

We have enabled the policies presented in Section 5 in our production clusters. Since the mix of training jobs and resources varies across datacenters, we are continuously tuning policy configurations for each cluster. These policies have helped *Shift* save significant amounts of power.

To demonstrate this, Figure 10 shows a representative trace of the IO absorbed by *Shift* nodes in a petabyte-scale production cluster over the course of 9 hours. We show a baseline that uses an *Expert*-tuned admission policy on top of LRU, which admitted only high-IOPS tables to cache; no admission policy (admit all) showed near-zero IO absorption due to significant cache contention across training jobs. We compared against *Shift* using a *Hybrid* policy, with a minimum admit threshold of 3.0 and without reinsertion. Both used client eligibility policies and our production write rate limit (the baseline additionally used *Dynamic* admission if necessary), and we normalized results to the "power-neutral" IO absorption point: the required amount of IO *Shift* needs to absorb to reduce power consumption compared to using only HDDs.

The *Expert* admission policy is ineffective at saving power due to its inability to capture the limited data reuse of training jobs we characterized in Section 3. Simply deploying a flash cache without intelligent and adaptable cache policies is inefficient; our production trace shows that doing so would only absorb $0.21\times$ the IO needed to achieve power neutrality. By employing the application-aware policies presented in Section 5, we show that *Shift* can exploit the unique characteristics of training jobs, saving 29% of power relative to using only HDDs for training data storage. At our scale, this corresponds to a massive efficiency improvement.

7 Lessons Learned and Open Questions

Define the right interface to users. Our focus on designing a *transparent* but *intelligent* interface to users was instrumental in the success of *Tectonic-Shift*. A transparent interface allowed us to quickly onboard new users by simply configuring the cache eligibility policy, requiring *zero* application modifications. Since applications could be agnostic to their use of *Shift*, this allowed us to dynamically manage the deployment and operation of *Shift* with fine granularity. For example, we could gradually roll-out to a new customer, A/B test different policies across SNs, or even roll-back to reduce request pressure — all without affecting customers' performance.

At the same time, we quickly learned that it was essential to work closely with customers to maximize *Shift* performance. We collaborated heavily with AI infrastructure and ML engineering teams to understand and extract the right set of application metadata to optimize *Shift* policies. Looking forward, we believe that a wide range of other ML domains (e.g., vision, NLP, etc.) and non-ML applications will benefit from *Shift*. Since these applications use the same *Tectonic* API, our focus can simply lie in working with customers to extracting the best features to maximize *Tectonic-Shift* efficiency.

Rely on a slate of robust testing, experimentation, and monitoring mechanisms. We use multiple tools such as stress tests, production A/B testing, trace-based simulation, shadowing, and dashboards to continuously tune the multiple *Shift* policies and configurations discussed in Section 5. These tools have also helped ensure a stable deployment of *Shift*. For example, data corruptions are common at our scale, requiring us to compute, store, and verify checksums for each *Shift* segment. To ensure data correctness prior to deployment, we used a shadow deployment to have clients fetch *Shift* checksums to compare against data read from *Tectonic*.

Effectively use DRAM. CacheLib uses both DRAM and flash to store data. For our use case, DRAM capacity was negligible relative to the orders of magnitude larger flash capacity. Instead, we prioritized using DRAM to store metadata (e.g., the RHW) to improve the effectiveness of *Shift* policies, but we still had to reserve tens of gigabytes of memory for CacheLib to buffer and serve requests at high throughput. Further CacheLib optimizations to reduce memory requirements and an investigation into the optimal split between data and metadata may further improve *Shift* performance.

Can data placement and job routing policies improve cache performance? A key opportunity we foresee is co-designing *Tectonic-Shift* with data placement and training job routing policies. Data placement policies govern how tables are replicated across our datacenters. Cache-aware data placement policies can help reduce cache working set sizes by intelligently reducing data replication while balancing for data availability. Cache-aware job routing policies can improve the IO absorbed by *Shift* by coalescing jobs that read similar data within the same datacenter.

How much can priority-aware evictions improve cache performance? Section 6 showed that while reinsertion was effective, it required significant flash writes due to reinsertion cycles. Reinsertions are necessary because CacheLib only offers LRU or FIFO eviction. We believe that further optimizations in CacheLib, such as allowing selective evictions based on a cache object's priority, can harness the benefits of reinsertion without write overheads.

Can historic and future knowledge inform better cache policies? *Shift* provides an extensible framework to build cache admission and reinsertion policies based historic and

future information. While we demonstrated that a hybrid policy based on the maximum of historic and future priorities was effective, a promising research direction is to explore novel cache policies that can leverage future information. For example, a potential cache policy may account for *when* objects will be read in the future and prioritize earlier objects.

8 Related Work

Software Flash/DRAM Caches. Systems such as Redis [36], memcached [45], RAMCloud [49], and Pocket [29] are widely used as caches across datacenter applications. These software caches commonly manage DRAM and/or flash using a mix of policies including admission (e.g., TinyFLU [12] and LARC [20]) and eviction/replacement policies (e.g., ARC [39], LRU [47], 2Q [22], and OPT [5]) that leverage historical (or oracular) access patterns. Techniques to predict file access patterns, e.g., access trees [33], are also well studied.

Recent works have also proposed mechanisms to dynamically tune these policies using ML models [34, 52, 59], hardware access signatures [63], NLP techniques [17, 69], and other heuristics [40, 66]. Meanwhile, flash-specific policies [6, 13, 38, 56, 65] largely focus on managing flash write amplification (WA). CacheSack [66] is used as the admission policy for Google's Colossus Flash Cache, which shares a similar goal to *Shift* in absorbing IO from HDDs. CacheSack splits objects by category and tunes the admission policy of each category. Janus [4] is also a flash tier used in Google's Colossus file system, but instead requires files to be written to flash first before being evicted to HDDs.

Various existing storage systems also leverage architectures similar to *Tectonic-Shift*. Swift uses a set of configurable hash rings to map objects to their respective storage device [48]. Numerous file systems leverage heterogeneous storage devices to optimize for performance and efficiency across various applications [24, 60, 62, 64]. For example, burst buffers, typically consisting of IO-performant devices such as flash, are commonly used to absorb peaks of high IO-demand from backend (e.g., HDD) storage systems in high-performance computing applications [35].

Tectonic-Shift is a composite storage fabric that employs a mix of cache policies across *Tectonic* Clients and *Shift* Storage Nodes to maximize its efficiency. *Shift* runs a CacheLib [6] instance in each SN. We use comparatively large segments (256 KB) and rely on CacheLib's Large Object Cache to handle WA. Each *Shift* SN dynamically tunes its cache policies, including admission and reinsertion, independent of CacheLib's. While *Tectonic-Shift* shares a similar goal with Google's CacheSack [66] and Janus [4], and leverages well-known techniques such as consistent hashing and heterogeneous devices, it uniquely targets industrial ML training jobs and adopts novel application-aware policies that infer future access patterns from job specifications.

ML-specific Caches. Recent work has shown the utility of caches for ML training workloads. CoorDL [41] eliminates data stalls in single-server training using local SSDs. Quiver [30] and OneAccess [23] cache and share data across highly-synchronized HP tuning jobs. DIESEL [61] targets training workloads over small files (e.g., images). DLFS [71] and DeepIO [70] randomize mini-batches using specialized hardware. Cachew [16] builds on tf.data [44], and puts intermediate data in cloud storage to reduce preprocessing costs.

While other ML caches require adoption effort, *Tectonic-Shift* is completely transparent to users. Furthermore, Section 3 explored why industrial ML training workloads present novel challenges not addressed by these caches. *Tectonic-Shift* is designed for exascale and continuously serves traffic to datacenter-scale GPU training clusters.

Production ML Workload Characterization. tf.data [44] provided an ML training workload characterization at Google, highlighting similar traits such as prevalent data reuse and selective reading. *Tectonic-Shift* is motivated by and builds upon prior characterization of Meta's training workloads [68].

Distributed File Systems. *Tectonic-Shift* is built on top of *Tectonic* [50] and provides the same API and append-only semantics as the *Tectonic* File System. Other distributed file systems, such as Spanner [10], GFS [15], Colossus [19], HDFS [54], and Lustre [53], are used across industry.

9 Conclusion

We presented *Tectonic-Shift*, the composite storage fabric used in Meta's production ML training infrastructure. *Tectonic-Shift* maximizes efficiency by balancing storage and IO capacity across HDD and flash. We provided an in-depth workload characterization and design space exploration which guided the principled design of *Tectonic-Shift*. *Shift* employs a set of application-aware policies that infer and exploit future access patterns using job specifications. We demonstrated how *Shift* absorbed $1.51-3.28\times$ more IO than an LRU flash cache and improved the power efficiency of *Tectonic-Shift* by 29%.

Abstract

Cloud storage is gaining popularity because of features such as pay-as-you-go that significantly reduces storage costs. However, the community has not sufficiently explored its contract model and latency characteristics. As LSM-Tree-based key-value stores (LSM stores) become the building block for numerous cloud applications, how cloud storage would impact the performance of key-value accesses is vital. This study reveals the significant latency variances of Amazon Elastic Block Store (EBS) under various I/O pressures, which challenges LSM store read performance on cloud storage. To reduce the corresponding tail latency, we propose Calcspar, a contract-aware LSM store for cloud storage, which efficiently addresses the challenges by regulating the rate of I/O requests to cloud storage and absorbing surplus I/O requests with the data cache. We specifically developed a fluctuation-aware cache to lower the high latency brought on by workload fluctuations. Additionally, we build a congestion-aware IOPS allocator to reduce the impact of LSM store internal operations on read latency. We evaluated Calcspar on EBS with different real-world workloads and compared it to the cutting-edge LSM stores. The results show that Calcspar can significantly reduce tail latency while maintaining regular read and write performance, keeping the 99th percentile latency under 550μs and reducing average latency by 66%.

1 Introduction

In recent years, the trend that many businesses and organizations shift their data to the cloud has fueled the growth of cloud storage [21, 34]. This is due to the advanced features and cost-effectiveness of cloud storage. For example, Amazon Web Services (AWS), the world's most broadly adopted cloud platform, provides various storage services with high scalability and reliability on a pay-as-you-go basis [8] (e.g., Elastic Block Store, EBS), making them more appealing. Another important trend is that LSM-Tree-based key-value stores (LSM stores), such as RocksDB [5], LevelDB [1], Bigtable [14], Dynamo [17] and TiDB [19], are becoming the building block for many cloud applications. However, none of the existing LSM stores is optimized for cloud storage to eliminate long-tail latency. Notably, it is challenging to balance the estimated peak performance with the budget for cloud storage performance (e.g., IOPS). Although many cloud storage providers advertise elastic storage volumes that can accommodate changing performance needs, these volumes' scaling capabilities fail to adapt to an inevitable traffic fluctuation. For instance, AWS EBS only supports increasing the purchased IOPS, which would take hours or even days to complete [2]. Hence, it is impractical to rely solely on elastic volumes for timely adjustments in the face of short-term workload changes.

To understand how cloud storage would respond to traffic fluctuation, we have explored the latency characteristics of AWS EBS volumes. Results show that EBS guarantees a service agreement called Service Level Agreement (SLA) in which the processing latency of each request falls within an appropriate threshold *if* the accesses do not exceed the paid IOPS. We observe that the processing latency of each consecutive request dramatically increases when the demands in a time window exceed the IOPS agreement. Besides, the cloud storage's contract model shows that the higher the paid IOPS, the lower the latency. However, such an agreement is constrained by IOPS budgets, and naturally, performance in terms of latency will suffer if the IOPS is overdrawn.

The latency spike caused by limited IOPS in cloud storage severely impacts the performance of latency-sensitive applications on top of LSM stores. We take one of the most widely deployed LSM store implementations, RocksDB, as an example. The RocksDB first writes the in-memory table (memtable) to respond quickly with reasonably low latency. Until the in-memory table is full, RocksDB then persists the table to the storage volume in large chunk writes (e.g., SSTables), thus aggregating the random writes into sequential ones. Such a write scheme reduces the number of write requests and achieves high write throughput. It then employs internal compaction mechanisms to merge and resort the incoming data

with multiple levels of on-disk tables. Although the internal compaction operation ensures the orderliness of data in each level to improve the lookup performance, a read operation still needs to traverse multiple levels, resulting in read amplification. As the IOPS on a cloud storage volume is limited, the read performance of RocksDB is significantly throttled.

There are several challenges to avoid read latency spikes in LSM stores. First, the read request performance fluctuates significantly because the cloud storage volume isn't flexible enough to timely keep up with the changing workload. The fluctuating workload causes the number of read I/Os of an LSM store to access cloud storage volumes to vary significantly. The request latency increases when the I/O number exceeds the paid IOPS of the cloud storage volume. Second, the read amplification in an LSM store further strengthens the workloads fluctuations. Multi-level data layouts inevitably cause read amplification problems, such as those found at the LSM-Tree L0 level requires traversing multiple tables, so reading a single key-value pair may generate multiple I/Os. Third, the speed limit mechanism of cloud storage volume conflicts with LSM stores' internal multi-thread concurrency mechanism, and requests among multiple threads congestion on the cloud storage volume leads to an increase in latency multiples. Fourth, LSM stores' internally inherent mechanisms amplify the damage on the read latency of cloud storage volumes. Irregular flush operations or indeterminate size compaction operations cause a sudden increase in the number of I/Os accessing the cloud storage volume, resulting in high tail latency. Finally, the tradeoff between cost and performance increases the cost exponentially to get better tail latency, resulting in significant resource waste and limited throughput improvement.

One natural solution to the above challenges is contracting a higher IOPS budget with cloud storage volumes, ensuring that the LSM store's I/O number do not exceed the paid IOPS to maintain optimal latency. However, this raises the costs. Also, the peak IOPS demand in real production environments is difficult to predict. Instead, we aim to explore the best performance of an LSM store under a specific IOPS budget.

This paper presents Calcspar, a cloud storage volume contract-aware LSM store based on Amazon's EBS with reduced latency spikes, and it tolerates both external workload fluctuations and internal operation contentions. Calcspar first employs fluctuation-aware caching, which combines hotspot-aware proactive prefetching and shift-aware passive caching, to adapt to changing workloads. The prefetching strategy identifies hotspots for high load periods and proactively fetches them during low load periods, thus smoothing out the external load changes. Then, during the high load periods, the passive caching leverages the temporal locality to extrude the stale prefetched data and adapt to hotspot shifts without issuing extra requests. Calcspar then leverages a congestion-aware IOPS allocator to assign priority for different internal requests and avoid elevated latency due to limited IOPS budgets. The allocator employs a multi-queues throttling structure to prevent thread congestion. The opportunistic compaction then assigns write requests in different LSM levels into different priority queues, thus balancing the read amplification and write throttling. The contributions of this paper include:

1) We conducted an in-depth analysis of the performance of cloud storage volumes, which first illustrates the unwritten contract between latency and load pressures.

2) We propose a rate-limiting performance model for cloud storage volumes based on the observations, experimentally validate the model and reveal opportunities to obtain optimal latency.

3) Our proposed Calcspar is better suitable for AWS cloud storage volumes where IOPS budgets are vital to the performance and significantly reduced the tail latency of LSM-Tree.

The rest of this paper is organized as follows. Section 2 takes Amazon's EBS as the example to models the performance characteristics of cloud storage volumes. The challenges of reducing the latency for an LSM store on cloud storage are discussed in section 3. Calcspar designs are then introduced in section 4 to address these challenges and they are evaluated in section 5. Finally, the related work and conclusions are presented in sections 7 and 8, respectively.

2 Modeling Cloud Storage Performance

2.1 Contract Model of Cloud Storage

The cloud storage providers, such as AWS, offer a variety of cost-efficient storage volumes for users to meet their distinct needs and adapt to the changing market. Table 1 shows the contract model of the cloud storage, which illustrates the price and performance relationship of the corresponding volume type. The pricing is based on block storage in the AWS ap-northeast-2 region in July 2022 [3, 4]. The contract model indicates that as the price of IOPS increases, the lower latency of the corresponding type. Thus, it entails users choosing the appropriate storage volume and IOPS budget based on their needs. However, the paid IOPS only guarantees the number of returned I/Os rather than the optimal latency. Also, EBS performance scaling supports only increasing paid IOPS and takes hours to days to take effect [2]. There's no agreement on how the request would be responded to when the loads exceed the IOPS. Hence the corresponding latency characteristics are widely ignored by existing LSM stores.

2.2 Unwritten Latency Performance

To unwrap the hidden latency characteristics and understand how the above contract model would affect the performance

Table 1: EBS IOPS prices and latencies.

Type	Init IOPS	IOPS price ($)	Latency (μs)
gp2	3×GB	0.038	∼200
gp3	3000	0.0058	∼300
io1	100	0.0666	∼100
io2	100	0.067	∼10

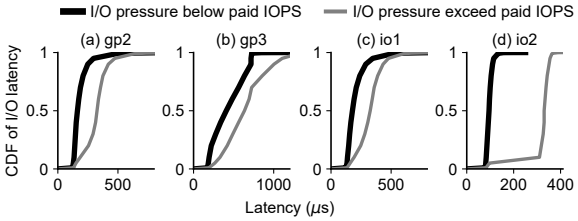

Figure 1: Latency CDF of different cloud storage.

of an LSM store, we first perform a series of experiments on cloud storage volumes, then proposing a performance model.

Experiment #1: *Cumulative Distribution Function (CDF) of latency under vary I/O pressures.* We measure the latency of EBS volumes gp2, gp3, io1, and io2 with paid 3000 IOPS for each by sending 4KB random read requests with varying pressures. We employ fio [22] to tune the I/O pressure by controlling the size of **Submit IOPS**, which is the number of I/Os submitted to EBS per second. Yet, the cloud storage volume *won't* handle more than the paid IOPS. Figure 1 shows the latency CDF results that support the following two findings.

Finding 1: When the I/O pressure exceeds the paid IOPS, the latency increases deterministically and significantly. On the contrary, their average latency performance is much better when the Submit IOPS is under paid IOPS. For example, the average latency of io2 even reached 100μs.

Finding 2: The IOPS budget is proportional to the cost when considering Table 1. The slightly higher-cost io2 has the best and most stable latency. The latency performance of the cheapest gp3, which initially provides 3000 IOPS, is far lower than the other three EBS types.

Experiment #2: *Limited IOPS budgets*. In this experiment, we explore the latency CDF under different IOPS budgets. We evaluate one io2 under two different pressures. Request latency distributions are given in Figure 2. Results indicate that regardless of the paid IOPS, the access latency when the Submit IOPS exceeds the paid IOPS is more than 5×

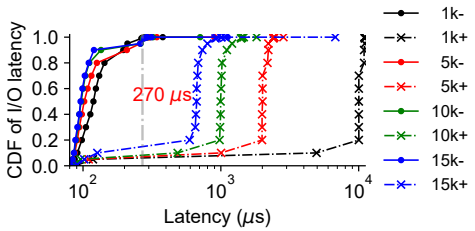

Figure 2: Latency CDF under different paid IOPS. "1k" means io2's paid IOPS. "+" indicates that the Submit IOPS exceeds the paid IOPS; "-" means not exceed.

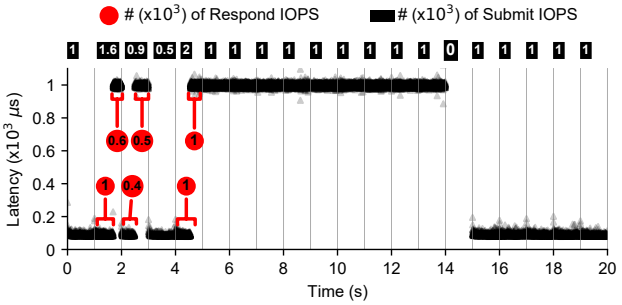

Figure 3: Latencies under rigorously controlled pressure. Respond IOPS is the number of requests returned.

worse than the access latency when not exceeded. The 99th percentile latency are below 270μs when the Submit IOPS does not exceed the corresponding paid IOPS. However, when the Submit IOPS exceeds the paid IOPS, the access latency increases to 1000∼11000μs. These long-tail latencies degrade the user experience.

Experiment #3: *Elevated latency spike*. To explore reasons behind the latency spike under high I/O pressures, we rigorously control the I/O send rate in a single thread for an 1000-IOPS io2 volumes. The latency of each request is shown in Figure 3. In the 1st second, when the Submit IOPS does not exceed the paid IOPS, the latency is lower than 200μs. In 2nd second, the Submit IOPS is 1600, the latencies of the first 1000 requests are identical to that of the first second. However, the latencies of the rest 600 requests increase significantly to about 1000μs, which renders $1/IOPS$ second. The Submit IOPS in the 5th second is twice the paid IOPS, the first 1000 requests can get low latency while the latencies of the last 1000 requests equal $1/IOPS$ second again. Although the Submit IOPS drops to 1000, the latencies of subsequent requests remain high. Until we pause the workload at the 14th second and resume it at the 15th second, the latencies recuperate.

Speculative Reason #1: *We speculate the reason behind the observation is due to the speed-limiting mechanism inside EBS, which handles the current excess I/O by overdrawing the next 1 second of IOPS, and at the same time, the "punitive" improvement latency is 1/IOPS to prevent the requests beyond the payment from continuing to be responded.*

For example, the last 600 I/O requests in the 2nd-second overdraw 600 IOPS from the 3rd second. Hence, only the remaining 400 (=1000 − 600) can be served quickly in the 3rd second. The overdraft is paid off when no I/O request is sent in the 14th second. Therefore, the latency returns to a lower level in the following 15∼19 seconds

Since the resources of cloud services are on a pay-per-use basis, cloud storage providers use this mechanism to maintain SLAs to prevent users from constantly acquiring benefits beyond what they paid. Meanwhile, by increasing the delay, the operation continues from the user's perspective; thus, there is no opportunity for recalling the service.

Experiment #4: *Thread congestion.* The effect of the num-

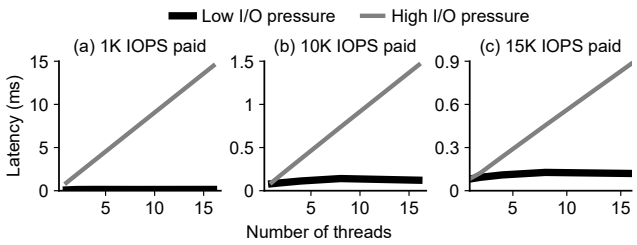

Figure 4: Average latency under different # of threads.

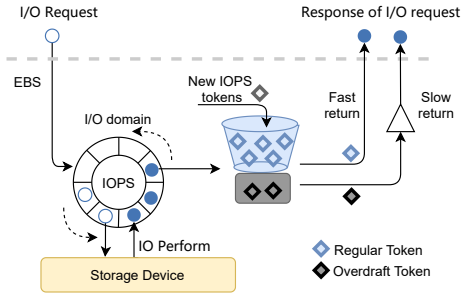

Figure 5: Estimated EBS IOPS throttling mechanism.

ber of threads on the latency is evaluated in this experiment. Two different I/O pressures are sent to each io2 volume with different number of threads. Request average latencies are shown in Figure 4. When the Submit IOPS does not exceed the paid IOPS, the average latency holds around 120μs and does not increase with more threads. However, when the Submit IOPS is higher than the IOPS paid, the access latency first grows to the level of $1/IOPS$ seconds while growing linearly with the number of threads. This phenomenon is consistent with queuing theory [30], so we conjecture the following based on the knowledge gained from queuing theory:

Speculative Reason #2: *Requests are queued when they enter the EBS, and the queue size equals the paid IOPS. The latency in the EBS will follow the following two rules: 1) When the Submit IOPS is lower than the paid IOPS, the latency of each request will be around the threshold, depending on the EBS type. 2) When the Submit IOPS exceeds the paid IOPS, the latency (respone time W) conforms to the queueing equation $W = L/A$, where A is the paid IOPS and L is the number of threads.*

2.3 Latency Model of EBS

Based on the above analysis, we construct an EBS latency model to reveal the internal latency mechanism of cloud storage, as shown in Figure 5.

Suppose an EBS volume a buffer queue (called I/O domain) to maintain requests, where the queue length is equal to the paid IOPS. When a request arrives, the I/O domain allocates a free slot in the queue. EBS then pulls requests from the I/O domain to promptly executes them. When the number of the responded requests exceeds paid IOPS, the EBS stops fetching new requests. Consequently, the pending requests are blocked until EBS can resume the services. Congestion can occur under multi-threaded workloads, although the total number of requests submitted by all threads is estimated to be no higher than the budget in one second. This is because thread scheduling uncertainties would fire some working threads more often, thus accidentally overdrawing the budget. Such an overdrawing leads the consequent requests to be blocked, resulting in significantly higher latency per request.

Overdraft Rule. EBS controls the responding speed of the request to manage the *rotation* of the I/O domain. Specifically, we use the “tokens" to describe the speed control mechanism of EBS. Each cloud storage volume retains a token bucket and a borrowing pool, which contains the same number of tokens equal to the paid IOPS. The user request first gets the regular token from the token bucket. If no token is in the bucket, the overdraft token must be obtained from the borrowing pool. EBS ensures that requests carrying regular tokens return quickly. In contrast, requests with overdraft tokens are processed slowly to ensure that the user does not use too many IOPS to maintain SLAs. The EBS is replenished with IOPS tokens per second, which are prioritized in the borrowing pool.

The above EBS latency model explains the aforementioned findings (#1 and #2) and speculations (reasons #1 and #2) about cloud storage latency: 1) When the Submit IOPS does not exceed the paid IOPS, requests get regular tokens and return quickly, and requests between threads do not block, so the optimal latency is obtained. 2) When the Submit IOPS exceeds the paid IOPS, some requests obtain overdraft tokens. 3) When the return speed is lower than the request arrival speed, the unprocessed requests will fill the I/O domain slots, and further tokens are replenished by replenishing the borrowing pool first so that the high latency state will last for a long time. 4) The inter-thread blocking in I/O domain leads to increasing user-perceived latency.

3 Modeling RocksDB Performance

3.1 RocksDB under IOPS Limitation

As suggested by the above performance model, cloud storage emphasizes more limitations on latency and IOPS rather than bandwidth. The evidence is that the allowed request size is relatively large, and increasing the IOPS budget is expensive. Such a contract and performance model fits bandwidth-sensitive workloads; however, it is unfavored by many latency-sensitive and request-heavy workloads. For example, our analysis indicates that the data write and compaction in RocksDB works well on cloud storage as its’ request sizes are more significant and the number of requests is limited. However, the read performance of RocksDB is seriously affected by the limited IOPS budget. Many applications that employ RocksDB to serve metadata indexing expect excellent read throughput as well as low and stable read latency [27]. Unfortunately, they will fail to achieve their purpose if the underline device

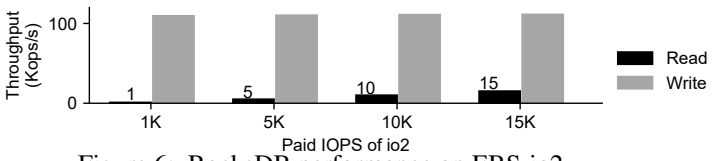

Figure 6: RocksDB performance on EBS-io2.

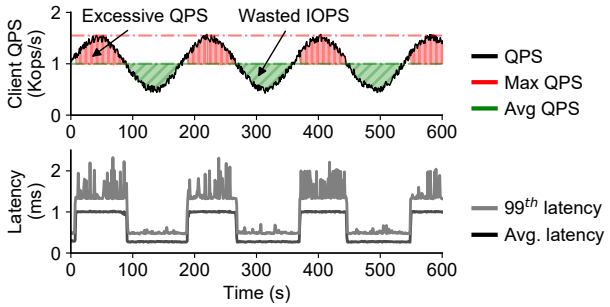

Figure 7: Client random read QPS and request latency with single thread.

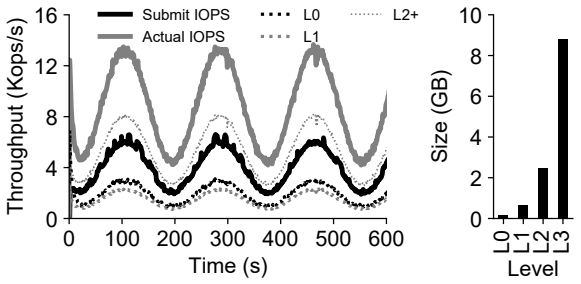

Figure 8: Read amplification of RocksDB.

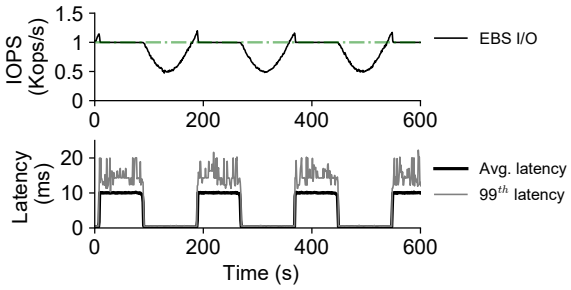

Figure 9: Io2 Respond IOPS and latency with 10 threads.

is cloud storage.

RocksDB does not work well on cloud storage because its LSM-Tree is generally a write-optimized indexing structure instead of tuned for reducing the number of read I/Os. Moreover, the hierarchical structure of the LSM-Tree results in many read requests needing to access multiple levels of the indexing table to locate the corresponding key. On the contrary, write operations can be cached and aggregated into large chunks before they finally hit the cloud storage in one backend request. As shown in Figure 6, we perform read and write stress tests on io2 storage volumes with different paid IOPS. As the IOPS increases, the read throughput increases, and the write throughput remains the same. Therefore, when deploying RocksDB on the cloud, the maximum 1000MB/s bandwidth of the cloud storage volume is usually sufficient. However, the RocksDB read I/Os will easily and repeatedly hit the IOPS limitations, which causes elevated tail latency.

3.2 Challenges in Avoiding Latency Spikes

This subsection elaborates on several challenges encountered when optimizing the read performance of RocksDB in cloud storage. To analyze the performance, we employ Facebook's most recent benchmark Mixgraph [12], which synthetically generates key-value requests that accurately represent the real-platform load fluctuation.

Challenge #1: *The read latency fluctuates significantly because cloud storage isn't flexible enough to meet the changing demand.* In this experiment, we send fluctuating read requests to an io2 volume in a single thread. To reduce expense, the paid IOPS of io2 storage volumes is the average of fluctuating requests. The experimental results in Figure 7 show that RocksDB is significantly affected by the latency characteristics of cloud storage volumes. When the client queries per second (QPS) exceeds the paid IOPS, the QPS being executed (the white part under the black line) can exceed the paid IOPS in a brief period, which is due to the overdraft rule. Then executed QPS will fall to the paid IOPS and the user-perceived latency is significantly higher than during low load. This also results in the user's excessive requests not being executed (the red part of the top in Figure 7), and they will be blocked. As the number of client requests drops below the paid IOPS, the latency drops to the bottom level, which causes another problem where the paid IOPS are wasted during low-load periods, as shown in green in Figure 7.

Challenge #2: *The read amplification in LSM-Tree further strengthens the workloads fluctuation.* RocksDB's write aggregation and hierarchical data layouts result in significant read I/O amplification. As shown in Figure 8, the actual IOPS is about 3× of the submit IOPS, amplifying the volatility of the load, when the access I/O exceeds the paid IOPS, the request latency will be high. In addition, the L0 and L1 level, which occupy a very small amount of data, but taking up close to 1/3 of the I/O accesses.

Challenge #3: *Thread I/O competition.* Requests among multiple threads are congested in the I/O domain resulting in a multiplication of tail latency. We send the same QPS as in Figure 7 with ten threads. The results in Figure 9 show that the latency increases 10× at high loads compared to single threads. This is because with more requests being sent to the io2 per second, the requests are returned slower than the requests that enter the I/O domain. When the I/O domain is full, requests are queued on each thread, so the latency perception is a multiple of the thread.

Challenge #4: *Bulk write blocking.* We sent some write requests while keeping the read QPS constant to measure the impact of write operations on user read requests, and the results are shown in Figure 10. At the 70th second, RocksDB launched compaction operations, which took up more IOPS,

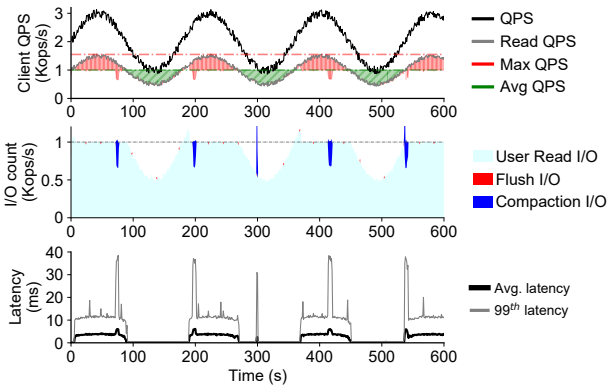

Figure 10: RocksDB I/Os and latency for a mixed read and write load with 10 threads.

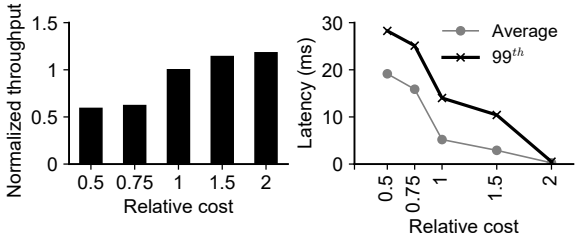

Figure 11: RocksDB performance at different storage costs.

causing some of the user's requests to wait in a queue. Hence the 99th percentile latency bursts to 40ms. Secondly, at the 300th second, even in low workload period, RocksDB internally initiates some compression operations, which blocks user requests, resulting in high latency.

Challenge #5: *Performance vs. cost.* We choose the average of the highest QPS and the lowest QPS of the load as the benchmark cost to measure the performance of RocksDB when choosing storage volumes with different costs under the same load. Results in Figure 11 show that, as the cost increases, although the latency appears to decrease, the throughput does not improve due to serious resource waste.

4 Calcspar Design

To build an LSM store that fully exploit the optimal latency of cloud storage volumes, the high latency caused by the observed overdraft rules and thread I/O congestion must be addressed. Rather than simply increasing expenses to improve the paid IOPS of storage volumes to avoid overdraft and congestion, we propose Calcspar to investigate the optimal latency of LSM stores in a cost-effective manner. With a limited number of IOPS available per second, Calcspar's four designs in Figure 12 holistically answer questions on getting the optimal latency: (1) How to smooth out I/O plateaus that are higher than the paid IOPS (§4.1 and §4.3). (2) How to take the most of available I/Os per second for user and LSM internal I/O requests (§4.2 and §4.4).

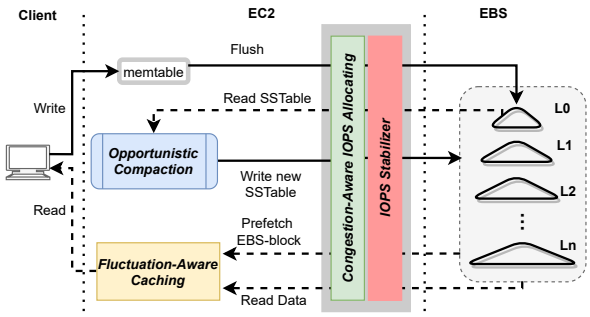

Figure 12: Architecture of Calcspar.

4.1 IOPS Stabilizer for EBS

Calcspar first aims to prevent latency fluctuation from the EBS. As discussed in §2.2, the overdraft rules do not result in throughput improvements but higher processing latency for EBS under high request pressures. Once the EBS enters the overdraft status, the application is not able to withdraw any pending requests, thus missing opportunities for further optimization but waiting. Rather than passively detecting unexpected latency spikes, Calcspar proactively controls the number of I/Os during high-load periods by only submitting requests with the highest priority. To achieve this, Calcspar employs the observed EBS latency model (§2.3).

Figure 13 details the IOPS Stabilizer, which throttles the request rate to match the EBS I/O budget, thus eliminating overdraft latency spikes. The essence is to mimic the token speed limit mechanism, which insides EBS and is widely ignored, to the upper-layer applications. We demand each request must obtain a token before accessing the EBS. The number of tokens is refreshed every second decided by the paid IOPS. By controlling the number of tokens, Calcspar guarantees requests sent to EBS do not exceed the paid IOPS, thus EBS processing latencies can be secured in the tens of microseconds. Consequently, applications can expect more stable latencies once a request successfully obtains a token.

4.2 Congestion-Aware IOPS Allocating

The second goal of Calcspar is to eliminate the latency spike caused by request congestion among threads. To minimize cloud storage costs, we assume the paid IOPS is only guaranteed to meet I/Os for the average usage. Hence, the muti-threads design adopted by modern LSM stores will inevitably congest due to limited tokens provided by the IOPS Stabilizer. Many works prioritize the execution of latency-sensitive I/Os by adjusting the I/O stack or leveraging multi-device parallelism [11, 20, 26]. However, they can not prevent less critical I/O requests from occupying precious available tokens in each time period (e.g. one second). To solve this problem, Calcspar uses multi queues of different priority together with the time window policy to ensure that critical requests are not occasionally blocked and are served in a best-effort manner.

Multi-priority Queues. Calcspar employs a multi-priority

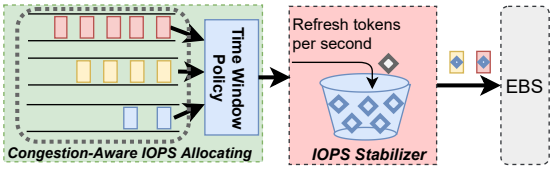

Figure 13: Congestion-Aware IOPS Allocator and Stabilizer

queue mechanism to categorize different I/O requests and allocate I/O tokens based on a dynamic time window policy. Calcspar treats I/Os that straightly affecting the LSM store as *user-aware requests*, and classifies I/Os that do not instantly hinder user requests as *non-user-aware requests*. User-aware requests are mainly for responding foreground user requests, so Calcspar places them into the highest priority queue. Non-user-aware requests are mainly from LSM background tasks (e.g., compactions and prefetching). Since different background tasks impact the read/write amplifications differently, Calcspar assigns them to medium-priority or low-priority queues. For example, prefetching requests go into the lowest priority queue. Note that compaction requests are further differentiated later (§4.4).

Dynamic Time Window Policy. Calcspar adopts a dynamic time window policy to optimize the utilization of paid I/Os per second. Under this policy, a time window represents a period within a second during which Calcspar grants requests to acquire tokens on a best-effort basis, so the size of a window matches the priority of the queue. The time windows of the queues are aligned at the tail within each one-second period, enabling Calcspar to prioritize processing I/Os from higher priority queues before those from lower priority queues. This ensures that requests from the highest priority queue are processed first, minimizing the chances of them being blocked by middle- or low-priority requests. Specifically, Calcspar always allocates a one-second time window for the high-priority queue. For other queues, Calcspar dynamically adjusts their time window sizes based on the allocated tokens in the previous second, using the formula `Allocated_IOPS` / `Paid_IOPS`. For example, during a one-second period, Calcspar assigns the time windows `[0,1)`, `[0.7,1)`, and `[0.9,1)` to the high-, middle-, and low-priority queues, respectively. In this case, the time window `[0.9,1)` signifies that requests in the low-priority queue cannot acquire tokens until the 0.9th second. Conversely, requests in the high-priority queue with the time window `[0,1)` are eligible to compete for tokens upon arrival.

4.3 Fluctuation-Aware Caching

Considering the read I/O amplification problem of an LSM store will cause significant latency spikes on the EBS, an EBS latency-aware cache plays an essential role on flattening I/O request plateaus to the EBS when the workload is heavy as well as improving the paid IOPS utilization when the workload is light. We find few existing cache schemes are designed on this purpose, and their design metrics do not take into account the available paid IOPS of the underlying EBS. This will significantly affect choices of the optimal cache policy when workload fluctuates.

Hotspot-Aware Proactive Prefetching. When the workload is light, Calcspar consumes spare paid IOPS to trade for a better cache hit ratio by prefetching SSTable. Calcspar manage data in the unit of EBS-block (e.g., 256KB, which is the maximum size allowed by the EBS for one I/O request), this ensures that each prefetching I/O reads as many data as possible. Calcspar then maintains a global table to track the hotness of EBS-blocks using the exponential smoothing algorithm based on their access history. Furthermore, Calcspar periodically and proactively rewarms the frequently accessed LSM top layer (e.g., L0 and L1) data, because LSM stores retrieves key-value pairs in a top-to-bottom layer fashion.

Shift-Aware Passive Caching. When the workload is heavy, an EBS latency-aware cache should minimizes its I/Os to the EBS while improving space efficiency. Calcspar manages the cache space passively in this case. Calcspar refines cache space management in the unit of 4KB and uses the LRU policy for better space efficiency because evicting any data can be punished by competing one I/O with user requests to access the EBS.

Cache Integration. Calcspar integrates the two cache policies introduced above and switches between them based on workload. These two policies manage the same cache space, but at any time, only one is active and evicts data. When the highest priority queue requests consume more than 95% of the tokens, Calcspar considers the workload to be heavy and activates the Shift-Aware Passive Caching policy. Otherwise, Calcspar harvests the available paid IOPS using the Hotspot-Aware Proactive Prefetching policy. It is worth noting that the global track table has a negligible memory overhead, as 1GB of data requires about 64KB of memory. Furthermore, the minimal cache pollution resulting from coarse-grained hotspot-aware proactive prefetching during periods of low load does not lead to a degradation in overall performance. This is because only frequently accessed data, known as hot data, is loaded based on historical access patterns. Additionally, given the ample IOPS budget available during low load and the consistently low latency of cloud storage, the penalty incurred from cache misses is negligible.

4.4 Opportunistic Compaction

The last goal of Calcspar is to remedy LSM compaction I/Os. After launching a compaction, its bulk read operations on at least two SSTables and write operations on at least one SSTable will compete with user I/O requests. An LSM store, on the other hand, retrieves a key-value pair level by level and merges SSTables in a copy-on-write manner, providing Calcspar with opportunities for differentiating I/Os for compaction jobs on different levels, thereby mitigating the competition on paid IOPS from LSM compaction operations. For L0 SSTables, which significantly affects read I/O amplifications,

Calcspar prioritizes compaction on them. For L1 and L2 SSTables, Calcspar puts their compaction I/Os into the medium priority queue, where they are opportunistically processed. As for SSTables in levels below L2, Calcspar assigns these compaction I/Os to the lowest priority queue, since short-term deferral has no noticeably affect on performance.

5 Evaluation

We implement Calcspar based on RocksDB and evaluate it to demonstrate its advantages. Specifically, we perform an extensive time delay to answer the following questions. (1) How does Calcspar perform compared to the state-of-the-art approach? (§5.2) (2) The impact of several techniques of Calcspar on performance. (§5.3, §5.4, §5.5) (3) The sensitivity analysis of Calcspar (§5.6).

5.1 Experimental Setup

Test platform. We employ the most widely deployed AWS as our test platform. The EC2 instance is m5d.2xlarge, configured with 8 vCPUs and 32 GB Memory. A representative io2 storage volume with 100 GB capacity and 1000 IOPS is used by default for performance evaluation.

Comparisons. We compare Calcspar with RocksDB and the other three state-of-the-art key-value stores. They are: 1) Autotuned RocksDB [6]: isolating the I/O bandwidth between user requests and internal flush/compaction operations to improve tail latency. 2) SILK [10]: Opportunistically allocates bandwidth to different internal I/O operations and allows low-level Compaction preemption. 3) CruiseDB [25]: Maintains SLAs employing an adaptive access mechanism based on memory usage, removes L0, and optimizes memory buffer. To make a fair comparison, all the databases take 4 threads for compaction and 4 for flushing. The default key, value, and SSTable sizes are set to 16B, 256B, and 8MB. The size of Memtables is set to the default value for RocksDB. A cache space of 500MB is opened for each database.

Table 2: YCSB workload characteristics.

Workload	Description
A	write-intensive:50% Update, 50% Read, Zipfian
B	read-intensive: 5% Update, 95% Read, Zipfian
C	read-only: 100% Read, Zipfian
D	read-latest: 95% Read, 5% Insert, Latest
E	scan-intensive: 5% Update, 95% Scan, Zipfian
F	write-intensive:50%Read,50%read-modify-write,Zipfian

Benchmarks. Two benchmarks, Mixgraph [12] and YCSB [15] are used to evaluate performance. YCSB is a widely used benchmark for evaluating the key-value store systems, providing six workloads configurations and key-value pair access distribution models listed in Table 2. YCSB can also provide uniform distribution workloads. Mixgraph is the latest benchmark test developed by Facebook. The workload is more spatially localized to simulate Facebook production workloads better and generate more accurate key-value queries. Benchmarks run in 10 threads in all the key-value stores by default, except for SILK, as multi-threading is not supported. In all experiments, 100 million Key-value pairs are first inserted into the key-value store system, and the key-value store has about 25 GB of data in its initial state.

5.2 Overall Performance

We first use the latest Mixgraph with fluctuating load characteristics to evaluate the overall performance of the five key-value stores on the cloud. Then we evaluate the performance using the YCSB benchmark and explore the effect under uniform load using the YCSB benchmark. To guarantee the fairness of the evaluation, the hardware resource allocation is the same for each key-value store. All evaluations start by randomly writing 100 million key-value pairs and executing one million requests.

The Mixgraph benchmarks. Figure 14 shows the performance for different read/write ratio configurations under Mixgraph. Since read requests affect IOPS more, the ratio of read requests is increased by varying the number of write requests. Based on the comparison of test results, the following conclusions can be drawn: 1) The throughput of Calcspar is better than other systems under all read ratios. In Figure 14(a), Calcspar throughput exceeds paid IOPS the most because of the high spatial locality of the Mixgraph load that is fully exploited. 2) Calcspar significantly reduces the average latency. As seen in Figure 14(b), the average latency of Calcspar does not exceed 200μs, which is 45$\sim$66% lower than the average latency of other key-value store systems. 3) Calcspar achieves a lower and more stable tail latency. Figure 14(c) shows the statistical plot of 99th percentile latency, and it can be seen that Calcspar has the smallest box plot volume with almost no outliers of extra-long delays. The 99th percentile latency can be stabilized at around 0.55ms with minimal fluctuations. CruiseDB also reduces tail latency by limiting request access, but it is unstable and sacrifices throughput.

The YCSB benchmarks. We use YCSB workloads with stronger time locality for performance evaluation. Figure 15 and Figure 16 show the throughput and the 99th percentile latency for each key-value stores system under the six workloads of YCSB. Calcspar can guarantee that the throughput is not lower than RocksDB in all cases, and the throughput can be improved under workload F. Throughput is not further improved due to the cloud storage IOPS budget constraints. Furthermore, the hot key of Zipfian distribution is scattered throughout the whole key space, resulting in underutilization of aggressive prefetching cache performance. Calcspar's main goal is optimizing latency, and as shown in Figure 16, the 99th percentile latency of Calcspar is reduced by 50% compared to other schemes. The best access latency is obtained because Calcspar is throttling the number of I/Os per second to access the cloud storage volume within a range of no more than paid IOPS. And cache redirection solves the queuing latency problem, so the latency per request is low. In other systems, requests beyond the paid IOPS will only to debit without strict

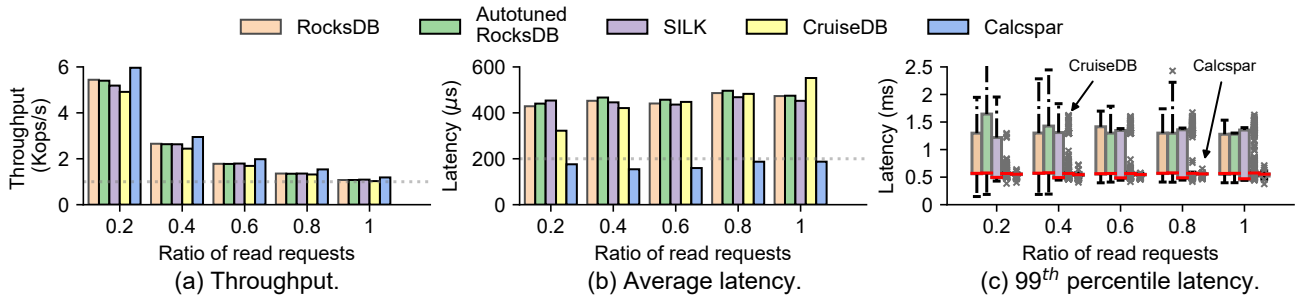

Figure 14: Evaluation results with different read request ratios under Mixgraph workload.

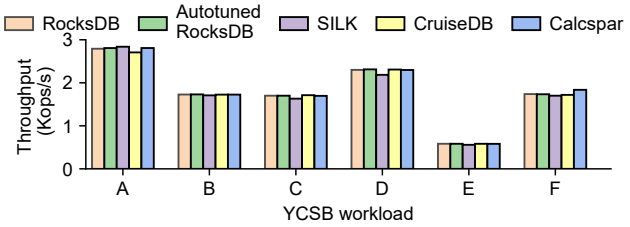

Figure 15: Throughput under YCSB workload.

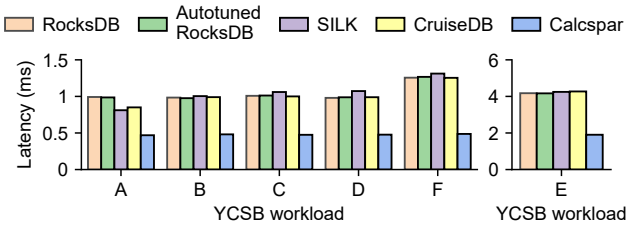

Figure 16: The 99th percentile latency under YCSB workload.

limits, and the request latency will be significantly higher.

For uniform workloads. We further use YCSB to evaluate the performance of calcspar under a uniform workload. Figure 17 shows that although the fluctuation-aware caching is less efficient under Uniform load, Calcspar exhibits shorter latency due to its flexible I/O throttling. CruiseDB's adaptive access mechanism can also reduce the average latency, but its tail latency increases to 20ms.

5.3 Congestion Mitigation Effectiveness

Here, we investigate the effect of Calcspar on solving thread congestion. We first test the latency performance under different threads and then explore the effect of the time window allocation IOPS strategy.

Avoid multi-thread congestion. Figure 18 shows the average latency and 99th percentile tail latency of the experiment running the default Mixgraph load on io2 with 1k paid IOPS using different user threads. Calcspar can keep the average latency at 175μs, 99th percentile latency always around 500μs, and the other schemes keep increasing both the average latency and 99th percentile latency as the number of threads increases. On cloud drives, the 99th percentile latency growth reaches 60$\times$ under 20 threads. Because other Key-value stores limit bandwidth without restricting the granularity of I/O. Therefore, as the number of threads increases, congestion becomes increasingly severe. Calcspar utilizes the EBS rate-limiting model, and the Congestion-Aware IOPS allocating avoids requests queuing in the I/O domain queue.

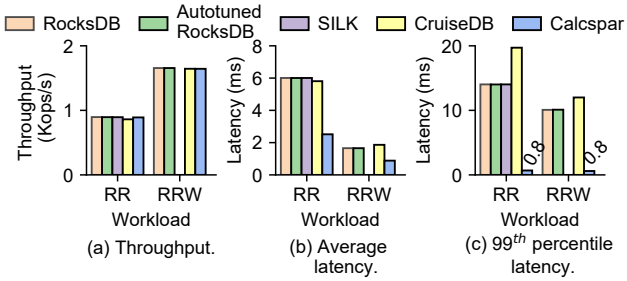

Figure 17: Evaluation results under Uniform workload. "RR" means random read, "RRW" means 50% random read and 50% random write.

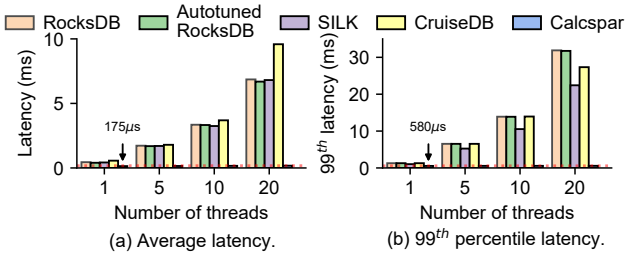

Figure 18: The latency with different user threads.

IOPS allocation strategy evaluation. We compared Calcspar's time window policy allocate IOPS (TWA) with three other IOPS allocation schemes: contention IOPS without allocation (NA), static allocation of IOPS among three queues in the ratio of 6:3:1 (SA), and dynamic allocation of IOPS based on the usage of the highest priority queue (DA). Using mixgraph load, where 5% are read requests and 95% are write operations, guarantees enough flush and compaction operations with 10 user threads running. The evaluation results in Figure 19 show that the time window strategy has a good throughput and 99th percentile latency is reduced by 50% compared to the NA. The SA has the worst performance because of resource wastage. The DA can fully utilize IOPS and the average latency is the lowest, but the 99th percentile latency is higher than TWA because the requests in other queues will block user requests.

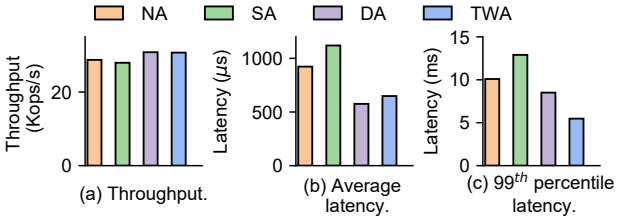

Figure 19: Performance of four IOPS allocation schemes.

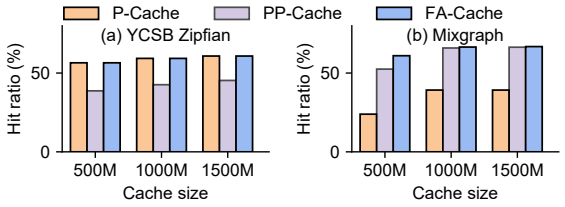

Figure 20: Hit ratios of different caching schemes under different workloads.

5.4 Cache Effectiveness

Then, we evaluate the effect of Fluctuation-Aware Caching regarding the cache hit ratio, the impact of cache size and the corresponding read amplification.

Cache Hit Ratio. We compared Calcspar's fluctuation-aware cache (FA-Cache) with only passive cache (P-Cache) and only proactive prefetching cache (PP-Cache) under YCSB and Mixgraph workloads. Figure 20 shows that FA-cache has the highest hit ratio under both workloads. For YCSB load, the hotkeys are randomly distributed in the key space, so it is more suitable for P-cache with small prefetching. However, under Mixgraph load, the hotkeys are relatively concentrated and more suitable for PP-cache. Calcspar's FA-cache combines these two advantages. Also, we can find less than 5% of data space can achieve up to 60% hit rate, which can increase the overall capacity of the system at a lower cost.

Impact of Cache Sizes. We increased the cache size from 0.1% to 20% of the total number to explore its impact on performance. Figure 21 shows that Calcspar outperforms RocksDB regarding latency at any cache size. With 1% cache size, Calcspar can reduce the average latency to below 200μs. RocksDB's block cache requires the cache size at least 5% of the total data to get an average latency close to 200μs, but the 99.9th percentile latency is still as high as 1200μs.

Read amplification. We count the number of read requests sent from the client side and the I/O accesses to the EBS to explore the effect of Calcspar in mitigating read amplification. We use Mixgraph default configuration for evaluation and

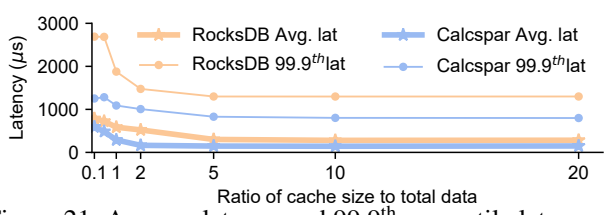

Figure 21: Average latency and 99.9th percentile latency of RocksDB and Calcspar with different cache sizes under Mixgraph load.

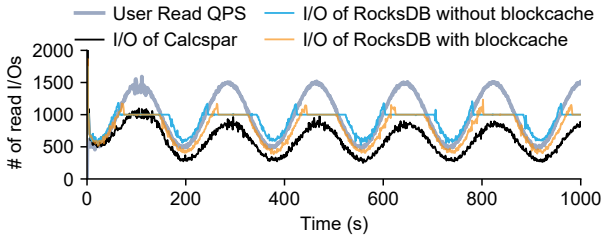

Figure 22: Read QPS and number of I/Os send to EBS.

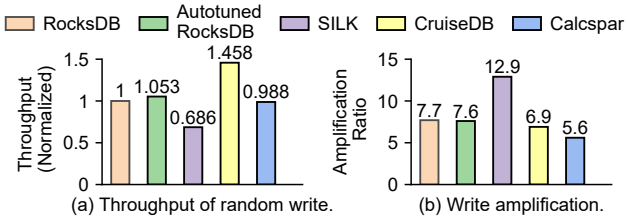

Figure 23: Write performance.

compare it with RocksDB without cache and RocksDB with the same size (500MB) blockcache turned on. In Figure 22, the results show that Calcspar sends the least number of I/O requests to EBS with the same user requests, even during peak periods, because the fluctuation-aware caching can cache L0 and L1 in advance during low-load periods. RocksDB with blockcache enabled is limited by the IOPS budget during high load, and RocksDB without blockcache enabled sends more I/O to EBS during low load because of read amplification.

5.5 Impact of Opportunistic Compaction

Write performance. We compare the performance of Calcspar with the rest of the schemes under full write load. Figure 23(a) shows the throughput of 10 threads writing 100 million key-value pairs randomly (except for SILK single threads). Compared to RocksDB, Calcspar's write performance is only 1.2% lower. Both Autotuned RocksDB and CruiseDB allocate bandwidth to prioritize upper-level write operations, which improves performance. SILK can only write in a single thread, so performance is poor.

Write amplification. Figure 23(b) shows that Calcspar reduces write amplification the most because Calcspar blocks L0 level to L1 compaction slightly. However, the write performance can not be improved because of IOPS allocation. CruiseDB removes the L0 level to reduce the write amplification. SILK prioritizes the execution of flush and L0 level compaction, resulting in frequent reads and writes of L1 level data, which in turn causes higher write amplification.

5.6 Sensitivity Analysis

Paid IOPS of EBS. We first evaluate five KV stores on io2 with different paid IOPS using Mixgraph to explore the impact of paid IOPS on performance, where Mixgraph uses the default read/write configuration and ensures that the average value of load fluctuations is equal to paid IOPS. Figure 24(a) shows that regardless of the paid IOPS of io2, Calcspar en-

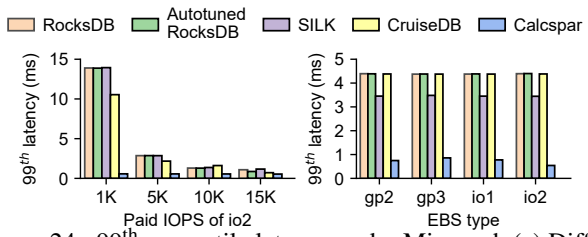

Figure 24: 99th percentile latency under Mixgraph.(a) Different paid iops. (b) Different EBS type.

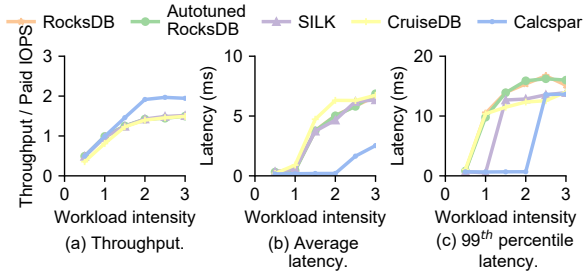

Figure 25: Performance at different workload intensities.

sures the 99th percentile latency stays low. As the paid IOPS increases, the request latency under high pressure becomes progressively smaller, but at 15k paid IOPS, Calcspar's 99th percentile latency is still 24% ~50% less than other solutions.

Type of EBS. We use four types of EBS volumes with 3000 IOPS to explore the applicability of Calcspar on AWS EBS. Figure 24(b) shows that Calcspar exhibits the lowest 99th percentile latency on all four EBS compared to the remaining four options. As the performance of the storage volume gets better, the 99th percentile latency of Calcspar gets lower, e.g., io2 has a lower 99th percentile latency than gp3 by 200µs. In contrast, the other schemes have a higher latency or no change. The results fully illustrate that our scheme is suitable for various types of cloud block storage devices in AWS.

Workload pressure. We evaluate the pressure resistance by varying the workload intensity, which is the ratio of the average read requests of Mixgraph fluctuating load to paid IOPS of io2. Figure 25(a) shows that Calcspar can handle up to twice the paid IOPS for read requests. Figure 25(b) shows that Calcspar can guarantee an average latency of 200μs even at twice the workload, while the rest of the solutions have higher latency when the read workload exceeds paid IOPS. The 99th percentile latency of Calcspar is still the smallest at high workloads in Figure 25(c). Overall, Calcspar has good pressure resistance and adaptability.

Different Cloud Vendors. To demonstrate the versatility of Calcspar, we conducted a performance comparison between Calcspar and vanilla RocksDB on three prominent cloud provider platforms, namely AWS, Alibaba Aliyun [7], and Microsoft Azure [29]. Our evaluation encompassed instances equipped with 8v CPUs and 32GB RAM, coupled with cloud block storage volumes configured with 5000 paid IOPS. Specifically, AWS utilized EBS io2, Aliyun utilized ESSD PL1, and Azure employed Azure managed disk Premium SSD v2. Figure 26 illustrates the evaluation results,

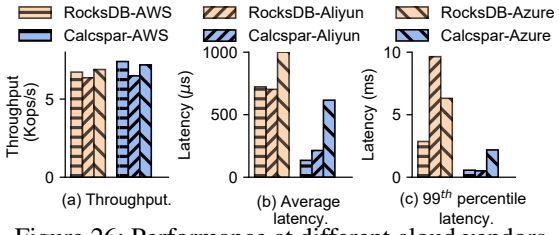

Figure 26: Performance at different cloud vendors.

highlighting Calcspar's better performance across all three cloud storage types when compared to vanilla RocksDB. On Aliyun, Calcspar exhibited notable achievements, with a significant decrease in the 99th percentile latency from 9.6ms to 509μs and an average latency reduction of 69.5%. These improvements arise from Aliyun's utilization of a throttling mechanism that triggers longer latencies when the number of requests exceeds the contractual agreement, which Calcspar is designed to avoid. While Azure managed disk Premium SSD v2 demonstrated comparatively higher latency than the other two cloud block storage devices, Calcspar still highlights its efficacy and managed to reduce both average and 99th percentile latencies.

6 Discussion

Cloud Storage Vendors. We selected AWS EBS as a representative cloud storage platform due to its significant market share (32%) and its provision of easy-to-use, high-performance block storage at any scale. While different cloud storage vendors may vary in terms of equipment and pricing for block storage volumes, they all follow an IOPS-based contract model to deliver services to the public. This model is also adopted by other providers such as Microsoft Azure [29], Google Cloud [18], and Alibaba Aliyun [7]. During periods of bursty large numbers of requests, it is common for paid IOPS to be exceeded, leading the cloud provider to enforce request processing limits in order to uphold the contract. However, simply restricting request processing or increasing the latency of each request would result in higher tail latency. Calcspar mitigates such issues through a series of techniques that can be applied across different cloud storage platforms. Figure 26 validates Calcspar's design on various representative cloud storage vendors.

Throttling Models. Cloud providers employ different measures to maintain contract compliance and minimize the impact on other users within the cloud environment. AWS EBS utilizes an overdraft rule, which offers little opportunity for applications to prioritize their request queues. Experiment 3 in Section 2.2 demonstrates that once requests are queued in EBS, they cannot be withdrawn to accommodate more urgent tasks. The overdraft rule, in effect, obscures the traffic congestion from users. On the other hand, blocks user requests for a relatively long duration, resulting in prolonged tail latency. This situation is unfavorable as it halts request processing during that period. Other cloud storage providers

employ varying throttling mechanisms, often achieved by introducing increased latency. Consequently, enabling priority masks or rejecting overdraft requests would be beneficial. Another possibility is to allow users to employ customized cache algorithms to digest temporary workload peaks.

7 Related Work

Latency-aware Storage Stack. Many works focus on providing fast I/O services by optimizing the I/O stack [11] to exploit the μs-scale latency of storage devices. Blk-switch [20] brings network switch techniques into the block storage stack and proposes an I/O scheduler, thus solving the head-of-line blocking problem and achieving low tail latency. FastResponse [26] targets on *ultra-low latency* SSDs, and it coordinates the scheduling of different I/O levels to mitigate I/O interferences. PAIO [28] proposes an I/O optimization framework, enabling flexible I/O scheduling policies through I/O information propagation. However, these efforts focus on either how to fully explore the potential of multi-core/hardware resources or how to alleviate contentions between latency-sensitive and throughput-demanding applications. Calcspar targets LSM-Tree key-value stores over the cloud storage, and Calcspar addresses the I/O contentions between user read I/Os and LSM internal I/Os, achieving low latency.

LSM Store Compaction. Compaction I/O operations within LSM-Tree will compete with user read operations, resulting in long-tail latency. There are approaches to reduce data writes by delaying or merging some compaction actions [31, 33, 41]. Some studies reduce contention for storage devices by tuning and scheduling internal tasks [9, 10, 13]. Some adaptive compaction schemes have also been proposed for performance optimizing [16, 35]. However, these are all compaction optimizations targeting bandwidth-constrained SSDs. Optimizing compaction operation alone is not enough, as user-read requests already dominate the paid IOPS.

Software and Hardware Co-design for Latency. Hardware and software coordination can better reduce long-tail latency. For example, RStore [24] fully utilizes the advantages of multiple cores to reduce the tail latency of in-memory key-value stores. BCW [37] achieves low write latency on HDDs by reshaping patterns that utilize the HDD internal buffer. Vigil-KV [23] demonstrates the latency state of NVMe SSDs using a predictable latency mode interface and ensures controllable tail latency by scheduling compaction/flush operations and client requests.

Data Cache. Prefetching or caching frequently accessed data to a high-performance cache device can greatly improve read performance by reducing the number of slow I/O operations. Leaper [40] leverages machine learning methods to predict hot data and proactively prefetch them to the cache. AC-Key [38] aims at LSM cache mechanisms in the memory, hybrids different kinds of cache objects, and dynamically adjusts their sizes to improve cache efficiency. To reduce cache invalidation due to hotspot shifting and internal compaction, A parallel cache prefetching method [43] is proposed to prefetch the most valuable blocks into the cache by hotspot key-value pair tracking. Thus, read operations are not affected by the compression. LSM-tree [36] uses a compaction buffer to minimize these cache pollutions.

Reduce Storage Cost. Cloud storage users are often sensitive to storage costs, and they usually hybrids cloud storage volumes of different prices to cut the overall storage cost. Mutant [42] controls the overall storage cost by adaptively tuning the size of expensive high-performance storage volumes. PrismDB [32] pines hot data in the upper LSM levels to reduce storage costs. RocksMash [39] stores all metadata and frequently accessed data in local storage, while putting the rest in the cloud for cost efficiency. SA-LSM [44] uses survival analysis algorithms to predict hot and cold data at records granularity, and schedules compaction with external services to reduce costs by storing hot and cold data separately. Calcspar trades higher IOPS capabilities with the smaller memory or higher performance storage devices as cache, rather than simply purchasing more IOPS for cloud volumes.

8 Conclusions

This paper profoundly explores and models the latency mechanism of AWS's EBS cloud storage. Experimental analyses show that limited IOPS budgets in EBS contracts cause high latency spikes to endpoint users when requests exceed a threshold. We specifically investigate the LSM-tree based key-value store, which both amplifies external workload fluctuations and develops internal request congestion. We propose Calcspar, a contract-aware LSM store for cloud storage with reduced latency spikes. The fluctuation-aware caching strategy in Calcspar reduces 99th percentile latency by more than 66% under varying workload pressures without incurring noticeable caching costs. The congestion-aware IOPS allocation further avoids up to 60$\times$ tail latency spikes by assigning different priorities for internal operations and preventing thread I/O contentions. Our sensitivity study demonstrates that Calcspar is generalizable for different cloud storage volumes. Accordingly, Calcspar can be offered as a companion service to cloud storage providers, significantly balancing the performance and cost for endpoint users.

Abstract

Big data applications extensively use cache techniques to accelerate data access. A key challenge for improving cache utilization is provisioning a suitable cache size to fit the dynamic working set size (WSS) and understanding the related item repetition ratio (IRR) of the trace. We propose Cuki, an approximate data structure for efficiently estimating online WSS and IRR for variable-size item access with proven accuracy guarantee. Our solution is cache-friendly, thread-safe, and light-weighted in design. Based on that, we design an adaptive online cache capacity tuning mechanism. Moreover, Cuki can also be adapted to accurately estimate the cache miss ratio curve (MRC) online. We built Cuki as a lightweight plugin of the widely-used distributed file caching system Alluxio. Evaluation results show that Cuki has higher accuracy than four state-of-the-art algorithms by over an order of magnitude and with better stability in performance. The end-to-end data access experiments show that the adaptive cache tuning framework using Cuki reduces the table querying latency by 79% and improves the file reading throughput by 29% on average. Compared with the cutting-edge MRC approach, Cuki uses less memory and improves accuracy by around 73% on average. Cuki is deployed on one of the world's largest social platforms to run the Presto query workloads.

1 Introduction

Nowadays, distributed data-intensive frameworks like Flink [9], Spark [49], Presto [37], which frequently read data from tables and files, commonly use a caching layer as one key optimization to improve data accessing performance. However, allocating the right amount of cache storage can be non-trivial: excessive resource unnecessarily increases the cost, while insufficient capacity degrades the performance. Dynamic online workloads [24, 42] make this problem even more challenging. Particularly, when operating the Presto deployments, we introduced Alluxio [1, 25] as its caching layer and observed a high cache hit ratio. It was important, however, unclear to us based on existing cache metrics to tell if we could reduce the cache capacity of Presto servers while maintaining the high cache hit ratio.

Existing approaches about how to tune the cache capacity can be mainly summarized into four categories: (1) Rule-based approaches [21, 24, 34, 42] tune cache sizes based on cache metric related rules. However, it always adjusts the cache size to fit the working set size blindly and frequently. (2) ML-based approaches [4, 28, 30, 33, 35] train machine learning models with historical data offline and predict proper cache sizes in the future. Nevertheless, the model might be inaccurate under online dynamic workloads. (3) MRC-based approaches [15,19,22,36,40,41,45,51,52] explore the optimal cache size by exploring a miss ratio curve (MRC) as the function of the cache size. However, MRC is generated by assuming each item has the same size or cost, which is not always true in practice. (4) Window-based approaches [5, 11, 20] determine the cache capacity by estimating the cardinality of items in a sliding window. But, it can not estimate the working set size of items in variable size or organized in multiple scopes.

Understanding the online accurate working set size (WSS) and item repetition ratio (IRR) is important for tuning appropriate cache capacity [35, 51].

Accurate WSS estimation supports better cache capacity planning, leading to higher cache hit rate and significant end-to-end performance improvement. In the cluster, WSS and IRRs insight need to be captured in real-time since the data access load may vary dynamically. In addition, it is imperative to use low CPU and memory resource, as it is long-running and may scale to dozens and hundreds of nodes. What's more, to monitor WSS and IRR of various applications, it needs to track the online items that have different sizes and structure levels. To sum up, ideally, to effectively tune the cache size online, an accurate, time-efficient, dynamic, light-weighted approach for tracking the working set size (WSS) and variable-size item repetition ratio (IRR) in a sliding window is needed.

We propose Cuki, an approximate data structure for estimating the online WSS and IRR for variable-size item access with proven accuracy guarantee and little overhead in the slid-

ing window. Generally, we face three challenges in the design and usage of Cuki.

The first challenge is how to estimate the WSS and IRR online with little resource and proven accuracy. The item size can span over 8 ~ 9 orders of magnitude [24, 42] in the production environment. Therefore, inaccurate tracking items such as sampling may lose critical items, which may cause a huge drop in WSS estimation. The amount of data accessed in a time window can be quite large. It would be very time-inefficient and space-costly to store and calculate the item information online. To address this challenge, we carefully design a compact data structure with the approximate and item-wise tracking mechanisms.

The second challenge is how to achieve good scalability in high concurrency scenarios like multi-threading. It is common for real-world applications to access data concurrently. As the number of threads increases, the consistency and efficiency of concurrent access issues become obvious. To address this challenge, we adopt and propose a series of fine-grained concurrency control methods (§ 4), such as opportunistic aging.

The third challenge is how to judge the cache status under various scenarios with Cuki. It is non-trivial to tell whether the cache is overloaded or underused at a moment due to the variety of WSS and the cache-friendliness of the applications online. To address this challenge, we get the cache status insights by comparing the real cache size and the cache hit ratio with the WSS and IRR estimated by Cuki online, respectively.

By working with both Presto and Alluxio open source communities, our contributions can be summarized as follows:

- **Lightweight and Accurate WSS/IRR Estimation:** We design an approximate data structure, called Cuki, to estimate WSS and IRR online over a sliding window with little resource overhead and proven accuracy. Cuki uses an item-wise fine-grained tracking mechanism to reduce WSS error caused by missing critical items (*e.g.,* large ones). In our experiment, with a 96KB memory space size, Cuki can provide 99.07% accuracy for a 511MB working set size over the MSR data trace (§ 6.3). In addition, Cuki supports multi-scope WSS estimation with an easy feature extension.
- **Fine-grained Concurrency Control Methods:** To improve the efficiency of the concurrent access in Cuki, we propose opportunistic aging which decreases the lock contention risk in high concurrency scenarios. In addition, we adopt the segmented lock and two-phase based insertion mechanisms to guarantee data consistency in concurrent access.
- **Adaptive Online Cache Capacity Tuning Framework Using Cuki:** Finally, we propose an adaptive online cache capacity tuning mechanism based on Cuki. It judges whether the current workload, such as table querying and file reading, is cache-friendly or not, and further tells whether the cache system is overloaded or underused. Accordingly, the proposed cache capacity tuning mechanism can adjust the cache storage size online to fit current workloads.
- **Extensive Evaluation and Application Practice:** Experimental results on extensive benchmarks show that Cuki achieves over 10× higher accuracy with more stable performance compared with state-of-the-art methods. The cache tuning mechanism using Cuki can reduce the table reading latency by 79% on average, and improve the file reading throughput by 29% on average, respectively. Compared with the cutting-edge MRC approach, Cuki uses less memory and improves the accuracy by 73% on average. In addition, end-to-end real-world query workload experiments show that the proposed approach is effective for large-scale cache systems.

2 Background

Cuckoo Filter: A Cuckoo filter [17] is a well-known approximate data structure for deciding whether a given item is in a set or not. It consists of several buckets, and each bucket has four slots by default. Each item has two candidate buckets in a Cuckoo filter. To save space, a Cuckoo filter stores the fingerprint of an item rather than the item itself.

To insert item x, the Cuckoo filter first gets the fingerprint of x as f. Then, the Cuckoo filter hashes the x to get the first candidate bucket position b_1. The other candidate bucket position can be obtained by computing $b_2 = b_1 \oplus hash(f)$. The item x will be inserted into an empty slot of these two candidate buckets. If both candidate buckets are full, the Cuckoo filter relocates other items iteratively until it finds an empty slot. To check whether item x is already in the set, the Cuckoo filter first computes the two candidate buckets of x as described above. Then, it checks the items' fingerprints in these two buckets. If the Cuckoo filter finds one's fingerprint is the same as x's fingerprint, it returns true. Otherwise, it returns false.

Miss Ratio Curve: A key challenge of cache resource allocation is understanding the relationship between the cache hit ratio and the cache size. The miss ratio curve (MRC) is a common approach to figure out this relationship. The basic idea of MRC is to generate a miss ratio curve as a function of the cache size. With the generated miss ratio curves, users can allocate the cache size properly by observing the trend of the cache miss ratio with the cache size.

A traditional way [29] to generate a miss ratio curve of the specific trace is to compute the reuse distance of each item. The reuse distance of a specific item x represents how many items have been cached since the last access of the x. Since the reuse distance of each item has been recorded, this approach will give an ideal miss ratio curve. However, the online overhead of this approach is non-negligible.

To reduce the overhead of generating MRCs, recent research work use sampling techniques. Counter Stack [45] uses down-sampled and pruned probabilistic counters. SHARDS [41] samples the input trace. AET [22] uses average eviction time to construct MRC. Mini-sim [40] extends SHARDS by using miniature simulation.

However, these methods [22, 40, 41, 45] have three limitations. First, they need to store or process a separate I/O trace. Second, they use sampling techniques, which are likely to miss heavy hitters (large-sized items) and incur inaccuracy. Third, they focus on processing fixed-size item accesses and need some redesign to handle variable-size objects. RAR-CM [51] uses the hashmap to store the item access information and estimate the item repetition ratio (IRR) for generating an approximate MRC. However, RAR-CM is still primarily designed for fixed-size item access and needs 128 bits to store each item. Our Cuki only needs 52 bits for each item to support variable-size item access MRC generation and is around 73% more accurate than RAR-CM (§ 6.7).

Though the overhead for Cuki to generate MRC is low, MRC generation brings additional overhead for Cuki after all. Since WSS/IRR estimation is usually sufficient for cache size tuning in our environment, we finally choose the WSS/IRR estimation as the main approach.

Prior Cache Size Tuning Approaches: The critical difficulty in improving cache utilization is tuning the proper cache size online with limited resource. Prior approaches can be mainly summarized into four categories:

- **Rule-based:** Rule-based approaches [21, 24, 34, 42] observe cache usage metrics. If the observed metrics exceed or are less than the predefined threshold, it tunes the cache size. For example, Pocket [24] increases the cache size when cache usage exceeds 80%. However, due to lacking knowledge of the working set sizes of online workloads, it does not know what the best cache size should be tuned to each time.
- **ML-based:** ML-based approaches [4, 28, 30, 33, 35] train machine learning models with historical data offline for further predicting proper cache sizes according to the workloads online. However, the pre-trained models based on historical data can hardly be adapted to dynamic online workload scenarios which have quite different data access patterns.
- **MRC-based:** MRC-based methods [15, 19, 36, 52] explore the optimal cache size by generating a miss ratio curve (MRC) as a function of the cache size. To reduce the overhead of generating MRCs, several approaches [22, 40, 41, 45] use sampling techniques. However, they are likely to miss heavy hitters, which would incur inaccuracy. Moreover, most MRC-based approaches are designed for fixed-size item access, which might be inaccurate for variable-size item.
- **Window-based:** Window-based methods [5, 11, 20] estimate the cardinality of items in a sliding window. However, they can hardly compute the accurate total size due to being unaware of each item's size with limited memory space and little time cost.

3 Design of Cuki

To efficiently estimate the real-time working set size (WSS) and the item repetition ratio (IRR) of various-granularity data access over sliding time windows, we design a compact approximate data structure called Cuki. In addition, we have theoretically proved that Cuki outperforms the state-of-the-art comparing algorithms in space usage under the same false positive rate. The proof details are moved in Appendix B due to page limitation. In this section, we introduce the main data structure and supported operations of Cuki.

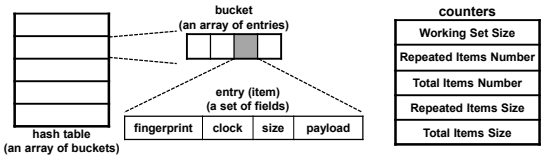

Figure 1: Data structure of Cuki.

3.1 Data Structure

Cuki is built on the Cuckoo filter [17]. The first reason we choose the Cuckoo filter is that it supports deletion so that we can remove stale items. Second, different from the Bloom filter, one item occupies one slot in the Cuckoo filter, so it is easy to extend cells for recording items' size.

In general, Cuki is an approximate membership query data structure with the following features: 1) similar to the Cuckoo filter [17], Cuki stores the items' fingerprints rather than the original data, which is memory-efficient. Different from the Cuckoo filter, Cuki has a more sophisticated design to support time window semantics, working set size estimation, and payload field extension. 2) Cuki supports insertion, lookup, deletion, and aging operations at the item level with efficient concurrency access control mechanisms. 3) Cuki provides built-in efficient and accurate working set size estimation in multi-scopes over the sliding time window based on the lightweight tracking of each item insertion and deletion.

Figure 1 shows the data structure of Cuki. It contains a *hash table* with multiple fixed-length *buckets*, each of which has several fixed-length *entries* to store items. Each entry has four fields to track an item's information: fingerprint, clock value, encoded size, and payload. In addition, there are five kinds of atomic *counters*, including *working set size*, *repeated items number*, *total items number*, *repeated items size*, and *total items size*, which are high-level global metrics. Particularly, *repeated items number* records the number of items that are repeatedly accessed in a sliding window, and the *total items number* is the total accessed items number in a sliding window. Cuki can calculate IRR by simply dividing *repeated items number* by *total items number*. All these five metrics are updated along with inserting or deleting items. Similar to the IRR, the bytes repetition ratio can also be easily calculated as *repeated items size* / *total items size*.

The **fingerprint** field is a succinct representation of an item. Usually, the fingerprint has few bits and is much smaller than the original item size. Moreover, similar to the Cuckoo filter, the fingerprint length of Cuki also offers a trade-off between accuracy and space, *i.e.,* Cuki can

achieve more accurate estimation with longer fingerprints.

The **clock** value represents the freshness of an item. The higher, the fresher. Cuki sets the clock value of an item to a predefined value of MAX_AGE when the item is accessed (insertion or lookup) and periodically decreases it over time by the aging operation. Using s bits for each clock, MAX_AGE is set to $2^s - 1$, where s is an accuracy-to-space trade-off parameter. Suppose the sliding window size is $\mathcal{T}$, the aging operation will be executed every $\frac{\mathcal{T}}{2^s-1}$. The aging operation ensures that the stale items are cleared timely. Moreover, since the aging operation is executed more frequently using a longer clock bits length, there will be fewer errors in sliding windows. Aging operations can work in the background. In addition, we can further amortize the computation overhead by the opportunistic aging strategy in § 4.2.

The **size** field stores the encoded size of each item. There exist some naive several size encoding techniques, such as **Full-size Encoding** which directly stores each item's exact accurate size and **Truncation Encoding** that only stores the higher bits of the item size, since they are more important than the lower bits. To make a better tradeoff between accuracy and space overhead, we propose the **Grouped Size Encoding** technique. It saves the lower bits of each item into size groups. Every prefix has a corresponding size group to record the size of items with the same prefix. Each size group has two counters: *counts* (total number of items) and *total_bytes* (total item size). For insertion, Cuki increases *counts* by 1 and *total_bytes* by the item's size. When an item is removed, Cuki decreases *total_bytes* by the average size *total_bytes*/*counts*, and *counts* by 1. For a prefix length of $\gamma \cdot len$ bits, there are $2^{\gamma \cdot len}$ size groups in total. The space overhead of grouped size encoding is $\gamma \cdot N \cdot len + 2^{\gamma \cdot len} \cdot C$, where C is the bits length of the above two counters for each size group.

Apart from the above size encoding methods, more sophisticated size encoding strategies [6, 7, 14] are also compatible with Cuki. However, these methods require additional computation. Thus, we choose not to use them as the main strategies.

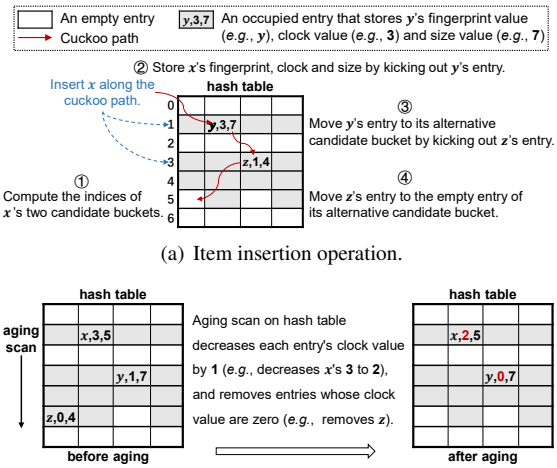
The **payload** field stores auxiliary information of an item. Although the former three fields are enough for the working set size estimation problem, we leave the payload as an auxiliary field for customized needs. In § 3.2, we introduce an example extension usage of the payload field, namely the multi-scope working set size estimation.

3.2 Operations in Cuki

Item Insertion: First, Cuki computes the fingerprint and two bucket indices b_1 and b_2 of a given item x by Equations (1) ~ (3), respectively.

$$f = fingerprint(x), \quad (1)$$
$$b_1 = hash(x), \quad (2)$$
$$b_2 = b_1 \oplus hash(f). \quad (3)$$

Through Equations (1) ~ (3), Cuki can compute two candidate buckets by fingerprint without original item information. Next, it searches for an empty entry in the two candidate buckets. If successful, Cuki stores the item's fingerprint and encoded size in that entry and initializes the entry's clock value to MAX_AGE. Otherwise, it relocates other entries iteratively until it finds an empty entry. Specifically, Cuki finds a cuckoo path in the hash table [18]. The cuckoo path starts with a candidate bucket and ends with an empty entry. Cuki performs the insertion by moving items along this cuckoo path. For example, the red color line in Figure 2(a) is a cuckoo path, which starts with the bucket 1 and ends with the bucket 5. For inserting x into bucket 1, the entry y in bucket 1 will be kicked out to bucket 3. This leads the entry z in bucket 3 will be kicked out to bucket 5. The Cuckoo path length will grow as item insertion, which might lead to long tail latency. We will discuss how to mitigate this in § 4.1.



(a) Item insertion operation.

(b) Aging operation.

Figure 2: Illustration of insertion/aging operations in Cuki.

Item Lookup: Cuki's item lookup first computes the fingerprint and two bucket indices of a given item x by Equations (1) ~ (3). Then, it checks if there exists an entry that matches the fingerprint within the two candidate buckets. If yes, it resets this entry's clock value to MAX_AGE and returns true. Otherwise, it returns false.

Item Deletion and Aging: Cuki supports removing an entry (item) by the item deletion operation or the item aging operation (§ 4.2) at an item's maximum age. Cuki's deletion method first looks up the candidate buckets which are described above. Then, it removes the entry which matches the fingerprint.

Item updating: If an item's attribute (*e.g.,* size) changes, Cuki needs only one-single table access to swiftly alter the hash table entry's fields without searching the cuckoo path. If an item's ID changes, Cuki considers it a new insertion. The old item can be deleted ad-hoc or via aging with performance-accuracy tradeoff. In addition, data updates are non-common in big data OLAP applications.

It is not trivial to automatically remove stale items from the sliding window. A straightforward accurate solution is to

record all item IDs and timestamps (64 bits). This method requires too much memory because of the large number of timestamps. In recent years, some methods [3,5,20] try removing stale items without timestamps. However, as we analyze in § 6.3, these methods are either poorly memory utilized or inaccurate. Different from these methods, the clock algorithm [13] can remove stale items in time with little memory overhead (8~16 bits, as shown in § 6.2).

Therefore, we introduce *clock* into our data structure. Every entry in Cuki is associated with a clock value. Once an entry's clock value reaches zero, it should be removed because of the staleness. This can be done by periodical aging operations in the background. Specifically, suppose the length of the sliding window is $\mathcal{T}$, the bits length of the clock field is s, then the aging period of Cuki is $\frac{\mathcal{T}}{2^s-1}$. The length of window $\mathcal{T}$ can be either time-based or count-based [11, 20]. The time-based sliding window contains items that arrive in the last $\mathcal{T}$ time units. The count-based sliding window contains the last $\mathcal{T}$ items. In each aging operation, it iterates the whole hash table in order and decreases each entry's clock value by 1. If an entry's clock value is already down to zero before aging, Cuki deletes this entry. Figure 2(b) shows an aging example. For items x and y, the aging operation decreases their clock values by 1; while for item z, whose clock value was zero, it is removed. Though using clock to remove stale items can save much memory, it brings errors in results. We have put the theoretical analysis of the above statement in Appendix B.1 due to space limitation.

Entire Working Set Size Enquiry: Besides the above item-level operations, Cuki also natively supports working size-level operations, such as the entire working set size enquiry.

In fact, computing the entire WSS by online scanning the entries in a full hash table and summing up their sizes is very time-inefficient and resource-costly for each query request. Instead, we maintain a counter inside Cuki. The counter tracks the WSS, updates it when inserting or deleting (*e.g.*, by aging) items, and can thus always answer entire WSS enquiry in constant time. The counter is implemented with an atomic class. Thus, it can be concurrently updated safely and efficiently.

Multi-scope Working Set Size Enquiry: In addition to entire WSS enquiry, Cuki also supports WSS enquiry at the scope level, which queries the sizes of specific scopes of the entire working set. Different scopes can be regarded as different parts of the entire working set (*e.g.*, different tables of a database, or different partitions of a table). The information of each scope size is useful for resource scheduling methods [39] and optimizing multi-tenant systems [23, 46]. For example, in a large-scale query engine, we can use multi-scope WSS estimation to find the table with the biggest WSS, which is usually queried frequently. Replicating this table to more nodes of the cache system may help increase the throughput of the query engine.

To estimate multi-scope WSS, we can easily encode the scope information (*e.g.,* mapping scopes to an integer by a hash table) into several bits and store them in the payload field of Cuki. In addition, we need to maintain a set of independent counters (*e.g.,* WSS, repeated items size, and total items size) for each scope in Cuki. For example, when an item x belonging to scope $Scope_k$ is inserted, Cuki will store the encoded scope $Scope_k$ along with the entry of x, and increase the independent WSS counter of $Scope_k$. When the deletion or aging operation removes x, Cuki can figure out the scope that x belongs to, by checking the encoded scope information in its payload field, and decreases the relevant WSS counter of that accordingly.

In practice, for existing methods, it is non-trivial to allocate a suitable memory size for each scope without prior knowledge of each scope's cardinality. Instead, in Cuki, the items of different scopes can share the same total hash table space, by using the encoded scope information in their payload fields to distinguish from each other. Thus, it is not necessary to allocate static memory space for each scope in Cuki.

4 Concurrency Control in Cuki

4.1 Segmented Lock and Concurrent Insertion

We first introduce the basic concurrency control technique called **segmented lock** adopted in Cuki. Then, we describe how Cuki supports concurrent insertion.

Segmented Lock: Cuki divides the whole hash table into several segments, and each segment is guarded by one single lock. Users can configure the number of buckets per segmented lock to tradeoff lock overhead and contention. On the one hand, the item insertion, lookup, and deletion may access different segments at the same time. To avoid deadlock in operations, we always acquire and release the locks in order. On the other hand, each segmented lock guards a group of adjacent buckets. Therefore, for the aging operation, there is no need to repeatedly acquire a lock for scanning items in the same segment. Moreover, each lock manages a physically continuous space. Benefiting from this cache-friendly design, the aging operation can be executed faster. This is because the aging operation accesses Cuki sequentially.

Concurrent Insertion: It is non-trivial to handle the concurrent insertion operations in Cuki. As analyzed in [18], there will be a false negative error under concurrency when moving items along the cuckoo path. To eliminate the false negative error, similar to [18, 26], we separate the insertion process into two phases: the path discovery and item movement phases. In the path discovery phase, Cuki finds a cuckoo path [18] that starts from two alternative buckets and ends at an empty entry. Then, in the item movement phase, Cuki moves items backward along the cuckoo path. Cuki always acquires locks before each above phase, guaranteeing each operation's atomicity.

With more items inserted into Cuki, the Cuckoo path length increases, which might lead to long tail latency. The item

movement may also fail as analyzed in [26]. The probability of insertion failure is less than 1.75×10^{-5} in their environment. In our experiment and production environment, there is almost no insertion failure most of the time. Also, we find that 97% of Cuckoo paths have lengths below 2, and 99.99% of Cuckoo paths have lengths below 4 in MSR trace with 192KB memory. To totally avoid insertion failure and long tail latency, one can allocate appropriate memory size for Cuki by using space resizing techniques [10, 27, 43, 50]. Specifically, when the load of Cuki reaches the high watermark, according to the solution proposed in [50], we can resize the Cuki's capacity by adding an extra homogeneous Cuki data structure after the existing one. The new incoming items can be inserted into the expanded data structure [50]. Except for this solution, we can adopt "partial-key linear hashing" technique proposed in [43] to increase the capacity of Cuki in a fine-grained fashion. Furthermore, similar to [26], we adopt **breadth-first search** to find an empty entry. It can be theoretically proven that the Cuckoo path found by BFS is shorter than that found by DFS [26].

4.2 Opportunistic Aging

To update the data freshness over the sliding window, Cuki performs aging operations periodically in the background. At each background aging, Cuki scans the whole hash table. It first acquires the lock of each segment, then ages the items in that segment in turn. However, the background aging suffers from the following issues in high concurrency scenarios.

Issue 1. Large fluctuation of estimation result: In background aging, massive obsolete items will be cleared simultaneously. As a result, the estimated working set size varies a lot before and after the aging execution. Therefore, the aging can significantly affect the error in the estimated WSS, which decreases the estimation accuracy and stability. We conduct an experiment to verify this, and it is in Appendix C.1.

Issue 2. Lock contention with user operations: Most operations in Cuki (*e.g.*, insertion, lookup, and aging) require holding the lock first, which causes lock contention among these operations. It brings in two kinds of issues. First, when the aging operation is in execution, if there are too many obsolete items that need to be removed, the other data access operations will be blocked for a long time until the lock held by the aging process is released. It increases the delay of other data access operations. Second, when the aging operation is waiting for execution, if there exist so many insertions or lookup operations, the aging operation might wait a long period before getting the lock. Thus, the obsolete items in Cuki may not be removed in time by aging, which decreases the estimation accuracy of Cuki.

To address these issues, we propose a lightweight concurrency control strategy called **opportunistic aging**. It amortizes the aging operation into the insertion operations in Cuki. It brings two main advantages. First, the full aging task is split into multiple minor aging tasks, making the sliding window move smoother. Second, since fewer entries need to be checked in background aging, it reduces the lock contention risk with the background aging.

Algorithm 1 Opportunistic Aging in Cuki

Input: S_i is the segment to be aged, P_i is the aging pointer of S_i.

1: $N_{oa} \leftarrow$ the number of items to be aged;
2: **while** $N_{oa} > 0$ && $P_i < S_i.length$ **do**
3: /* aging the P_ith buckets of segment S_i */
4: AgingBucket(GetBucket(S_i, P_i));
5: $P_i \leftarrow P_i + 1$;
6: $N_{oa} \leftarrow N_{oa} - 1$;

Specifically, each segment in Cuki has a pointer to track its aging progress. Both opportunistic aging and background aging start working from the pointer's position. N_{oa} items are aged during each opportunistic aging. The pointer advances accordingly. Subsequently, background aging ages the remaining items in each segment from the position of the pointer left by opportunistic aging. If the aging pointer is at the end of the segment, background aging will skip this segment. Therefore, opportunistic aging reduces lock contention.

Algorithm 1 elaborates the procedure of opportunistic aging. First, it computes the number of items that need to be aged (noted as N_{oa}) by the elapsed time from the beginning of the aging period (Line 1). Suppose S_i is the segment to be aged, P_i is the aging pointer (index) of S_i, N_i is the number of buckets in S_i, T is the time interval of each aging period, t_{cur} is the elapsed time from the beginning of the aging period, N_{oa} can be computed by the equation:

$$N_{oa} = N_i \times \frac{t_{cur}}{T} - P_i. \tag{4}$$

It guarantees that the aging progress is consistent with the movement of the sliding window. Besides, to reduce the latency of each insertion operation, we limit the maximum number of items cleared during each opportunistic aging. Then, We conduct the aging operation on the N_{oa} items in the segment S_i (Lines 2-6). The remaining stale items, which have not been removed by opportunistic aging, will be cleared by the background aging.

Regarding accuracy, ClockSketch [11] reveals that some stale items are not cleaned timely by background aging (also analyzed in our Appendix B). Opportunistic aging can mitigate this error by preemptively removing certain stale items before background aging.

5 Cache Capacity Online Tuning Using Cuki

In this section, we show how Cuki can facilitate online cache capacity tuning for many data access applications. First, Cuki can be used in implementing the cache size adaptive tuning mechanism. Based on that, it can accelerate data access, including table querying and file reading. In addition, Cuki can

also help generate miss ratio curves (MRCs), which provides an in-depth understanding of the relationship between the cache hit ratio and the cache size.

5.1 Data Access Application Acceleration

During setting the cache capacity for applications, we are mainly faced with two key cache-related questions: 1) What is the degree of the data access temporal locality for a given data access stream? 2) How to optimize the cache utilization online for a given data access stream?

5.1.1 Adaptive Cache Capacity Tuning Framework

In the following, we introduce the key metrics of the Cuki, which can be used for adaptive cache capacity tuning. To explain how to track and optimize the cache utilization with Cuki, we define the following key metrics.

- **CSS:** The cache space size, which can usually be obtained from configurations or metric monitoring of the cache system.
- **WSS:** The working set size over the time window, which is estimated by Cuki online.
- **CHR:** The realistic cache hit ratio of the cache system, which is often exposed by the cache metric monitor system.
- **IRR:** The item repetition ratio over the time window estimated by Cuki. IRR is computed by $\frac{\|R\|}{\|O\|}$, where O and R are the set of total accessed items and repeatedly accessed items in the time window, respectively.

The proposed adaptive cache capacity tuning mechanism can answer the above questions by tracking WSS and IRR in constant time with Cuki.

IRR measures the data access temporal locality of the application online. Specifically, since every repeatedly accessed item is counted by Cuki, IRR can be regarded as the upper bound of the cache hit ratio for the realistic cache system over the past time window. WSS is the total size of recently accessed items. It reflects the realistic cache demand of the application in the time window. In fact, as we observed in our real-world query service scenarios and other applications reported in existing work [48, 53], the working set size and data repetition ratio do not significantly change in a short period, following the law of temporal data locality. Thus, for a workload, its estimated WSS and IRR over adjacent time windows are likely similar, and we can use the current estimation to optimize the cache capacity for the near future.

Cuki has two main advantages in estimating WSS and IRR. First, it can track the WSS over sliding time windows accurately and stably. Second, it supports updating and querying WSS with constant time complexity, which makes real-time tracking and dynamic adjustment possible.

Figure 3 illustrates how Cuki and the above defined metrics can help to improve the cache system efficiency. Cuki is embedded into cache layer and cooperates with

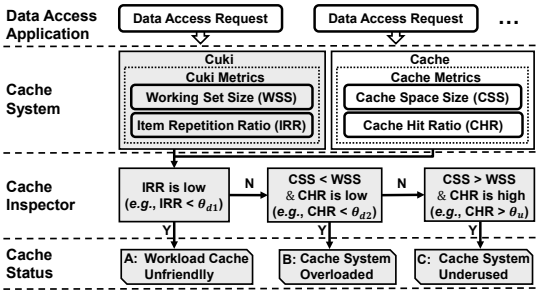


Figure 3: Workflow of adaptive cache capacity tuning mechanism based on Cuki (grey components are proposed by us).

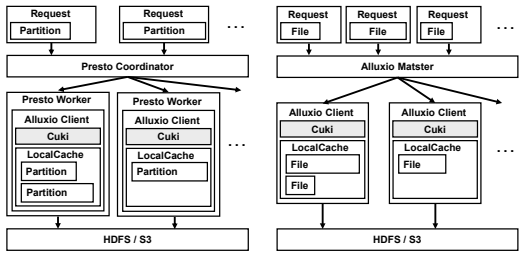
the cache system seamlessly. The cache system has online CSS and CHR metrics, while Cuki contains WSS and IRR statistics during the corresponding time windows. When a data access request arrives, the metrics of the cache system and Cuki are simultaneously updated.

The cache inspector figures out the cache system status by comparing these metrics according to the logic in Figure 3. Based on the cache status and the metrics in Cuki, the cache space size can be appropriately tuned up and down online.

Specifically, the cache inspector will measure the data temporal locality of the workload by checking the item repetition ratio IRR estimated by Cuki. For case A in Figure 3, if IRR is low (smaller than a predefined threshold θ_{d1}, *e.g.*, 50%), the workload itself is not cache-friendly, which means that there exists little repeated data access during the time window. In this case, even if adding huge cache space, we can barely get a higher cache hit ratio CHR.

In other cases, when IRR is high, the cache inspector will check CHR, cache space size CSS, and the working set size WSS over the time window. For case B in Figure 3, when CHR is low (smaller than a predefined threshold θ_{d2}, *e.g.*, 50%) and CSS<WSS, it means that the cache system is overloaded, and there indeed exists some room to improve the cache performance further. This is because the CHR is low, but CSS is still less than the realistic cache demand measured by the estimated WSS. In this case, we can improve the cache efficiency by increasing CSS. For example, the size of an application's data table usually increases as the number of application users grows. The cache system will be under-provisioned if CSS is not carefully configured accordingly. However, with the estimated WSS as the indicator, we can allocate an appropriate amount of cache resource easily online.

Besides, if both IRR and CHR are high (larger than a predefined threshold θ_u, *e.g.*, 90%), it means that the cache system has sufficient cache resource. However, the resource might be wasted when we allocate superfluous cache space over the realistic cache demand measured by the estimated WSS in Cuki (case C in Figure 3). In this case, the cache system is underused. In real-world practice, we can tune down the cache space or leverage this information to optimize the query task scheduling algorithms or the cluster resource routing strategies. For example, we can facilitate the load balance of the cache system by prioritizing scheduling the query tasks



(a) Table querying framework (b) File reading framework

Figure 4: Data access applications using Cuki.

to the compute nodes where the cache is still underused.

In the last case, where both the cache hit ratio CHR and the item repetition ratio IRR are high, and the cache space size CSS matches the estimated realistic cache demand WSS, the cache system is working in healthy status.

5.1.2 Table Querying Acceleration Framework

Figure 4(a) shows how the proposed adaptive cache capacity tuning mechanism is integrated with Presto and Alluxio. Presto is designed for performing SQL query computation in memory. The Presto coordinator distributes the execution plan fragments to Presto workers according to the scheduling strategy. Presto workers execute query plan fragments on the data read from the remote HDFS/S3. Since Presto workers do not store the data, they tend to use Alluxio clients as their cache tier. We implement the Cuki in Alluxio client to track the LocalCache access. In order to use Alluxio LocalCache as Presto worker's cache, Alluxio client Jar files are distributed to each Presto worker.

Each Presto worker queries Alluxio LocalCache inside the same JVM through a standard HDFS interface. First, Presto transforms the queried partitions into several splits. Then, Presto coordinator makes the best attempt to assign the same split to the same worker, which is cache-friendly. If the queried splits are in the Alluxio LocalCache, splits are directly read from local RAM and returned to Presto. Otherwise, it retrieves data from HDFS/S3 and caches the data to local RAM of Presto worker. Cuki monitors the whole process of the split access in each Presto worker and updates WSS/IRR.

5.1.3 File Reading Acceleration Framework

File reading is common in distributed applications, such as online video websites and cloud downloading services. It's common that there exist some hot files which are more likely to be accessed by applications in a nearby time period. Thus, we can use a cache system to accelerate file reading by storing hot files. However, the size of hot files changes as time flies, which makes it hard to determine the proper cache size. As shown in Figure 4(b), the proposed adaptive cache capacity tuning mechanism based on Cuki can be used to solve this problem. The implementation of the proposed adaptive cache capacity tuning mechanism in file reading is similar to the above section. First, the requests for files are sent to the Alluxio master. Then, the Alluxio master checks whether the requested files are stored in one of the Alluxio clients. If so, the requested files are directly read from the local RAM of the Alluxio client. Otherwise, Alluxio reads files from HDFS/S3 and caches the data to the local RAM of the Alluxio client. Cuki monitors the whole file access process in each Alluxio client and updates WSS and IRR accordingly online.

5.2 Miss Ratio Curves Generation Using Cuki

Although WSS and IRR are useful enough for the adaptive cache capacity tuning mechanism, they still can not show in-depth insights into the relationship between the cache hit ratio and the cache size. Generating a miss ratio curve (MRC) as a function of the cache size is a common method to understand the relationship between the cache hit ratio and the cache size thoroughly. It only needs a little change in Cuki to generate MRCs for variable-size item access.

Similar to most MRC generation approaches [40, 41, 51], Cuki needs to store the reuse distance distribution as $RD(x)$. $RD(x)$ represents how many items are re-accessed at x LRU stack size (x is also called as the reuse distance). With $RD(x)$, Cuki can compute $MRC(x)$ simply by $\frac{\sum_{i=1}^{x} RD(i)}{TC}$, where TC is the total items number. To compute $RD(x)$, Cuki tracks each item's clock value and stores the clock distribution as $CD(y)$. $CD(y)$ represents the total size of items whose clock value is y. With CD, Cuki computes the reuse distance of the accessed item by $distance = \sum_{i=y}^{max} CD(i)$, where y is the clock value of the accessed item. Then, Cuki increases the $RD[distance]$ by one. The length of the array CD is the MAX_AGE, which is decided by the clock bits length. Because the clock bits length is a small constant number (never exceeding 16 in our evaluation), the space cost of CD is negligible.

In the following, we introduce how Cuki maintains CD when the item's clock value changes. We use oc and nc to represent the old clock value and the new clock value, respectively. The item's clock value changes when the item is accessed or aged. Then, Cuki decreases the $CD[oc]$ by the item size and increases the $CD[nc]$ by the item size.

6 Evaluation

6.1 Experimental Setup

To be consistent with Alluxio and Presto, we implement Cuki and comparison methods in Java. If not explicitly mentioned, all approaches run on a server with Intel Xeon(R) Gold 6248 CPU with ten 2.5GHz cores. The version of Alluxio and Presto in the experiment is 2.7.0 and 0.266, respectively.

Datasets and Workloads. Experiments are run on both existing benchmarks and real-world datasets with workloads:

(1) **MSR I/O trace dataset [31].** We choose the first 12,518,968 records of MSR web proxy workload

as a typical dataset. Each record consists of three disk access information: timestamp, offset, and size. In our experiment, we use the offset to represent the item ID.

(2) **Twitter dataset [48]**. We choose the representative Twemcache-cluster37 first-hour data which has 10,169,267 records, and the similar Twemcache-cluster35 first-day data as our datasets. The record's key is regarded as the item ID, and the item's size is the sum of key_size and value_size.

(3) **YCSB dataset [12]**. We generate a concatenated trace that contains 10 million records by the YCSB generator [47]. Each base trace follows a zipfian distribution [32] with a skewness factor of 0.99. The item size of each base trace ranges from 512B to 1MB, but follows different zipfian distributions.

(4) **TPC-DS [38]**. Typical I/O bound queries in TPC-DS are used for the end-to-end performance evaluation.

(5) **Real-world query workloads**. We also adopt the real-world query workloads from one of our large scale Presto clusters with 200 servers in § 6.8. The total data access size of the workload is PB-level, and the cache space is TB-level.

Comparison Approaches. Following methods are evaluated:

(1) **ClockSketch [11]**. We add a 32-bit size counter for each cell of ClockSketch for WSS estimation. When a cell is first inserted, its size counter will be set to the item's size.

(2) **SlidingSketch [20]**. We apply SlidingSketch to the Bloom filter [8] for WSS estimation. Each domain of its bucket is used to record the item size.

(3) **SWAMP [5]**. SWAMP stores each item's frequency in a data structure called TinyTable [16]. We extend the TinyTable in SWAMP to record each item's size.

(4) **MBF [3]**. We use the Multiple Bloom Filter (MBF) implementation in the latest Alluxio version [3]. Each Bloom filter [8] is implemented with Google's Guava library [2].

(5) **RAR-CM [51]**. In RAR-CM, each block has a counter to record the last access number. To support variable-size item, we use the RAR-CM's counter to record its last access bytes.

(6) **Cuki and Cuki-OA**. Cuki is the basic approximate data structure proposed in this paper. Cuki-OA further uses the opportunistic aging strategy in § 4.2.

Metrics. We measure accuracy and speed performance by following metrics:

(1) **Weighted Error Rate (WER)**. Let *error_bytes* be the total size of items that are evicted faster or slower than the ideal sliding window. The WER can be calculated by $\frac{error\_bytes}{total\_bytes}$.

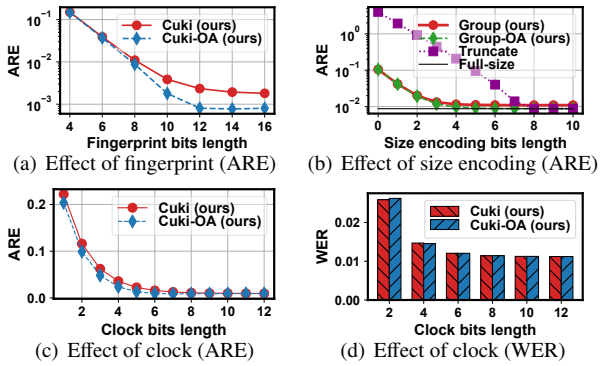
(2) **Relative Error (RE)**. $\frac{w-\hat{w}}{w}$, where w and $\hat{w}$ are exact and estimated working set size (WSS), respectively.

(3) **Average Relative Error (ARE)**. $\frac{1}{|T|}\Sigma_{t\in T}\frac{|w_t-\hat{w}_t|}{w_t}$, where w_t and $\hat{w}_t$ are the exact and estimated WSS at moment t.

(4) **Mean Absolute Error (MAE)**. $\frac{1}{N}\sum|MRC(x)-MRC'(x)|$, where N is the length of reuse distance array, $MRC(x)$ is the hit ratio at the cache size x.

(5) **Throughput**. In file reading experiment (§ 6.7), it is the number of MB/s. In other experiments, it is # of operations/s.

(6) **Query Latency**. The end-to-end SQL query latency.



(a) Effect of fingerprint (ARE) (b) Effect of size encoding (ARE)
(c) Effect of clock (ARE) (d) Effect of clock (WER)

Figure 5: Effects of parameters in Cuki.

Parameter Settings of Approaches. All methods use the same memory size in each experiment. For the count-based sliding window, we set the window size to 262,144 (2^{18}) and measure RE every 64 time units. For the time-based sliding window, we set the window size to one-hour and one-day for the MSR and Twitter traces as different traffics, respectively. The default size encoding approach for Cuki is grouped size encoding. The bits length of the fingerprint, clock and size fields in Cuki are set to 8 if not explicitly mentioned. The settings of the comparing methods are fully tuned to nearly achieve their best performance for a fair comparison.

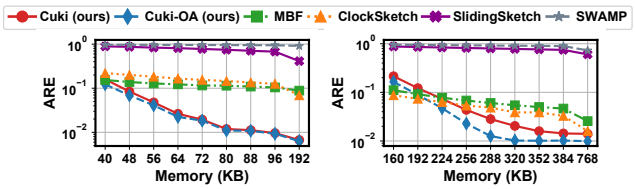
6.2 Effect of WSS Estimation Parameters

To understand the impact of the Cuki's parameters, we conduct experiments on the YCSB trace with a count-based sliding window. The number of entries in Cuki is fixed to 262,144 (2^{18}), just enough to track all the items within a sliding window. To reduce other parameter interference, we use the full-size encoding method by default in this section.

(1) **Effect of fingerprint bits length.** As shown in Figure 5(a), as the fingerprint bits length grows, the ARE of both Cuki and Cuki-OA is dramatically decreased. In fact, an item's key is represented by its fingerprint. Thus, a small fingerprint bits length leads to different items being hashed to the same fingerprint, resulting in high ARE. Moreover, compared with Cuki, Cuki-OA decreases ARE by 37% on average, which verifies the effectiveness of the opportunistic aging strategy.

(2) **Effect of size encoding methods.** Figure 5(b) illustrates the influence of different size encoding methods. The performance of the truncation encoding method using and not using opportunistic aging is the same. Thus we only show the truncation encoding in the figure. The black line represents the ARE of the most accurate baseline (full-size encoding).

As shown in Figure 5(b), on the one hand, full-size encoding achieves the best accuracy but it stores the entire accurate size. Compared with the truncation encoding strategy, the grouped size encoding strategy decreases ARE by 92% on average when the group bits length is small (< 6 bits). Thus, we can conclude that grouped size encoding achieves the best trade-off between memory space and estimation accuracy.



(a) ARE on MSR trace (b) ARE on Twitter trace

Figure 6: Performance comparison of accuracy.

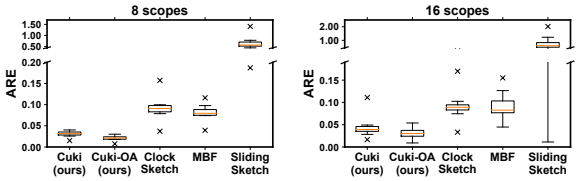


Figure 7: Accuracy of multi-scope estimation.

(3) **Effect of clock bits length.** As shown in Figures 5(c) and 5(d), the ARE and WER can be reduced by using more clock bits. As shown in Figure 5(c), opportunistic aging (Cuki-OA) decreases the ARE of Cuki by 26% on average when the length of the clock bits is small (< 8 bits). Also, we can observe from Figure 5(d) that Cuki-OA barely increases WER.

Besides the above three parameters, the parameter sliding window size can be set as the user demands. In the above experiments, Cuki only needs a few extra bits to track each item's key, access freshness, and size. Therefore, we can conclude that Cuki can track each item only using several bits by sacrificing negligible accuracy.

6.3 Accuracy of WSS Estimation

In this subsection, we evaluate the accuracy of Cuki by comparing it with cutting-edge WSS estimation methods over the sliding window mechanism. Figure 6 exhibits the ARE of different methods measured in the same run on two traces. We double the memory size at the last point of each experiment to meet the memory requirement of each approach. As shown in Figure 6, while the performance of all comparison approaches gets improved with more space, Cuki and Cuki-OA exhibit better memory-accuracy efficiency. For example, Cuki-OA decreases ARE from 12.26% to 0.93% as the memory space increases to 96KB on the MSR trace. In addition, Cuki-OA decreases the ARE of Cuki by an average of 11% and 37% on the MSR and Twitter traces, respectively. As the memory space gradually becomes larger, the ARE of Cuki decreases to 1% and lower. However, the ARE of coarse-grained tracking methods, such as MBF, SlidingSketch, and ClockSketch, can hardly further decrease even with sufficient memory.

Finally, we compare the accuracy of various methods on multi-scope WSS estimation. We use the MSR dataset as a typical benchmark and replay it with a 144× speedup. The time-based sliding window size is set to one hour. All methods in the experiments use the same 24MB memory size because of the large multi-scope combined workload. As shown in Figure 7, Cuki-OA reduces the ARE of Cuki by 33% and 22%

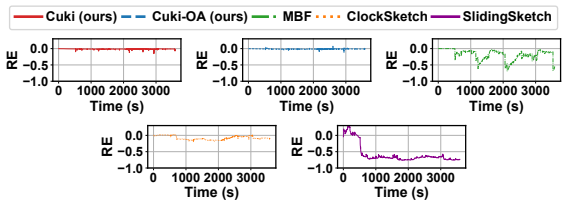

Figure 8: Performance comparison of stability on MSR trace (comparison methods use 2× larger memory than Cuki).

on average for the 8 and 16 scopes WSS estimation, respectively. Secondly, the ARE of Cuki-OA is 11 and 8 times lower than the comparison algorithms on average for the 8 and 16 scopes WSS estimation, respectively. It mainly benefits from Cuki's extensibility which allows items of different scopes to make better usage of memory together.

To conclude, Cuki and Cuki-OA achieve the best accuracy with the same memory consumption among all the methods. More experiments on the YCSB trace or using the WER metric are in Appendix C.2. They have similar conclusions.

6.4 Stability Performance of WSS Estimation

We evaluate the stability performance of different methods under the time-based sliding window. More experiments on the Twitter trace and the count-based sliding window are available in Appendix C.3. They have similar conclusions.

We replay the MSR trace with 168× speedup and use 192KB memory for the Cuki. In order to meet the comparison methods' memory requirements, they use double amount of memory than Cuki. Figure 8 illustrates the stability performance of different methods over the time-based sliding window. SWAMP is omitted due to it only supports the count-based sliding window. There are jagged fluctuations in estimation for all methods because of the movement of the sliding window. Specifically, MBF switches a Bloom filter out periodically and drops the corresponding items. ClockSkech's fluctuations are mainly due to hash collision with limited memory. SlidingSketch can hardly track all items within a sliding window due to limited memory space.

For Cuki, despite its performance being affected by aging operations, its estimation is stable. The stability is mainly attributed to its per-item size tracking. Notably, opportunistic aging can make the movement of sliding windows smoother.

To conclude, Cuki and Cuki-OA use less memory and achieve the most stable estimation results.

6.5 Scalability of WSS Estimation

We evaluate the thread scalability of the comparison methods. Specifically, we use the MSR trace with the count-based sliding window, and the memory size is set to 40KB. SWAMP is omitted due to not supporting multi-thread concurrency.

Figure 9 shows that increasing concurrency can not improve ClockSketch's throughput significantly. SlidingSketch

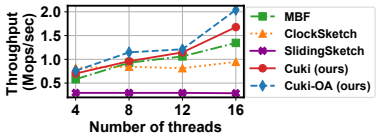

Figure 9: Throughput with concurrent threads.

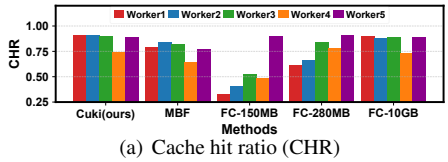
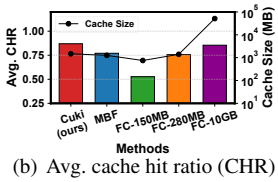
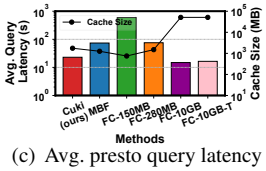


(a) Cache hit ratio (CHR)



(b) Avg. cache hit ratio (CHR)



(c) Avg. presto query latency

Figure 10: Performance of adaptive cache capacity tuning mechanism in table querying (**FC-100MB** represents the fixed cache size 100MB, **FC-10GB-T** represents running with WSS estimation in the fixed cache size 10GB, others are similar).

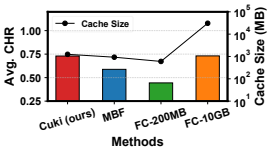
has heavy aging tasks after each operation. Thus, its scalability is limited. MBF can improve throughput by increasing concurrency, but it needs to manage Bloom filters for insertion and lookup, resulting in lower throughput than Cuki.

Cuki and Cuki-OA have near-linear multi-threading scalability due to their fine-grained concurrency control optimization strategies. To conclude, both Cuki and Cuki-OA achieve near-linear multi-threading scalability.

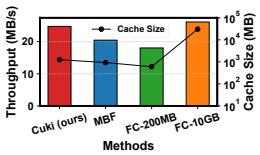
6.6 Cache Tuning Performance with Cuki

(1) **End-to-End Performance in Table Querying :** The experiments run on a Presto cluster with one coordinator and five workers using the I/O-bound TPC-DS dataset. FC-150MB, FC-280MB, and FC-10GB represent the cache system is in overloaded, healthy, and underused statuses, respectively. The 280MB cache size is manually chosen because it is the most competitive cache size that makes a good trade-off between the cache hit ratio and the cache capacity.

The adaptive cache capacity tuning mechanism use 125MB memory, which is the default value in MBF [3]. As shown in Figure 10(a), the cache hit ratio of FC-150MB is the lowest one. And, the cache hit ratio of FC-10GB can be regarded as the upper bound. By using Cuki, the cache system nearly achieves the upper bound of the cache hit ratio. Figure 10(b) shows the average cache hit ratio and the maximum total cache space allocated by the proposed adaptive cache capacity tuning mechanism and others. Compared with FC-280MB, our method improves the average cache hit ratio by around 11% while using a similar total cache size. This is because that our method allocates the cache space to each Presto worker according to their different demand. Overall, by using Cuki, the cache system can not only reach the upper limit of the

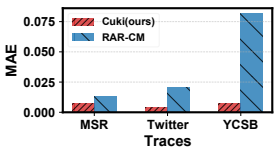


(a) Avg. cache hit ratio (CHR)

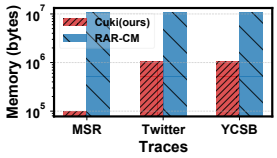


(b) File reading throughput

Figure 11: Performance of adaptive cache capacity tuning mechanism in file reading (**FC-200MB** and **FC-10GB** represent the fixed cache size are 200MB and 10GB).



(a) Mean absolute error



(b) Memory

Figure 12: Performance of Cuki in MRCs generation.

cache hit ratio, but also improve the cache utilization.

The average query latency of different approaches is shown in Figure 10(c), the average query latency of FC-10GB-T (the fixed 10 GB cache size with WSS estimation) is close to FC-10GB. The average query latency of Cuki is close to the FC-10GB which is the lower bound of latency. Compared with MBF, FC-150MB, and FC-280MB, Cuki can reduce the query latency by around 69%, 97%, and 71%, respectively.

(2) **End-to-End Performance in File Reading:** This experiment uses the first 9000 data access requests in YCSB [47] trace as the workload. For each unique trace item, we generate a file whose size is the item value and store the file in remote storage S3. We run the experiments on an Alluxio cluster with three EC2 servers and deploy an EC2 client which runs in three threads to access data. Each thread sends 3000 file reading requests and repeats three times.

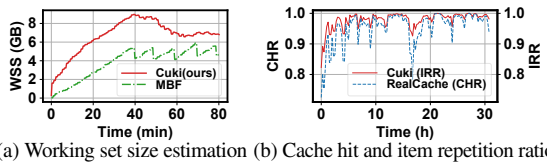
As shown in Figure 11(a) the cache hit ratio of FC-200MB is the lowest. The cache hit ratio of FC-10GB can be seen as the upper bound because the 10GB cache size is enough to cover all workloads. The cache hit ratio of Cuki is close to the FC-10GB, which means Cuki helps the cache system to reach almost the upper bound of the cache hit ratio.

As shown in Figure 11(b), we compare the end-to-end file reading throughput of the above comparison methods. The throughput of Cuki is close to FC-10GB which is the upper bound of the throughput. Overall, Cuki can improve the cache utilization of file reading to reach higher throughput.

6.7 Accuracy of Miss Ratio Curves Generation

We compare the accuracy of miss ratio curves (MRCs) generation among Cuki and RAR-CM. Considering the poor support for the sliding window mechanism in RAR-CM [51], the window length is the same as the trace length.

As shown in Figure 12(b), Cuki uses 96KB memory for MSR trace and 1MB memory for other traces. Each item in RAR-CM needs 128 bits to be stored, which is larger than Cuki's 56 bits. In order to make RAR-CM more accurate, we



(a) Working set size estimation (b) Cache hit and item repetition ratios

Figure 13: Large-scale real-world practice.

allocate RAR-CM 10 MB memory, which is 10× larger than Cuki. Figure 12(a) shows the accuracy of Cuki in MRCs generation. Compared with RAR-CM, Cuki reduces the MAE by around 48%, 82%, and 91% in the MSR, Twitter, and YCSB traces, respectively. This is because that Cuki can better support variable-size item. Moreover, RAR-CM estimates the re-access ratio to compute the reuse distance, which is inaccurate. In addition, Cuki achieves comparable throughput with RAR-CM in experiments. Overall, Cuki costs less memory and generates more accurate MRC than RAR-CM.

6.8 Real-world Practice

We elaborate on how Cuki is used in our real-world large-scale query platforms with the cache system called ShadowCache. ShadowCache is being leveraged to understand the system bottleneck and help with query system routing design decisions. Specifically, with ShadowCache, the overall system can efficiently decide how to size the cache for each tenant, and what the potential cache hit ratio improvement is. In the following, we evaluate the usability of the working set size estimation methods on a middle-scale Presto cluster (GB-level cache space). We implement the proposed Cuki-based cache capacity tuning mechanism. MBF is also used for comparison.

Figure 13(a) shows the estimated WSS of Cuki and MBF on a middle-scale cluster. There exist fluctuation for MBF in its estimation due to periodically removing a part of its statistics as analyzed in § 6.3 and § 6.4. In fact, the cache system can hardly distinguish the normal workload changes from the MBF fluctuations. In contrast, Cuki provides stable working set size estimation with little fluctuation. Thus, Cuki is more credible and effective in real-world scenarios.

Next, we deploy the proposed approach on a large-scale real-world Presto cluster (TB-level cache space with 200 servers). Figure 13(b) shows the performance of query workloads over one day on the Presto cluster, showing the realistic cache hit ratio (CHR) performance of the cache system and the item repetition ratio (IRR) estimated by Cuki. It can be seen that IRR is much higher than the CHR of cache between the 16th hour to the 19th hour. We can find that there is an opportunity to increase the cache capacity based on the estimated WSS during that period to improve the cache hit ratio.

Another interesting discovery during our deployment is that the WSS of each Presto worker is quite unbalanced. This is because that the data hotness of each table or partition is different in real-world scenarios. The extent of the imbalance is related to the access patterns. Cuki is very helpful for global cache space allocation with multiple-scope optimization.

7 Related Work

A key challenge for improving cache utilization is provisioning the suitable cache size to fit dynamic workloads online. As analyzed in § 2, we summarize the prior works in four categories: Rule-based approaches [21, 24, 34, 42], ML-based approaches [4, 28, 30, 33, 35], MRC-based approaches [15, 19, 22, 36, 40, 41, 45, 51, 52], and window-based approaches [5, 11, 20].

The most recent works related to ours are ClockSketch [11], RAR-CM [51], and MBF [3]. ClockSketch [11] maintains a clock value for each item to support the sliding window mechanism. However, ClockSketch uses the bitmap [44] or the Bloom filter [8] to estimate cardinality. It brings WSS estimation error as not being aware of items' various sizes but using maximum likelihood estimation with inferior ARE. RAR-CM [51] uses a hashmap to record item access information and estimate the item repetition ratio. However, RAR-CM is designed for fixed-size item tracking and might be inaccurate for variable-size item tracking. Moreover, RAR-CM has non-negligible memory consumption when handling a large number of unique items. MBF [1, 25] uses a series of Bloom filters to record different statistics in segments of the sliding window. However, the switching of Bloom filters makes the estimation result accuracy unstable.

8 Conclusion and Future Work

In this paper, we propose Cuki, an approximate data structure for estimating the online WSS and IRR for variable-size item access with proven accuracy guarantee. Cuki can also be extended to solve the multi-scope WSS tracking problem. Experimental results show that Cuki outperforms the cutting-edge algorithms by 10× in accuracy. Moreover, the proposed adaptive cache capacity tuning method based on Cuki can significantly improve the cache performance online.

In the future, we plan to explore more application scenarios of Cuki in the cloud-native data processing environment.

Technical Appendix

A Artifact Appendix

Abstract

Cuki is implemented on Alluxio. It also relies on Presto, Hive, and HDFS to function properly. We prepare the programs, assemble a workflow of Cuki and package the artifact into the Git repository.

Scope

The artifact estimates the WSS of different traces. It verifies the basic function of Cuki and validates the accuracy improvement brought by item-wise fine-grained tracking. In addition, this artifact also validates the MRC generation accuracy of Cuki is higher than the SOTA algorithm.

Contents

The artifact includes the source code of Cuki and experiments scripts. A "README.md" file can be also found in the artifact. It contains detailed description of the artifact and a step-by-step instruction for evaluation.

Hosting

The artifact is available at GitHub[1]. All branches are needed to be cloned or downloaded for evaluation. The commit version is the latest one.

Requirements

The environment of the artifact includes Hive 3.1.3, Maven 3.5.4, Hadoop 3.3.1, Java 8, Prometheus 2.37.0, Mysql 8.0.3, and S3.

B Theoretical Proof of Cuki

We first analyze the false positive rate of Cuki. Then, we theoretically demonstrate that Cuki outperforms the competitive state-of-the-art algorithms in space usage under the same false positive rate. We summarize the notations in Table 1.

Theorem B.1. *For Cuki with f-bits fingerprint and s-bits clock, the false positive rate is given by*

$$\varepsilon = 1-\left(1-\frac{1}{2^f}\right)^{2b\cdot\frac{2^s}{2^s-1}\cdot\frac{\mathcal{D}}{n\cdot b}} \approx \frac{2^s}{2^s-1}\cdot\frac{2\mathcal{D}}{n\cdot 2^f}, \tag{5}$$

[1]Our artifact: https://github.com/shadowcache/Cuki-Artifact-WSS-Estimation.

Table 1: Notations

Notations	Definition
f	Bits length of the fingerprint
s	Bits length of the clock
ε	False positive rate
b	Number of entries in a bucket
$\mathcal{D}$	Number of distinct items in a sliding window
n	Number of buckets in a Cuki
α	Load factor of a Cuki
N	Number of items in a Cuki
$\mathcal{T}$	Size of a sliding window

where b represents the number of entries in each bucket, $\mathcal{D}$ represents the number of distinct items in each sliding window, and n represents the number of buckets in Cuki.

Proof: The false positive rate of Cuki comes from two aspects: (i) Cuki stores fingerprints instead of original item keys. (ii) The outdated items in Cuki might not be cleaned up timely. For Cuki with n buckets, we define the load factor as

$$\alpha = \frac{N}{n\cdot b}, \tag{6}$$

where N represents the number of fingerprints stored in Cuki, and b represents the number of entries in each bucket.

When querying an element that does not exist in Cuki, $2\cdot b\cdot\alpha$ fingerprints need to be checked. For Cuki with f-bits per fingerprint, each check may match a wrong fingerprint and return a false positive with a probability of $1/2^f$. Therefore, the false positive rate caused by storing fingerprints is

$$\varepsilon = 1-(1-1/2^f)^{2b\alpha}. \tag{7}$$

For any item in Cuki, it will be cleaned up after performing 2^s rounds of the aging operation. For a sliding window of size $\mathcal{T}$, to prevent an item from being mistakenly deleted before its time window ends, the frequency of the aging operation is $\frac{\mathcal{T}}{2^s-1}$. Thus, for an item in the data stream, the time interval between insertion and clean-up is $\frac{2^s}{2^s-1}\mathcal{T}$. In other words, Cuki actually stores all the items inserted within the time interval $\frac{2^s}{2^s-1}\mathcal{T}$, which is $\frac{2^s}{2^s-1}$ times of the sliding window size. Suppose the number of distinct items within each sliding window is $\mathcal{D}$, the number of items stored in Cuki is given by

$$N = \frac{2^s}{2^s-1}\mathcal{D}. \tag{8}$$

Combining Equations (6), (7), and (8), we have

$$\varepsilon = 1-\left(1-\frac{1}{2^f}\right)^{2b\cdot\frac{2^s}{2^s-1}\cdot\frac{\mathcal{D}}{nb}} \approx \frac{2^s}{2^s-1}\cdot\frac{2\mathcal{D}}{n\cdot 2^f}. \qquad \square$$

Experimental verification: We conduct experiments to validate Theorem B.1. We vary f from 4 to 11, and set s as 12 - f. Other parameters follow the settings in § 6. As shown in Figure 14, the experimental results show that the theoretical false positive rate well matches the experimental results.

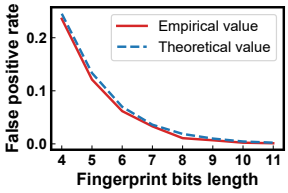

Figure 14: Verification of Theorem B.1.

Corollary B.1.1. *For a fixed memory consumption M, when $s = 1$, the minimum false positive rate is given by*

$$\frac{8\mathcal{D}}{n \cdot 2^{M/n \cdot b}},$$

where $M = n \cdot b(f+s)$ represents the memory consumption of fingerprints and clocks in Cuki, n represents the number of buckets in Cuki, b represents the number of entries in each bucket, f represents the bits length of the fingerprint, s represents the bits length of the clock, and $\mathcal{D}$ represents the number of distinct items in each sliding window.

Proof: As per Theorem B.1, the false positive rate is mainly affected by f and s. Thus we only analyze the memory consumption of fingerprints and clocks. Plug $f = \frac{M}{nb} - s$ into Equation (5), and we get

$$\varepsilon(s) = \frac{2\mathcal{D}}{n \cdot 2^{M/nb}} \cdot \frac{4^s}{2^s - 1},$$

where $s = 1, 2, \ldots, \frac{M}{nb} - 1$. Obviously, the false positive rate increases as s increases, and $\varepsilon(s)$ is the minimum when $s = 1$. This completes the proof. □

Corollary B.1.2. *For the same false positive rate ε, Cuki requires less space than ClockSketch [11] and SWAMP [5].*

Proof: According to Corollary B.1.1, let $\mathcal{T} = n \cdot b$, $n > 8$, the memory consumption of Cuki can be computed as

$$M(\varepsilon) = \mathcal{T}\log_2\frac{8\mathcal{D}}{n\varepsilon} < \mathcal{T}\log_2\frac{\mathcal{D}}{\varepsilon} \leq \mathcal{T}\log_2\frac{\mathcal{T}}{\varepsilon}. \tag{9}$$

According to [11], by ignoring the memory consumption caused by storing the size field and the payload field, the memory consumption of SWAMP is

$$M_1(\varepsilon) > \mathcal{T}\log_2\frac{\mathcal{T}}{\varepsilon}. \tag{10}$$

Therefore, to achieve the same false positive rate ε, the memory consumption of Cuki is always lower than that of SWAMP.

As per [11], the memory consumption of ClockSketch is

$$M_2(\varepsilon) \approx \frac{8}{3\ln 2}\mathcal{T}\log_2\frac{1}{\varepsilon} \approx 3.8472\mathcal{T}\log_2\frac{1}{\varepsilon}. \tag{11}$$

Let $\mathcal{T} = 2\mathcal{D}$, the memory consumption of Cuki is given as

$$M(\varepsilon) = 4\mathcal{T} + \mathcal{T}\log_2\frac{1}{\varepsilon}. \tag{12}$$

When $\varepsilon < 37.76\%$, which is often satisfied in real-world applications [17], $M(\varepsilon) < M_2(\varepsilon)$. This completes the proof. □

C Evaluation

C.1 Motivated Example of Opportunistic Aging: Estimation Fluctuation

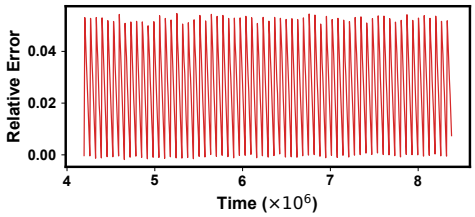

Figure 15: An example of estimation result fluctuating on the YCSB dataset (The size of a count-based sliding window is 65,536, and the clock bits is set to 4).

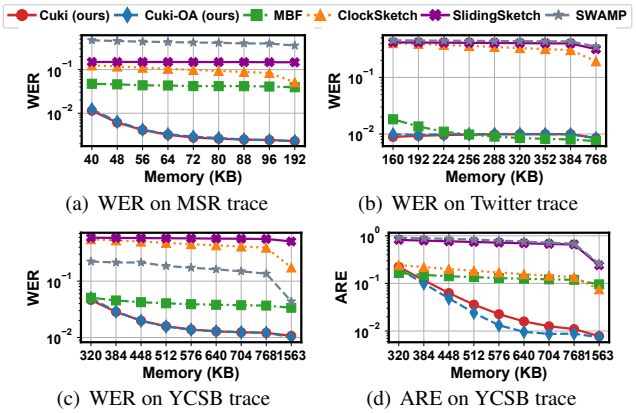
A large number of items will be cleared at the same time in the background aging process. As shown in Figure 15, the working set size is overestimated before aging. After the execution of aging, a tremendous amount of items are instantly cleared. Therefore the estimation result are fluctuating, and may affect the error of the estimated WSS. We propose an optimization method named opportunistic aging to alleviate this problem in aging operation.

C.2 Accuracy Evaluation of Cuki

In this experiment, we evaluate the accuracy of different WSS estimation methods. This experiment observes an additional metric WER on three traces (including the YCSB trace not shown in § 6.3), which can be seen as a supplement to § 6.3.



(a) WER on MSR trace (b) WER on Twitter trace

(c) WER on YCSB trace (d) ARE on YCSB trace

Figure 16: Performance comparison of accuracy.

Figure 16 shows the ARE and WER of different methods measured in the same run on three traces. The ARE or WER of All methods is high without sufficient memory. The ARE or WER of Cuki decreases to 1% and lower as the memory space gradually becomes larger. However, even with sufficient memory, the ARE or WER of other methods can hardly further decrease. Take the ClockSketch as an example, The WER of

ClockSketch is decreased from 12.52% to 5.13% on MSR trace as the memory increases to 1563KB. In contrast, Cuki decreases the WER from 1.14% to 0.24% as the memory increases to 768KB. This is due to the fine-grained per-item tracking method in Cuki. Although the WER of MBF is close to Cuki on the Twitter trace, Cuki performs much better in other traces. This is because MBF switches a Bloom filter out periodically and causes errors for the estimated result.

To conclude, similar to the experiment results in § 6.3, Cuki and Cuki-OA still achieve the best accuracy with the same memory consumption regarding the WER metric and YCSB trace.

C.3 Stability Evaluation of Cuki

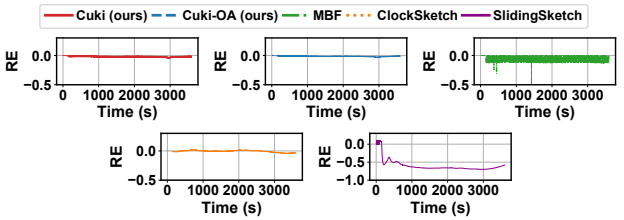


Figure 17: Performance comparison of stability in Twitter trace (time-based)

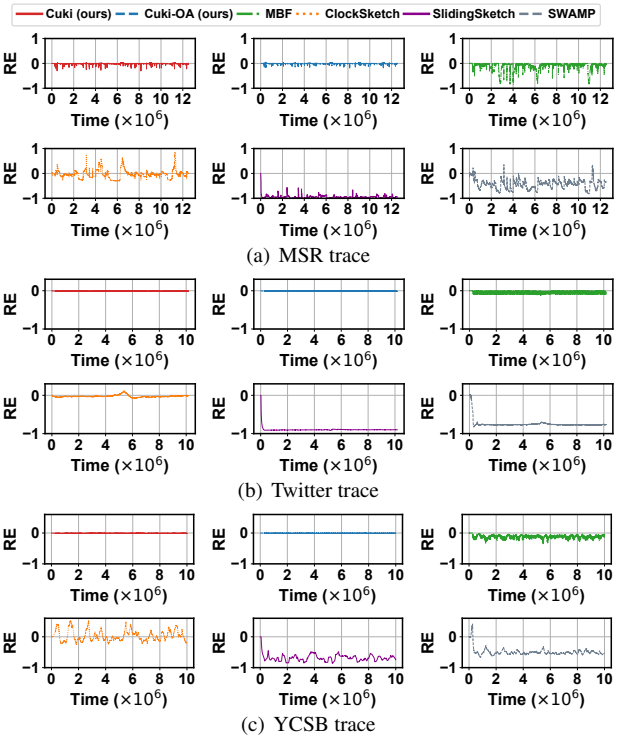

(a) MSR trace

(b) Twitter trace

(c) YCSB trace

Figure 18: Performance comparison of stability (count-based)

In this experiment, we evaluate the stability of different methods under the time-based sliding window and the count-based sliding window. For the count-based sliding window, We use the default configuration described in § 6.1. For the time-based sliding window on Twitter trace, we allocate 1408KB memory for Cuki and double memory for other methods to meet their memory requirements. We replay the Twitter trace with 24× speedup according to the data request traffic. Figures 17 and 18 illustrate the stability performance of different methods over the time-based sliding window and the count-based sliding window, respectively. The estimation results of a count-based sliding window are more stable than that of a time-based sliding window. This is because the number of items in a count-based window is fixed. However, there are still some jagged fluctuations in all methods. The reasons for these fluctuations are the same as we show in § 6.4. Benefiting from the per-item size tracking, the RE of Cuki and Cuki-OA is the most stable of the other four methods. Cuki-OA has a more stable estimation result than Cuki because of the opportunistic aging. To sum up, we conclude that Cuki and Cuki-OA also achieve the most stable and accurate estimates on a count-based window.

SAGE: Software-based Attestation for GPU Execution

Abstract

With the application of machine learning to security-critical and sensitive domains, there is a growing need for integrity and privacy in computation using accelerators, such as GPUs. Unfortunately, the support for trusted execution on GPUs is currently very limited – trusted execution on accelerators is particularly challenging since the attestation mechanism should not reduce performance.

Although hardware support for trusted execution on GPUs is emerging, we study purely software-based approaches for trusted GPU execution. A software-only approach offers distinct advantages: (1) complement hardware-based approaches, enhancing security especially when vulnerabilities in the hardware implementation degrade security, (2) operate on GPUs without hardware support for trusted execution, and (3) achieve security without reliance on secrets embedded in the hardware, which can be extracted as history has shown.

In this work, we present SAGE, a software-based attestation mechanism for GPU execution. SAGE enables secure code execution on NVIDIA GPUs of the Ampere architecture (A100), providing properties of code integrity and secrecy, computation integrity, as well as data integrity and secrecy – all in the presence of malicious code running on the GPU and CPU. Our evaluation demonstrates that SAGE is already practical today for executing code in a trustworthy way on GPUs without specific hardware support.

1 Introduction

Fueled by recent trends such as machine learning and the declining yields from Moore's Law, the use of accelerators to process the vast volumes of data is becoming indispensable. In fact, it is expected that the majority of compute cycles in public clouds will be executed on accelerators [29].

With the application of machine learning to security-critical or sensitive domains such as healthcare or financial modeling, there is a growing need for a mechanism that maintains integrity and secrecy for both code and data despite the computation being offloaded to the GPU.

With the wide-spread deployment of trusted execution environments (TEEs), e.g., Intel SGX [4] and ARM TrustZone [2], an important question is how security-sensitive computation tasks can be accomplished on GPUs. While first hardware-based TEEs on GPUs are starting to emerge [13, 20, 24, 27, 46, 49], how can we execute code securely on GPUs *in current environments*? As we have witnessed from the introduction of hardware-based TEEs on x86 platforms, it took over a decade until it became possible to fully and widely utilize these mechanisms. At the same time, technology progress in this space is a moving target as new attacks (among other factors) force vendors to phase out one specific hardware-based technology in favor of more robust successors (such as with the case of the deprecation of Intel SGX [39]). Given the importance of software executing on GPUs, it is clear that we need to find approaches to speed up the long lag time between deployment and wide-spread utilization.

A promising approach for bridging this gap is a software-only approach to trusted execution. In the context of CPU-based execution, a rich research field has contributed numerous approaches [8, 32, 33, 48]. The basic idea of the prior software-based or timing-based attestation approaches was to design a verification function that would run on an untrusted system and compute a checksum over itself – where both the correctness of the checksum and the time duration are measured by a trusted verifier. A correct checksum value that is returned before a threshold point in time, indicated to the verifier that the TEE was correctly set up and that the correct code is now executing (code integrity and launch point integrity). In combination with a system for control-flow verification, control-flow integrity can also be achieved.

The challenge of such software-based TEE establishment approaches lies in the creation of a verification function that will slow down noticeably or produce an incorrect checksum, if an adversary attempts to tamper with its execution.

The creation of a verification function for GPU environments poses numerous research challenges, which may be the reason why it has so far not been achieved, to the best of our knowledge. First and foremost, achieving (1) code se-

crecy and integrity, and (2) data secrecy and integrity, (3) in the presence of a malicious OS, (4) malicious code on GPU, and (5) a malicious CPU-GPU interconnect is a formidable challenge. Other challenges that we have to overcome include the absence of a true random number generator on the GPU, the lack of documentation from GPU vendors for a specific target architecture, no toolchain support to write native GPU microcode, and the difficulty in achieving optimal GPU utilization.

We design the SAGE system, which establishes a TEE on NVIDIA GPUs of the Ampere architecture (A100). SAGE utilizes an SGX enclave running on the host to act as a local verifier, and to bootstrap the software primitive to establish a dynamic root-of-trust (RoT) on the GPU. RoT establishment ensures either that the state of an untrusted system contains all and only content chosen by a trusted local verifier and the system code begins execution in that state, or that the verifier discovers the existence of unaccounted content. SAGE also sets up a shared secret key between the verifier and the GPU, which can be used to establish a secure channel to achieve integrity and secrecy for code and data transferred. Our results indicate that after a successful invocation of SAGE, the verifier obtains assurance that: (1) the user kernel on the untrusted device is unmodified; (2) the user kernel is invoked for execution on the untrusted GPU device; and (3) the user kernel is executed untampered, despite the potential presence of a malicious actor.

This paper presents the following contributions:

- We design a software-based attestation mechanism for GPU execution that enables secure code execution on NVIDIA Ampere GPUs, providing code integrity and secrecy, computation integrity, as well as data integrity and secrecy.
- We implement the race-condition TRNG and Verification Function used as basic security components in the software TEE. This requires an understanding of the GPU architecture and the format of the instructions used in the microcode, which we derive from our decoding and instruction generation framework.
- Through a proof-of-concept implementation on the NVIDIA A100 platform, we demonstrate the technical feasibility of the approach. Our implementation is publicly accessible at `https://github.com/spcl/sage`.

2 Background: GPU Fundamentals

In the following, we describe the fundamentals of NVIDIA GPUs and their programming model (CUDA) to illustrate how compute tasks are offloaded and executed on the GPU.

The GPU is connected via the PCI control engine to the host CPU and uses an internal bus for communication between its core components. The core components are the command processor, compute and DMA engines, and the memory system, consisting of a memory controller, registers, on-chip and device memory.

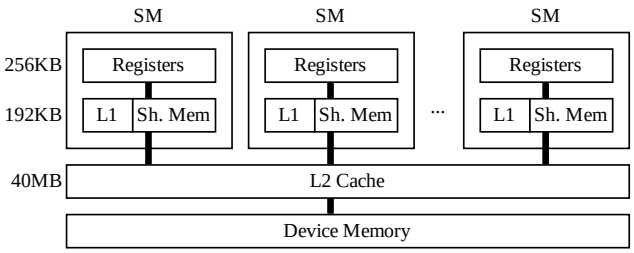

Figure 1: Memory hierarchy of a GPU with memory sizes of NVIDIA A100 GPU.

Controlling the GPU. Commands to the GPU are transmitted using a set of command queues known as *channels*. The GPU's command processor receives these commands and forwards them to the corresponding engines.

Data transfer to the GPU. GPU programming inevitably incurs data transfers between host and device memory. This is handled using direct memory access (DMA). The copy engine is responsible for handling DMA commands and their corresponding memory accesses.

GPU execution. The GPU's compute engine contains multiple Processor Clusters (PCs), each containing multiple Streaming Multiprocessors (SMs). SMs are partitioned into multiple processing blocks, each containing specialized processing cores (e.g., INT32 cores), a scheduler and a dispatch unit. *GPU kernels* to be executed on the GPU are scheduled to SMs and specify the number of threads to be created. These threads are organised in thread blocks and grids. Thread blocks are divided into warps. Each warp is a group of 32 parallel threads and gets scheduled by a warp scheduler.

Modern GPUs have multiple processing pipelines [23] for different data types. The FMA pipeline executes 32-bit floating point instructions and integer multiply and add (`IMAD`). The ALU pipeline executes 32-bit integer, logical, binary, and data movement operations. In addition, there are pipelines for 64-bit and 16-bit floating point, and Tensor core operations.

GPU memory system. The memory system on GPUs consists of a memory controller and different memory levels. The memory levels are associated to the compute system as follows (see Figure 1). Each processing block includes an L0 instruction cache and a register file. The combined processing blocks of a SM share a combined L1 data cache/shared memory that can be partitioned depending on the workload. Multiple SMs share an L2 cache before pulling data from global (off-chip) GDDR memory. *Registers* are a shared resource and are allocated among the thread blocks executing on a SM. Accessing a register consumes zero extra clock cycles per instruction, but delays may occur due to register read-after-write dependencies and register memory bank conflicts. In case a thread requires more registers than available, the data contained in the registers is spilled into shared memory. *Shared memory* is not only used for register spilling, but also enables communication and memory reuse between threads in a block.

3 Problem Definition

We first describe the design goals we strive to achieve, as well as the assumptions and the adversary model we consider.

3.1 Design Goals

Verifiable code execution on the GPU. Verifiable code execution describes the problem in which a verifier wants a guarantee that some arbitrary code has executed untampered on an untrusted platform, despite the potential presence of a malicious entity (e.g., malicious software) [32]. This problem is typically approached by verifying code integrity through root of trust attestation, setting up an untampered code execution environment, and then executing the code.

Data integrity and confidentiality. In addition to code integrity also the integrity and/or confidentiality of the data executed on the GPU must be ensured. Specifically, we aim to guarantee that the adversary cannot observe or tamper with data transferred to/from the GPU by a trusted application that runs in a CPU TEE.

Dynamic root of trust without hardware support. Dynamic root of trust establishment denotes the problem of dynamically setting up a trusted computing base (TCB) on an untrusted platform without hardware support. All code contained in the dynamic root of trust is guaranteed to be unmodified and it can thus be used to provide externally verifiable code execution.

3.2 Assumptions

Verifier and GPU on the same machine. We assume that the verifier is executed on the same machine as the GPU we want to attest. The GPU is directly connected to the host CPU over a bus (e.g., PCIe with a latency of ~500 ns [18]).

GPU hardware configuration. We assume that the verifier knows the exact hardware configuration of the GPU, including the GPU model, the number of cores, the memory architecture, and the GPU clock speed. This assumption is practical when the hardware configuration is managed by the user or a trusted cloud provider. The machine owner has knowledge of the hardware configuration, which cannot be altered by software. In this configuration, we aim to protect against remote attackers who may arbitrarily modify software.

3.3 Threat Model

In the following, we discuss the threat model by defining the trusted compute base (TCB) and outlining the capabilities of an adversary. The TCB of a system refers to all hardware and software components that are critical to its security, in the sense that bugs or vulnerabilities occurring inside the TCB might jeopardize the security properties of the entire system.

Trusted compute base (TCB). We assume that the remote adversary has full control over the software of the untrusted host system. In other words, the adversary has administrative privileges, can tamper with the operating system, or the guest operating system and the hypervisor in case of virtualization. However, we assume that the hardware primitives of the CPU and GPU, including firmware are contained in the TCB. Since SAGE uses Intel SGX, it inherits the TCB of SGX (which includes the CPU package, trusted libraries, etc.).

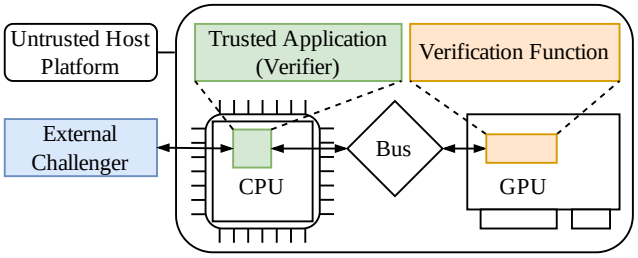

Figure 2: Abstract system model.

Capabilities. Considering these capabilities, an adversary can read and tamper with code or data of any victim process, and can access or modify data in DMA buffers or commands submitted to the GPU. Furthermore, the adversary could inject packets in arbitrary locations on the I/O communication path between the host and the GPU. This gives the adversary control over attributes, such as the address of GPU kernels being executed and parameters passed to the kernels. The adversary may also access device memory directly over MMIO, or map a user's GPU context memory space to a channel controlled by the adversary. In GPUs that support multi-tasking, malicious kernels can be dispatched to the GPU, thereby accessing memory belonging to a victim's GPU context.

Out of scope. Since this work tackles the problem of trusted execution on the GPU, we do not consider attacks that target SGX, such as physical attacks to the CPU package or side-channel attacks on SGX. In addition, we do not consider system availability attacks that prevent the execution of our process, as an adversary with the described capabilities can always prevent the deployment of computing tasks on the GPU. We assume that the adversary is not capable of using undocumented GPU capabilities to execute an attack. We believe that it is the responsibility of the manufacturer to ensure that such attacks are not possible, since the details of hardware and driver implementations are hidden from users.

4 SAGE Overview

SAGE addresses the problem of verifiable code execution on a GPU without hardware support, in which the verifier wants a guarantee that the user kernel has executed untampered on an untrusted GPU platform, even in the presence of an adversary. Figure 2 illustrates the abstract system model we consider.

SAGE comprises two main components. The first component is the verifier, which runs as a trusted application on the host CPU (e.g., using Intel SGX [4]) and is attested by an external challenger. The second component is the verification function (VF), which runs on the the untrusted GPU. The VF computes a checksum over its own code, and is constructed in an intricate way such that if a change is applied to the VF then either the execution will slow down in an externally

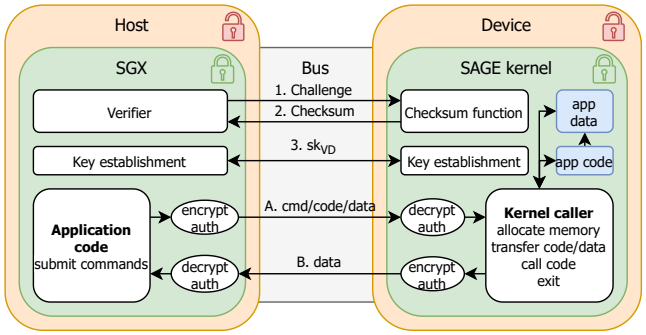

Figure 3: Overview of SAGE. The numbers represent temporal ordering of events. The letters show repetitive operations.

detectable manner, or the checksum value will be incorrect.

The verifier dispatches to the GPU the VF and then invokes it with a challenge while measuring the VF execution time. The VF computes a checksum value and returns it to the verifier. Using the same VF logic, the verifier independently computes and verifies the correctness of the checksum value. If the checksum returned by the VF is correct *and* it is returned within the expected time, the verifier obtains a guarantee that a dynamic root of trust on the GPU was established.

Once the dynamic root of trust has been established, the VF sets up an untampered execution environment. During the setup of the execution environment, a shared key between the verifier enclave and GPU is established; afterwards, only commands authenticated with this key are accepted, including the movement of encrypted kernel code and data between host and GPU. SAGE guarantees execution integrity and memory protection for the code and data stored in the GPU memory (see §8). Figure 3 shows an overview of SAGE including a sequence of events.

5 Verification Function (VF)

The VF that runs on the untrusted GPU is the fundamental component of SAGE. We now describe in detail these tasks and the challenges they entail.

5.1 Design Requirements

The VF must be carefully constructed in such a way that if an adversary were to tamper with the VF or the user kernel, it would result in either a wrong checksum or a noticeable time delay. Before offering a concrete design for the VF, we describe several required properties and outline how these properties influence the correctness of the checksum or the VF execution time. We defer our security analysis to §8; the following properties also account for the attack surface analyzed therein.

Time-optimal implementation. The implementation of the VF must be *time-optimal*. Otherwise, the adversary could use a faster implementation and use the time saved to forge the checksum (e.g., by injecting instructions).

Maximize resource usage during checksum computation. To prevent the adversary from running any other computation during the checksum computation, the VF maximizes its resource usage on the GPU by using all available SMs and avoiding "empty" threads. Moreover, each thread should use the maximum number of available registers to prevent the adversary from using those registers. Thus, if a malicious computation attempts to use more registers than available, the values of the affected registers are spilled into shared memory, resulting in a noticeable execution time difference (4- vs. 30-cycle latency for registers and shared memory, resp.).

Predictable execution time. The execution on GPUs is optimized to achieve high data throughput with deterministic latency, but the execution time is non-deterministic (e.g., due to multi-threaded execution, scheduling, and caching). The VF execution time should have low variance so that the verifier can predictably determine the execution time.

Challenge-dependent checksums. To prevent the adversary from pre-computing the checksum before making changes to the VF, and to prevent the replay of old checksum values, the checksum needs to depend on an unpredictable challenge sent by the verifier.

5.2 Concrete VF Design

The VF consists of initialization, self-verifying checksum function to establish a dynamic root-of-trust, and establishing an untampered execution environment including a key establishment protocol between the verifier and the GPU.

During the initialization phase, the memory buffer is allocated on the GPU and returned to the verifier. Then the VF code is copied into the buffer.

5.2.1 Self-Verifying Checksum Function

The checksum function is used to obtain a guarantee that the integrity of the VF code running on the GPU is unaffected by an adversary. For this purpose, the checksum function computes a checksum over the entire VF code. The resulting checksum can be used as a *fingerprint* of the VF and enables detection of changes to the VF code. If an adversary modifies the VF code, the checksum will differ with high probability. Thus, once the verifier receives a correct checksum within a threshold time, it has a guarantee that the VF code running on the GPU is unmodified.

Since the checksum computation code is part of the VF and will thus be included in the checksum calculation, the checksum function computes the checksum over its own instruction sequence and verifies itself. This property is further referred to as *self-verification*.

Checksum initialization. GPUs contain multiple multiprocessors that can be used for parallel execution. To achieve the maximal computational power of a GPU, the verifier sends a set of challenges containing a specific challenge value for each multiprocessor. Upon receiving a set of challenges, each multiprocessor uses its challenge as a seed value to initialize all per-thread state with pseudo-random data. Each thread has its own set of registers which are used to store the run-

ning checksum values and a data pointer. The data pointer references the VF code in the initially allocated buffer.

Checksum loop. The checksum computation is performed iteratively. Each iteration executes the same number and type of instructions and has a constant execution time.

Pseudo-random memory access prevents the adversary from predicting which instruction will read the potentially-modified memory location and forces the adversary to monitor every memory read by the checksum code, resulting in a noticeable time overhead. Indirectly, this process performs the inclusion of the data pointer in the checksum to prevent memory copy attacks (see §8).

Update the checksum. The running checksum values are updated to include the accessed VF code into the checksum value using a sequence of instructions. To achieve a time-optimal implementation, we use simple arithmetic and logical instructions (e.g., +, <<, >>, etc.) that are challenging to implement faster or with fewer operations. Taking inspiration from the strong ordering in [32], the instructions used to update the checksum alternate between arithmetic and logical instructions to enforce a strong ordering of the instructions.

Self-modifying code. The instructions of the self-modifying code fragment depend on current value of the checksum and are changed in each iteration of the checksum function. In our case the current value of the checksum function is used as an immediate value for an instruction (see §6.5 for details).

Checksum epilogue. Since the checksum computation is conducted using individual threads located on different multiprocessors, the checksum values need to be aggregated before sending the checksum result back to the verifier. This aggregation is conducted in three steps. First, we aggregate the checksum per warp. Each of the per-thread checksums is added pairwise to obtain a warp-level checksum. Second, the warp-level checksums are aggregated by thread block using shared memory. Finally, we aggregate the checksum per grid using global memory. Each of the aggregation steps uses a pairwise addition (which is mapped to an atomic add instruction in native assembly). The final result of the checksum computation is then sent to the verifier.

5.2.2 Untampered Execution Environment

After establishing a dynamic root-of-trust on the device, the VF sets up an execution environment in which the user kernel is guaranteed to run untampered. This includes setting up a shared secret between the verifier and the device, and checking the authenticity of the user kernel to be executed on the GPU using a hash function. The shared secret can then be used to authenticate and encrypt commands and data sent by the verifier to the device and vice versa.

Key establishment. To establish a shared secret between the verifier and the device, we rely on the SAKE protocol [31], a protocol for key establishment between neighboring nodes in sensor networks without requiring any prior secrets. The protocol is based on the Diffie-Hellman key exchange protocol and uses the Guy Fawkes protocol [1] for authentication. The Guy Fawkes protocol is based on hash chains and relies on the property that each of the participants needs to authenticate the other party's hash chain. In SAKE, this authentication is achieved using software-based attestation and exploits the asymmetry in the computing time between the genuine checksum function executing on the device and an external entity computing the checksum value. This allows us to use the resulting checksum as a short-lived secret. Furthermore, the SAKE protocol assumes that the adversary does not introduce any computationally more powerful nodes into the network, which aligns with the assumptions for SAGE (see §3.2).

To apply the SAKE protocol to SAGE, we change the protocol as follows: 1) The checksum function in SAKE that was proposed for the use in sensor networks is replaced with SAGE's checksum function. 2) Instead of both participants acting as challengers, only the host enclave will engage as a challenger. 3) We replace the cryptographic primitives used in the protocol with AES-CMAC as the MAC function and SHA256 as the hash function.

The key establishment protocol in SAGE works as follows. First, the verifier sets up its own hash chain for the Guy Fawkes protocols and DH public key as:

$$V: \quad v_0 = g^a \bmod p \quad v_1 = H(v_0) \quad v_2 = H(v_1) \tag{1}$$

where a is a random bitstring $a \leftarrow^{\mathcal{R}} \{0,1\}^n$ Then, it sends v_2 to the device and records the current time as t_0.

$$[t_0] \quad V \rightarrow D : v_2 \tag{2}$$

Upon receiving v_2, the device uses it as a challenge for the checksum function and then uses the computed checksum and a random value to generate its own hash chain and replies to the verifier:

$$D: \quad w_0 = H(c \,\|\, r) \quad w_1 = H(w_0) \quad w_2 = H(w_1) \tag{3}$$

where r is a random bitstring $r \leftarrow^{\mathcal{R}} \{0,1\}^n$, c is the result of the checksum computation and $\|$ denotes to concatenation.

$$[t_1] \quad D \rightarrow V : w_2, \ \mathrm{MAC}_c(w_2) \tag{4}$$

The verifier checks if the measured execution time $(t_1 - t_0)$ matches the expected execution time and aborts the protocol otherwise. In the meantime, the device sets up its own DH public key:

$$D: \quad b \leftarrow^{\mathcal{R}} \{0,1\}^n \quad k = g^b \bmod p \tag{5}$$

Then, the verifier and the device gradually disclose the remaining of their hash chains to each other:

$$V \rightarrow D : v_1 \qquad D \rightarrow V : w_1, \ k, \ \mathrm{MAC}_{w_0}(k) \tag{6}$$

$$V \rightarrow D : v_0 \qquad D \rightarrow V : r \tag{7}$$

For each message the recipient checks whether the received value matches the expected hash chain. Finally, the verifier V and the device D compute the shared secret key sk_{VD}:

$$sk_{VD} = k^a = (g^b)^a \bmod p \quad sk_{VD} = v_0^b = (g^a)^b \bmod p \tag{8}$$

After the dynamic RoT has been established on the GPU and the integrity of the user kernel has been checked, the host enclave can start transferring code and data to the GPU. Depending on the sensitivity and security criticality of the domains, the data could be either *authenticated* and/or *encrypted* using the established symmetric key sk_{VD}.

6 Implementation

The requirements to achieve a time-optimal (see §5.1) implementation on the Ampere architecture (further discussed in §6.3) include maximizing GPU utilization, consuming all available compute resources, optimally filling the processing pipelines, and optimizing cache usage.

Unlike the higher levels of the CUDA computing platform such as the CUDA C++ language extension and the parallel thread execution (PTX) virtual machine and instruction set architecture, NVIDIA provides very little information about the hardware-specific instruction sets for a specific target architecture. Moreover, even if one resorts to write inline PTX virtual assembly, the Streaming (or Shader) Assembler (SASS) code emitted by the compiler often does not achieve the performance of native GPU applications. The execution of microcode that has been compiled using the regular CUDA compiler often is on the order of 10x slower compared to optimized microcode [14, 15]. As a consequence, libraries used for high-performance computing (e.g., cuBLAS [25]) contain highly optimized microcode tailored to a specific architecture. In addition to the performance gap to native GPU code, the user has no control over the translation from PTX virtual assembly to the SASS assembly for the target architecture.

To achieve a time-optimal implementation, we needed to implement a custom instruction generation framework that allows patching of binary microcode with a highly optimized version. The implementation of this framework requires understanding the Ampere architecture and the instruction format used in microcode. Although our focus in this paper is on the A100, we expect that small modifications to the code generator can provide support for the Volta and Turing architectures as well. Figure 4 illustrates the pipeline used to generate the VF. The VF is implemented using CUDA C++ and compiled using `NVCC`. However, the section containing the checksum function is patched using an optimized implementation generated as binary microcode using our framework.

6.1 Instruction Decoding

To understand the instruction format used in the recent Ampere GPU architectures, we implemented a framework that allows decoding of instructions using `cuobjdump` and `nvdisasm` [21] by decoding handcrafted code samples and samples from existing CUDA libraries (e.g., cuBLAS [25]).

Instruction format. NVIDIA's Ampere architecture adopts the same general instruction format as its predecessors Turing and Volta [14, 15]. All these architectures use 128 bits to encode both an instruction and its associated scheduling control information. The encoding that is used in these architectures is fixed length and uses similar encodings for all instructions. Figure 5 illustrates a typical instruction encoding.

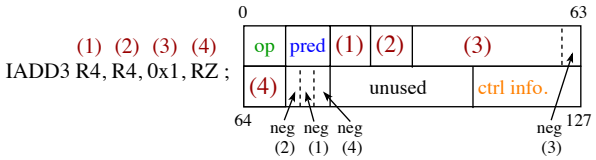

Figure 5: Instruction as decoded by `nvdisasm` and its format. `pred` denotes predicates, `op` refers to the operation code, and `neg` allows negating the corresponding parameter.

Control information. The control information section in the instruction encodes scheduling decisions taken by the compiler that the hardware must enforce. The control information is organized as follows: reuse flags (4 b), wait barrier mask (6 b), read barrier index (3 b), write barrier index (3 b), yield flag (1 b), and the number of stall cycles (4 b). The reuse flags allow data reuse between instructions without accessing any register ports. The wait barrier mask and indices are used for instructions with variable latency (e.g., instructions involving a memory access). These dependency barriers can be used to enforce the completion of variable-latency instructions. The yield flag is used to balance the workload assigned to a processing block. The stall cycles indicate the latency of the instruction before issuing the next instruction. Jia et al. present a detailed description of the control information [14].

6.2 Instruction Generation

Understanding the instruction format allows us to generate the specific instructions we need for our implementation. These instructions then need to be translated to the correct binary format. For this purpose, we implement an instruction generation framework that allows emitting instructions either in CUDA C++, the virtual assembly language PTX, or as binary microcode that is natively executed on the GPU.

The instruction can be defined in the following format, where the section separated using `|` symbol describes the control information for the instruction (barrier mask B, read barrier index R, write barrier index W, yield flag Y, and number of stall cycles S):

```
B......|R.|W.|Y1|S1| IMAD.U32 R28, R28, 2048, R28;
```

Our instruction generation framework then translates the instruction to the selected target language (CUDA C++, PTX, microcode). This allows us to rapidly prototype checksum functions and compare performance between implementations in each of the languages.

6.3 Time-optimal Technical Requirements

We formulate the following technical requirements for a time-optimal implementation of the checksum function. These are subject to characteristics of the target architecture; in our case, the NVIDIA Ampere architecture.

Maximize resource consumption. To maximize the resource consumption during the checksum computation, the checksum function must use all available compute resources. The NVIDIA A100 GPU has 108 Streaming Multiprocessors (SMs) each containing 64 `FP32` and 64 `INT32` units [19] that must be used during each clock cycle.

Optimally fill FMA and ALU pipelines. Since both the FMA and ALU pipelines have an instruction issuing latency of 2 clock cycles, `FP32` and `INT32` instructions must be interleaved to fully saturate both pipelines. In addition, instructions that use registers with a direct dependency must be executed with a latency of at least 4 clock cycles to avoid pipeline stalls (e.g., read-after-write dependency).

Optimal GPU utilization. To achieve full GPU utilization, the number of threads per thread block needs to be picked according to the target architecture. The A100 achieves full GPU occupancy by assigning 2 blocks of size 1024 to all the 108 available SMs (216 total). Each SM has 65,536 32-bit registers available for threads. To use all registers during the checksum computation while maintaining full utilization of the GPU, 32 registers are assigned per thread [22].

Cache size. The code blocks should not exceed the capacity of L0 and L1 instruction caches (see Figure 1).

6.4 Selection of Optimal Overheads

An optimal implementation of a checksum function should perform a useful computation step in each clock cycle. In practice, this requires a highly optimized use of the underlying hardware. In the following, we show a recipe for building such a checksum function for the A100 GPU.

Unutilized clock cycles are mainly caused by instruction cache misses, global memory access latency, pipeline stalls, and jumps. In the beginning of each clock cycle, the SM warp scheduler selects a subset of warps (up to `S=4` on A100) from all active warps (up to `A=64` on A100) to execute. This selection mechanism can avoid performance losses if at least `S` are ready to execute on each clock cycle.

To analyze the performance of the checksum function, we use a simplified model of the number of clock cycles per instruction. In the following, we will demonstrate that it helps to reach the performance with the precisely specified number of clock cycles. We distinguish the total number of useful clock cycles `X` and overhead cycles `Y`, so that the total number of clock cycles spent by the code using a single thread is `X+Y`. For example, with proper instruction ordering to avoid pipeline stalls, an `IMAD` instruction has `X=1` and `Y=0`. An instruction reading from global memory has `X=1` and approximately `Y=250`. To prevent attacks on the checksum function by executing some instruction each clock, the value of `Y` must not exceed `X(A/S-1)`. Then, the GPU scheduler will be able to completely hide the overhead `Y` so that the actual amount of time spent will be `X`.

Integer shifts and multiplications with addition directly affect the result of the checksum calculation. However, the instruction to jump from the end of the loop body to its beginning does not change the checksum. The attacker may try to unroll a few iterations of the loop to save the clock cycles required to perform this jump (and potentially misuse them for an attack). To prevent such attacks, we unroll the loops until it is not possible to unroll them further without causing instruction cache misses. The target value `Y` for unrolling must be so large that one additional instruction cache miss will increase it to `Y′` without the possibility for a hardware scheduler to compensate for the increase (and potentially hide it) using scheduling.

In practice, we have noticed that achieving this level of control over the order of instructions, and the arrangement of unrolled loops is very difficult without vendor support: the documentation on SASS and hardware details is deliberately kept closed to reduce backward-compatibility issues. It is especially difficult to control instruction cache misses because of the use of self-modifying code to protect against memory copy attacks. The only way to invalidate the instruction cache on the A100 is to overflow it with the block of instructions of the cache size, so controlling the value of `Y` by changing the size of the checksum function is not possible. That leaves only memory accesses and jumps that can change `Y`. We assume that adding an instruction to invalidate the instruction cache requires minimal (or no) changes to the GPU architecture because a similar instruction already exists for the data cache (`discard` in PTX ISA or `CCTL` in SASS).

6.5 Implementation of SAGE

Verifier. We implement the verifier enclave using the Intel SGX SDK [11] and its `tcrypto` library [10]. The enclave creates a CUDA context on the GPU, loads the VF as a module, and calls the VF kernel. To generate nonces in the enclave that are then transferred to the GPU as challenges, we use AES-CTR with an IV that has been generated using a TRNG during the enclave creation.

VF. The VF is implemented in CUDA C++, except the checksum function component, which is patched by binary microcode using our framework. The checksum function executes a loop containing the following operations.

First, the iteration counter is increased and checked if the maximum number of iterations is reached. Then the VF data block `D` is read from memory from the location defined by the current checksum value `C`, used as an offset: `D=data_ptr+(4×C mod data_size)`. After the load is complete, it is included in the checksum `C+=D`.

The read from main memory may take 250 – 500 cycles to be completed. The GPU compiler sets a read barrier for this instruction and the GPU stalls the compute pipeline until

the read has been completed. Instead of the stall, we develop an instruction pattern that is executed while waiting for the memory read to complete ("busy waiting"). We use interleaved (see §6.3) `X+=X<<N` with `IMAD` (FMA) and `X+=X>>N` with `LEA.HI` (ALU) instructions where `X` is any of 32 registers. The security of this computation depends on the existence of an alternative sequence of instructions which can compute the result faster. We expect that for some cases of long sequences or poorly chosen shift amounts, it is possible to find a shortcut constructed similarly to the jump ahead function in the xorshift pseudo-random number generator (PRNG) [45]. To prevent such shortcuts, we partition long sequences by requiring materialization of intermediate values, breaking them with random memory accesses included in the checksum. We aim for sequences of such length that the cost of implementing a shortcut is higher than performing the actual computation.

After updating the checksum function, we compute the self-modifying code that consists of the following binary instruction: `C+=C>>N`, where the immediate `N` depends on the current checksum value. We overwrite immediate parameter with the current value of the checksum. Thus, the value of `N` changes for each iteration and ensures that we are executing the code that we are verifying. To avoid race conditions when updating the immediate value of these instructions, these instructions are required to be located in different memory areas for each thread block.

6.6 Random Number Generation on GPUs

For the key establishment protocol based on the modified SAKE protocol, the GPU needs to be able to generate random values. Given that the adversary knows the entire code executing on the GPU, we cannot use a secret provided by verifier to initialize the PRNG used in the protocol, but instead must rely on a true random number generator (TRNG).

TRNG implementation on GPUs. Approaches that use physical unclonable functions (PUFs) to initialize PRNGs on the GPU [7, 30, 43] are not practical to be used in SAGE as they either require resetting the GPU or use features that are under control of the adversary (e.g., voltage supplied to the GPU). Consequently, we use a TRNG implementation which is based on race conditions in multi-core environments caused by simultaneous memory accesses to shared variables. It takes advantage of uncertainties that arise when cores simultaneously access a particular memory location [40]. In our case, each simultaneous memory access unpredictably flips bits stored in shared variables. This unpredictability enables the GPU to generate noise which can be sampled and then used as an entropy source. We evaluated our implementation using statistical tests such as NIST SP 800-22 [36], DIEHARD [17], and ENT [47]. The TRNG implementation passes all standard tests and achieves a throughput of 4 kB/s on NVIDIA A100 GPUs and thus takes around 8 ms to generate an output of 256 bits. The TRNG provides 7.999 996 bits of entropy per byte (measured using ENT [47]).

7 Evaluation

Evaluation setup. To evaluate the performance of the checksum function, we use a setup based on an ASUS RS720-E10-RS12E equipped with a A100-PCIE-40GB GPU and Intel Xeon Gold 6348 CPU [12] which natively supports SGX instructions. We run the SGX enclave in both native and simulation mode. To benchmark the execution time of the verification process and evaluate runtime overheads, we also run the VF on a dual-socket system with an A100-SXM4-40GB and AMD EPYC 7742 CPU.

Register consumption. For the execution of the checksum function, the loop counter, data pointer, and the checksum result are stored in registers. In addition to those registers, we use 22 additional registers to store intermediate state during the computation of the checksum. In total, the checksum function verifies 524,288 bytes. The beginning of the buffer contains the checksum function itself, whereas the remainder is filled with pseudo-randomly generated values.

Experiment Nr.	1	2	3	4
self-modifying code	✗	✗	✓	✓
instructions	428	429	8,342	8,342
iterations	100,000	100,000	1,000	1,000
inner iterations	0	0	0	5000
inner instructions	0	0	0	216

runtime T_{min} [s]	—	0.4966	—	—
$T_{avg} + 2.5\sigma$ [s]	0.4964	—	—	—

Table 1: Evaluation of checksum implementations.

Summary of results. Table 1 summarizes our experiment series conducted to evaluate the performance of SAGE's VF. We distinguish between two categories depending on whether the checksum function contains self-modifying code or not. Depending on the category, the total number of instructions and number of checksum loop iterations are adapted. For each experiment, we report the VF's execution time on the GPU, the utilization ratio during the checksum execution, the verification time on the CPU, detection threshold, etc.

Experiment 1 demonstrates our best reference implementation. Experiment 2 simulates an attack on the checksum function from the first experiment. In Experiment 3, we show the effect on the performance of adding self-modifying code to the reference implementation. Experiment 4 shows a possible technique to compensate for the loss of performance with enabled self-modifying code.

7.1 VF Performance

To evaluate the performance of VF, we report its average runtime and utilization ratio during the checksum execution (Table 1). As a reference for this ratio, we use the *peak GPU performance*, which assumes that the number of warps that are executed concurrently per clock cycle is 4 (see §6.4).

We compare our reference implementation from Experiment 1 (in SASS) with the same code written in PTX (virtual assembly), that has been processed using the NVIDIA PTXAS assembler with the highest possible level of optimization enabled. In comparison, the optimized version of the checksum function that we generated using our instruction generation framework is around ∼230% faster than an implementation in PTX.

The checksum functions in Experiments 3 and 4 contain self-modifying code. This requires triggering cache eviction of the instruction cache such that the modified instruction gets updated. To trigger the cache eviction for the L2 instruction cache (128 kB), the checksum loop is required to be larger than the cache size. As a consequence, we use 8342 16 B instructions in the checksum loop. With this cache eviction strategy, our implementation is able to achieve 75% of the maximum utilization. Upon closer inspection with a GPU profiler, we find that 99% of all pipeline stalls that happen during the execution of the checksum function are caused by the fact that no instructions are available in the instruction cache to be executed. On average, each warp of this kernel spends 14.1 cycles being stalled due to not having the next instruction fetched yet. In comparison, reducing the size of the checksum loop to 6.7 kB (as in Experiment 1), we achieve a utilization of 99% without triggering cache eviction. This means that the hardware is unable to load the modified instructions in time for execution without causing any pipeline stalls. By comparing the VF's performance in Experiments 1 and 3, we can conclude that a higher utilization can be achieved in case other cache eviction strategies become available (see §6.4).

In addition to the previous experiment, we modified the checksum function by adding an "inner" loop to the main loop of the checksum function calculation (Experiment 4). This effectively hides the performance loss due to cache misses in the instruction cache and achieves 100% of the GPU peak performance. However, the time required to verify the code outside of the nested loop drastically increases and is thus considered too long to be practical.

7.2 Attack Robustness

To evaluate the robustness of our VF implementation with regards to attacks, we estimate the number of instructions that can be injected by an adversary without causing a noticeable time overhead. For this purpose, we measure the performance of the checksum function for 100,000 iterations and record the standard deviation σ of the total execution time based on 100 runs. We assume that the results of this experiment series are normally distributed and set the threshold value to detect adversarial tampering to be at $2.5 \cdot \sigma$ from the mean. The probability of a false positive is about 0.5%, in which case the verification process is restarted. Depending on the application requirements, the probability of false positives can be decreased at the expense of a larger number of iterations.

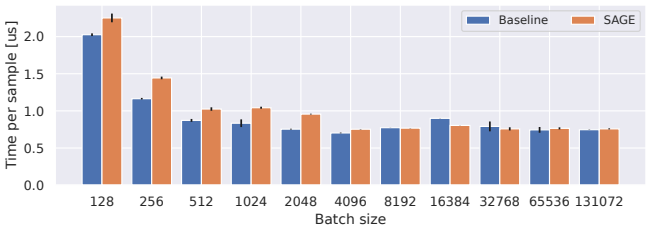

Figure 6: Time per batch sample in MLP.

To evaluate the robustness of this approach, we insert one additional NOP instruction in Experiment 2 (adversarial NOP) and report the minimum run time T_{min} (averaged over 100 runs). Assuming a detection threshold of $T_{avg} + 2.5\sigma$, we can conclude that $T_{avg} + 2.5\sigma < T_{min}$ and thus it is impossible to insert one or more instruction without detectable overhead.

Time measurement occurs on the CPU, including the time of communication between the CPU and GPU, in addition to the checksum computation loop. This raises the question of performance portability across hardware configurations. Since the configuration is fixed and assumed to be trusted, communication adds a constant time that can be measured offline once and then reused. This approach allows us to consider only the checksum loop in the detection threshold.

7.3 Memory Region Inclusion Probability

To evaluate how resilient our approach is regarding minor modifications in memory region containing the VF code (e.g., bit flips), we estimate the probability that a particular location is never included into the checksum result. We assume that memory accesses are distributed uniformly. Each block contains a single random memory access that loads an aligned 32-bit integer. For 2,500,000 iterations and a total checksum size of 524,288 integers, the probability that a memory location is never included in the checksum result is negligible:

$$(1 - 1/524288)^{2500000} = 0.0085$$

7.4 Runtime Overheads

Figure 6 shows a performance evaluation of SAGE using a multilayer perceptron (MLP) as an example. It consists of two Linear layers with weights of size `784×100` and `100×10`, with a Relu layer in between. As the workload increases, the overhead associated with the non-standard SAGE communication protocol becomes less noticeable.

The main sources of overhead are data transfers and kernel launches. Figure 7 shows that the copy operation requires additional time, which is a linear function of the input data size due to the additional data transfer between the host-accessible GPU memory and the GPU memory allocated by the SAGE kernel. SAGE adds less than 5% extra execution time to user

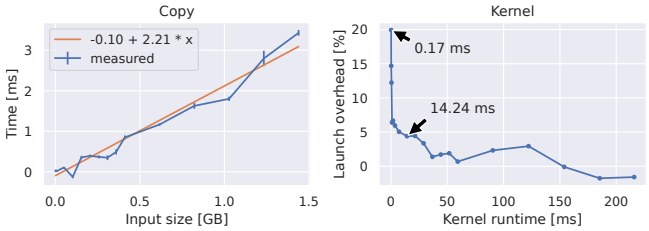

Figure 7: Overheads of data transfers and kernel launches.

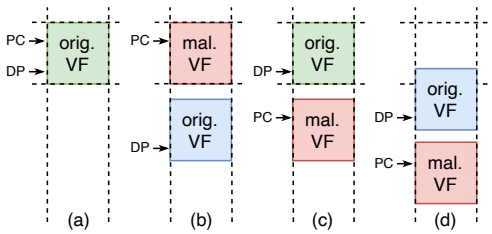

Figure 8: Memory copy attack variants.

kernels, which originally took more than 14.24 ms. Our evaluation does not take into account the overhead associated with the implementation of the encryption-decryption protocol, since its choice is left to the user.

7.5 Limitations of the Prototype

The use of self-modifying code requires triggering cache eviction of the instruction cache such that the modified instruction gets updated. With this cache eviction strategy, our implementation is able to achieve 75% of the maximum utilization. This is due to the GPU hardware not being able to load the required instructions in time for processing after the L2 cache eviction. If other cache eviction strategies become available to user code, higher utilization can be achieved. Unfortunately, triggering cache eviction using a large checksum loop limits the time difference caused by an adversary inserting instructions into the checksum loop. We believe that GPU vendors with in-depth knowledge of GPU architecture would be able to reduce the checksum loop size and use self-modification.

8 Security Analysis

In the following, we systematically analyze potential attacks given our threat model (see §3.3).

Pre-computation. The result of the checksum function depends on an unpredictable challenge issued by the verifier enclave. This prevents pre-computation attacks where the checksum value or part of the checksum (e.g., intermediate values) are pre-computed to later run code other than the VF.

Computation optimizations. The checksum function implementation must be time-optimal as algorithmic optimization would allow the adversary to find computationally faster or more efficient way of computing the checksum value (see §6.3 for details). SAGE is designed to prevent optimization, but to achieve provable guarantees the method of Gligor and Woo could be applied [8].

Attacks on the host system. The host system is untrusted (except for the verifier enclave) and the adversary is assumed to have administrative control over the system. This enables the adversary to eavesdrop, intercept, modify, or delay challenges or checksum results being transmitted between the verifier and the device. Given that the communication channel during the checksum computation is unauthenticated, the adversary could also inject challenges or checksum results. Modifications to the challenge would lead to a different checksum result. By injecting challenges the adversary could treat the VF as an oracle; however, given the unpredictable challenge generation, the probability of the verifier reusing the same challenge value is negligible.

Attacks on the device / Resource takeover. Before running the verification function, the device is considered untrusted. An adversary could be present on the device and interfere with the execution of the VF (e.g., by replacing or reordering instructions). This is prevented by the self-verification property and the strongly-ordered design of the checksum function. A strongly-ordered function requires the adversary to perform the same operations on the same data in the same sequence as the original function to obtain the correct result. Otherwise, the output differs with high probability if operations that have dependencies among them are evaluated in a different order.

Our design uses all available SMs simultaneously and maximizes thread and register usage. Thus, if an adversary would run a computation, the checksum computation would be deferred resulting in a considerable time overhead. However, the execution of a user kernel might not require all available GPU resources and would allow the adversary to take over these available resources. To prevent such attacks we require the user to develop kernels to achieve maximum GPU occupancy.

Memory copy attacks. Seshadri et al. [32,33] specify memory copy attacks that can be conducted by the adversary in the following three different ways as illustrated in Figure 8:

(b) The adversary replaces the checksum function with an altered checksum function and executes it, but computes the checksum over a correct copy of the checksum function elsewhere in memory. Thus, the program counter is correct, but the data pointer points to the original copy of the checksum function in a different memory location.

(c) The adversary uses the correct checksum function code in the original memory location to compute the checksum value, but executes a modified checksum function elsewhere in memory. Thus, the data pointer points to the original checksum function, but the program counter will be different.

(d) The adversary places both the original checksum function code and its altered version elsewhere from the memory locations where the correct checksum code originally resided. Thus, both the program counter and the data pointer will be different compared to an execution of the original checksum function.

To prevent memory copy attacks, both the program counter and the data pointer need to be included in the computation of the checksum. The DP is included in each step of the

computation, whereas the PC is indirectly included using self-modifying code. In addition to these specified attacks, the attacker could also copy the entire checksum function to a different location. This will not lead to a successful attack because the absolute location of the checksum function is irrelevant to security as long as the function pointer and the data pointer remain the same relative to the location of the effective checksum function in memory.

Proxy attacks. We refer to proxy attacks as attacks where the adversary eavesdrops on the communication and obtains the challenge sent to the device, sends it to a proxy, computes the checksum function there and returns the result to the verifier. We distinguish between the following cases. *GPUs on the same host*: we establish (and maintain) root-of-trust in sequence starting from the most powerful GPU to the least powerful one. *GPUs on a different host*: by involving a remote entity, the measured execution time will increase by the network latency for both sending the challenge and receiving the response. Tuning the number of checksum iterations to make the detection threshold smaller than the network latency, prevents using a more powerful GPU in a remote location.

Time-of-check to time-of-use attacks [5] / Execution environment takeover. In SAGE, these attacks are considered because the checksum computation happens prior to the execution of the user kernel. In particular, the adversary has two points where it could take over the execution environment set up by the VF: 1) before the launch of the user kernel, and 2) after the execution of the user kernel has completed. The former case is prevented by launching the user kernel(s) from within the VF epilogue. In the latter case, the execution of the user computation has finished and thus the user is indifferent whether the dynamic root-of-trust has been compromised. If the user wants to execute another kernel, the dynamic RoT needs to be re-established.

Replay attacks. To protect against duplicate transmissions of encrypted code and data between the SGX enclave and GPU, we add sequence numbers to each transmission.

Execution integrity and memory protection. While code and data are encrypted in transit, they have to be decrypted before use and placed into GPU memory. We control the allocation of memory from the kernel caller by calling `malloc()` from the device code. CUDA guarantees that the memory allocated in this way (unlike `cudaMalloc()`) is not accessible from the CUDA runtime or driver API. Therefore, even an attacker with root access to the operating system will not be able to access application code and data from such areas.

8.1 Formal Verification of Modified SAKE

To show that our modified SAKE protocol securely establishes a key between the verifier and the GPU, we have formally modeled the key establishment protocol and verified its security properties using the Tamarin prover [38] under the assumption that the computed checksum provides a short-lived secret. To model this property in Tamarin, we use a single-use authentic channel over which we send $w_2, \mathrm{MAC}_c(w_2)$. We show that the established symmetric key remains secret and is unique, a weak agreement exists between the verifier and the device, and recent liveness for each run of the protocol [37].

9 Related Work

To support trusted execution on GPUs, the following approaches were proposed. Graviton [46] specifies an architecture for supporting trusted execution environments on GPUs by changing the GPU's command processor to perform remote attestation based on device specific keys and ensure isolation between multiple processes running on the GPU. This is achieved by utilizing a set of keys where the root key gets embedded into the hardware of the device upon its creation. The latter requires modification to the GPU hardware by modifying the GPU's internal command processor to impose a strict ownership discipline.

HIX [13] proposes a heterogeneous isolated execution environment. HIX does not require modifications to the GPU architecture to offer an isolated execution environment, but instead physically modifies the I/O interconnect between the CPU and GPU and refactors the GPU device driver to work from within a TEE on the host. The TEE can then allocate trusted enclaves on the GPU.

HETEE [49] is based on a standalone computing system to dynamically allocate accelerators (such as GPUs or FPGAs) for either secure computing, or available to the host OS using PCIe switches. The security controller (and its software) is assumed to be trusted and interacts with the management CPU to control PCIe switching. HETEE attempts to provide isolation by selectively making accelerators available to specific applications by controlling communication to the accelerator through the security controller.

Telekine [9] illustrates side-channel attacks against TEE on GPUs based on observing the timing of GPU kernel execution. It then introduces a GPU stream abstraction that ensures execution and interaction through untrusted components are independent of any secret data. Telekine requires a GPU TEE to be deployed.

Machine learning represents a major use case for using GPUs as accelerators and can require privacy-preserving approaches for sensitive data. Slalom [42] uses a combination of a trusted enclave and untrusted GPU. The system decomposes the machine learning into two parts, where the control flow part runs inside the trusted enclave and operations that are not privacy sensitive (such as convolutions based on matrix multiplications) are offloaded to the GPU. Unfortunately, the split results in a decrease of training and inference accuracy.

SOTER [35] relies on the associativity property of operators present in DNN models. It assumes that the GPU is untrusted and sends modified parameter data from the SGX enclave. The output data received from the GPU is converted again to produce the expected result. To check the integrity of

the result, SOTER creates challenges and expects the GPU to return a proof of computation. If the integrity is compromised, the proof will be incorrect.

9.1 Hardware-based Attestation

NVIDIA has introduced a *confidential computing* [26] feature in the Hopper architecture. While technical details are currently scarce, this feature is touted to require no changes to the application code, while ensuring both the confidentiality and integrity of data and code running on the device.

With the addition of a vendor-backed hardware TEE solution, there is a question regarding the relevance of software-based attestation. While a hardware implementation provides reasonable levels of security, there have been several examples where the hardware-based techniques were flawed [6, 28, 44]. In these cases software-based techniques could come to the rescue. Software attestation can be complementary to the newly-added confidential computing feature and add another level of security to achieve defense in depth. Further, since the software layer doesn't rely on the private keys embedded in hardware by the manufacturers, it also reduces the TCB.

The trust required to obtain the properties provided by attestation is further reduced by combining both hardware- and software-based approaches. In essence, as long as one of the attestation methods is secure, the properties obtained using attestation hold.

9.2 Software-based Attestation

SWATT [33] uses a verification function that is based on pseudo-random memory traversal to compute the checksum. The verifier measures the execution time and verifies the checksum. Malicious code is required to verify each memory access to replace memory reads of changed locations with expected content, resulting in detectable time overhead. SWATT checks the entire memory of a system and its running time becomes prohibitive on systems with large memories.

PIONEER [32] verifies the integrity and guarantees the execution of code using a checksum function that is closely tied to the Pentium 4 architecture. The checksum function computes a fingerprint of the verification function and sets up an untampered execution environment. It is constructed such that manipulations by the adversary will noticeably increase the computation time.

Kovah et al. [16] and Butterworth et al. [3] extended the checksum computation to work on a Microsoft Windows system (CPU only), enabling a remote verifier to attest to a running system in a corporate environment.

Shaneck et al. [34] describe a software-based approach to remotely attest the static memory contents of sensors without requiring any additional hardware on the sensors nor precise measurements of execution timing. They use self-modifying code that generates memory read and jump instructions during the execution of their code.

Gligor and Woo [8] proposed a system that allows to provably establish a root of trust and provide secure initial states for all software unconditionally. The authors design a family of k-independent (almost) universal hash functions based on polynomials and use Horner's rule to show time- and memory-optimal evaluation of polynomials. An interesting area of future work is to translate these results to the context of computation on GPUs.

10 Conclusion

The prospect of software-only trust root establishment and secure code execution on GPUs offers exciting opportunities: execution of sensitive GPU code that should not be leaked to the GPU operator (code secrecy), correct execution of GPU code in an adversarial environment (code and execution integrity), preserving data correctness and confidentiality in the presence of malicious code on the system (data secrecy and integrity). SAGE represents a first step for achieving these properties on the NVIDIA Ampere architecture, under the circumstances that the architectural details about the Ampere architecture are closed-source. Since architectural knowledge for designing the verification function (VF) is key, our software-based approach to provide secure code execution on GPU paves the way forward for GPU vendors: they are naturally in a position to align the design of the VF to their architectural knowledge and lead the standardization process for trust establishment on GPUs.

Remaining open challenges include the design of software-based secure execution on alternative platforms, improving the execution speed of the verification function, and extend the execution model to support libraries that use a hybrid CPU+GPU compute model (e.g., TensorFlow [41]). Ultimately, an interesting future research question to answer is the interplay between hardware- and software-based approaches for trusted execution to achieve the strongest possible security properties for GPU-based execution.

Abstract

We present IPU Trusted Extensions (ITX), a set of hardware extensions that enables trusted execution environments in Graphcore's AI accelerators. ITX enables the execution of AI workloads with strong confidentiality and integrity guarantees at low performance overheads. ITX isolates workloads from untrusted hosts, and ensures their data and models remain encrypted at all times except within the accelerator's chip. ITX includes a hardware root-of-trust that provides attestation capabilities and orchestrates trusted execution, and on-chip programmable cryptographic engines for authenticated encryption of code/data at PCIe bandwidth.

We also present software for ITX in the form of compiler and runtime extensions that support multi-party training without requiring a CPU-based TEE.

We included experimental support for ITX in Graphcore's GC200 IPU taped out at TSMC's 7nm node. Its evaluation on a development board using standard DNN training workloads suggests that ITX adds $< 5\%$ performance overhead and delivers up to 17x better performance compared to CPU-based confidential computing systems based on AMD SEV-SNP.

1 Introduction

Machine learning (ML) is transforming many tasks such as medical diagnostics, video analytics, and financial forecasting. Their progress is largely driven by the computational capabilities and large memory bandwidth of AI accelerators such as NVIDIA GPUs, Alibaba's NPU [2], Google's TPU [18], and Amazon's Inferentia [3]. Their security and privacy is a serious concern: due to the nature and volume of data required to train sophisticated models, the sharing of accelerators in public clouds to reduce cost, and the increasing frequency and severity of data breaches, there is a realization that machine learning systems require stronger end-to-end protection mechanisms for their sensitive models and data.

[†]Work done while at Microsoft; [‡]Work done while at Graphcore.

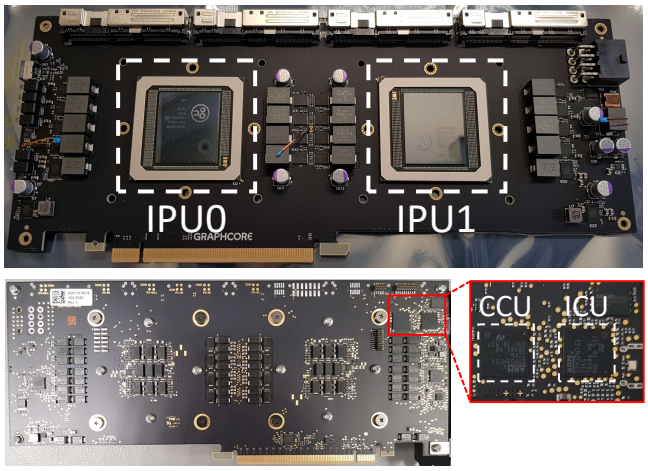

Figure 1: Graphcore Intelligence Processing Unit (IPU) development board (May 2020) with ITX extensions, showing two IPUs on the front side connected to the CCU via the ICU on the back.

Confidential computing [1, 4, 11, 31] relies on custom hardware support for trusted execution environments (TEE), also known as enclaves, that can provide such security guarantees. Abstractly, a TEE is capable of hosting code and data while protecting them from privileged attackers. The hardware can also measure this code and data to issue an *attestation report*, which can be verified by any remote party to establish trust in the TEE. In principle, confidential computing enables multiple organizations to collaborate and train models using sensitive data, and to serve these models with assurance that their data and models remain protected. However, the predominant TEEs such as Intel SGX [22], AMD SEV-SNP [5], Intel TDX [16], and ARM CCA [6] are limited to CPUs. Recently, NVIDIA has announced TEE support in upcoming Hopper GPUs [25] that works in conjunction with CPU TEEs.

Adding native support for confidential computing into AI accelerators can greatly increase their security, but also involves many challenges. Security features such as isolation, attestation, and side-channel resilience must be fitted in their

highly optimized architecture, with minimal design changes, and without degrading their functionality, performance, or usability. An additional requirement is the flexibility to operate with various hosts, including CPUs with no TEE support, CPUs with process-based TEEs such as Intel SGX, and CPUs with VM-based TEEs such as AMD SEV-SNP. None of the accelerator TEE designs that have been proposed meet this requirement, including NVIDIA GPU TEEs. Finally, the manufacturing and assembly process and protocols must be hardened against supply chain attacks.

This paper describes our effort to support TEEs in Graphcore's GC200 Intelligence Processing Unit (IPU), a state-of-the-art custom AI accelerator. We introduce *IPU Trusted Extensions* (ITX), a set of experimental hardware capabilities in IPUs. We show that, using ITX in conjunction with appropriate compiler and runtime support, we can delegate ML tasks to the IPU with strong confidentiality and integrity guarantees while delivering accelerator-grade performance. In particular, ITX can guarantee isolation of an ML application from an untrusted host: application code and data appears in cleartext only within the IPU, and remains encrypted otherwise, including when transferred over the PCIe link between the host and the IPU. Once an application is deployed within an ITX TEE, the host can no longer tamper with the application state or the IPU configuration. ITX can also issue remotely verifiable attestations, rooted in a Public Key Infrastructure (PKI), enabling a relying party to establish trust in a given ML task before releasing secrets such as data decryption keys.

The main components of ITX are a new execution mode in the IPU for isolating all security sensitive state from the host and securely handling security exceptions, programmable cryptographic engines capable of encrypting/decrypting CPU-IPU PCIe traffic at line rate (32 GB/s bidirectional throughput supporting PCIe Gen4), and a novel authenticated encryption protocol for ensuring confidentiality and integrity of code/data transfers without requiring trust in the host.

Trust in ITX is rooted in the *Confidential Compute Unit (CCU)*, a new hardware Root-of-Trust (HRoT) on the IPU board. The CCU provides each device with a unique identity based on a hardware secret sampled within the CCU at the end of manufacturing. The CCU firmware is responsible for managing the entire lifecycle of TEEs on the IPU, including creation, issuing attestation reports that capture IPU and task specific attributes, key exchange, launch, and termination of TEEs. Our design also features protocols for securely provisioning firmware to the IPU in a potentially hostile manufacturing environment, for issuing certificates that capture the identity of all updatable firmware, and for supporting firmware updates without requiring device re-certification.

Several distinguishing aspects of ITX and the IPU programming model result in stronger security than one may expect from CPU-based TEEs:

- An ITX TEE spans the entire IPU, and has exclusive access to all IPU resources until it terminates. Therefore, it is not possible for an adversary to run concurrently on the same resources and exploit the resulting side-channels. This execution model is feasible as most AI workloads require at least one accelerator, with larger workloads requiring thousands of accelerators for hours.

- The IPU memory system consists of large on-chip SRAM attached to its cores, which is loaded with data from untrusted external memory during explicit synchronization phases. Thus, during computational phases, code and data accesses to IPU memory have a fixed latency. This has two security implications: (1) traffic between IPU cores and memory need not be encrypted, as it stays within the chip; (2) this avoids the need for optimizations such as caching or speculation to hide memory access latency, and the resulting side-channels.

- The IPU supports a programming model where allocation and scheduling of all resources on the IPU (cores, memory, and communication channels) are statically managed by the compiler. Hence, the IPU application binary defines its entire data and control flow, including data transfers within the IPU, and between IPU and host memory. This is unlike GPUs where the host software stack (runtime and driver) remain in full control of the execution, and must be trusted to guarantee integrity.

There are many ways for software to utilize ITX to provide end-to-end guarantees for ML workloads, depending on the threat model and capabilities of the host. This paper focuses on configurations where a multi-party ML training workload is deployed to the IPU *without trusting the host CPU*. This mode has the strongest security properties and can be used with any CPU. We describe a prototype software stack and protocols for it, and present its end-to-end evaluation using standard DNN training workloads. Software to support other configurations, e.g., where the IPU is coupled with a hardware-protected CPU TEE, are left for future work.

We have fully implemented ITX in the IPU, taped out in 2020 and manufactured in TSMC's 7nm node. Our extensions use less than 1% of this large ASIC, and do not require any changes to its compute core or memory subsystem. Its evaluation on a development board using confidential ML training workloads suggests a performance overhead of less than 5% compared to non-confidential IPU workloads. While our prototype demonstrated promising results, significant work remains to turn our work into production.

Due to implementation constraints, our prototype uses a discrete HRoT (instead of an on-die core) and it does not encrypt traffic over IPU-IPU links. It is therefore vulnerable to physical attacks, e.g., on the link between the CCU and IPU, or between multiple IPUs. These vulnerabilities are not limitations of our design and can be addressed in future IPU generations by integrating the HRoT on the IPU chip, and by introducing encryption engines on IPU-IPU links.

In summary, this paper makes the following contributions:

1. A set of experimental hardware extensions to the IPU, a commodity custom AI accelerator, that enable high-performance confidential multi-party machine learning.
2. Support for remote attestation and secure key exchange based on a discrete hardware root-of-trust.
3. A pipelined application-level protocol for authenticated encryption & decryption of code and data over PCIe.
4. Protocols for securely provisioning secrets, firmware, and certificates to a device during manufacturing.
5. Prototype software support for enabling confidential multi-party training of ML models expressed in TensorFlow on the IPUs without requiring trust in the CPU.
6. Hardware implementation of ITX in the IPU ASIC manufactured by TSMC in 7nm node, and its initial evaluation on a development board in 2020, suggesting low overheads and orders of magnitude improvements over CPU TEEs. This made our prototype the first AI accelerator to support confidential computing.

While some aspects of our design are specific to IPUs, we hope it can serve as a blueprint for adding TEE support in other specialized devices and accelerators.

2 Background

This section outlines the IPU architecture and programming model, focusing on aspects relevant to security. The section also reviews hardware-based confidential computing.

2.1 IPU Hardware Architecture

Tiles. Each IPU consists of a set of *tiles*, each with a multi-threaded core and a small amount of private on-chip SRAM. The IPU features 1472 tiles, totalling roughly 900 MB of on-chip SRAM. The cores support an instruction set tuned for AI, including specialized vector instructions and low-precision arithmetic. Each core can execute up to six statically scheduled threads. Since on-chip memory is accessed at fixed latency, instructions can be exactly scheduled by the compiler.

Interconnects. The tiles are connected over *internal exchange*, an all-to-all, stateless, synchronous and non-blocking high-bandwidth interconnect whose operation is similarly orchestrated by software. The internal exchange is connected to an *external exchange* interconnect via a set of *exchange blocks*. Each exchange block manages a subset of the tiles and mediates traffic between the two interconnects. Each IPU has a pair of PCIe links that connect to a host server, and additional IPU-Links that connect to other IPUs.

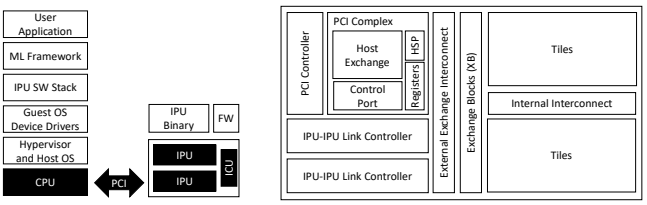

Figure 2: System stack (left) and IPU floorplan (right).

The external interconnect is a packet-switched Network-on-Chip. Tiles use the external interconnect to dispatch packets to the host via PCIe links and unicast/multi-cast packets to tiles on other IPUs via IPU-links. Tiles read data from the host by issuing a *read request* packet and waiting for all associated *read completion* packets. Tiles write data to the host by issuing one or more *write request* packets. Packets are routed based on tile identifiers. For requests, packets from exchange blocks are placed onto lanes based on the source tile identifier of the exchange packet. For read completions, the exchange lane is chosen based on the destination tile identifier, which is recorded in a lookup table in the PCI complex for each outstanding read request.

Exchange Address Spaces. The IPU exposes three address spaces to facilitate communication between the host and the IPU and between IPUs. The *Tile address space* is used by tiles to address one another. The *Host PCI space* is used by the host to address tile memory and on-chip page tables in the Host Exchange block. The *Tile PCI space* is used by tiles to address read requests to host memory over PCI. The IPU can be configured to re-map read requests from tiles to the PCI domain using on-chip page tables.

Host-IPU Interface. The IPU exposes a set of configuration registers to the host via a PCI BAR space. These registers are hosted in a component known as the *PCI Complex*. The PCI complex consists of a *Host Sync Proxy (HSP)* responsible for external synchronization between the host and the IPU, a *host exchange* that translates packets between PCI format and a proprietary external-exchange packet format, *on-chip page tables* for address translation of read/write requests from tiles to the PCI domain, on-chip lookup tables for keeping metadata for outstanding PCI read requests, and a *control port* that provides access to configuration registers of all other internal components.

The host exchange subsystem also includes a component known as the *autoloader*, which enables efficient scrubbing and initialization of tile memory. To initialize a binary in tile memory, the host can load small programs (e.g., a bootloader) into the autoloader, which can then broadcast it to all tiles.

Host-IPU Synchronization. The IPU execution model is based on the Bulk Synchronous Parallel (BSP) paradigm with barriers and supersteps. A superstep involves a global synchronization barrier between all tiles on one or more IPUs, followed by an exchange phase that transfers data between

tiles, followed by a compute phase which ends at another barrier. This process repeats until some application specific criteria is met—e.g., loss is under a threshold.

Using the HSP registers, the host can configure the frequency of synchronization barriers and indicate barriers at which it expects to be notified—e.g., when one or more batch of data has been processed, at epoch boundaries. Once configured, the IPUs can execute multiple supersteps independently without requiring involvement from the host.

IPU Control Unit (ICU). The ICU is a microcontroller integrated on the board and connected with the IPUs via JTAG, and with PCB peripherals for power supply and environmental monitoring. It is responsible for initialization of the IPUs.

Resets. The main means of resetting the IPU from the host is a *secondary bus reset (SBR)* that resets the entire device including the IPUs, the ICU, and the host link; the ICU must re-enable the host link once it comes out of reset. Alternatively, a *Newmanry Reset* can be triggered by writing the IPU control register; it resets the device logic including the host and IPU links, but does not reset the physical links. In both of these resets, tile memory is not scrubbed.

2.2 IPU Software Stack

The IPU software stack compiles and executes applications written in ML frameworks such as TensorFlow and PyTorch. It consists of a compiler, a host runtime, and a set of libraries supported by the IPU device driver.

Compiler. Given a computation graph representing a task (e.g., a TensorFlow XLA graph), the compiler partitions each layer of the graph between tiles, so that each tile holds a part of the model state (weights and activations for some layers) and a part of the input data. The compiler also assigns resources (threads, memory) to each node of the graph, schedules its computation, and finally emits specialized code for each tile.

The resulting IPU binary captures the different phases of execution, including I/O for reading batches of data, code for running the training loop, and I/O for writing the weights of the trained model. I/O phases also include synchronization and internal exchange code for exchanging data among tiles.

The compiler maps all data transfers between the host and IPUs to an abstraction called *streams* supported by the runtime. Data transfers from the host to an IPU (and IPU to the host) are mapped to input (output) streams and compiled to sequences of read (write) instructions to the Tile PCI address space. The compiler also uses streams to implement checkpoints: checkpoint creation maps all model weights to a single output stream, and checkpoint restoration reads them back from a single input stream.

The compiler supports an offline mode, which decouples compilation from execution. In this mode, the compiler generates self-contained IPU binaries, which can be persisted and loaded into one or more IPUs at a later point in time.

Host Runtime. The runtime provides code for loading IPU binaries, and for streaming data in and out of the IPUs. It loads IPU binaries by deploying a small bootloader into a reserved section of each tile memory. The bootloader in turn reads each tile-specific binary from the host into tile memory.

The runtime implements input streams by repeatedly copying data into a ring buffer in host memory and mapping the pages of the ring buffer into Tile PCI space in the on-chip page table. Once the ring buffer is ready and the mapping is defined, code on tiles can issue read requests. Similarly, output streams are implemented by copying data from the ring buffer to application memory.

2.3 Confidential Computing

Confidential computing is a paradigm where code/data remain protected from privileged attackers throughout their lifecycle: at rest, in transit, and *during use*. Central to confidential computing is the notion of a *trusted execution environment* (TEE) with two key capabilities: it can host an application in a hardware-isolated environment, which protects the application from any external access including access from privileged attackers; and it can issue remotely verifiable attestations that capture security claims about the application hosted in the TEE and the platform supporting the TEE. The attestations can be used by a relying party to gain trust in an application.

TEEs are supported by recent processors from Intel and AMD; ARM also recently defined a specification for supporting TEEs. There are broadly two classes of CPU TEEs: process-based and VM-based. Process-based TEEs (e.g., Intel SGX) are designed to isolate a user-space application from an untrusted operating system (both guest and host) and the hypervisor. VM-based TEEs (e.g., AMD SEV-SNP, Intel TDX) are designed to protect an entire guest VM from the host operating system and the hypervisor. TEEs offer varying degrees of protection from attackers with physical access to the CPU. Most TEE implementations assume that attackers can snoop on interconnects between the CPU package and external components (e.g., off-chip DRAM) and protect data by encrypting and integrity-protecting memory traffic.

Remote attestation is typically rooted in an on-die hardware root of trust (HRoT) with exclusive access to a unique device secret provisioned into one-time programmable fuses during manufacturing. During boot, the HRoT uses the secret to derive a device-specific identity key. This key typically endorses keys used for signing attestation reports. The corresponding public key is endorsed by the hardware manufacturer.

3 Threat Model

TEE hardware is subject to a variety of attacks throughout its lifecycle, from chip design and manufacturing up until the hardware is decommissioned.

Trust in TEEs is rooted in hardware, and consequently in the chip designers and their OEMs involved in designing and manufacturing the chips. Additional trust is also required in the infrastructure for issuing certificates to each chip, and for publishing the last known good version of firmware trusted computing base (TCB). While this is also the case with the IPU, we wish to minimize trust in the rest of the supply chain. Hence, we conservatively assume that attackers control the manufacturing and assembly process after tapeout, including the process of provisioning firmware and/or secrets to each device and harvesting their Certificate Signing Requests.

After deployment, we assume a strong adversary that controls the entire system software stack, including the hypervisor and the host operating system, and also has physical access to the host. The adversary can access or tamper with any code and data transferred between the host and the IPU, either in operating system buffers or over PCIe. The adversary can also tamper with device memory directly via the PCI BAR, or map the victim application's tile PCI address space to host-side memory controlled by the attacker. Information leakage through side-channels such as timing, power analysis, and physical probes on the IPU are generally out of scope. However, we wish to offer protection from side-channels based on memory access patterns, and from low-level integrity attacks such as glitching.

We trust the IPU and HRoT packages, and we assume that the adversary cannot extract secrets or corrupt state within the packages. In particular, the IPU includes trusted SRAM within the IPU tiles accessed only via on-chip channels.

With the current generation of IPUs, we make additional trust assumptions in the ICU, which provides connectivity between the hardware RoT and the IPUs, and in links between IPUs. We trust the ICU firmware and the physical links that connect the HRoT, the ICU and the IPU. These trust assumptions can be removed in subsequent generations of the IPU by placing the HRoT on the IPU die, and encrypting communication over IPU-IPU links.

The ML source script and configuration are trusted. The ML framework and the compiler are trusted for integrity of the computation—i.e., to compile the model defined in the ML script correctly into a manifest and IPU binaries. In multi-party configurations (involving parties that do not trust one another), these assumptions can be met by having all parties review the script and configuration for the workload, then confirm that they all locally compile to the same manifest and binaries. Each party is trusted with the integrity and confidentiality of the data streams they provide for the computation; in particular, honest parties are trusted to correctly encrypt their data streams with a fresh encryption key, and to release this key to IPUs only after verifying their attestation report.

In configurations that couple the IPU with a host CPU TEE (e.g., Intel SGX and TDX, AMD SEV-SNP), the CPU package is also trusted, along with any software hosted in the TEE.With process-based TEEs, the CPU-based software

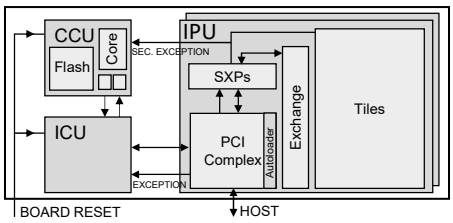

Figure 3: IPU hardware extensions to support trusted execution.

TCB may include the ML training or inferencing script and its framework (e.g., TensorFlow, PyTorch), compiler, and runtime. With VM-based TEEs the TCB may additionally include the kernel-mode driver and a guest operating system. The host runtime is trusted for confidentiality—i.e., to setup a secure, attested channel between the CPU TEE and IPU, and to transfer code/data over the channel.

Under this threat model, we wish to provide confidentiality and integrity guarantees for model code and data, including initial weights, input data, checkpoints and outputs. For training, integrity implies that the trained model is bitwise equivalent to the model obtained in the absence of the attacker. For inferencing, integrity implies that requests yield same results as those obtained in the absence of the attacker.

We wish to provide remote attestation, which refers to the ability of the platform to make remotely verifiable claims that a relying party can use to reason about the TEE's security properties and thereby establish trust in the application hosted within the TEE. Specifically, we wish to ensure that the attestation can deliver temporally fresh evidence that contains all security-sensitive parts of the platform and application state.

4 Overview

Trusted execution in IPUs enables model developers to securely offload an ML job (training or inference) while protecting both its model and data from the hosting platform. In turn, model developers can prove to data providers that their data remains protected from both the hosting platform and the model developers themselves. (Appendix A.1 provides a comprehensive security analysis of ITX.)

The workflow for offloading a job involves TEE creation, generation of an attestation report, its verification by remote parties, code/data encryption, secure exchange of encryption keys, job execution, and decryption of the outcome.

4.1 Hardware Extensions (ITX)

The IPU hardware contains several components (shown in Figure 3) to support this workflow, including a new hardware root-of-trust (RoT), called the CCU, and a new execution mode, called the *trusted mode*, in which all security sensitive state is isolated from a potentially malicious host. This mode

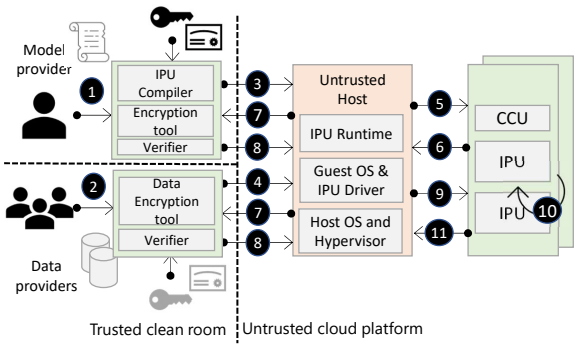

Figure 4: Multi-party training in trusted offline mode. Before training, the remote parties upload their encrypted code, data and certificates (1–4) Once training starts (5–6), they verify the attestation report (7) then release their encryption keys to the CCU (8-9); they can be offline for the rest of the computation. The IPUs train the model in a TEE (10) and releases an encrypted trained model (11), whose key can be shared with model receiver(s).

is entered by writing to a configuration register. (For remote verifiability, this register is measured by the CCU and included in the attestation report.) Once the IPU enters this mode, its configuration registers and tile memory can be accessed only by the CCU and ICU. The only way to exit this mode is via a chip reset, which is extended to scrub all key registers and tile memory.

The IPU also includes programmable AES-GCM engines for authenticated encryption and decryption of code and data transferred between the host and the IPU at PCIe line rate. These engines are hosted in new components, called *Secure Exchange Pipes (SXP)*, located on the interconnect between the PCIe block and the exchange blocks. The SXP and its use are described in Section 6.1.

4.2 Software Support

There are many ways to utilize ITX. For this paper, we illustrate a particular mode, called the *offline mode* (Figure 4). In this mode, a multiparty ML training workload can be deployed in an IPU-based TEE *without requiring a CPU-based TEE*. This mode has strong security properties (e.g., small TCB) and minimal dependencies on the host CPU hardware.

Job Preparation. In offline mode, a model developer uses an extended IPU compiler to statically compile a model training job expressed in an ML framework such as TensorFlow or PyTorch to standalone IPU binaries in a trusted, offline *clean room environment* (1). In addition to the binary, the compiler generates a *job manifest*, which contains auxiliary information required at runtime to execute the job. Next, the model developer encrypts binaries and parameters such as initial weights and learning rate using encryption keys that remain in the clean room environment. The model developer also generates a fresh public key share for key exchange, and a signature over the key share using their certificate. These artifacts, along with the model developer's certificate are packaged together to create an *application package*. Separately, data providers pre-process and encrypt their input data and labels in their own clean room environments, and create *data packages* which include their key shares and certificates (2). The resulting packages are uploaded to an IPU server (3, 4).

Job Initialization. Any entity can initiate execution of the training job using the host runtime, which has been extended to load encrypted code/data into IPUs. For confidential computing jobs, the runtime provides user-mode APIs for operations such as creating TEEs (5) for a job, fetching their attestation reports and additional collateral such as device-specific certificates (6), and relaying key-exchange messages from relying parties to the CCU (8). This runtime is not trusted.

Remote Attestation. In trusted mode, the CCU can issue remotely verifiable attestations, which are relayed to relying parties (7) as proof of TEE configuration for their workload. The attestation is a certificate chain from the IPU manufacturer root CA to an end-certificate signed by the CCU with custom extensions that embed initialization attributes (e.g., measurement of all security-sensitive IPU registers) and job-specific attributes, such as the measurement of the job manifest, and the hash digest of other runtime attributes, including certificate fingerprints of all parties and the CCU's fresh public keyshare. The model developer and data providers verify this report, the model, and identities of other participants. If they decide to make their data available for this job, they derive shared keys using the CCU's public key share and securely exchange their secrets with the CCU.

Job Execution. After the model developer and data providers have released their keys to the CCU, the CCU deploys the keys into the SXPs and starts the job (9) by installing a bootloader into the IPU tiles using the autoloader. The bootloader fetches the application binary from host memory to each tile in 1KB blocks. In trusted mode, these blocks are decrypted and integrity checked by the SXPs before being written to tile memory (see Section 7.3). Once the application binary has been transferred, the runtime initiates execution of the job. During execution, tiles generate read requests for data, also in blocks of 1KB. In trusted mode, the blocks are fetched from host memory over PCIe, and decrypted and integrity checked by the SXPs before being written to tile memory. Similarly, all write requests (e.g., checkpoints and trained model) are encrypted and extended with authentication tags before being written to host memory. The encryption protocol is mostly transparent to the compiler, which can compile *any training algorithm* into binary relying on the data being in tile memory in cleartext and utilizing all available IPU compute resources. Finally, the IPU encrypts the trained model with a key made available only to the model receivers listed in the job manifest.

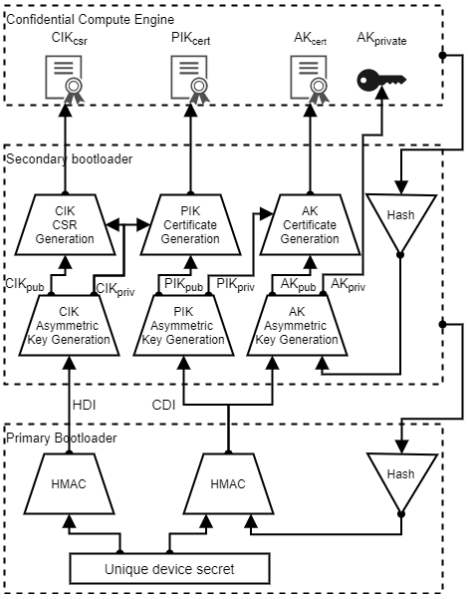

Figure 5: CCU firmware architecture and key hierarchy.

5 Trusted Execution on IPUs

5.1 Confidential Compute Unit (CCU)

The CCU is responsible for associating each device with a unique cryptographic identity and managing trusted execution in its IPUs. The CCU is a discrete chip based on STMicro's STM32H753 microcontroller [24]. This chip was selected as the RoT based on several security features required to implement measured boot and to offer protection from a variety of attacks throughout the IPU lifecycle, such as the ability to provision a custom bootloader during manufacturing and a mode that prevents external access via interfaces such as JTAG. As shown in Figure 3, the CCU is connected to the IPU via the ICU. A dedicated pin receives all exceptions generated by the IPU in trusted mode, giving the CCU firmware full control over exception handling. The CCU reset pin is coupled in hardware with the ICU reset pin and IPU reset, so they cannot be independently reset.

Firmware Architecture and Attestation. The CCU implements a measured boot protocol which is a variant of the Device Identity Composition Engine (DICE) architecture [12, 33]. DICE ensures that each device is assigned a unique identity while minimizing exposure of hardware secrets. Except for the stable device identity, all derived secrets and keys automatically change when firmware (and its measurement) changes, which ensures that low-level firmware attacks do not compromise secrets used within other firmware.

The CCU firmware (Figure 5) consists of three layers: an immutable primary bootloader provisioned in one-time programmable flash memory at manufacturing; a mutable secondary bootloader responsible for device identity and attestation certificates; and a confidential compute engine (CCE) that manages the TEE lifecycle.

During manufacturing, the CCU is provisioned with the primary bootloader firmware. When the device is brought out of reset for the first time, this primary bootloader receives control from ROM firmware, samples a *unique device secret* (UDS) using a hardware-based TRNG, stores it in a region of flash memory, and permanently blocks its access from any other firmware layers. The UDS is the root of the IPU key hierarchy, and this protocol ensures that it is never exposed outside the CCU, not even to the manufacturer.

On every subsequent boot, the CCU loads and authenticates the secondary bootloader from flash using the IPU manufacturer's firmware signing key. Next, it derives two intermediate secrets: a *Hardware Device Identifier* (HDI) from UDS, and a *Composite Device Identifier* (CDI) from UDS and the measurement of the secondary bootloader. HDI is unique to each card, while CDI is unique to each card and secondary bootloader. It then scrubs UDS from memory and transfers control to the secondary bootloader, handing over HDI and CDI.

The secondary bootloader further derives two public-private key pairs: a *Card Identity Key* (CIK) from HDI, and a *Platform Identity Key* (PIK) from CDI. Hence, CIK gives each card a stable identity whereas PIK is unique to each card and secondary bootloader. The bootloader also generates a self-signed CSR for CIK, a PIK CSR, and a PIK certificate signed by CIK. The PIK CSR and certificate contain a custom extension that records measurements of the secondary bootloader and the ICU firmware along with additional device-specific information. The CSRs can be securely harvested during manufacturing and endorsed by the IPU manufacturer CA, which issues CIK and PIK certificates. (See Appendix A.2.)

The secondary bootloader derives the *Attestation Key* (AK) from CDI and the CCE measurement. Hence, AK is unique to each device, secondary bootloader, and CCE. The bootloader issues an AK certificate with the CCE measurement in a custom extension, signed by PIK, and finally scrubs all secrets and transfers control to CCE, handing over AK.

The CCE uses AK to sign attestation reports containing IPU- and job-specific information (Section 5.2). A relying party can validate attestation reports using the device-issued AK certificate, and manufacturer-issued CIK/PIK certificates.

Firmware Update. Per DICE, a secondary bootloader update invalidates PIK certificates issued by the manufacturer and, as UDS is provisioned within each device, the IPU manufacturer cannot independently derive and certify the updated PIK. Instead, we rely on CIK, acting as a local CA, to sign the updated PIK certificate. Additionally, the manufacturer would issue TCB update certificates containing measurements of old and new versions of firmware. A relying party can validate attestations using device-issued PIK certificates, the original PIK and CIK certificates, and TCB update certificates. (See Appendix A.3–A.4 for more details and a hardened variant.)

5.2 TEE Lifecycle Management

The CCU exposes an API for TEE management on the IPU.

TEE Initialization. The first step in securely offloading a job to an IPU is to create a fresh TEE for this job. TEE initialization requires a job manifest (Appendix A.5), public key shares, signatures over the key shares and certificates for each relying party, and a checkpoint counter indicating whether the job is starting or resuming from a checkpoint. During TEE initialization, the CCU first *quiesces* the IPU, ensuring that there are no in-flight read and write requests between the host and IPU. It then switches the IPU into trusted mode, scrubs all tile memory using the autoloader, and measures the state of the configuration registers. It then checks the signatures over the key shares using the certificates, and generates its own fresh EC share, which is used to establish an ECDH shared secret between each relying party and the CCU.

The CCU generates an attestation report signed by the attestation key containing various IPU-specific attributes (e.g., configuration register measurements) and job-specific attributes such as the job manifest, certificate fingerprints for all parties, and the checkpoint counter consisting of the epoch counter and checkpoint identifier. (See Appendix A.6 for the details.)

Each relying party can review the attestation together with the supporting certificate chain, to validate the device and the initial state of the CCU and IPU, then it can compute its ECDH shared secret and wrap a key package that contains the party's data encryption keys and nonces to run the job. (See Table 2 in Appendix A.6 for the keying details.)

TEE Launch. After gathering wrapped encryption keys from all relying parties, the host launches the execution of a job.

First, the CCU computes the ECDH shared secret for each party and uses them to unwrap the key package(s) received from each party. It then combines the nonces to derive a checkpoint key and a final-model encryption key for this run of the job (and, if resuming from another run, the checkpoint key from that previous run to restore its state). This key derivation ensures both that the checkpoint key for this run is fresh (as long as one relying party's nonce is fresh) and that the checkpoint key of a prior run can be recomputed once all relying parties agree to resume from a checkpoint. (See Table 2 in Appendix A.6 for the keying details.)

Next, the CCU deploys a pre-defined bootloader on the IPU tiles using the autoloader, and it deploys a first set of encryption keys to the SXP (including the model key) as specified in the job manifest. It then activates the bootloader (whose measurement is included in the attestation report) on every tile, which issues requests to read their encrypted application binary from host memory. Responses to these read requests are authenticated and decrypted by the SXPs before being copied into private tile memory.

Finally, the CCU deploys the next set of encryption keys (including data keys) as specified in the job manifest, and triggers the main execution loop on the IPU tiles.

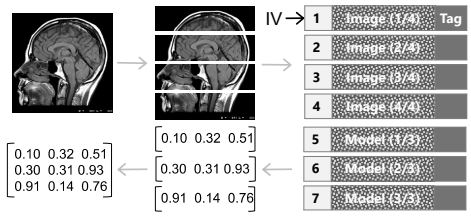

Figure 6: Authenticated encryption with explicit IVs. Data is partitioned into frames with unique IVs. Hardware-level decryption ensures their integrity based on their authentication tag; the receiver must verify that frame IVs match the expected IVs.

TEE Termination. At any point after initialization of a TEE, the host runtime can also request that the TEE be terminated. The CCU may also terminate the TEE in the event of a security exception raised from the IPU such as failure to authenticate a response of a read request. During TEE termination, the CCU quiesces the IPUs, scrubs tile memory using the autoloader, and disables all SXP keys. Finally, the CCU switches the IPU into normal mode via *Newmanry* reset.

A TEE may also be terminated by a hard reset of the device. In this case, all CCU state is cleared and the IPU reverts to normal mode. When it comes out of reset, prior to re-enabling the host links, the ICU scrubs tile memory to ensure that any secrets left over from a previous execution are erased before the host re-gains access to the device.

6 Encrypted Direct Memory Access

Next, we describe the ITX protocol for encrypted code and data transfers to/from IPU tiles. The protocol is application-level as opposed to transport-level. While it is transparent to ML frameworks, it relies on application software (e.g., the IPU compiler) to assign IVs for authenticated encryption and to program the tiles to securely load code, initial weights, training data, and save/reload checkpoints and results. The protocol is supported in IPU hardware by fully pipelined AES256-GCM engines for authenticated encryption at PCIe line rate. This choice results in simpler hardware, allows the IPU to be coupled with untrusted CPUs (or CPUs with varying TEE support) and retains the compiler's ability to maximize PCIe utilization by parallelizing data transfers across tiles.

6.1 Data Format

In the encryption protocol (illustrated in Figure 6), application software partitions each code and data stream into equally-sized encrypted *frames*. Each frame consists of a 128-bit IV, followed by a series of cipher blocks that carry the encrypted contents of the frame, and by a 128-bit authentication tag. Application software is free to use different frame sizes for different streams, as long as the total frame size (including IV and authentication tag) is a multiple of 128 bytes with a maximum of 1KB, which is the largest supported PCIe read. Application

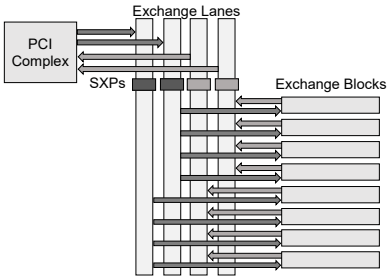

Figure 7: IPU External Exchange Interconnect, with an SXP on each exchange lane. Traffic is forwarded from and to exchange blocks to exchange lanes based on the exchange block identifier.

software can use different keys to encrypt different streams. This is critical for multi-party scenarios where streams are provided and accessed by different parties. Crucially, application software must ensure that IVs are never reused across frames encrypted with the same key, which would be catastrophic with AES-GCM. In our implementation, this invariant is ensured by the compiler, which constructs the IV by combining stream-specific identifiers and frame indexes, and the fact that both code and data streams are write-once abstractions. Together, this guarantees that unless the associated key has been compromised, authenticated decryption with the correct IV yields the correct payload.

6.2 Hardware Support

Multiple components in the IPU support ITX encryption. The IPU includes blocks, called *Secure Exchange Pipes*, extensions to packet formats for carrying encryption-related information, and extensions to exchange blocks and the PCIe complex for supporting the task of mapping frames to keys.

Secure Exchange Pipe (SXP). The SXP is a programmable hardware block that supports AES256-GCM authenticated encryption and decryption of frames. Each SXP achieves 16 GBps unidirectional throughput with negligible impact on latency. As shown in Figure 7, there are four SXPs placed on the exchange interconnect (two per direction) to support encryption/decryption at PCIe Gen4 line rate (32GBps bidirectional). In trusted mode, each SXP is configured to intercept read/write requests from four exchange blocks.

AES-GCM Engine. The SXP's core is a fully pipelined AES-GCM engine that supports 16 *physical key contexts* to enable concurrent requests. Each context can be programmed by loading a 256-bit key into control registers exposed to the CCU via an internal control bus. While frames may be interleaved, for functional correctness we require that *each context processes a single frame at a time*. This invariant is enforced by the compiler, as detailed in Section 7.1.

The core implements the standardized AES256-GCM algorithm with two restrictions: the additional authenticated data is always empty; and the plaintext is block-aligned and not empty. For convenience, we also treat the IV as a full 16-byte block, including the 32 bits of internal block counter. In each cycle, the core performs one of the following operations on its context: (i) the context is idle and the core receives the IV for the frame, (ii) the context is active and the core receives a block of data, or (iii) the context is active and the core receives a MAC. The core detects context switches by comparing key context identifiers between consecutive cycles, so that it can fetch the next context before the next operation.

Frame encryption/decryption. The SXP receives three types of external exchange packets: read requests (egress); read completions requiring decryption (ingress); and write requests requiring encryption (egress). Their headers are extended to carry additional information to help the SXP determine how the packets should be handled: an `AES` bit indicates that the read completion or the write request is encrypted; a 4-bit `KEY_INDEX` field identifies the physical key context to use; and a `CC` bit indicates the last packet of the frame and triggers the computation of its authentication tag.

In write request packets (outbound to the host PCIe domain), the `AES` and `CC` bits are set by the tile, whereas the `KEY_INDEX` is set by the SXP. In read completions packets, the information is set by the PCIe complex based on trusted state it maintains about pending read requests.

Read request packets and packets with the `AES` bit unset do not require encryption/decryption; they are passed unchanged. For all other packets, the header bypasses the AES core, then the AES core handles each packet (and its blocks) depending on whether a frame starts, a frame continues, or a frame ends.

Key Selection. Each SXP supports multiple physical key contexts to enable encryption/decryption of concurrent I/Os. The SXP provides a set of programmable (by CCU) registers to define a mapping between packets and the physical key context to use for encrypting/decrypting their payload. The compiler produces this mapping by assigning a set of tiles associated with an exchange block context to access a single stream. Upon receiving a packet, the SXP looks up the physical key context using the exchange block context index computed from the source tile identifier in the header.

Once the SXP infers the physical key context, it updates the `KEY_INDEX` field in the request packet header. For write requests, the field is then used by the SXP to switch the AES core to the inferred physical context for encrypting its payload. However, for read requests, the situation is more involved, as the read requests bypass the AES core, and the inferred physical key context must be used to decrypt the read completions that will be returned by the host after the read request has been processed. When the PCI complex receives the read request, it caches the `KEY_INDEX` and `AES` fields in an on-chip lookup table along with other metadata, such as the source tile identifier. When the corresponding read completions arrive from the host, the PCI complex retrieves these fields from this lookup tables and inserts them into the read completion packets. The SXP can then use these values to identify the physical key context to use for decrypting the payload. The

PCI complex tracks the number of pending read completion packets for each request, and sets the `CC` bit on the last one.

7 Software Extensions

We now describe a set of extensions to the IPU software stack to compile and execute confidential ML tasks using ITX in offline mode. This mode is triggered by a Tensorflow configuration option. When enabled: (1) The XLA backend transforms the computation graph to use a new abstraction called *confidential data streams* for all data transfers including initial weights, training data, checkpoints and the trained model. (2) The IPU compiler compiles the computation graph into a set of IPU application binaries (one for each IPU), where each binary is a concatenation of tile-specific binaries. The compiler encrypts tile binaries into a set of encrypted frames using a freshly sampled model key. A frame is assigned a unique IV comprised of code type, IPU/tile IDs and frame index. (3) The IPU runtime is extended to securely bootstrap the task, then transfer the encrypted binaries and data between the host and IPU. (See Appendix A.8 for a sample scenario.)

7.1 Confidential Data Streams

Confidential data streams is a compiler and runtime abstraction for transferring data to/from the IPU with confidentiality and integrity guarantees, leveraging SXPs. Each stream is a sequence of data instances encrypted with the same symmetric encryption key. Each data instance is partitioned into a sequence of frames, and each frame is encrypted using a unique IV composed of a stream type (data), a stream identifier, and the index of the frame within the stream.

The compiler and the runtime implement reads and writes to confidential data streams as follows. As discussed in Section 6.1, the compiler first assigns a region in tile PCI space to each stream, subject to the constraint that it never exceeds the total capacity of the IPU ring buffer (e.g., 256 MB).

Next, the compiler assigns sets of tiles to read from or write to each stream, reserves SRAM on each tile to hold a part of the stream, and generates SXP mappings, subject to the constraints that (a) the exchange block context associated with these tiles map to physical key contexts assigned to the stream, and (b) the number of physical key contexts in use at any point in the program does not exceed 16 for any SXP.

To maximize performance under these constraints, the compiler may introduce synchronization points in the application where existing keys are invalidated and new keys are loaded. The compiler includes these synchronization points in the job manifest, along with their key identifiers; and the (untrusted) IPU runtime uses this part of the manifest to ask the CCU to load the next decryption keys into the SXPs at these points. The key changes apply only to input streams. Keys for output streams are derived and loaded by the CCU at TEE launch, and do not change throughput its lifetime. A malicious runtime not following the job manifest's key schedule can only cause decryption failures, resulting at most in denial-of-service.

Next, the compiler schedules read/write operations on each tile. The schedule is required to satisfy a hardware constraint that, at any point, the tiles that generate requests targeting any given physical key context be associated with a single exchange block context. This is because, while the exchange block can dynamically synchronize and regulate requests within each exchange block context (so that its physical key context is used by one tile at a time) there is no such synchronization across exchange block contexts.

Finally, the compiler generates code on each tile that implements the schedule, to issue read/write requests for the accessed frames. (Details are omitted due to space constraints.)

7.2 Secure Checkpointing

Checkpoints are saved to and restored from host memory, and are implemented via data streams. Secure checkpointing is implemented via a special form of confidential data streams, where the IV captures the epoch (counting the number of checkpoint resumptions for this job) and the checkpoint identifier (counting the number of checkpoints stored within an epoch.) The CCU uses a separate checkpoint key for each epoch, and makes the epoch counter and checkpoint identifier available to IPU tiles via the bootloader at the start of the application. (See Appendix A.7 for more details.)

7.3 Secure Bootstrapping

Secure bootstrapping is the process of securely loading encrypted application binaries into the IPU, either at the start of a job, or while resuming a job from a checkpoint.

Bootstrapping involves the following steps. First, the IPU runtime loads the encrypted IPU binary in host memory and creates a TEE using the CCU APIs; this switches the IPU into trusted mode. Next, the CCU installs a *bootloader* (shown in Appendix A.5) onto every IPU tile using the autoloader described in Section 2.1, and also configures the SXPs with the model-decryption key. The bootloader on each tile fetches the tile's binary from host memory by issuing a sequence of read requests. Each frame received from the host is intercepted by the SXPs, authenticated and decrypted, and copied into tile memory. The bootloader then checks that the received IV matches the expected IV built into the bootloader logic; this check is performed in software because the SXPs only guarantee authenticity of each frame, not the integrity of the entire stream. Failure of this check indicates an attempt by the host to tamper with the code stream, such as by replaying/reordering frames. In such event, the tile raises a security exception, which is handled by the CCU. If all checks pass, the bootloader reconstructs the original binary by stripping IVs and authentication tags from all frames.

Finally, the bootloader computes a hash of the tile binary; the tiles accumulate a hash of the whole application; and the CCU checks that it matches the measurement in the job manifest, or generates a security exception otherwise. This protocol, together with bootloader integrity (its measurement is included in the attestation) guarantees application integrity.

8 Evaluation

Our evaluation focuses on TEE overheads for ML training when using CPUs and IPUs.

Implementation. We have implemented ITX on the IPU on a non-production development board. The IPU chip has been fabricated in TSMC's 7nm node, including the on-chip security extensions, which account for $< 1\%$ of the chip size. As part of post-fabrication validation, these extensions have been tested to verify they conform to their specified behavior.

We have integrated the CCU on the board and implemented the architecture described in Section 5, including the protocols for measured boot and TEE management.

We have implemented a software prototype for confidential training tasks where the host CPU server is untrusted. Our prototype includes experimental support in the ML framework, IPU compiler and runtime. There are a few gaps in our prototype: (1) our implementation currently supports only one IPU on the board; (2) the compiler makes use of only one logical key region onto which code, data, label, checkpoints, and outputs are mapped; nevertheless, every encrypted frame is statically assigned a unique IV, preserving the invariant that each IV is used only once; (3) secure resumption is not yet implemented; and (4) the bootloader deployed on IPU tiles does not measure the IPU binary after decryption.

Experimental Results. Figure 8 summarizes the hardware and software configuration of our testbeds. We evaluate the performance of confidential training on ResNet models of various sizes (20, 56, and 110) on the Cifar-10 dataset. The dataset consists of 60,000 32x32 images spanning 10 classes; 50,000 of these images are used for training the dataset and the remaining are used for testing the resulting model. We ran the same training code and data configurations in clear and confidential modes, and confirmed that they both yield models with the same prediction accuracy.

We compare IPU TEEs against CPU TEEs based on the largest available AMD SEV-SNP server. The early IPU development boards operate at reduced frequency of 900 MHz. The AMD CPU testbed utilizes 48 single-threaded cores; hyper-threading does not improve performance due to high vector unit utilization leaving little room for another hyper-thread. Scaling from 32 to 48 cores improved performance by 10%.

Figure 9 shows the training throughput that we achieve in clear and confidential modes. IPU-based training even with a single IPU operating at reduced frequency is 12-20x and 13-17x faster than CPU-based training in clear and confidential

Testbed	Training configuration
AMD SEV-SNP 48-core VM on EPYC 7763	ResNet-20. Batch size: 1534; 32 epochs. ResNet-56. Batch size: 768; 32 epochs. ResNet-110. Batch size: 384; 64 epochs.
ITX IPU @ 900 MHz, Intel Xeon 8168	ResNet-20. Batch size: 64; 32 epochs. ResNet-56. Batch size: 32; 32 epochs. ResNet-110. Batch size: 16; 64 epochs.

Figure 8: Testbed configuration for TensorFlow training of ResNet models on Cifar-10 dataset. In each configuration, batch sizes are optimized to yield maximum performance. (Smaller batches do not affect correctness, but may improve convergence or accuracy.)

Figure 9: Training throughput of ResNet models on cifar-10.

modes respectively. Enabling SEV-SNP introduces modest overheads, ranging from 8% (small model) to 14% (large model) while the overheads of enabling ITX range from 3% (large model) to 58% (small model). The ITX overhead is dominated by one-time setup cost, which is amortized over large training times; this cost includes TEE initialization and attestation (40%), TEE launch including SXP setup (43%) and TEE termination including SXP scrubbing (13%). Runtime encryption introduces only 4% of the total overhead. More generally, we expect the one-time cost to be negligible with state-of-the-art models, which take weeks or days to train. With ResNet-110 model, the overall overhead is just 3% (1123 vs 1089 seconds for running 64 epochs). We also expect that utilizing both IPUs at full frequency would deliver an additional performance improvement (up to 3.5x) over CPUs.

In summary, the evaluation shows that using ITX, AI workloads can continue to benefit from the use of accelerators without compromising on performance or security.

9 Discussion

Trusted CPU TEEs. While this paper mainly focuses on a configuration where IPUs are attached to an untrusted CPU, ITX supports configurations with varying trust in CPU TEEs.

For instance, ITX can be used in a configuration where IPUs are coupled with a process-based CPU TEE (e.g., Intel SGX) hosting TensorFlow, the IPU compiler and the IPU runtime, with the IPU kernel-mode driver and the OS running outside the TEE. In this configuration, the enclave would receive an encrypted model script from the model developer,

and the IPU runtime would encrypt the compiled IPU binary with fresh keys. Similarly, the enclave would receive encrypted training data from data providers on the basis of an Intel SGX and IPU attestation. Within the process-based CPU TEE, the data can be decrypted, pre-processed and aggregated (in parallel with job execution), and re-encrypted by the IPU runtime with fresh keys. Encrypted code/data still then need to be copied to a run buffer allocated outside the enclave (in the host process) accessible to the IPU. While this configuration has a larger TCB and incurs higher CPU cost, it offers greater flexibility and support for inferencing scenarios.

Inferencing. While this paper mainly focuses on training, ITX does support inferencing workloads. Scenarios, where the number of remote inference clients using a model is small and mostly static, can be served by the existing architecture (no trust in the CPU) without additional overhead by assigning a key context to each client. Scenarios, where the number of clients is large and dynamic, could be supported by introducing a trusted front-end server component (in a process-based TEE on the host CPU or a remote CPU) that terminates TLS connections, receives inference requests from the clients, and re-encrypts them in batches using a smaller number of key contexts on the IPU (to avoid frequent expensive re-keying in the IPU). This architecture still allows decoupling the choice of CPU TEEs and accelerator TEEs. This is unlike GPU TEEs that require the CPU and GPU TEEs to be on the same platform. Finally, the TCB of the re-encrypting TEE is relatively small and independent of the application.

Side-channels. Our design intends to minimize leakage from side-channels. On the IPU itself, leakage due to memory access patterns and timing is minimized for two reasons. First, computation on the IPU is statically scheduled by a trusted compiler. It is therefore possible to analyze a workloads at compile time to ensure that memory access patterns are data independent, or add padding otherwise. Second, the IPU cores do not rely on speculative execution and on-chip memory accesses incur a fixed latency. As a result, all I/O between the untrusted host CPU and IPUs occurs at fixed time intervals. Thus, the attacker can observe the time taken to process an entire batch, as opposed to time taken to process each layer in the model [15].

10 Related Work

Trusted hardware. There is a history of work [7, 8, 10, 13, 20, 20, 21, 27, 32, 35] on trusted hardware that isolates code/ data from the rest of the system. Intel SGX [22] and AMD SEV-SNP [5] are the latest in this line of work. Our work extends this approach from general-purpose CPUs to accelerators.

Trusted execution on accelerators. Our work is the first to demonstrate an ASIC with confidential computing capabilities and the only one that does not require trust in CPU TEEs.

NVIDIA recently announced confidential computing support in upcoming Hopper GPUs [25]. Their design shares the same core principles as ITX on IPUs. Hopper GPUs are equipped with an on-package hardware RoT responsible for attestation and enforcing course-grained GPU isolation under the assumption that on-package GPU memory is trusted. Hopper GPUs also support encrypted and integrity-protected communications (kernels and data) to and from the GPU. However, the NVIDIA design requires a VM-based CPU TEE as the responsibility of attesting and establishing a secure channel with the GPU lies within the kernel-mode driver.

Numerous mechanisms have been proposed to enable CPU TEEs to securely interact with I/O devices—e.g., GPUs [17, 34, 37], FPGAs [19, 26, 30, 38], and AI accelerators [14, 36, 39]. Some of this work has attempted to reduce trust on privileged host via hardware support on the GPU [34] or on the CPU [17]. Graviton [34] extends the GPU with support for secure resource management, and relies on a trusted GPU runtime hosted in a process-based CPU TEE to manage the TEE lifecycle. HIX [17] requires extensions to process-based CPU TEEs, including the PCI interconnect and the CPU's MMU. GuardNN has attempted to remove the CPU from the TCB [14] by introducing instructions for establishing a secure channel between remote users and the device, and for decrypting/encrypting inputs/outputs. However, such architecture does not guarantee integrity as the instruction schedule can be tampered by attackers controlling the CPU.

TEE-I/O. In parallel with our work, there has been an industry-wide effort to develop TEE-I/O, a standard framework for assignment of devices to VM-based CPU TEEs. This effort also includes the development of TEE Device Interface Security Protocol (TDISP [29]), an architecture for devices that support TEE-I/O. TDISP provides specifications for establishing trust between the VM-based TEE and the device (SPDM [9]), and for secure TEE-device communication (IDE [28]) and secure management of the device's lifecycle.

CPUs and devices that support TDISP are expected to be deployed in the next couple of years. Compared to application-level protocols (such as Section 6), TDISP is more efficient and transparent. CPUs that support TDISP provide hardware encryption for PCIe communication, removing the need for software encryption using explicit IVs. However, TDISP currently supports only VM-based TEEs, which brings the OS, device drivers, and other user-mode components in the TCB.

11 Conclusion

We presented ITX, a set of experimental hardware extensions for Graphcore IPUs. Our design provides application-level confidentiality and integrity for ML tasks offloaded to an untrusted cloud provider. We also presented a software architecture that removes trust from host CPUs, thereby minimizing the trusted computing base and removing dependencies on CPU TEEs. We implemented them in the GC200 IPU taped out at TSMC's 7nm node, and experimentally confirmed small performance overheads for training large models.

A APPENDIX

A.1 Attack Vectors and Security Analysis

Table 1 summarizes the attack vectors discussed in Section 3 and, for those covered by our threat model, how ITX mitigates each of these attacks.

A.2 Firmware Provisioning and Device Certification

In this section, we describe an example process for firmware provisioning and device certificates that would be followed if ITX were to be used for IPUs in a production environment. During board manufacturing, the CCU would be provisioned with firmware followed by a board reset to harvest certificate signing requests (CSRs) generated by the execution of the primary and secondary bootloaders. The CSRs would then be used by the IPU manufacturer to issue device certificates.

Firmware Provisioning. The CCU is provisioned with firmware using the SoC's Secure Firmware Install (SFI) feature [23]. The firmware package consists of all firmware layers discussed in Section 5.1 and the configuration bytes (called `OPTION`), whose secure user memory registers are configured so that secure user memory includes only the regions onto which the secure bootloader is deployed. The firmware package is encrypted with a symmetric key, which is provisioned to a hardware security module (HSM).

The encrypted firmware package and the HSM are used by the board manufacturer to deploy CCU firmware during

Threat	Mitigation
Host (Software, Physical)	
IPU Memory Access, e.g., host software uses MMIO and PCI BARs, physical attacker tampers with on-chip memory	MMIO blacklist prevents CPU from accessing code/data in IPU; access via interfaces JTAG prohibited; IPU memory cannot be physically accessed w/o breaking into the package.
Host CPU, Memory, and PCIe bus, e.g., read/write, replay, or re-ordering of code/data in host memory or in transit, including DMA buffers, PCIe bus	Code/data are encrypted with AES-GCM with explicit IVs, and keys not shared with the host; uniqueness and integrity of IVs are ensured by trusted code executed on tiles.
IPU Binary Malleability, e.g., host replaces model encryption key or encrypted code	Bootloader computes hash of the tile binary; hash accumulated and checked against expected measurement in the job manifest. (Not implemented.)
IPU Connectivity, ICU-CCU or ICU-IPU Tampering on the development board	**no**; attacker can mount a physical attack to (1) retrieve the key(s) sent to IPU, and (2) tamper with ICU FW measurement sent to CCU
IPU-IPU Tampering	**no**; attacker can mount physical attacks against multi-IPU tasks; tamper with data sent across IPUs.
Supply Chain, Firmware	
Primary Bootloader Provisioning Tampering	The IPU manufacturer checks whether the signed bootloader manifest includes the expected nonce provisioned into the CCU primary bootloader.
Using non-genuine, known vulnerable TCB components	Firmware authorization; hardened measurement protocol outlined in Appendix A.4.
Side-channels	
IPU Memory	IPU memory access patterns cannot be observed by co-located attacker as the IPU is entirely assigned to one job at a time.
Host Memory and PCIe Bus	**no**: attacker can observe access patterns to host memory and on PCIe bus. However, these patterns do not leak much information in the BSP model, e.g., the size and number of minibatches, but not their contents.
Power and Timing	**no**: attacker can measure power consumption and/or execution time of a superstep. Similarly, this does not leak much information for typical ML tasks.

Table 1: Potential threats and how ITX mitigates them. Physical access attacks on the CCU-ICU-IPU and the IPU-IPU channels can be mitigated once the CCU is integrated on the IPU and AES-GCM is utilized to protect the IPU-IPU channels.

the manufacturing and testing. The chip tester implements a multi-stage protocol between the CCU secure bootloader and the HSM, during which the HSM authenticates the certificate issued by the CCU and wraps its firmware encryption key using the certified public key. This enables the CCU secure bootloader to decrypt the firmware package, to install the firmware, and to configure the `OPTION` bytes based on the requested configuration.

While this SFI process guarantees confidentiality of the firmware, it does not directly protect its integrity: provisioning may be subject to supply-chain attacks that would replace CCU parts provisioned using SFI with CCU parts containing malicious firmware. We extend SFI with protection against such attacks by injecting a secret known only to the IPU manufacturer into the primary bootloader. Once the CCU has been integrated onto an IPU board, a challenger can ask the primary bootloader to prove possession of the secret.

This process entails the following three steps. First, the IPU manufacturer generates a fresh secret for every batch of CCUs. The secret is injected to the primary bootloader of the CCU firmware. Second, the IPU manufacturer derives from the secret an asymmetric batch-specific bootloader manifest signing key. After deriving this key, the IPU manufacturer keeps only the public part. Third, the IPU manufacturer issues a certificate for the public bootloader manifest signing key. The certificate is signed by the IPU manufacturer Firmware certificate authority (CA). This certificate contains a batch number, and is valid till the production date of the batch.

Device Certification. In order to certify its device identity keys, the board tester resets the board and harvests the CIK and PIK CSRs generated for the board and platform identity keys, as well as the bootloader manifest. The command to harvest the bootloader manifest includes a fresh nonce, to be echoed in the signed bootloader manifest.

In response, the IPU manufacturer verifies the CSRs received by the card manufacturer and issues CIK and PIK certificates that are signed by the CIK and PIK CAs of the IPU manufacturer. In addition, the IPU manufacturer validates the bootloader manifest against the bootloader manifest signing key certificate specific to the batch to which the CCU belongs, and ensures that the nonce matches the expected one.

A.3 Firmware Updates

The CCU firmware includes a secondary bootloader and a CCE, both authenticated by the primary bootloader and possibly updated after the card has been deployed in production.

Updating the Secondary Bootloader. The secondary bootloader involves relatively complex cryptographic operations, and may need to be updated in the field. As discussed in Section 5, the platform identity key (PIK) is derived from UDS depending on the hash of the secondary bootloader. Therefore, any updates to the secondary bootloader changes the platform

identity, and PIK certificates issued by the manufacturer are no longer valid, requiring device re-certification.

Unfortunately, re-certification of a remote device by the IPU manufacturer can be a complex and lengthy operation as the manufacturer (by design) does not retain unique device keys. Thus, it requires collection of CSRs from the device, and more importantly an authentication mechanism to ensure that the manufacturer signs only PIK certificates exported from devices in the cloud provider's datacenters.

We overcome this challenge via a protocol that enables updates to the secondary bootloader without invalidating manufacturer-issued certificates.

Prior to updating the secondary bootloader (say to version Y), the cloud provider's IPU Firmware CA issues a TCB update certificate capturing the measurement of the new version of the secondary bootloader and revokes previous certificates for versions of the secondary bootloader that should no longer be deployed.

After a firmware update has been deployed, the primary bootloader generates a new CDI (CDI^Y). The secondary bootloader generates platform identity and attestation keys specific to this version of firmware (PIK^Y and AK^Y). However, the card identity key (CIK) stays the same as it does not depend on the measurement of the secondary bootloader. The PIK^Y certificate, hence, is signed by the original CIK, which has been certified by the manufacturer.

Subsequently, a remote challenger can combine the TCB update certificate with the CIK certificate originally issued by the manufacturer to verify the PIK^Y certificate is issued by the device using the original CIK, and that the measurement of the new secondary bootloader in the PIK^Y certificate matches the measurement of the secondary bootloader in the TCB update certificate.

Updating the CCE. Updates can be applied at any point without the need for any additional certification from the manufacturer. When a device boots with a new version of CCE, it generates a new attestation key with a signature over the public AK along with a hash of the CCE using the PIK. Quotes generated by the updated version of CCE firmware can be validated using a valid PIK certificate.

A.4 Measured Boot Protocol

The protocol discussed in Section 5.1 is still susceptible to advanced chosen-firmware attacks: a malicious secondary bootloader could impersonate another version of the firmware by using CIK to endorse a PIK certificate for the corresponding firmware measurement. Firmware authorization provides a strong defense against such attacks—the malicious firmware would need to be correctly signed by the IPU manufacturer to run as secondary bootloader. We can harden the boot protocol further by moving CIK and PIK generation into the primary bootloader (as shown in Figure 10) without revealing the private CIK to the secondary bootloader.

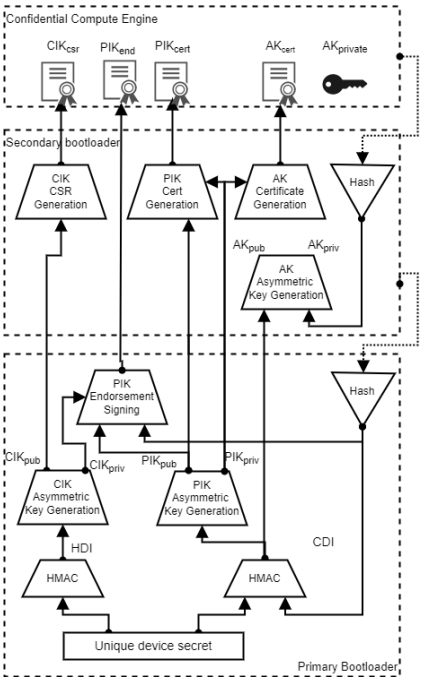

Figure 10: Hardened boot protocol that protects against bootloader impersonation attacks.

In this protocol, the primary bootloader generates CIK from UDS, and generates PIK using CDI and the measurement of the secondary bootloader. To allow a relying party (e.g., IPU manufacturer CA) to attest that the PIK was indeed generated by the primary bootloader, the primary bootloader creates a custom structure, known as PIK endorsement, containing the PIK public key along with a measurement of the secondary bootloader, and a signature over these two attributes using the CIK. The bootloader then scrubs the CIK private key and passes public CIK and PIK keys along with the private PIK and the PIK endorsement to secondary bootloader. During manufacturing, the IPU manufacturer PKI issues a PIK certificate only after validating the PIK endorsement structure. (Our prototype CCU does not implement this protocol to keep the primary bootloader simple.)

A.5 Compiled Manifests and Bootloader

Job Manifest. The compiler-generated job manifest includes all the information required by the IPU runtime and CCU to create and launch a new TEE, which will host the ML task. The manifest contains the hash digest of the application binary loaded into each IPU. It lists the synchronization points at which the IPU needs to synchronize with the host, and for each synchronization point, it keeps the following information:

- the key region identifier assigned to each stream that will be read or written following the end of synchronization (i.e., the mapping between a stream identifier j to a key region identifier);

- the ring buffer region (i.e., Tile PCI space in the ring buffer) assigned to each key region (key region definition registers);
- the part of each stream that has been mapped to the ring buffer region (stream offset);
- the set of physical key contexts to which the stream key needs to be loaded;
- the physical key context assigned to each exchange block context (exchange block context map registers); and
- the key region to which each physical key context is assigned (physical key map registers).

Secure Code Bootstrapping. The code snippet below illustrates the bootloader code that fetches the application binary frames and confirms the integrity of the IV of each frame.

```
def bootloader():
  IPU_id = get_current_ipu_id()
  tile_id = get_current_tile_id()
  num_frames = TOTAL_TILE_MEMORY / (MAX_FRAME_SIZE
       - IV_SIZE - TAG_SIZE)
  for index in range(1, num_frames):
    expected_iv = StreamType::CODE | ipu_id |
        tile_id | index
    frame = read_next_frame_from_host()
    if expected_iv != get_iv(frame):
      raise_security_exception()
    strip_iv_and_tag(frame)
  compute_hash()
```

A.6 Attestation

Cryptographic Operations. Table 2 details the keys sampled, derived, and exchanged at the start of a run in trusted mode. We rely on standard algorithms: Elliptic Curve Diffie-Hellman for establishing shared secrets, a KDF for deriving keys, and an AES-based authenticated key-wrapping scheme. These operations rely on the attestation of the manifest and runtime parameters, including all public keyshares. Each party provides its own random nonce, and the CCU combines them to deterministically derive keys for checkpoints and the final model; these keys are fresh secrets as long as one party is honest. To resume from a checkpoint saved in a previous run, the attested runtime parameters ensure that all parties agree on the epoch counter and checkpoint identifiers, and the parties provide their nonces for the previous and new run.

Remote Attestation. During TEE creation, the CCU generates an attestation report that captures security-critical attributes about the IPU and runtime configuration, including:

- the measurement of configuration registers;
- the measurement of the IPU bootloader used for loading application binaries onto IPUs;
- the measurement of the job manifest;

Key or secret		**Provider**	**CCU**
public/private keyshare for each relying party p	X_p, x_p	fresh EC share	receive X_p
encryption key for each input stream j	k_j	fresh key	unwrapped
public/private keyshare for the CCU in this run	Y, y	receive Y	fresh EC share
nonce for p in this run	$s_{p,Y}$	fresh secret	unwrapped
wrapping key for p, Y with salt $a = X^p \|\| Y \|\| M$	w_p	$\mathsf{KDF}[x_p \cdot Y](a)$	$\mathsf{KDF}[y \cdot X_p](a)$
key to load checkpoints saved by prior run Z	k_{load}	N/A	$\mathsf{KDF}[\vec{s}_{p,Z}]('ck')$
key to save checkpoints	k_{save}	N/A	$\mathsf{KDF}[\vec{s}_{p,Y}]('ck')$
key to save final model	k_m	unwrapped	$\mathsf{KDF}[\vec{s}_{p,Y}]('m')$

Table 2: Keying for a workload with manifest M between relying parties identified by their public keyshares $\vec{X}_p$ and a CCU identified by its fresh CCU public keyshare Y for this run. After attestation, an ECDH shared secret w_p is used for wrapping k_j, $s_{p,Y}$, and $s_{p,Z}$ when resuming from Z from p to the CCU, and optionally for wrapping k_m from CCU to any party p designated as a receiver of the final model. The keys used for encrypting checkpoints and the final model are derived from nonces from all relying parties, ensuring these keys are fresh (as long as one party is honest) and require agreement from all parties to be released.

- the hash digest of the attributes for this run, including:
  - the public keyshare of the CCU for this run (Y);
  - the epoch e and checkpoint counter c from which the job is restarted (if any);
  - the certificate fingerprints of all parties ($\vec{X}_p$);
  - a stream assignment, specifying a party for each input, and parties (model receivers) that receive the model key.

The host collects the attestation report, along with a CCU-issued certificate chain, which includes the AK, PIK and CIK certificates, and is rooted at the self-signed CIK certificate. These are presented to relying parties along with: the original CIK and PIK certificates, the TCB update certificates for the secondary bootloader and ICU firmware, and any intermediate CA certificates.

A relying party can verify the attestation report as follows:

1. Validate the CCU-issued certificate chain and auxiliary certificates; and check for certificate revocation.
2. Confirm that public key of the CIK certificate issued by IPU manufacturer matches the public key in the CIK certificate obtained from the CCU.
3. Confirm that any updates to the secondary bootloader and ICU firmware are rooted to a valid certificate chain. Two checks are required: (i) if there exists a TCB update certificate issued for the secondary bootloader with a

hash digest matching the hash digest in the CCU-issued PIK certificate; (ii) if there exists a TCB update certificate issued for ICU firmware with a hash digest matching the hash digest in the CCU-issued PIK certificate.

4. Review the attested manifest and attributes for this run.

Secure Key Exchange. For each run, each party p derives a fresh wrapping key w_p using its private keyshare x_p and the public keyshare of the attested CCU Y. This key is used to wrap a key package containing the streams identifiers assigned to the party and the party's key for these streams k_j, and the nonce(s) $s_{p,Y}$ for the current run (and $s_{p,Z}$ for the previous run if the current run is resuming from a checkpoint saved in run Z.) The CCU can derive the wrapping key for party p using its private keyshare y and the party's public keyshare X_p. In possession of $\vec{w}_p$, the attested CCU can unwrap the key packages of all parties, which are made available during the TEE launch stage.

The parameters of the model are encrypted using the final-model key k_m that has been derived by the CCU using the nonces obtained from all parties. The parties engage in a protocol for exchanging their nonces so they can derive the key once they possess all nonces. The CCU can additionally release the final-model key to model receivers listed in the attestation report using the wrapping key shared between itself and each model receiver.

A.7 Secure Checkpointing

Each IPU periodically checkpoints its state to enable recovery from failures. A checkpoint is created by writing the weights of the model to an output stream. The checkpoint also includes metadata, such as the current offset for all confidential data streams. These offsets are also written in plaintext, so that the IPU runtime can restart the job and resume loading of confidential data streams at the correct offset. Conversely, a checkpoint is restored by reading the weights using an input stream and resuming confidential streams from the checkpointed offsets. A checkpoint along with the job manifest and binaries suffice to resume an application from the checkpoint instead of restarting from the beginning.

In trusted mode, checkpoints are encrypted and integrity protected. In particular, tiles enforce the integrity of the process of restoring state from a previously created checkpoint. This includes protecting against attacks, such as tampering a checkpoint or loading a wrong checkpoint onto an IPU. (Guaranteeing freshness, e.g., resumption from the latest checkpoint, would involve some form of trusted persistent storage and is out of scope in this paper.)

Checkpoints are implemented using confidential streams. The code generated to read a checkpoint stream generates a sequence of expected IVs, checks that the IVs returned in the frames match the expected IV, and strips the IV and authentication tag from the frames. Conversely, the code generated to write a checkpoint stream generates a sequence of IVs and places them in the header of the frame. The IV for each frame uniquely encodes the checkpoint type, the epoch counter (incremented at each resumption), the checkpoint identifier (incremented at each saved checkpoint), the IPU and tile IDs, and the frame index. The CCU uses a separate key for each epoch; it installs the key of the epoch of the checkpoint it is resuming from, if any, and the key of the current epoch for writing all its checkpoints.

The tiles read and write checkpoints as follows:

1. Tiles obtain initial values of the epoch counter and checkpoint identifier (assigned by the CCU along with the bootloader code) from pre-determined locations in tile memory. If the epoch counter is not null, the tiles use it (with the checkpoint identifier) to compute their expected IVs and read part of their corresponding checkpoint.

2. Each tile increments their local epoch counter and start (or resume) the application.

3. At regular intervals, the tiles checkpoint their part of the state, using IVs computed from their current values, and then increment their local checkpoint identifier.

A.8 Sample Training Scenario

Figure 11 shows a sample training scenario with three parties. Given the job manifest generated by the compiler, IPU runtime, CCU, and IPU synchronize at various points where the IPU runtime populate the ring buffer with the data expected by the IPU, and the CCU loads keys to the IPU SXPs.

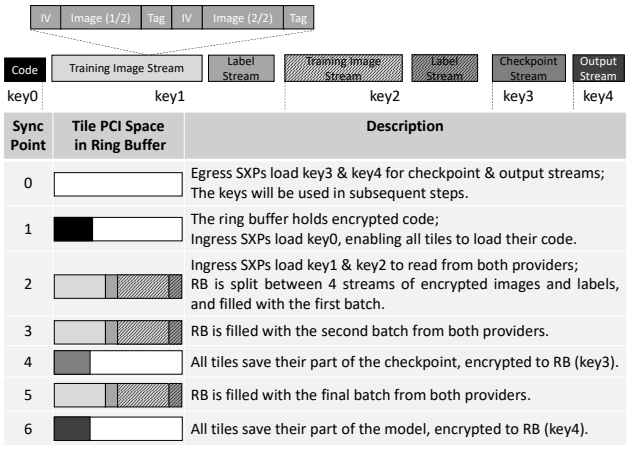

Figure 11: Sample training scenario with 3 parties: one providing model code (using key0) and the others (using key1 and key2) each providing their own streams of training images and labels; this task saves checkpoints (using key3) and a final model (using key4). The compiler emits a job manifest that indicates, for each synchronization point of the task, which part of each stream is mapped to the ring buffer (1..6) and which keys the CCU should load for ingress. The keys for egress streams are programmed in the start of the job (0).

Arbitor: A Numerically Accurate Hardware Emulation Tool for DNN Accelerators

Abstract

Recently there has been considerable attention on designing and developing hardware accelerators for deep neural network (DNN) training workloads. However, designing DNN accelerators is often challenging as many commonly used hardware optimization strategies can potentially impact the final accuracy of the models. In this work, we propose a hardware emulation tool called Arbitor for empirically evaluating DNN accelerator designs and accurately estimating their effects on DNN accuracy. Arbitor takes advantage of modern machine learning compilers to enable fast prototyping and numerically accurate emulation of common DNN optimizations like low-precision arithmetic, approximate computing, and sparsity-aware processing on general-purpose GPUs. Subsequently, we use Arbitor to conduct an extensive sensitivity study to understand the effects of these optimizations on popular models such as ResNet, Transformers, Recurrent-CNN, and GNNs. Based on our analysis, we observe that DNN models can tolerate arithmetic operations with much lower precision than the commonly used numerical formats support. We also demonstrate that piece-wise approximation is effective in handling complex non-linear operations in DNN models without affecting their accuracy. Finally, enforcing a high degree of structured sparsity in the parameters and gradients can significantly affect the accuracy of the models.

1 Introduction

Deep neural networks (DNNs) have shown unprecedented accuracy on many complex tasks like computer vision [26, 44], natural language processing [15, 65], recommendation systems [50], speech recognition [6], and robotics [55]. This superior performance of DNNs, however, comes at the expense of high computational costs in the training process. As the models are getting larger and more complex, the computational requirement for training these models has also been growing steadily. Therefore, designing and developing specialized hardware accelerators for DNN training has become an active area of research in both industry and academia [16].

Modern DNN accelerators are equipped with thousands of parallel processing units to leverage the abundant computational parallelism available in DNN training workloads. Moreover, they also employ many hardware-level optimizations that are designed to take advantage of the error-resilient nature of the DNN models. For example, DNN accelerators commonly use *low-precision numerical formats* for arithmetic operations to improve hardware utilization and energy efficiency [18, 48, 74]. Additionally, *approximate computing* techniques like the linear approximation of non-linear functions are widely used to reduce the hardware design complexity and cost [7, 43]. Finally, modern accelerators support *sparsity-aware processing* cores to minimize redundant computations in DNN workloads by skipping arithmetic operations over zeros. In recent years, there have been many studies proposing different variations of such hardware-level optimizations that have shown to be highly effective in improving the performance of DNN training workloads [56, 72].

Despite being a well-studied area, making the right design decisions for DNN accelerators is still a challenging task as many of the proposed hardware optimizations have non-trivial effects on the convergence accuracy of the DNN training algorithm and can potentially hurt the final accuracy of the model [18, 48]. Understanding the influence of these optimizations on the convergence of different DNN models requires rigorous experimental analysis on the DNN accelerator design. Unfortunately, currently available methods and tools are inadequate for such analysis as we explain below.

Software-based architectural simulators are widely used for the initial prototyping and analysis of different hardware design choices [8, 9, 34, 64]. These tools are primarily designed to perform hardware simulations at circuit-level precision and measure accurate low-level performance counters like instructions per cycle (IPC), cache miss rate, and branch prediction accuracy. As a result, architectural simulators are generally $6-7$ orders of magnitude slower compared to the real silicon performance [20, 63]. Since standard DNN benchmark models [49, 75] take anywhere from hours to months of training to reach peak accuracy, using software-based simulators to

analyze DNN accelerator designs can get prohibitively time-consuming. Even though other approaches like FPGA-based prototyping can offer performance close to the real hardware, programming FPGAs requires unique expertise that is rare even among hardware researchers. Moreover, building the software stack that can provide runtime support for training DNNs on FPGAs requires substantial engineering effort.

To address the limitations of these traditional methods, recent works [45, 47, 59, 70] have proposed hardware emulation frameworks specifically designed for analyzing the accuracy effects of common DNN optimizations like low-precision training. These tools provide convenient APIs to configure and emulate low-precision arithmetic in the training process by modifying the computation graphs of DNN models. Unlike architectural simulators, DNN emulators are built as extensions over popular machine learning frameworks like TensorFlow [3] or PyTorch [54] and can be executed over general-purpose accelerators like GPUs. This enables fast prototyping of arbitrary low-precision numerical formats and evaluating their effects on standard DNN benchmark models within reasonable time frames. However, we observe that extending these tools to support other hardware features like approximate or sparsity-aware computing require significant effort from the user. On top of this, current DNN emulators are designed to perform low-precision arithmetic emulation at the DNN layer-level granularity. Under this strategy, the computation of individual layers in the DNNs like matrix multiplication and convolution is performed using standard 32-bit floating point format, and the output is rounded down to the user-defined numerical format. We observe that this *coarse-grained emulation* approach can produce numerically inaccurate results compared to the real hardware. Our empirical evaluation reveals that the relative numerical error of low-precision arithmetic emulation in state-of-the-art DNN emulators can be as high as 15% (more details in section 3). We argue that such inaccurate emulations could lead to incorrect evaluation of hardware designs in DNN accelerators.

In this work, we build an easy-to-use, extensible, and more importantly numerically accurate emulation tool called Arbitor for empirically evaluating DNN accelerator designs. Arbitor is built on top of TensorFlow and provides extensions to its Keras front-end APIs for users to easily configure and emulate common hardware features like low-precision training, approximate computing, and sparsity-aware processing on standard DNN models. In contrast to other DNN emulators, Arbitor emulates the user-defined hardware features at the granularity of the primitive mathematical operations in the DNN layers to accurately mimic the behavior of real hardware. We support this *fine-grained emulation* in Arbitor with the help of the XLA compiler-backend in TensorFlow [23]. Modern machine learning compilers like XLA use domain-specific intermediate representations (IR) for defining the operations in the DNN computation graphs. These IR definitions of DNN operations are designed to be hardware-independent and are progressively lowered to GPU executable kernels by the compiler. We make a key observation that it is possible to automatically generate GPU kernels that emulate the user-defined hardware features by modifying the code generation pipeline of TensorFlow XLA. We empirically show that, compared to the state-of-the-art layer-level emulation approach, the operator-level emulation strategy of Arbitor can perform arithmetic operations and generate results that accurately match the results from real hardware.

We subsequently use Arbitor to conduct a series of sensitivity studies on the effects of low-precision training, approximate, and sparse computing on popular DNN architectures like Transformer [65], ResNet-18 [26], Convolutional Recurrent Neural Network (CRNN) [66], and Graph Neural Network (GNN) [73]. First, we conduct an extensive analysis of various non-standard floating point specifications and find that DNN models can maintain their accuracy with much lower precision than many standard floating point formats supported in current DNN accelerators. We also observe that the numerical precision can be reduced even further by combing low-precision formats with the standard single-precision floating point. Second, we also analyze the effectiveness of newly proposed non-floating point numerical formats like Posit [25] on DNN training. We find that, contrary to the prior observations [59], Posit does not yield better model accuracy compared to floating point. Third, we evaluate a popular approximate computing optimization technique called piece-wise linear approximation [35] and find that natural language processing (NLP) models like CRNN can maintain their baseline accuracy even with aggressive approximations. Finally, we analyze the effect of sparse computing and observe that enforcing more than 50% sparsity on DNN training can significantly affect the model accuracy. To the best of our knowledge, we are the first open study to conduct such an extensive analysis of common DNN accelerator designs using numerically accurate methods and tools.

In summary, we make the following contributions:

- We highlight that the hardware research community is currently lacking a fast and accurate hardware analysis tool for DNN training accelerators as state-of-the-art tools are either prohibitively slow or are susceptible to numerical inaccuracy.
- We build a hardware emulation tool Arbitor using a compiler-assisted fine-grained emulation strategy for numerically accurate emulation of optimizations like low-precision, approximate, and sparse computation.
- Using Arbitor, we conduct the first in-depth empirical analysis on the effects of low-precision arithmetic, approximate computing, and sparsity-aware processing on the accuracy of popular DNN models like Transformer, ResNet-18, CRNN, and GNN. We will be open-sourcing Arbitor soon for supporting empirical research in DNN accelerators.

2 Hardware Accelerators for DNN Training

Modern DNN models [15, 17, 26, 44] contain millions to even trillions of parameters and are trained for hours to months by iteratively processing large batches of data from humongous datasets and updating the model parameters to minimize the prediction error until the model converges to the desired accuracy. The DNN training process primarily consists of the repeated execution of computationally expensive algebraic functions such as matrix multiplication, convolution, and element-wise operations. Fortunately, these functions exhibit abundant computational parallelism which can be leveraged to speed up the training process using parallel processing hardware accelerators like graphics processing units (GPUs).

While GPUs have been the mainstay for DNN training, in recent years, there has been an increasing interest in developing more specialized accelerators. For example, Google TPU [31], Habana Gaudi [30], Graphcore IPU [24], Cerebras Wafer-Scale engine [14], and Amazon Trainium [5] are a few notable examples of commercial DNN accelerators. In addition to massively parallel processing capabilities, these accelerators also employ several hardware-level optimizations that exploit the inherent error-resilient nature of DNNs to improve training performance and hardware utilization. Below, we describe the three most common categories of hardware-level optimizations supported in DNN accelerators.

1. Low-precision arithmetic. Unlike regular parallel processing applications that require high-precision floating point computation, DNN models are highly tolerant towards using reduced-precision arithmetic due to the error-correcting nature of the training algorithm. Therefore, many DNN accelerators support low-precision numerical formats that use fewer bits than the standard 32-bit single-precision floating point (FP32). This enables accelerators to provide higher processing power from the same hardware budget. For example, Nvidia GPUs can perform 2× higher floating point operations (FLOPS) with half-precision (FP16) than using single-precision format [52]. Additionally, low-precision data formats can also help reduce the memory footprint of DNNs and in turn, improve the cache utilization and lower the memory bandwidth pressure during training. As a result, many modern DNN accelerators support a wide range of low-precision floating point formats outside the traditional IEEE-754 standard [2] as shown in Figure 1.

In general, floating points are represented using a sign bit, exponent bits, and mantissa bits. The range and the precision of a particular format are determined by the number of exponent and mantissa bits respectively. Therefore, different low-precision formats make the fundamental trade-off between the range and the precision of values the type can represent. For example, FP16 uses 5 exponent and 10 mantissa bits and has a limited range (i.e., $\pm 65,504$) compared to FP32 (i.e., $\pm 3.40 \times 10^{38}$). An alternative 16-bit format called brain float 16 (BF16) [32], on the other hand, uses 8 exponent bits and 7 mantissa bits and can support a similar range of values as that of FP32. Since BF16 format trades precision in favor of a wider range, it has shown to be better suited for DNN training than the standard FP16 and is widely supported in many DNN accelerators [32].

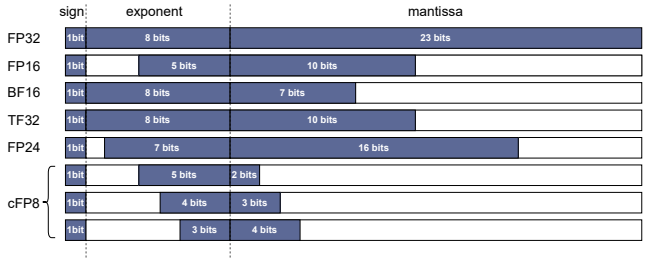

Figure 1: Common floating point formats in DNN accelerators

In addition to floating point formats, hardware researchers have also been exploring other data formats e.g., fixed-point arithmetic [41, 71, 74]. In contrast to floating points, fixed-point arithmetic lends itself to a simpler hardware design with a smaller chip area and lower power consumption [27] but lacks the dynamic range and precision that floating point formats have. In recent years, there has also been proposals [13, 46] in using the novel Posit formats [25] for DNN training as it takes less circuitry than floating point processing units while providing a wider dynamic range. Despite this significant research attention, finding numerical formats that make the right trade-offs in DNN training workloads is still an open research problem.

2. Approximate computation. The training computation of DNN models is mostly dominated by linear algebraic functions like matrix multiplication and convolution. These functions are composed of numerous primitive mathematical operations like addition and multiplication that maps very well with the thousands of parallel arithmetic units provided by the DNN accelerators. In addition to these, many DNN models also contain operations that use non-linear functions. For example, modern NLP and image classification models use complex activation functions like tanh, sigmoid, GeLU [28], and Swish [58] which are shown to play an important role in achieving high accuracy for the models. However, the exact computation of these functions is often very expensive to perform in the hardware because of the exponentiation and division terms present in the functions. Instead, DNN accelerators employ approximations of such functions that are cheaper to implement in hardware. Examples of such approaches include piece-wise linear/non-linear approximations [35, 61], lookup table [37], bit-level mapping [69], or a hybrid of these methods. Such approximations in DNN accelerators enable them to achieve improved hardware performance and lower chip area at the expense of imprecise computation of the non-linear functions. Therefore, more aggressive approximations can potentially affect the convergence of DNN training.

3. Sparsity-aware computation. Large DNN models are known to exhibit a significant amount of redundancy due to the over-parameterization of the model architecture [22]. There have been several efforts in exploiting this redundancy to improve performance and reduce the memory footprint of DNN workloads. For example, software-level optimizations such as DNN pruning [10] has found effective in significantly reducing the model size by removing the redundant parameters from the model. However, naïvely applying DNN pruning often ends up with models having randomly distributed sparsity patterns. Since DNN accelerators are primarily designed to process dense data structures, extracting performance benefits from DNNs with unstructured sparsity is often challenging. To address this issue, modern DNN accelerators are equipped with specialized processing cores that can improve the performance of DNN applications in the presence of semi-structured sparsity patterns. For example, the latest Nvidia A100 GPUs support Sparse Tensor Cores that can accelerate matrix multiplication operations by 2× for operands having 2:4 structured sparsity.[1] Recent works [56, 72] have proposed hardware-software co-optimizations that follow structured DNN pruning strategies during the training process to take advantage of such sparsity-aware processing units. Despite the potential performance improvements, enforcing structured sparsity during training is shown to have a significant impact on the convergence of the DNNs [68]. Finding the right balance between structural sparsity and model accuracy is currently an active area of research.

3 Need for an Accurate Hardware Analysis Tool for DNN Accelerator Design

Many of the aforementioned optimization strategies have the potential to significantly improve the performance of DNN training. However, at the same time, depending on the degree and aggressiveness of the optimizations, they can also negatively affect the model accuracy. Therefore, designing accelerators for DNN training requires taking both hardware performance and accuracy effects of the optimizations into consideration. Even though there are standard methods and tools available to prototype different chip designs and estimate their performance, they fail to be a good fit for analyzing their effects on model accuracy as we explain below.

Limitations of Traditional Verification Tools. One of the most common and cost-effective approaches for prototyping and verifying hardware designs is to use architectural simulators [4, 29]. Hardware researchers use simulators like GPGPU-sim [8], gem5 [9], and Multi2Sim [64] to evaluate architectural design choices by running software-based simulations of the proposed features and collecting hardware performance counters like instructions per cycle (IPC), cache utilization, and energy consumption. These tools are designed to run simulations with circuit-level precision, but they come at the cost of high execution time. Our empirical evaluation shows that running a single 1024×1024 FP32 matrix multiplication using GPGPU-sim is more than 5 orders of magnitude slower than running on bare-metal GPUs. Since training involves iteratively executing many such operations and can take anywhere from hours to months to finish even on powerful hardware [49, 75], it becomes prohibitively time-consuming to use these simulators to analyze the convergence effects of hardware optimizations on modern DNN models.

FPGA-based prototyping is another approach followed in the industry for hardware design verification. Programmable chips like FPGAs allow accurate verification of the functional logic of a design and the ability to run benchmark applications on custom-designed chips at a speed closer to the performance of the physical hardware. But programming FPGAs to reliably implement the desired hardware features is a labor-intensive task and requires special expertise and infrastructure support that is often beyond the reach of many independent researchers [60]. On top of this, building a full-fledged software stack that can provide the requisite runtime support for training DNN models is a major engineering undertaking that requires significant time and financial investment.

Since analyzing the statistical effects of DNN accelerator optimizations using traditional hardware verification tools is difficult and time-consuming in practice, hardware researchers often end up making design decisions using limited empirical analysis of the design or based on speculations. As hardware manufacturing is an extremely lengthy and expensive process, this could potentially cost a substantial amount of time, money, and resources. To take a real-world example, Nvidia first introduced half-precision floating point (FP16) support in Tesla P100 GPUs [52] in 2016 to deliver higher performance for deep learning workloads. However, it was soon observed that using half-precision in training can cause serious convergence issues on many models as algebraic functions like matrix multiplication, convolution, and batch normalization perform reduction over large dimensions of matrices and can suffer from higher accumulation error compared to single-precision (FP32) training. To correct this issue, it took researchers another two years to find a software-level fix called mixed-precision training [48] that uses a combination of FP16 and FP32 precision (for computation and reduction respectively) to curtail the numerical errors. More recently, Nvidia introduced a 19-bit floating point format called Tensor Float (TF32) in their Ampere architecture-based GPUs [51] as a drop-in replacement for FP32 data type. This again caused major pushback from the machine learning community for the numerical instability it caused on certain non-standard deep learning workloads [57]. These anecdotes suggest the importance of having rigorous methods and tools for analyzing the accuracy effects of DNN accelerator designs as early in the hardware manufacturing process as possible.

[1] Here, an N:M sparsity indicates that out of every block of M contiguous values in the input operands, only N values are non-zero.

Inadequacy of Current Emulation Tools. To meet this unique requirement of DNN accelerator research and development, recent works have proposed hardware emulation tools such as TensorQuant [45], QPyTorch [70], and GoldenEye [47]. Unlike architectural simulators that perform expensive cycle-accurate simulations of the entire hardware, these tools are specifically designed for analyzing DNN optimizations like low-precision training by emulating arbitrary numerical formats on general-purpose accelerators like GPUs. State-of-the-art DNN emulators are built on top of popular machine learning (ML) frameworks like TensorFlow [3] and PyTorch [54], and provide extensions to their front-end APIs to configure and train DNN models using user-defined numerical formats. These tools take advantage of the fact that the ML frameworks represent DNN models as layers of well-defined algebraic functions, and therefore, the numerical errors introduced by low-precision arithmetic in DNN training can be emulated by replacing the individual layers with corresponding software-emulated functions. Since these tools are well-integrated with ML frameworks and allow fast experimentation through GPU-accelerated emulation, they make a convenient tool for quick exploration of the low-precision data formats on a wide range of DNN models.

Despite being a promising approach, current DNN emulation tools suffer from two major limitations. First, they are primarily designed to target only a *narrow scope* of DNN optimizations, namely, low-precision training. Supporting other optimizations like approximate or sparsity-aware computation require intrusive changes in these tools due to their tightly coupled design and implementation with the underlying ML frameworks and the targeting GPU backend. Second and more importantly, we observe that the current DNN emulators are susceptible to *numerical inaccuracies* due to a coarse-grained emulation strategy that they follow. Under this strategy, the low-precision arithmetic emulation is achieved by performing individual algebraic functions in the DNN model using the standard FP32 format supported in GPUs and then rounding the output down to the user-defined low-precision format. Even though this layer-level rounding approach lends itself to a simpler DNN emulator design, we observe that this strategy fails to accurately reproduce numerical errors that can occur with low-precision arithmetic. For instance, many DNN layers like matrix multiplication and convolution internally perform several primitive mathematical operations like multiplication and addition. Under the coarse-grained layer-level emulation approach, these primitive operations are performed using higher-precision FP32 arithmetic. As a result, they fail to account for the low-precision multiplication and accumulation error occurring within the algebraic functions.

$$rnd((a_1 * b_1) + (a_2 * b_2) + (a_3 * b_3)) \quad (1)$$

To illustrate this limitation, we use a simple matrix multiplication between a 1×3 matrix ($[a_1 \quad a_2 \quad a_3]$) and a 3×1 matrix ($[b_1 \quad b_2 \quad b_3]^T$) as an example. Equation 1 shows the

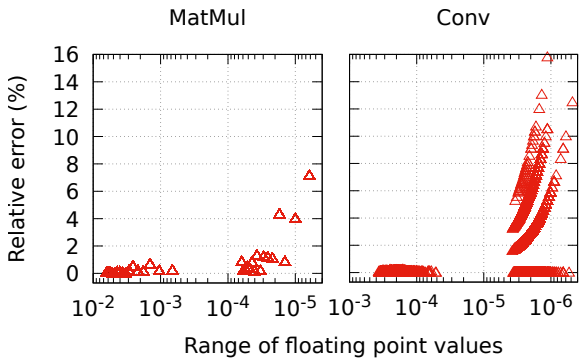

Figure 2: The numerical difference between real hardware and the layer-level emulation

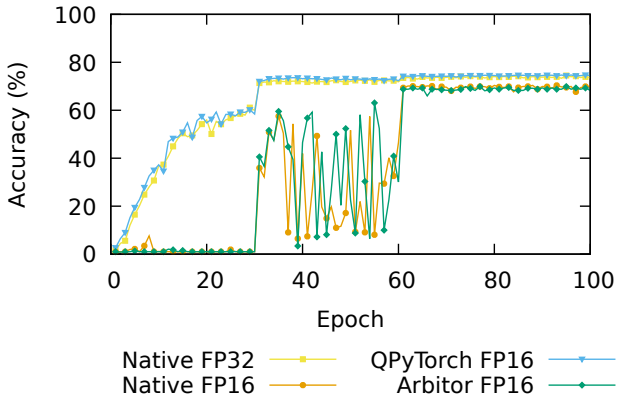

Figure 3: Comparison of training curves for ResNet-50 with native FP32, native FP16, QPyTorch-emulated FP16, and Arbitor-emulated FP16

definition of this matrix multiplication performed using FP16 arithmetic following the layer-level emulation strategy. In this case, all the primitive multiplication and addition operations are performed using FP32 arithmetic, and only the final result is rounded to FP16 using $rnd()$. In contrast, an accurate emulation of FP16 matrix multiplication requires rounding on every primitive operation as shown in Equation 2.

$$rnd(rnd(rnd(a_1 * b_1) + rnd(a_2 * b_2)) + rnd(a_3 * b_3)) \quad (2)$$

To empirically estimate the extent of the inaccuracy, we emulate FP16 arithmetic using the layer-level strategy on matrix multiplication and 3×3 convolution operation over 128×128 matrices. Then we compare the output matrix generated with that obtained using the native FP16 supported in real hardware such as Nvidia 2080 Ti GPU [53]. Figure 2 shows the relative error between the emulated and the hardware native outputs on different input matrices with floating point values randomly generated from the range $[10^{-6}, 10^{-2}]$. As we show, in comparison to the GPU native FP16 results, the re-

sult generated by the emulated version can differ by as much as 15.74%. Since DNN training is an iterative process, such numerical inaccuracies in emulation can accumulate over the course of training, leading to making incorrect assessments about the effects of low-precision data formats on the DNN accuracy. To demonstrate this, we first train ResNet-50 using both FP32 and FP16 on Nvidia 2080 Ti and get validation accuracy curves as shown in Figure 3. The highest accuracy with FP16 is 70.36%, which is 3.7% lower than FP32 due to the numerical error with low-precision arithmetic. We subsequently use the state-of-the-art QPyTorch which applies layer-level emulation to run the training with emulated FP16. However, the validation accuracy using emulated FP16 in QPyTorch is observed to be close to the native FP32 accuracy. This shows that the layer-level emulation strategy fails accurately reproduce the numerical error of FP16 arithmetic.

Based on the above observations, we argue that current DNN emulators are ill-suited for accurately estimating the accuracy effects of low-precision arithmetic on DNN training due to their inherent design limitations.

4 Arbitor: Overview

To address the aforementioned limitations, we propose Arbitor. Arbitor strives to achieve three main goals. First, to propose a DNN emulator with an *extensible design* that can emulate common hardware-level optimizations like low-precision training, approximate computation, and sparsity-aware processing. Second, to enable *easy prototyping* of these optimizations and facilitate empirical analysis on their statistical effects on popular DNN models. Finally, we strive to provide *numerically accurate emulation* support that precisely mimics the functional logic of the hardware optimizations on general-purpose accelerators like GPUs. To achieve these goals, we make the following implementation choices.

First, we build Arbitor on top of the popular machine learning framework TensorFlow [3]. TensorFlow supports the convenient and user-friendly Keras front-end APIs for writing DNN training applications and offers implementations of a wide range of state-of-the-art DNN models [33]. To allow fast prototyping of low-precision arithmetic, approximate computation, and sparsity-aware processing on DNN models, Arbitor provides extensions in the Keras APIs for the users to define two emulation policies: (i) Data type policy for defining arbitrary precision numerical formats and the implementations of basic primitive mathematical operations on top of the user-defined data types. (ii) Masking policy for enforcing $N:M$ sparsity patterns on the parameter updates during training.

Providing numerically accurate emulation support for these hardware features requires fine-grained manipulations of the computations involved in DNN training workloads. However, manual modifications to the implementation of algebraic functions in the ML framework are intrusive and require significant engineering effort. Such modifications can also hamper the extensibility of the emulation tool, as supporting new DNN models or hardware features would require potential code changes. To address these challenges, we make a key observation: despite the apparent differences among hardware features like low-precision arithmetic, approximate computing, and sparsity-aware processing, all of them can be emulated by manipulating a small set of primitive operations, such as addition, multiplication, memory read and write, which constitute the DNN algebraic function implementations.

Based on this observation, we design Arbitor with the help of the XLA compiler in TensorFlow [23] to provide fine-grained emulation support. The XLA compiler operates on an intermediate representation (IR) named HLO IR, which precisely represents the computation through a concise set of fundamental primitive operations. This representation format of DNN computation is particularly well-suited for fine-grained manipulations to support numerically accurate emulation. Moreover, due to the model and hardware-independent nature of HLO IR, this compiler-based design of Arbitor provides seamless support for a wide range of DNN models and easy extensions for the emulation of more DNN accelerator optimizations. The XLA compiler compiles the high-level computation graph of DNN progressively down to hardware-specific kernels using standard code generation techniques, as illustrated in Figure 5. Initially, the computation graph described in the Keras front-end is transformed to HLO IR. The XLA compiler takes the HLO IR as the input and proceeds to perform a series of optimizations and analyses, ultimately lowering the HLO IR to hardware-specific kernel implementations. Notably, XLA leverages LLVM infrastructure for generating kernels on GPU, which is the target environment of Arbitor. During this process, Arbitor incorporates user-defined emulation policies into the computation by modifying the compilation pipeline.

Below, we provide details about the emulation policies and the fine-grained emulation strategy supported in Arbitor.

4.1 Emulation Policies

Figure 5 shows an example of Keras computation using the two emulation policies supported in Arbitor. Users can define and configure the `dtype` and `mask` policies using the Keras APIs. The policies can be assigned either to specific layers (in the Figure 5), or as a global policy for the entire DNN model.

The data type policy allows users to configure low-precision arithmetic and approximate computing emulation. Under this policy, the user can define a custom data type specification as an implementation of an abstract C++ class called `Cus`. The specification should include two components. First, two **casting functions** to convert the custom data type to and from the standard FP32 data type. Second, implementations of **primitive mathematical operations** over the custom data type such as addition and multiplication, and mathematical functions such as exponent and logarithm.

```
class EmuBF16: public Cus {
public:
    unsigned int v;
    EmuBF16(unsigned int v) : v(v) {}
};
EmuBF16 from_float(float f) {
    unsigned int bits = *(unsigned int*)&f;
    unsigned int rounding_bias = 0x7fff + ((bits >> 16) & 1)
    return EmuBF16((bits + roounding_bias) >> 16);
}
float to_float(EmuBF16 b) {
    unsigned int bits = b.v << 16;
    return *(float*)&tmp;
}
EmuBF16 operator+(const EmuBF16& a, const EmuBF16& b) {
    return from_float(to_float(a) + to_float(b));
}
EmuBF16 operator*(const EmuBF16& a, const EmuBF16& b) {
    return from_float(to_float(a) * to_float(b));
}
....
```

Figure 4: Custom data type specification of BF16

Figure 4 shows a specification of BF16 [32] data type in Arbitor named `EmuBF16`. In this example, `from_float` and `to_float` are the two casting functions. In addition, the Figure also shows example implementations of addition and multiplication operations defined over `EmuBF16`. It should be noted that the abstract class `Cus` makes very few assumptions about the specification of the data type and the implementations of the primitive operators. This allows Arbitor to support a wide range of arbitrary numerical formats and customized operator implementations on top of them to emulate low-precision arithmetic and approximate computing.

Next, the masking policy allows the users to configure an arbitrary $N : M$ sparsity pattern on the layers during the training process. In addition to N and M, the masking policy also takes a scoring function as a configuration parameter. The scoring function is a user-defined function that takes an array of M values as input and assigns an importance score for each value in the array. The masking policy defined in Figure 5 uses the absolute value as the scoring function. Based on these configurations, Arbitor dynamically generates masks for each parameter and gradient matrices accessed during the training and selects the top N values with the highest importance score on every block of M contiguous values in the matrix.

Once the policies are defined and assigned, Arbitor automatically takes care of emulating the corresponding hardware feature in the DNN training computation as we explain below.

4.2 Compiler-Aided Fine-Grained Emulation

Arbitor generates customized GPU kernel implementations to achieve numerically accurate emulation of user-defined data types and masking policies by leveraging the XLA compiler. For the emulation of low-precision arithmetic and approximate computing, Arbitor injects user-defined data types and operator specifications into the generated kernels. This is accomplished by compiler passes that replace the primitive operations in the HLO IR with the corresponding user-defined operations and automatically insert casting operations for FP32 inputs, as shown in Figure 5. For example, when emulating the user-defined `EmuBF16` arithmetic in matrix multiplication, the default FP32 addition and multiplication operations within the kernel are replaced with the corresponding functions defined in the data type specification. This approach could also support emulating approximation of intricate mathematical operations, such as exponential function and hyperbolic tangent (tanh) function, where users are granted the capability to define customized implementations of these complex operations based on approximation techniques like the piecewise-linear approximation [35]. All of these are made possible because Arbitor makes few assumptions of specifics of data type representation and operator behavior that users provide.

Similarly, the masking policy in Arbitor enforces sparsity patterns on weight and gradient matrices by overriding the memory access operations to these matrices with masking operations, as shown in Figure 5. Therefore, whenever the values in the matrices are read during the training process, Arbitor dynamically generates the corresponding mask according to users' specifications and computes the element-wise product between the user-defined mask and the accessed matrix, returning the resulting masked values. This approach allows Arbitor to preserve the original matrices to handle dynamically changing sparsity patterns during training.

Emulating at the granularity of these primitive operations allows Arbitor to accurately mimic the numerical behaviors of the algebraic functions on real hardware, as shown in Equation 2. To empirically validate this, we re-run the experiment in Figure 2 and Figure 3 using Arbitor-emulated FP16 and compare the results against the hardware native FP16 results. The results of matrix multiplication and convolution using Arbitor's emulated FP16 precisely match with the hardware-native FP16 results with zero relative error, affirming that Arbitor is numerically accurate. Furthermore, we also show in Figure 3 that the validation accuracy curve of ResNet-50, employing Arbitor's emulated FP16 arithmetic, closely matches that obtained with native FP16. The margin of error in the validation accuracy achieved is only 0.48%. In contrast, the accuracy obtained by QPyTorch exhibits a discrepancy of 4.32% from native FP16 accuracy. These findings underscore Arbitor's capability to accurately estimate the effects of low-precision arithmetic on DNN training. In addition, we also analyse the emulation overhead of Arbitor compared to hardware native performance that can be found in Appendix B.

5 Arbitor: Case Studies

We build Arbitor to provide a reliable analysis tool for hardware research to explore DNN accelerator design space. We

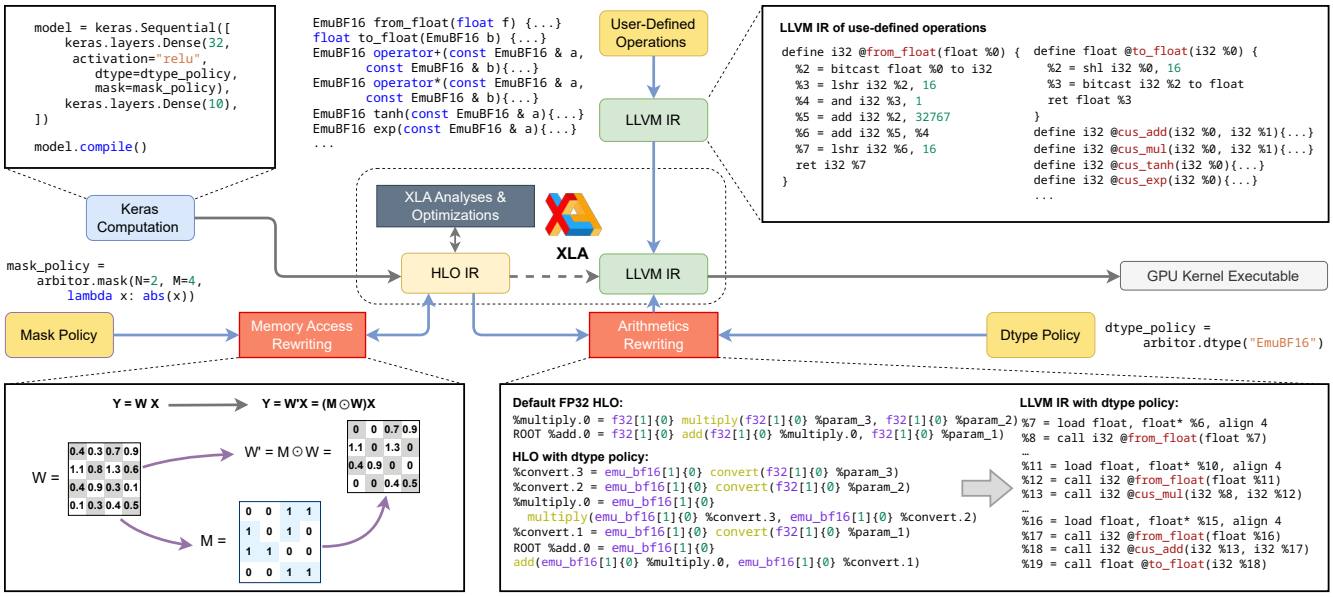

Figure 5: Arbitor workflow and multiple layers of IR

illustrate the benefits of Arbitor through a series of case studies on common hardware-level optimizations proposed for DNN accelerators. Specifically, we conduct an in-depth empirical analysis on the sensitivity of low-precision training, approximate computing, and sparsity-aware processing on DNN training. To the best of our knowledge, we are the first open study to conduct a numerically accurate and extensive study on these optimizations. We would also like to highlight that the case studies presented in this section are just a few examples of the many potential applications of Arbitor. We believe Arbitor is flexible and extensible to provide emulation support for an even wider range of hardware features.

5.1 Experiment Setup

Model	Dataset	Accuracy
ResNet-18 [26]	CIFAR-10 [36]	93.78
GNN [73]	Cora [62]	84.06
Transformer [65]	FordA [1]	87.24
CRNN [66]	eng-fra [12]	87.25

Table 1: Benchmark models, datasets, and baseline accuracy

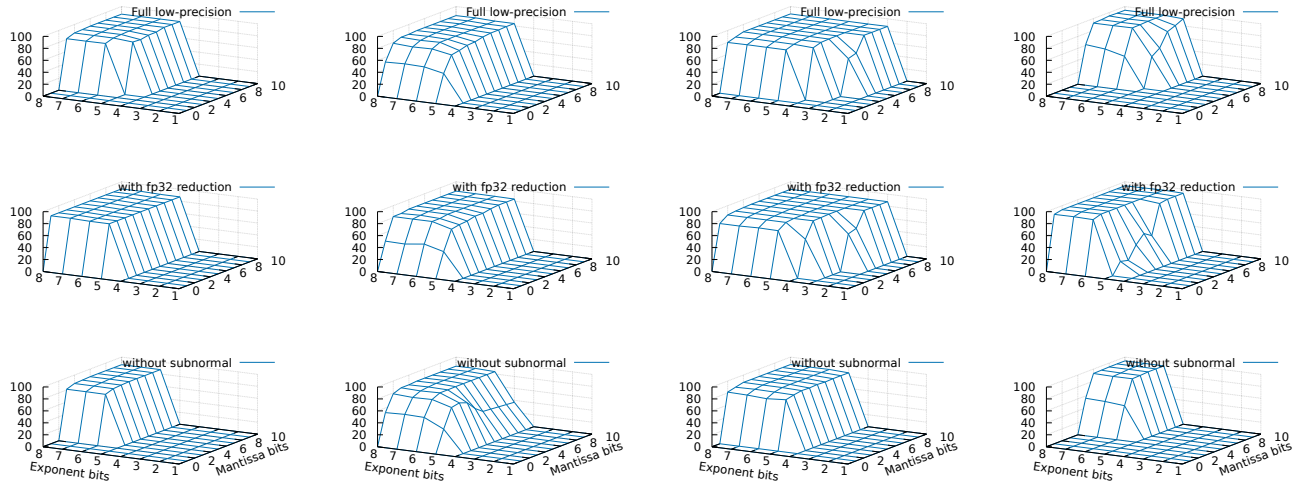
Workloads: Table 1 shows the DNN models we use in our experimental study, namely ResNet-18 [26], Transformer [65], GNN [73], and CRNN [66], selected from the Keras model hub [33]. These model implementations are based on a diverse range of model architectures that are part of the standard DNN training benchmark suite MLPerf [49]. For instance, ResNet-18 is a convolutional neural network (CNN) that is used for image classification applications. Transformer model is an attention-based DNN used in sequence classification and translation. GNN is a graph neural network used for node prediction in graph datasets. CRNN is a recurrent neural network (RNN) based model used for natural language translation.

Hardware and Runtime: We conduct our experiments on 32-core AMD EPYC 7371 machines with four Nvidia 2080Ti GPUs each with 12 GB memory. The runtime environment uses Ubuntu 20.04 with CUDA 11.0, cuDNN 8.0, and CUTLASS 2.6. Arbitor is built on top of TensorFlow v2.4.0 [3].

Metrics: In our experiments, we use the peak validation accuracy as the main evaluation metric. To measure the accuracy, we train ResNet-18 for 100 epochs, Transformer for 120 epochs, GNN for 300 epochs, and CRNN for 100 epochs on their respective data sets. We train each model three times and use their averaged accuracy for comparison to minimize the effects of slight variations in the final accuracy. We use the validation accuracy of each model trained using single-precision floating point (FP32) as the baseline for all our comparisons. The baseline accuracy of each model is shown in Table 1.

5.2 Case Study #1: Low-Precision Training

We use Arbitor to investigate the impact of low-precision arithmetic on the model accuracy by training the DNN models in Table 1 with different numerical formats. Current DNN accelerators support a variety of floating point formats with different numbers of exponent and mantissa bits, as described in Section 2. Therefore, we conduct a sensitivity study on different floating point formats and analyze how they affect the model accuracy. In addition, we also evaluate the effects of other numerical formats like Posit [25] on DNN training.



(a) CRNN (b) GNN (c) Transformer (d) ResNet-18

Figure 6: Validation accuracy of models trained using different exponent and mantissa widths of floating point format

5.2.1 Sensitivity Study on Floating Point Numbers

Single-precision floating point (FP32) is one of the most commonly used numerical formats for DNN training. According to IEEE 754 standard [2], FP32 is specified as follows.

$$value = \begin{cases} (-1)^s \times 2^{-126} \times 0.m & \text{if} \quad e = 0x00 \quad \text{(subnormal)} \\ NaN \text{ or } inf & \text{if} \quad e = 0xFF \\ (-1)^s \times 2^{(e-127)} \times 1.m & otherwise \quad \text{(normal)} \end{cases} \tag{3}$$

Here, s, e, and m correspond to the sign, exponent, and mantissa of the FP32 value. As shown in Equation 3, the specification primarily follows two different modes, normal and subnormal, depending on the value of the exponent. Other floating point formats supported in DNN accelerators also follow a similar specification but with different numbers of exponent and mantissa bits, each making different trade-offs in the range and precision of values it can represent.

To analyze the sensitivity of model accuracy towards different floating point specifications, we define a data type policy in Arbitor of a generic floating point specification with configurable exponent and mantissa bits based on the IEEE 754 standard. We use *eXmY* to represent a floating point specification with 1 sign bit, X exponent bits, and Y mantissa bits. Using the custom floating point format, we train the DNN models in two ways. First, we train and measure the accuracy of the models while only using the custom floating point format for the whole model. Second, we use a combination of the custom floating point and FP32 arithmetic following the mixed-precision training strategy described in Section 3. Under this strategy, all arithmetic operations are performed using the custom floating point except the reduction operations in algebraic functions like matrix multiplication, convolution, and batch normalization which are performed using FP32 arithmetic. Figures 6a to 6d shows the validation accuracy measured on models trained using custom floating point format by varying the number of exponent and mantissa bits.

Observation 1: DNN models can maintain their accuracy with much lower precision than many standard low-precision floating point formats supported in current DNN accelerators (e.g., BF16 and TF32). Additionally, the precision can be reduced even further by using single-precision arithmetic for reduction operations.

From our results, CRNN, GNN, Transformer, and ResNet-18 can train to the FP32 accuracy with *e6m6*, *e6m3*, *e6m4*, and *e6m6* respectively. That means, reserving 6 bits for the exponent is sufficient to represent the floating point values generated during the training of these models which is lower than the standard floating point formats like FP32 (*e8m23*), BF16 (*e8m7*), and TF32 (*e8m10*), but higher than FP16 (*e5m10*). Reducing the exponent and mantissa bits beyond these configurations either causes a drop in accuracy or makes the models fail to converge altogether. We also observe that the accuracy of the models is less sensitive towards mantissa bits than exponent bits. This reasserts the fact that an optimal numerical format for DNN training workloads should allocate more bits for exponent and less for mantissa to be able to represent a wide range of values. Moreover, the mantissa bits can be further reduced for CRNN, GNN, and ResNet-18 to *e6m1*, *e6m2*, and *e6m2* respectively using FP32 arithmetic for reduction operations. This suggests that the numerical errors in low-precision training are primarily contributed by reduction operations. Therefore, using a combination of low and high-precision floating point formats in training can provide higher training performance with little to no loss in accuracy.

Next, we evaluate the importance of handling subnormal numbers in floating point formats. The subnormal mode in the floating point specification is introduced to gracefully handle underflow for the values that fall between zero and the smallest floating point number normal mode can represent. However, handling the subnormal mode in floating point implementation adds extra complexity to the hardware design. Therefore, certain implementations like BF16 in TPUs [31] do not support subnormal mode. In Figures 6a to 6d, we show the model accuracy measured using the custom floating point specification but with the subnormal numbers set to zero.

Observation 2: Subnormal mode has negligible impact on the model accuracy.

Comparing the accuracy measurements with and without subnormal mode, we observe that the subnormal numbers can often be safely ignored on configurations with sufficient exponent bits without affecting the model accuracy in almost all cases. This is due to the fact that floating point specifications with larger exponent bits have a smaller subnormal range and therefore approximating a small range of subnormal numbers to zero only introduces minimal numerical error in low-precision training. However, in certain cases like ResNet-18, low-precision training without subnormal mode can cause a slight drop in the accuracy of about 1.46%. We also observe that this accuracy loss can be compensated by adding more mantissa bits. For instance, ResNet-18 can achieve the baseline accuracy using *e6m8* without subnormal compared to *e6m6* with subnormal mode.

5.2.2 Posit as an Alternative for Floating Point

Even though floating point formats are the industry standard, there have been proposals for alternative numerical formats in the literature. Posit [25] is one such example and is a novel data type designed as a direct drop-in replacement for IEEE standard 754 floating point formats. Posit format is purportedly more hardware-friendly with lower power use and a smaller silicon footprint and can perform more operations per watt and per dollar than floating points under the same hardware budget. Moreover, the original paper [25] and subsequent studies [42] have shown that Posit can represent decimal numbers more precisely than floating point format on common arithmetic and linear algebra operations. Therefore, Posit is considered to be a viable alternative for floating point in deep learning applications. In this section, we evaluate the effectiveness of Posit in DNN training with Arbitor.

An n-bit Posit format with es exponent bits, abbreviated as $P(n,es)$, is represented using a sign (s), regime (k), exponent (e), and fraction (f) bits as follows:

$$value = (-1)^s \times 2^{2^{es} \times k} \times 2^e \times (1.f) \quad (4)$$

Similar to the floating point sensitivity study, we specify a data type emulation policy in Arbitor using the software-based Posit implementation available in the BFP library [40]. Then we train CRNN, GNN, and Transformer models using Posit configurations with different n and es values. Figure 7 shows the validation accuracy measured on these models.

Observation 3: Contrary to the observations made in prior works [59], low-precision training with Posit does not yield better accuracy compared to floating point.

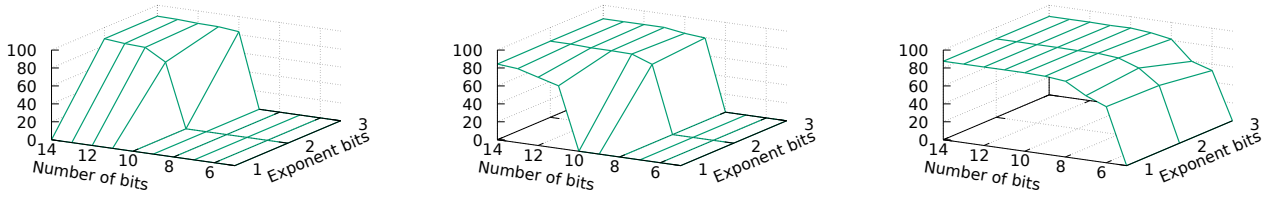
CRNN, GNN, and Transformer achieves the FP32 accuracy with *P(13,3)*, *P(11,3)*, and *P(9,2)* respectively. However, comparing a Posit and floating point configuration that uses the same number of bits in total, we observe they both converge to similar accuracy. This suggests that the higher precision of the Posit representation has limited benefits for DNN training workloads which are known to be tolerant of low-precision arithmetic. Despite this, we believe that Posit can still be a viable replacement for floating point in DNN accelerators due to its comparatively simpler and hardware-friendly design.

It is important to note that, the observation we make above goes against some of the prior works that claim that Posit can achieve better accuracy compared to floating point with a smaller hardware budget. For instance, Raposo et. al [59] have shown that 8-bit Posit can substitute 32-bit floating point for DNN training with no impact on accuracy. This underscores the importance of using a numerically accurate hardware emulation tool like Arbitor for such analysis. Moreover, the experimental evaluation conducted in this work was based on smaller models and datasets than what we use in our study. We believe our emulation tool can help hardware researchers to conduct accurate experimental analysis in the future and avoid making suboptimal design decisions.

5.3 Case Study #2: Approximate Computing

In this section, we use Arbitor to conduct a sensitivity study on a common approximate computing technique called *piece-wise linear approximation*. As described in Section 2, piece-wise linear approximation has been proposed as a cost-effective way to support non-linear algebraic functions like exponents and tanh that are common in natural language processing (NLP) models [35, 61, 69]. The key idea of this optimization is to break down curves of a non-linear function into pieces of line segments each approximating a part of the curve. Therefore, the fewer the pieces of line segments, the higher the numerical error in the approximation.

We analyze piece-wise linear approximation of the non-linear functions tanh and sigmoid in the CRNN model and their effect on the model accuracy by varying the number of pieces in the approximation. For this, we use the data type emulation policy in Arbitor to override the tanh and sigmoid function implementations of FP32 arithmetic with the piece-wise approximated version. Table 2a shows the validation accuracy curve of CRNN measured during the training.



(a) CRNN (b) GNN (c) Transformer

Figure 7: Validation accuracy of models trained using Posit format with different total bit widths and exponent bits

Observation 4: CRNN model can tolerate aggressive approximation on non-linear functions without affecting the accuracy.

We observe that even with an aggressive 3-piece approximation on both tanh and sigmoid functions, CRNN can maintain the baseline FP32 accuracy. This shows that piece-wise linear approximation is an effective optimization for DNN training. We also observe that a more aggressive 2-piece approximation on either function can significantly reduce the accuracy by up to 5%, and the accuracy drops further by 12% if both use 2-piece approximation. Since piece-wise linear approximation is often used in FPGAs and ASICs designed for NLP models, we believe our tool can be helpful in estimating the trade-offs of the approximation for specific models.

5.4 Case Study #3: Sparsity-Aware Processing

Finally, we use Arbitor to analyze how structured sparsity can affect the model accuracy. Sparsity-aware processing units are one of the recent innovations in DNN accelerators, e.g., Sparse Tensor Cores in Nvidia A100 [51]. Sparse tensor processing cores are designed to accelerate matrix multiplication over matrices with $N:M$ sparsity patterns, i.e., at most N values in every contiguous M block of values are non-zero. However, prior works [72] have pointed out that sparsity in DNN training is inherently unstructured, and enforcing any kind of structure to it in order to leverage Sparse Tensor Cores can affect the accuracy of the model.

We analyze the extent of these effects on ResNet-18 and Transformer with different sparsity patterns enforced on the weight parameter update operations during training. For this experiment, we define a masking policy in Arbitor with different N and M values. We use the absolute value of the weight parameter as the scoring function as it is one of the common heuristics for estimating the importance score in DNN pruning techniques [22]. Tables 2b and 2c shows the validation accuracy measured on ResNet-18 and Transformer.

Observation 5: The accuracy effects of sparse weight updates is highly model dependent. Moreover, enforcing more than 50% sparsity can have a significant impact on the model accuracy.

We observe that ResNet-18 can achieve close to the baseline FP32 accuracy with sparse weight updates. We also observe that ResNet-18 accuracy has slightly improved from the baseline accuracy with 50% sparsity patterns $1:2$, $2:4$, and $4:8$. We believe this improvement is due to the regularization effects of the sparse computation. On the other hand, Transformer shows a significant 4.3% drop in accuracy with 50% sparsity. This suggests that different models affect differently with sparsity-aware processing and require rigorous experimental analysis to accurately estimate the trade-offs. Applying patterns with more than 50% sparsity shows a significant drop in accuracy on both models by up to 7.5%.

6 Related Work

TensorQuant [45] is one of the first DNN emulation tools proposed and is specially designed for analyzing fixed point arithmetic primarily using layer-level quantization strategy. In addition, TensorQuant offers provision for fine-grained emulation strategy but requires users to write custom implementations for the operators in the DNN model. In contrast, Arbitor can support fine-grained emulation automatically with minimal effort from the user because of the compiler-based design that we follow. Moreover, due to the narrow focus on fixed point arithmetic emulation, the applicability of TensorQuant is limited to the analysis of DNN quantization methods. Arbitor, on the other hand, is capable of emulating arbitrary numerical formats using the data type emulation support and has a wider application. PositNN [59] is another DNN emulator built specifically for analyzing the efficacy of Posit numerical formats in DNN workloads. Therefore, like TensorQuant, PositNN also only has limited applicability. Moreover, PositNN uses a considerable amount of hand-written code for emulating Posit and only support a narrow range of DNN models. As we explain in Section 5.2.2, our analysis on a wider range of standard DNN models has refuted some

(c) Transformer with sparse weight updates

Table 2: Validation accuracy of CRNN, ResNet-18, and Transformer with approximate and sparse computing

of the observations made using PositNN. Specifically, the authors of PositNN claim that 8-bit Posit format can substitute $32-bit$ floating point, which we find to be untrue on the models that we analyzed.

More recent emulators, QPyTorch [70] and GoldenEye [47] are both implemented on top of PyTorch. These tools are primarily designed for exploring low-precision formats on DNN training and provide emulation support for a wide range of numerical formats like floating point, fixed point, and block floating point [21] and follow layer-level emulation strategy with the help of the `hook` functionality in the framework. GoldenEye also provides hardware error injection support to evaluate the reliability of DNN accelerators. However, as described in Section 3, these tools are susceptible to numerical inaccuracies in emulation which can lead to incorrect assessment of the hardware design. We argue that numerically accurate emulation should be a necessary quality of hardware emulators. Moreover, unlike QPyTorch and GoldenEye, Arbitor is capable of supporting other common optimizations like approximate and sparse computing.

7 Discussion

We have presented a numerically accurate approach for emulating hardware optimizations and estimating their effects on DNN accuracy to guide the hardware design. Below, we discuss the generalizability and limitations of Arbitor, as well as our future plans to overcome these limitations.

Supporting a broader set of numerical data formats. Although we focus on case studies of floating point formats and Posit formats in this work, Arbitor is designed to support any arbitrary data formats through the generic data type emulation policy. Hence, other floating point formats like FP8 and fixed point formats like INT8 can also be emulated under this generic emulation policy. We have also extended Arbitor to support more complex block-based data formats, such as block floating point format [21] and MSFP [19]. These formats employ a block-based representation, where values within each block share the same exponent. Emulating such data formats is more challenging compared to regular data formats that only require considering individual data points, as the operations for each value depend on global information like the value of the shared exponent. The extensible design of Arbitor allows for adding compiler passes to rewrite operations for different blocks to support such data formats.

Supporting more front-end frameworks. We chose to implement Arbitor on top of XLA because we find it to be the most mature ML compiler with training support and is well-integrated with popular front-end frameworks like TensorFlow [3] and JAX [11]. However, the compiler-based approach is not tied to any specific compiler backend. We plan to migrate Arbitor to the latest OpenXLA that is based on the MLIR [38] infrastructure. Additionally, since the concept of operation-level emulation is not tied to any specific compiler backend, it is possible to apply the design of Arbitor to other ML compilers like TorchDynamo [67].

Supporting other complex hardware features. In this work, we demonstrate Arbitor's support for the three most common categories of hardware-level optimizations supported in DNN accelerators. However, it is worth noting that there exist intricate hardware features that are out of Arbitor's current scope. For instance, complex custom processing units, such as $3D$ cube in Huawei NPU [39], are currently not supported by Arbitor. We consider addressing these advanced hardware features as future work.

8 Conclusion

In this paper, we showcase that hardware researchers currently lack an accurate hardware analysis tool for empirically evaluating different design choices for DNN training accelerators. To fill this gap, we propose Arbitor, a hardware emulation tool for analysing common hardware optimization strategies like low-precision training, approximate computing, and sparsity-aware processing. Unlike prior emulators, Arbitor follows an extensible design and numerically accurate emulation support with the assistance of modern machine learning compilers like TensorFlow XLA. We subsequently demonstrate the utility of Arbitor by conducting an extensive sensitivity analysis on the aforementioned optimization strategies and their influence on the accuracy of popular DNN models.

Acknowledgments

We would like to thank our shepherd and the anonymous reviewers for their valuable feedback and comments. We also thank members of the EcoSystem lab for their support, inspiration, and constructive feedback during the development of this work. A Artifact Appendix

Abstract

We provide the source code and scripts for Arbitor to reproduce the results of our experiments (in Section 3 and 4) and case studies (in Section 5) presented in the paper. While our paper explores three hardware optimizations: low-precision arithmetic, approximate computing, and sparsity-aware processing, the artifact focuses specifically on low-precision arithmetic. To this end, it contains the validation of accurate emulation of Arbitor. Additionally, the artifact conducts a sensitivity study between the validation accuracy and a subset of floating-point formats we study in the paper, similar to Figure 6. By following our provided instructions, users can expect to obtain results that closely align with those presented in the paper.

Scope

The artifact comprises two main components. Firstly, it generates the validation accuracy of training ResNet-18 using FP16 format emulated with Arbitor and QPyTorch and compares it to the native FP16 accuracy on GPU. This analysis highlights the negligible difference in accuracy between Arbitor-emulated FP16 and native FP16 while revealing a significant accuracy difference when using QPyTorch. Therefore, it could validate our claim that prior approaches like QPyTorch struggle to accurately replicate the numerical behavior of training with specific data formats, such as FP16, while Arbitor is designed to overcome this limitation.

Furthermore, the artifact automates the training process of GNN using a subset of floating-point formats evaluated in the paper, employing full low-precision training. This sensitivity study explores the variations in validation accuracy as the floating-point data format changes, thus validating the results presented in the corresponding section (Section 5) and supporting all associated claims. The results of all these training instances will be aggregated to generate a figure similar to Figure 6b but with fewer data points.

Contents

The artifact includes the source code of Arbitor, providing researchers with the ability to reproduce and modify the implementation. In addition to the evaluated ResNet-18 and GNN model, the artifact also includes the other two models, CRNN and Transformer, used in the case studies. Their corresponding datasets, including CIFAR-10 for ResNet-18, Cora for GNN, FordA for Transformer, and eng-fra for CRNN (as outlined in Table 1), are provided in the artifact. Therefore, researchers can readily evaluate these models and datasets, allowing for result replication, fast customization, and further investigation. Furthermore, the artifact provides a set of predefined data formats tailored to the experiments and case studies in the paper, including the floating-point and Posit formats, along with guidelines for incorporating these data formats in the training.

Hosting

The artifact can be downloaded from the main branch of GitHub link https://github.com/arbitor-project/artifact.

Requirements

A.0.1 Hardware requirement:

Arbitor requires the use of a multi-core CPU and an NVIDIA GPU with the Turing architecture or a more advanced counterpart to run the artifact. In our experiment, we employed four NVIDIA 2080Ti cards, but augmenting computation power by utilizing GPUs like NVIDIA A100, could further optimize the efficiency of artifact execution.

A.0.2 Software requirement:

The experiments provided in this artifact is prepared to run inside a docker container. We recommend using a machine with Ubuntu 20.04 with docker installed to reproduce the results.

Installation and Environment Setup

We provide docker files to set up the runtime environment for all the experiments.

- Install docker following the instructions in https://docs.docker.com/engine/install/ubuntu/.
- Make sure the machine has NVIDIA GPU(s) and the corresponding driver installed. If the NVIDIA driver is not installed, follow the instructions at NVIDIA tutorial to install it.
- Clone the git repository using the following command:
  `git clone --recursive https://github.com/arbitor-project/artifact`
- Build a docker image and enter the docker environment:
  `cd artifact && bash run.sh`

Experiment Workflow

We provide an end-to-end script to run everything all at once. When inside the docker environment, execute `e2e.sh` to run all the experiments and generate the results. The total execution may take several days to finish.

We also provide the step-by-step workflow as shown below:

1. Reproduce QPytorch ResNet-18 result with emulated FP16: `bash qpytorch.sh`
2. Reproduce Tensorflow ResNet-18 result with native FP16:
   `cd native_half && bash ./expr.sh resnet`
3. Reproduce Arbitor ResNet-18 result with emulated FP16:
   `cd /root/arbitor && bash ./expr.sh resnet`
4. Generate a subset of data formats for GNN training sensitivity study:
   `cd /root/ && bash ./gnn.sh`

Evaluation and Expected Results

Once the above execution has finished, two files, namely `results/validation.csv` and `results/sens.pdf` will be generated. `results/validation.csv` presents the final validation accuracy for three configurations: QPyTorch, native, and Arbitor FP16. It is expected that the validation accuracy of QPyTorch will be closely aligned with the FP32 baseline accuracy (93.78%), while both results of native and Arbitor are around 2% less than FP32 accuracy, consistent with the findings from Figure 3. Since the training process involves inherent randomness, it may be necessary to run multiple trials and compute an average for more accurate results. The file `results/sens.pdf` encompasses a figure depicting the relationship between accuracy, exponent bits, and mantissa bits. This is anticipated to bear resemblance to the first figure of Figure 6b, with fewer data points presented.

Experiment Customization

The emulated data format can be modified by modifying the `arbitor/data_format.sh` script to specify properties of data formats. Specifically, `F_OR_P` decides whether to emulate float or posit numbers. `ACC` represents the data type for accumulation, where `f32_acc` is to use FP32 to accumulate during a dot product, and `cus_acc` is to use the same type as computation for accumulation. In floating point configs, `EXP` and `MANTISSA` represent the bit-width of exponent and mantissa respectively. Setting `SUBNORMAL=_subnormal` causes subnormal numbers to be enabled during emulation and `SUBNORMAL=_wo_subnormal` otherwise. For Posit configs, `POSIT_NBITS` is the whole width of the number format, and `POSIT_ES` is the width of the exponent of Posit.

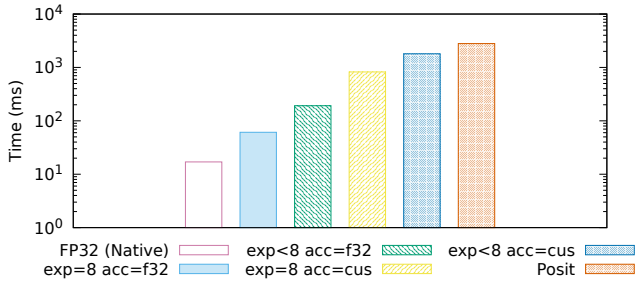

Figure 8: GNN training time with different number formats emulated by Arbitor

After changing `data_format.sh`, run
`bash ./expr.sh [gnn | transformer | crnn | resnet]`
to train the model with the specified data format.

B Overhead of Arbitor

In addition to accurate emulation, generating customized GPU kernels enables execution of Arbitor on GPU, in contrast to accurate software-based simulators that primarily rely on CPU-based execution. This allows Arbitor to leverage the high bandwidth and massive parallelism of GPU to achieve a level of performance that is more practical for executing DNN training workload compared to software-based simulators. To demonstrate the performance impact of Arbitor, we train the whole GNN model with different data formats emulated by Arbitor using the same experiment setup in Section 5.1. Figure 8 shows the training time for each step with different data formats, where `exp` is the width of exponent bits, and `acc=cus` or `acc=f32` represents whether the accumulation type is the same as computation type or is FP32. Emulating different data formats introduces different amounts of overhead, as the execution of emulated operations for each format requires a distinct number of cycles on the GPU. For the floating point format with 8 exponent bits with FP32 accumulation, Arbitor incurs a 3.59× overhead. When the data format is significantly different from FP32, such as Posit, Arbitor could introduce a slowdown of up to 164.7×. These results show that with the GPU acceleration, the performance of Arbitor is significantly better than software-based simulators and is practical for the accurate emulation of DNN training. Moreover, Arbitor can also leverage data parallel training to scale the training over multiple GPUs to compensate for the emulation overhead.

oBBR: Optimize Retransmissions of BBR Flows on the Internet

Abstract

BBR is a model-based congestion control algorithm that has been widely adopted on the Internet. Different from loss-based algorithms, BBR features high throughput since it characterizes the underlying link and sends data accordingly. However, BBR suffers from high retransmission rates in deployment, leading to extra bandwidth costs. In this work, we carefully analyze and validate the reasons for high retransmissions in BBR flows. In a shallow-buffered link, the packet losses are deeply correlated to both the bottleneck buffer size and the in-flight data cap. Additionally, bandwidth drops also cause unwanted retransmissions. Based on the analysis, we design and implement oBBR, which aims at optimizing the retransmissions in BBR flows. In oBBR, we adaptively scale the in-flight data cap and update the bandwidth estimate timely so that few excessive data are injected into the network, avoiding packet losses. Our Internet experiments show that oBBR achieves 1.54× higher goodput than BBRv2 and 39.48% fewer retransmissions than BBR-S, which are both BBR variants with improved transmission performance. When deploying BBR in Internet streaming sessions, oBBR obtains greater QoE than BBRv2 and BBR-S without incurring more retransmissions. To summarize, oBBR is designed to help a transmission session reach high goodput and low retransmissions simultaneously, while other CCAs only achieve one of them.

1 Introduction

Congestion control algorithms (CCAs) are essential for data transmission on the Internet. The loss-based CCAs like CUBIC [18] treat the packet loss as a signal of network congestion and thus throttle their sending rate. However, this significantly underutilizes the underlying link capacity since packet losses do not necessarily indicate congestion in the Internet nowadays. To effectively exploit the bandwidth resources, Google developed a model-based CCA based on measuring bottleneck bandwidth and round-trip propagation time, or BBR [8]. BBR ignores packet losses but adjusts its behaviors according to the estimated bandwidth and round-trip time (RTT). After switching to BBR from CUBIC, the throughput in Google's B4 network is consistently improved by 2-25× [9]. Since its release, BBR has been deployed on 22% of websites and accounts for over 40% of Internet traffic [36]. This attracts content providers, like YouTube [7] and Spotify [12], to adopt BBR.

While BBR exploits the bandwidth more effectively, this algorithm also leads to high retransmission rates. BBR is expected to send in-flight data at a volume of the bandwidth-delay product (BDP) only, i.e., operating at Kleinrock's optimal point [29], but it is still observed that BBR injects excessive data to the transmission channel because of bandwidth overestimation [22, 50]. To avoid the excessive data accumulated at the bottleneck, BBR imposes an upper bound to the volume of in-flight data at 2×BDP. But this results in a high packet loss ratio if the bottleneck buffer is not large enough to hold the excessive in-flight data. As a result, a large amount of data needs to be retransmitted, bringing extra bandwidth costs to content providers.

Directly reducing the upper bound of in-flight data in BBR is not feasible. By capping the in-flight data at 2×BDP, a BBR flow could "fairly" share the bandwidth with a loss-based flow (∼40%) when the bottleneck buffer is deep [14, 43, 52, 53]. If we limit the in-flight data in BBR further, it can no longer compete with the loss-based flows, thus achieving a degrading throughput.

Additionally, the high retransmission rates in BBR also result from bandwidth drop. BBR estimates the bottleneck bandwidth with the maximum delivery rate samples collected in an RTT-based time window. If the bandwidth drops, BBR will not update the bandwidth estimate until the outdated (and overestimated) samples leave the time window. While BBR keeps sending data and caps the in-flight data according to the overestimated bandwidth, the bottleneck buffer is quickly crammed and starts to discard packets. Moreover, the congestion at the bottleneck buffer enlarges the latest RTT samples

*Corresponding author

and thus the window size, making the old bandwidth samples expire even later.

In this paper, we propose oBBR, optimizing the retransmission rate and throughput in a BBR session. By extending the analysis model proposed in [52], we notice that the behaviors of a BBR flow are deeply correlated to the bottleneck buffer size and the in-flight data cap. Capping the in-flight data to a smaller value than 2×BDP mitigates the retransmissions in shallow buffers, but also weakens BBR's competitiveness in deep buffers. Furthermore, BBR can no longer compete with loss-based flows if the in-flight data is exactly 1×BDP. Following the analysis, oBBR detects if the bottleneck buffer is shallow once a packet loss event occurs. Then, oBBR reduces the in-flight cap accordingly so that the retransmissions are avoided. The in-flight cap is gradually recovered in case the packet loss is not caused by congestion. Furthermore, identifying a bandwidth drop event is not straightforward in BBR. Bandwidth samples with smaller values than the estimate are common because only the maximum is selected. In oBBR, we use consecutive samples of decreasing bandwidth or increasing latency to identify a bandwidth drop event. However, it is still possible that we falsely detect a bandwidth drop. We compare the delivery performance before and after the bandwidth estimate update. If the delivery performance degrades, we revert it to the old value.

We implement oBBR within a userspace implementation of Quick UDP Internet Connection (QUIC) [30], which is an appealing solution to network applications like video streaming due to its improved performance, high flexibility, and ease of deployment. We evaluate oBBR in both a lab environment and the Internet. In a stable network environment, oBBR reduces the packet loss ratio by up to 30× when compared to BBR. With 2% packet losses, oBBR achieves 14.65× higher goodput than BBRv2 which reacts to packet losses for alleviating retransmissions. In a network with fluctuating bandwidth between 40 Mbps and 10 Mbps, oBBR reduces the retransmissions by 52%. The realistic network emulation and the experiments on the Internet both show that oBBR achieves low retransmission ratios as loss-based algorithms, like BBRv2 and CUBIC, and high goodput as model-based ones, like BBR. Especially when continuously delivering data in a long Internet link, oBBR has the retransmission at ∼6.5% while gaining 1.54× more goodput compared to BBRv2, which retransmits 6.71% data. Compared to BBR-S, another BBR variant that also has reduced retransmissions and high goodput in our experiments, oBBR reduces retransmissions by 39.48%. We also implement oBBR in a video streaming system and measure the user's quality of experience (QoE) of streaming sessions on the Internet. Our experiments show that oBBR guarantees the QoE of a video session in terms of average quality, quality switches, and rebuffering ratio better than other CCAs including BBRv2 and BBR-S while suppressing the retransmission ratio as low as ∼4%. In summary, oBBR achieves both high goodput and low retransmissions in a transmission session,

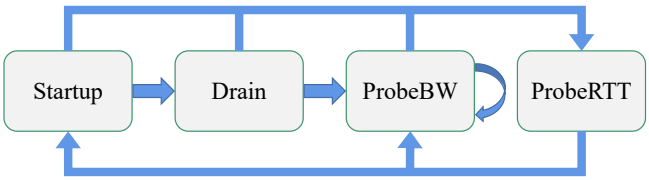

Figure 1: Overview of the BBR algorithm

while other CCAs only achieve one. The contributions of this paper are as follows:

- We carefully analyze why retransmissions are common in BBR flows. The high retransmissions in shallow-buffered links are deeply correlated to both the in-flight data cap and the buffer size. Moreover, the mechanism of BBR modeling the network becomes inaccurate if the bandwidth drops.
- We design and implement oBBR, optimizing the retransmissions of the BBR algorithm. oBBR adjusts the in-flight data cap according to the bottleneck buffer size and updates the bandwidth estimate promptly. Both reduce the excessive data sent by oBBR, avoiding packet losses.
- We carry out extensive experiments in both a lab environment and the Internet, justifying the design of oBBR. We also implement oBBR in a video streaming system on the Internet, and the results show that oBBR reaches higher QoE than BBRv2 while both have low retransmission ratios.

We briefly introduce how BBR works in Section 2 and analyze why the transmission rate of BBR flows is high in Section 3. The design of oBBR is presented in Section 4. In Section 5, extensive experiments are carried out to evaluate our design. Section 6 discusses related work and Section 7 concludes our work.

2 Background

BBR. BBR is a model-based congestion control algorithm released by Google in 2016 [8]. In a transmission session, BBR estimates the bottleneck bandwidth and the round-trip propagation time of the underlying link. To get unbiased estimates, BBR extracts the maximum from recent bandwidth samples and the minimum from recent RTT samples.

To regulate the traffic, BBR matches its average sending rate to the bandwidth estimate and caps the in-flight data by 2×BDP. Two key parameters, `pacing_gain` and `cwnd_gain`, are used in controlling the sending behaviors. `pacing_gain` inflates or deflates the sending rate while setting it to 1 means the sender transmits data at the rate of estimated bandwidth. This parameter is dynamically scaled in operation. `cwnd_gain` caps the in-flight data and is set to 2 in practice,

which means at most 2×BDP data are sent without acks. A BBR session always switches among four phases: *Startup*, *Drain*, *ProbeBW*, and *ProbeRTT*. An overview of the BBR algorithm is shown in Figure 1

1) Startup: BBR detects the available bandwidth by inflating its sending rate, where `pacing_gain` and `cwnd_gain` are both $2/ln2$. It switches to the *Drain* phase if the measured bandwidth stops growing.

2) Drain: BBR drains the excessive data queued at the bottleneck buffer because of the exponential growth of sending rate in the *Startup* phase. `pacing_gain` is set to $ln2/2$ until the in-flight data is less than 1×BDP. BBR then enters the *ProbeBW* phase.

3) ProbeBW: BBR spends most time in the *ProbeBW* phase, where `pacing_gain` is periodically set to {1.25, 0.75, 1, 1, 1, 1, 1, 1} and `cwnd_gain` is fixed to 2. Periodically inflating the sending rate helps BBR detect if the available bandwidth has increased, and deflating the rate could drain the queued data if the bandwidth is unchanged.

4) ProbeRTT: The *ProbeRTT* phase is independent of the other phases. BBR enters *ProbeRTT* once the RTT estimate has not been updated for 10 seconds. In this phase, BBR sends only 4 packets in-flight and observes their RTTs.

BBRv2. Though BBR gains high throughput in transmission, its mechanism has raised a few concerns: BBR does not react to the packet losses caused by network congestion and thus has high retransmission rates in links with a shallow bottleneck buffer; BBR does not share bandwidth with loss-based algorithms fairly; The throughput drops drastically in the *ProbeRTT* phase. To address these shortcomings, BBRv2 [11] is proposed and has been deployed in Google's internal network [10].

In BBRv2, packet loss events are considered signals of network congestion again. BBRv2 reduces the in-flight data cap multiplicatively if the packet loss ratio exceeds a threshold (2% in practice). But this also impairs the flow throughput as the loss-based CCAs do in a network environment with a high packet loss ratio (> 2%). In this work, we also compare oBBR with BBRv2, and the results are reported in Section 5.

3 Retransmissions in BBR

In this section, we analyze two major reasons that cause high retransmission rates of BBR flows in depth: 1) the underlying link is shallow-buffered, and 2) the available bandwidth drops in the transmission session.

3.1 Shallow-Buffered Link

Ideally, BBR operates at the optimal point of the transmission channel, i.e., no packets are queued in the bottleneck buffer and the latency approximates the physical delay. To achieve this, the in-flight data should equal 1×BDP of the channel. In practice, the bandwidth is usually overestimated [22, 50, 52], and thus the data would be gradually accumulated at the bottleneck buffer until packet losses. To avoid this, the sender employing BBR caps the in-flight data as

$$inflight = \texttt{cwnd\_gain} \cdot \widehat{RTprop} \cdot \widehat{BtlBw},$$

where $\widehat{RTprop}$ and $\widehat{BtlBw}$ are the estimates of round-trip propagation time and bottleneck bandwidth, respectively. `cwnd_gain` bounds the in-flight data to a small multiple of the BDP and is commonly set to 2. We can safely assume the volume of in-flight data reaches the upper bound most of the time because BBR overestimates its bandwidth share when competing with other flows [22].

However, $\widehat{RTprop}$ and $\widehat{BtlBw}$ are substantially affected by the competing flows, especially the ones with loss-based congestion control algorithms (CCAs). If the data from competing flows are also queued in the bottleneck buffer, $\widehat{RTprop}$ is then composed of the physical delay and the queue length, and $\widehat{BtlBw}$ is the link capacity proportional to BBR's buffer occupancy ratio [52]. The volume of in-flight data is calculated as

$$inflight = g \cdot (\frac{pq}{c} + l) \cdot (1-p)c,$$

where g represents `cwnd_gain`, q is the queue capacity of bottleneck buffer, p is the buffer ratio occupied by competing loss-based CCA flows, l is the RTT without congestion, and c is the link capacity. Then, the queued data of a BBR flow is

$$\begin{aligned} queued &= g \cdot (\frac{pq}{c} + l) \cdot (1-p)c - (1-p)cl \\ &= gq \cdot p(1-p) + (g-1) \cdot cl \cdot (1-p). \end{aligned} \tag{1}$$

By defining the occupied ratio of BBR flow at the bottleneck as $Q_r = \frac{queued}{q}$ and the relative size of bottleneck buffer to the BDP as $R = \frac{q}{cl}$, we have

$$Q_r(p; g, R) = gp(1-p) + (g-1)R^{-1}(1-p).$$

This helps us understand the behaviors of BBR with different configuration sets of g and R. We plot Q_R *vs.* p in Figure 2.

The left side of Figure 2 shows how a BBR flow behaves if $g = 2$, the current setup in BBR implementations. When the bottleneck buffer is as deep as 16×BDP, the BBR flow occupies almost half the buffer no matter how many loss-based flows coexist, which has been confirmed in prior studies [52]. If we reduce R, the shallower buffer will be more occupied by the BBR flow. When the buffer is as shallow as 1×BDP, the loss-based CCAs can not compete with BBR anymore. When the buffer size is lower than 1×BDP, we do not have enough space to hold the in-flight data and the packet loss ratio drastically increases.

If we set g to 1, expecting that no packet is queued when there is no competing flow, this also leads to another severe problem. As shown in the right of Figure 2, no matter how large the bottleneck buffer is, the BBR flow can not compete

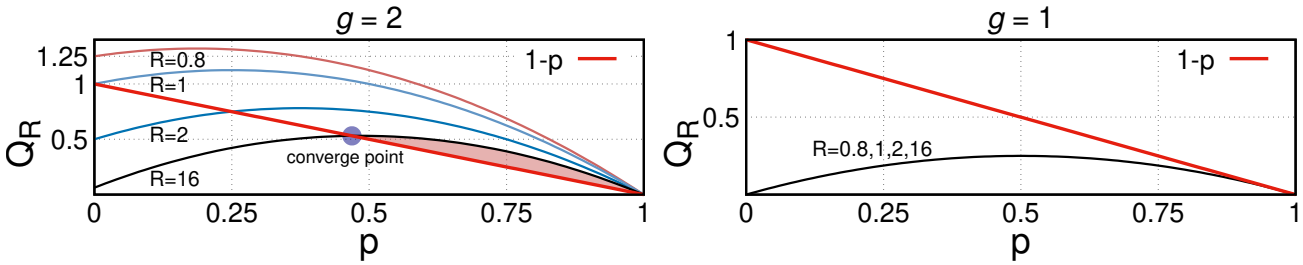

Figure 2: Q_R *vs.* p when setting g to 2 and 1. $1-p$ indicates the remaining buffer space for the BBR flow (from loss-based flows). We take $g = 2$ and $R = 16$ as an example. When $1-p$ is above the Q_R curve (at the left side of the figure), the buffer has enough space to hold the in-flight data of the BBR flow. As the loss-based CCA flows keep ramping up their in-flight data since no packets are discarded, p is increasing, which lets the BBR flow also accumulate more data in the buffer. The intersection of $1-p$ and the Q_R curve means that the buffer is fully occupied and loss happens. The loss-based CCA flows start to back off and then the BBR flow also backs off. As a result, the BBR flow operates around the converge point.

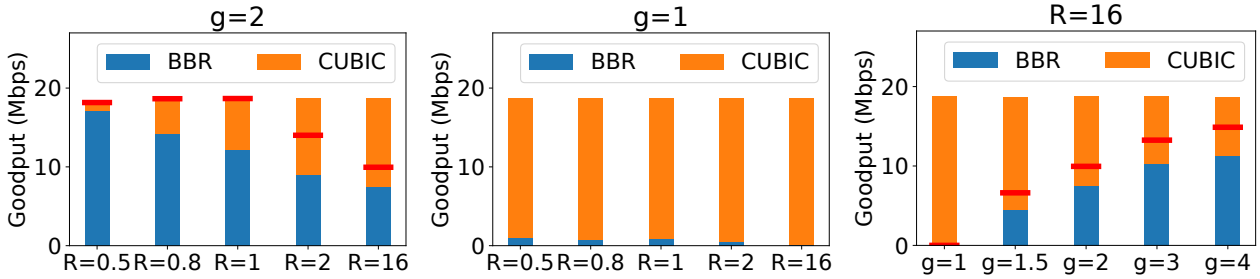

Figure 3: The average goodput of a BBR flow and a CUBIC flow with various configuration sets g and R

with the loss-based CCAs anymore, leading to poor performance.

Experimental verification: We set up the testbed in our lab environment based on nginx-quic [3], where we implement the BBR and CUBIC algorithms in the QUIC protocol. The details of the experimental setup are presented in Section 5.1. In the experiments, we simultaneously launch a BBR flow and a CUBIC flow. Both of them keep sending data without limitation from the application layer. The bandwidth is set to 20 Mbps and the RTT is set to 40 ms. By skipping the first 60 seconds, we measure the average goodput of two flows for 7 minutes when setting g and R to different values.

In Figure 3, the leftmost reports the average goodput of two flows when setting $g = 2$ and varying the bottleneck buffer size. We can see that the goodput proportion of the BBR flow decreases as R is greater, but it is still lower than the converge point $\frac{R-g+1}{gR}$ found in the model, which are marked as red lines on the bars. The reason is that BBR can not adjust its behavior as fast as the CUBIC does at the converging point: When two flows fully occupy the bottleneck buffer and packets are discarded, the CUBIC flow reduces its congestion window and the queue size shrinks, leading to that smaller RTTs are detected by the BBR flow. This immediately updates $\widehat{RTprop}$ and BBR calculates a smaller BDP. However, in the recovery phase, the CUBIC flow ramps up its congestion window quickly while BBR still uses the small BDP because the new RTT samples are greater than $\widehat{RTprop}$. The inaccurate RTT estimate expires in 10 seconds but before that, the CUBIC flow has occupied all free space in the buffer and backs off because of the packet loss again. Furthermore, BBR periodically enters *ProbeRTT* which reduces the in-flight data to 4 packets, also yielding bandwidth to the competing flows. But since the BBR ignores packet loss, this results in the BBR flow evicting the CUBIC flow and starting to experience apparent packet losses in a shallower buffer. When R is reduced to 0.5, BBR dominates the bandwidth and the packet loss ratio increases to 13.36%. The middle of Figure 3 confirms that when g is set to 1 and no matter how large the bottleneck buffer is, BBR can hardly compete with CUBIC and almost all the bandwidth is used by the CUBIC flow. The rightmost of Figure 3 shows the goodput of two flows when setting the bottleneck buffer to 16×BDP and varying g, where BBR gains more goodput with increasing g.

Based on the models and the experiments, we can derive that the packet losses of a BBR flow in a shallow-buffered link are correlated to g and R. If we reduce g, a BBR flow only evicts the coexisting loss-based flows and experiences packet losses in a shallower buffer. But this weakens the

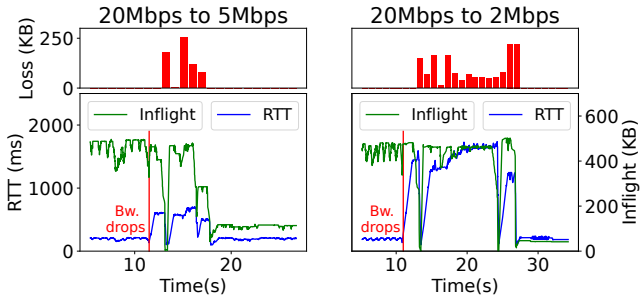

Figure 4: The network characteristics of a BBR flow when the bandwidth drops from 20 Mbps to 5 Mbps or 2 Mbps.

competitiveness of BBR in deep buffers. When g decreases to 1, BBR can hardly compete with loss-based flows no matter how large the bottleneck buffer size is. If set it to a high value, BBR flows have to sustain a high packet loss ratio when the bottleneck buffer is shallow.

3.2 Bandwidth Drop

BBR collects the delivery rate samples in a time window (typically 10 RTTs) and chooses the maximum as the bandwidth estimate. The rationale behind this is that acks can only be delayed. However, such a mechanism makes BBR react to the bandwidth drop sluggishly. When the bandwidth decreases, BBR keeps sending data at a high rate until the overestimated samples expire after 10 RTTs. This ramps up the queue size at the bottleneck buffer and leads to packet loss once the queue is crammed. More severely, as the packet delivery delay is extended due to the congestion at the bottleneck, the overestimated bandwidth samples expire in a longer period.

We conduct experiments to observe how a BBR flow reacts to the bandwidth drop in our testbed. In the experiments, the bandwidth is initially 20 Mbps, the RTT is 100 ms, and the bottleneck buffer is 200 KB. A BBR flow is launched to constantly send data. After ∼10 seconds since the flow starts, we throttle the bandwidth to a lower value (5 Mbps or 2 Mbps).

The experimental results are reported in Figure 4. The x-axis is the time elapsed since the flow starts in seconds and we plot the RTT samples in milliseconds, in-flight data volume in KB, and lost data volume in KB. We can observe that even the bandwidth drops, the in-flight data volume stays almost the same because of the unchanged $\widehat{BtlBw}$ and $\widehat{RTprop}$. While the actual bandwidth can not match the sending rate of BBR, the RTTs of packets rise sharply due to the increasing queue size at the bottleneck. The lost data volume also increases during this period. Only after 10 RTTs, i.e., ∼7 seconds on the left of Figure 4 (the RTT samples rise to ∼700 ms) and ∼15 seconds on the right of Figure 4 (the RTT samples rise to ∼1500 ms), the bandwidth estimate is corrected and the in-flight data match the BDP again. During the overestimation stage, the sudden drops of RTTs are caused by the *probeRTT* phase, but this does not help the BBR client realize the actual BDP.

4 Design

As discussed in Section 3, the main reasons for high retransmission rates in BBR are: 1) In a shallow buffer, the data in-flight could not be fully contained when g is fixed to a constant; 2) The bandwidth estimate is not timely updated when the bandwidth drops. To solve these problems, we propose to

- *Adaptive g*: We estimate the bottleneck buffer size with the RTT samples, and when a packet is discarded, the value of g is adjusted accordingly.
- *Timely bandwidth updates*: We identify the bandwidth drop based on both the RTT and delivery rate samples, updating the bandwidth estimate in time. This is reversible if the transmission throughput decreases.

4.1 Adaptive g

In practical BBR sessions, g is set to a fixed value of 2. This leads to the packet loss ratio drastically rising if the bottleneck buffer is shallower than $(g-1)\times$BDP. In this case, BBR packets are dropped because the in-flight data volume is larger than the buffer size q. By setting $p=0$ in Equation 1, the excessive data volume of a BBR flow is $(g-1)cl$. To avoid the packet loss events, we could adjust g to match the excessive data volume to the shallow buffer size q, i.e.,

$$g = \frac{q+cl}{cl}.$$

Whenever a packet loss event occurs, we can assume this results from a shallow bottleneck buffer. To scale g, we need to evaluate the buffer size by

$$q = c(l' - l),$$

where l' is the delivery latency of a packet that is queued at the end of the bottleneck buffer. Since the current buffer is full, l' can be reasonably estimated using the latest RTT sample RTT_{latest}. Then, we know that if

$$\frac{l'}{l} = \frac{RTT_{latest}}{\widehat{RTprop}} < g,$$

the bottleneck buffer is shallow.

Once we discover the packet loss is caused by a shallow buffer, we could scale g to

$$\min\left(1+\mu\cdot\frac{RTT_{latest}-\widehat{RTprop}}{\widehat{RTprop}}, g_{max}\right),$$

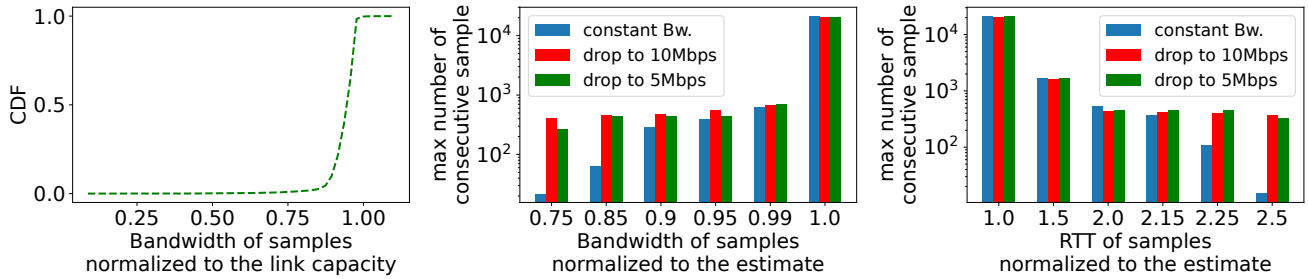

Figure 5: The network statistics of a BBR flow in various network environments. The network bandwidth is consistently set to 20 Mbps in the transmission session or decreases to 5/2 Mbps after 10 seconds. The leftmost figure presents the cumulative distribution function (CDF) of bandwidth samples normalized to the actual bandwidth when the bandwidth is constant. The figure in the middle shows the max number of consecutive bandwidth samples that are below the proportions of the estimated bandwidth. The rightmost figure shows the max number of consecutive RTT samples above thresholds of multiplicative RTTs.

where $0 < \mu < 1$ indicates the proportion of the shallow buffer attributed to the BBR flow and g_{max} is referred to as the fixed value used in deep buffer cases.

When the bottleneck buffer is non-shallow and there are competing flows, RTT_{latest} is expected to be greater than $g_{max} \times \widehat{RTprop}$ no matter if the packet loss event is caused by random loss or congestion. The $\min(\cdot)$ filter helps oBBR behave like the vanilla BBR in these cases if $g_{max} = 2$. If there are no competing flows, a smaller g but greater than 1 still guarantees the bandwidth is fully utilized. As a result, oBBR can adapt to the shallow buffer cases without affecting other scenarios.

Only scaling down g is not enough: 1) RTT_{latest} might be less than l'. For example, a packet loss happens before the shallow buffer is crammed. 2) The bottleneck might migrate to a deep buffer during the transmission session. Thus, we design a recovery stage to increase g back to g_{max}. Whenever an ack is received, we have

$$g = \min\left(g + \alpha \cdot \frac{S_{ack}}{BDP}, g_{max}\right),$$

where S_{ack} is the acked data size and α is a parameter preventing the congestion window growing too fast. In this way, after the congestion window is shrunk, it keeps increasing the value back until the packet loss happens again.

4.2 Timely Bandwidth Updates

BBR selects the maximum of bandwidth samples during the latest 10 RTTs as $\widehat{BtlBW}$. In the *ProbeBW* stage, BBR periodically inflates the sending rate to $1.25 \times \widehat{BtlBW}$ to verify if the actual bandwidth has increased. As long as a sample of higher bandwidth is observed, $\widehat{BtlBW}$ is updated so that BBR reacts to bandwidth increase timely. However, BBR fails to adapt to the bandwidth drop in time. Though the latest acks could show that fewer data has been received per unit time, these signals are ignored in estimating $\widehat{BtlBW}$. As a result, BBR keeps sending the data at a high rate until all samples of high bandwidth expire.

However, observing a sample of low bandwidth does not necessarily indicate the bandwidth has decreased. Acks might be delayed in the transmission and this is the reason of selecting maximum as the estimate. We collect bandwidth samples by running a BBR flow in the lab with 20 Mbps bandwidth and 100 ms RTT. The bandwidth samples are normalized to the realistic bandwidth and the results are shown in the leftmost of Figure 5. We can find that even for an experiment in the lab, 59% of samples are lower than $0.95 \times BtlBw$, and 24% of samples are lower than $0.85 \times BtlBw$.

Though the bandwidth samples could be inaccurate (we observe a sample of $0.09 \times BtlBw$ in the experiment), the samples that are highly deviated from the realistic bandwidth rarely appear consecutively. The middle of Figure 5 shows the max length of consecutive samples that are below varying thresholds proportional to the bandwidth estimate. We can see that for the constant bandwidth, at most 22 consecutive samples are observed below $0.75 \times \widehat{BtlBw}$. We also manually throttle the bandwidth to 10/5 Mbps in the transmission, and in both cases, the length of consecutive bandwidth samples could clearly signal the bandwidth drop. To effectively detect the decrease of bandwidth, we check if **there are k consecutive bandwidth samples less than $0.75 \times \widehat{BtlBW}$**. With a longer k, we are more confident to believe that the bandwidth has decreased rather than acks are occasionally delayed.

On the other hand, the bandwidth samples could be overestimated in realistic network environments. For example, routers could aggregate acks or have the capacity of handling burst traffic, both leading to calculating a greater bandwidth at the BBR sender. To detect the bandwidth drop even if the bandwidth samples are not reliable, we also use RTT samples. Since at most $g_{max} \times$BDP data are sent in-flight, the RTT samples should be about $g_{max} \times \widehat{RTprop}$ and samples with obviously greater values indicate the bandwidth estimate is not accurate anymore. We plot the max number of consecu-

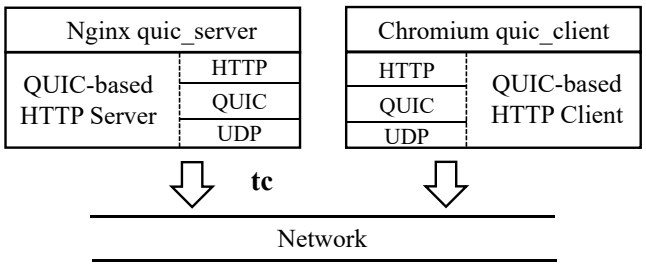

Figure 6: Overview of the testbed

tive RTT samples that are above thresholds of multiplicative $\widehat{RTprop}$ in the rightmost of Figure 5. When the bandwidth is constant, at most 15 samples are observed consecutively higher than $2.5\times\widehat{RTprop}$. This number increases to 373 or 328 if the bandwidth drops to 10/5 Mbps during the transmission, respectively. Thus, we also detect if **there are k consecutive RTT samples greater than** $(g_{max}+0.5)\times\widehat{RTprop}$. To the end, if **any of the two cases happen**, we think the bandwidth has decreased, and we use the average of k most recent bandwidth samples to update $\widehat{BtlBW}$.

Though we update the bandwidth estimate cautiously, it is still possible that an inaccurate value is used. So we monitor the delivery performance before and after the bandwidth update, reverting to the old value if the delivery performance decreases. Specifically, we calculate a delivery score of a fixed time interval T following

$$U = delivered - 10\times unacked,$$

where *delivered* is the amount of data acked and *unacked* is that not acked in T. We calculate the average score for $2T$ before and $2T$ after the bandwidth update. $\widehat{BtlBW}$ is reverted if the score drops.

4.3 Competitiveness Analysis

As discussed in Section 3.1, the competitiveness of BBR is determined by g and R. oBBR scales g to a smaller value once discovering the current link is shallow-buffered, while using a fixed g_{max} in deep buffers. By setting g_{max} to 2, oBBR behaves just like the vanilla BBR in deep-buffered links. A smaller or greater g_{max} weakens or strengthens its competitiveness.

In shallow-buffered links, the competitiveness of an oBBR flow is determined by μ, i.e., the excessive in-flight data proportional to the shallow buffer size. With a greater μ, oBBR is more competitive, but also has a higher risk of packet losses. Since the vanilla BBR selects a fixed g of 2, oBBR can hardly compete with it. But we can still expect that oBBR is less aggressive than BBR when competing with loss-based algorithms.

5 Evaluation

In this section, we evaluate oBBR and other peer methods in both a lab environment and the realistic Internet. We also build a video streaming system with oBBR that verifies our design also benefits network applications.

5.1 Experimental Setup

Implementation: We implement oBBR[1] in *nginx-quic* [3], which only has an RFC-defined congestion control algorithm.[2] In all experiments, we set α that controls the speed of recovery from the packet loss to 0.01. For detecting the bandwidth drop, we set k to 30 and T to 200 ms. We vary μ in 0.5, 0.75, and 1 to have oBBRs with different competitiveness, which is referred to as oBBR-0.5, oBBR-0.75, and oBBR-1 in the following discussion. In oBBR, we also set a lower bound 1.25 to `cwnd_gain` when the *ProbeBW* phase is probing for more bandwidth.

Additionally, we implement a couple of CCAs for comparison: **CUBIC** [18] is the default CCA in the Linux kernel, which considers packet loss as congestion and uses a cubic function to grow the congestion window. The vanilla version of **BBR** [8] manipulates its sending behaviors only depending on the estimates of bottleneck bandwidth and propagation round-trip time. **BBRv2** [11] is the successor of BBR proposed by Google, adding reactions to packet loss and greatly reducing retransmission rates. **BBR-S** [50] handles the bandwidth overestimation caused by the burst capacity of routers. It estimates the bandwidth at the 85th percentile of collected samples. **B3R** [44] is a BBR variant, which adjusts `pacing_gain` to regulate the sending rate in the *ProbeBW* phase. It aims at reducing the packet loss ratio when the bottleneck buffer is shallow. To compare all of these CCAs with oBBR on an equal footing, we implement these CCAs within nginx-quic. Implementing all of the CCAs within the same system architecture allows us to eliminate irrelevant factors that would otherwise complicate our comparison of CCAs.

It is worth noting that the *pacing* mechanism is not limited to BBR and its variants. The pacing mechanism sends data in a controlled manner so that the sending behavior becomes smoother. It has been proven effective in TCP connections with shallow bottleneck buffers [4]. So we also implement the pacing mechanism in CUBIC. Specifically, CUBIC calculates `pacing_rate` by `cwnd` / `srtt` × `pacing_ratio`, where `cwnd` is the congestion window and `srtt` captures the statistics of RTTs in both short-term and long-term. `pacing_ratio` is 2 in slow start and is 1.2 otherwise.

Testbed: We evaluate various CCAs in the client-server mode. nginx-quic is deployed as an HTTP server so that the transmission sessions in our experiments are HTTP sessions. In our lab environment, the server resides on a Linux machine

[1] Our prototype is available at https://github.com/bpq233/oBBR
[2] RFC 9002

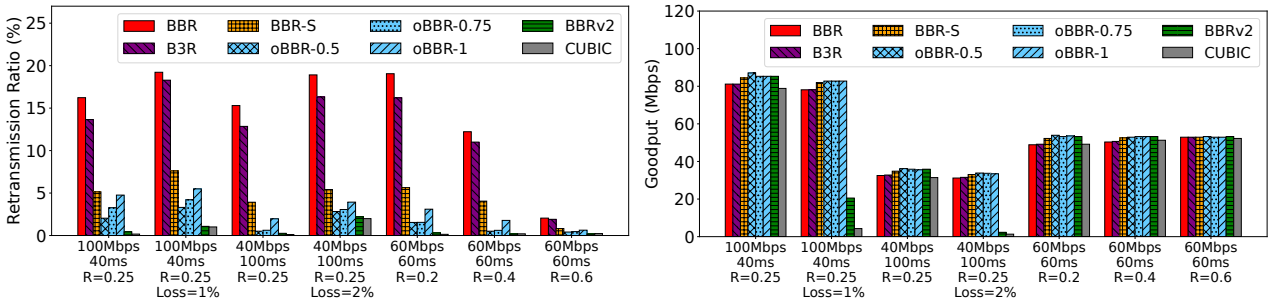

Figure 7: Performance of various CCAs in stable network environments

running Ubuntu 20.04 LTS with an Intel i5-7300HQ CPU @ 2.5 GHz (4 cores) and 16 GB RAM. The HTTP client is a simple implementation in the Chromium project [1] that also supports QUIC. For controlling the network conditions in our lab environment, *tc* [21] is used. In addition to changing the bandwidth, the latency, and the packet loss ratio, we adjust two parameters, `Limit` and `Burst`, to emulate the buffer size and the capacity of handling traffic exceeding the bandwidth at the bottleneck router. In experiments that use *tc*, `Burst` is set to 100 KB. An overview of the testbed is shown in Figure 6.

5.2 Retransmissions and Throughput

In the following experiments, we configure the client to fetch a data file of 1 GB via the HTTP protocol in a transmission session. The performance of various CCAs is measured in stable networks, variable networks, real network traces, and the Internet.

5.2.1 Stable Network Environment

Single flow: We first run various CCAs in stable network environments, where the bandwidth and the latency are set to {100 Mbps, 40 ms} or {40 Mbps, 100 ms}. We measure the retransmission ratio and the average goodput in a transmission session. The retransmission ratio is the volume of retransmitted data divided by the overall delivered data. R is 0.25 and the random packet loss ratio at 1% or 2% is also added. The results are shown in Figure 7. We can see that CUBIC and BBRv2 have the lowest retransmission ratios since they aggressively reduce the in-flight data when detecting packet losses. But both of them are vulnerable to random packet losses. Introducing a 1% random packet loss ratio reduces their goodput by 76% (BBRv2) and 94% (CUBIC), respectively. And the numbers increase to 94% (BBRv2) and 96% (CUBIC) with a 2% random packet loss ratio. On the other hand, BBR maintains its goodput across all cases but its retransmission ratios are also the highest, reaching 17.42% on average. This is because BBR does not throttle its sending rate until the packet loss ratio, whether caused by congestion or random losses, reaches a relatively high threshold of ~20%, which is not the case in our experiments. Across all scenarios, oBBR schemes consistently have high goodput, which is at least 82.76% of the link capacity. oBBR also suppresses its retransmission ratio of a session to a low value. For example, in the network with 40 Mbps bandwidth and 100 ms latency, oBBR keeps its retransmission ratios at 0.51% (μ=0.5), 0.62% (μ=0.75), and 1.97% (μ=1), respectively. By introducing 2% random packet losses, oBBR has the retransmission ratios at 2.82% (μ=0.5), 3.06% (μ=0.75), and 3.93% (μ=1). B3R lowers its sending rate to avoid excessive in-flight data, but this does not work in our experiments because of the bandwidth estimation. As a result, the retransmission ratios of B3R are similar to those of BBR. BBR-S more accurately estimates the bandwidth in our scenarios where the bottleneck router could handle burst traffic. Benefiting from this, BBR-S retransmits fewer data than BBR and B3R, but is still worse than oBBR schemes.

Then, we vary R to 0.2, 0.4, and 0.6, and fix the bandwidth and latency to {60 Mbps, 60 ms}. The results are also reported in Figure 7. With increasing bottleneck buffer size, BBR, B3R, and BBR-S reach a lower retransmission ratio accordingly because more in-flight data could be held in the buffer. The fewer retransmissions also improve their goodput. oBBR schemes have relatively high retransmission ratios when R=0.2, which are 1.54% (μ=0.5), 1.55% (μ=0.75), 3.10% (μ=1). This is due to we set a lower bound of 1.25 to g to match the 1.25×`pacing_gain` when probing for more bandwidth. When the R increases, the retransmission ratios of oBBR decrease again. For instance, when R=0.4, the retransmission ratios of oBBR are 0.51% (μ=0.5), 0.61% (μ=0.75), 1.78% (μ=1). BBRv2 and CUBIC still have the lowest transmission ratios while BBRv2 flows have goodput (similar to oBBR schemes) higher than CUBIC flows.

Multiple flows: We simultaneously launch at most 5 flows with the same CCA and measure the retransmission ratio and goodput per flow. In the experiments, the bandwidth and the latency are set to {100Mbps, 40ms}, and R is 0.5. No random packet loss is introduced. The results are shown in Figure 8. BBR still has the highest retransmission ratios, ranging from 8.41% (1-flow) to 15.25% (3-flows). As loss-based CCAs,

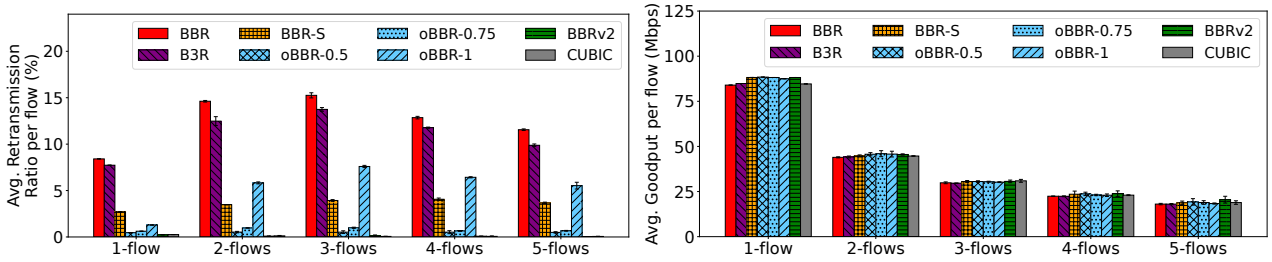

Figure 8: Performance of various CCAs in multi-flow scenarios

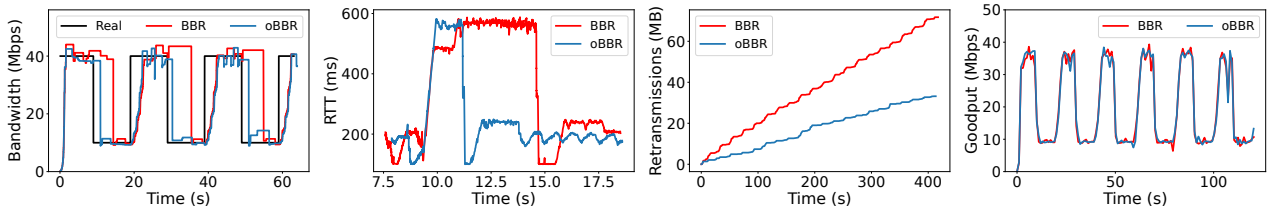

Figure 9: Performance of BBR and oBBR when bandwidth varies in a transmission session

CUBIC and BBRv2 retransmit few packets. When launching multiple BBR-like flows, i.e., BBR, B3R, BBR-S, or oBBR, higher retransmission ratios per flow are observed. The reason is that for each flow, the bandwidth overestimation is more severe: while some of the flows periodically switch to the drain cycle (`pacing_gain=0.75`) of *ProbeBW* or to *ProbeRTT* and yield bandwidth, the other flows obtain bandwidth estimate samples higher than the current ones. These overestimated samples are continuously used even though the co-existing flows scale back their sending rates. Such overestimations are alleviated when the number of flows increases (4-flows and 5-flows) because less bandwidth is allocated to each flow. For oBBR, if we set μ to 1.0 which intends to send excessive data exactly matching the bottleneck buffer, the overestimation easily results in the in-flight data being more than that. As a result, the retransmission ratio per flow of oBBR-1 grows to 7.59% at most (3-flows). When setting μ to 0.5 and 0.75, the bandwidth overestimation can hardly affect the transmission since oBBR leaves a margin in the bottleneck buffer on purpose. The highest retransmission ratios of oBBR-0.5 and oBBR-0.75 are 0.52% (2-flows) and 0.99% (3-flows), respectively. We also report goodput per flow in Figure 8, and it shows that all CCAs could effectively exploit and fairly share the link capacity.

5.2.2 Variable Bandwidth

We also set dynamic bandwidth to observe if oBBR reacts to the bandwidth drop timely as expected. In the experiments, the latency is 100 ms and the bottleneck buffer is 300 KB. We periodically change the bandwidth between 40 Mbps and 10 Mbps every 10 seconds. We evaluate oBBR and BBR, and the results are shown in Figure 9. The left two figures plot

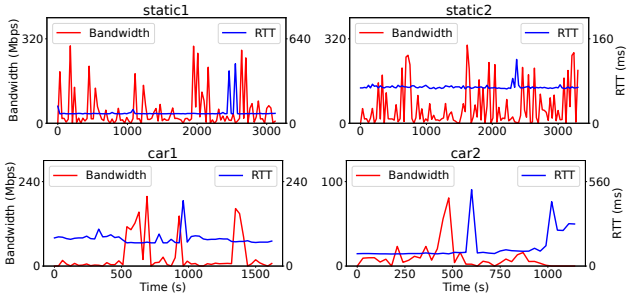

Figure 10: Characteristics of the realistic network traces

the bandwidth samples and the latency samples collected at the sender, respectively. We can see that oBBR reacts to the bandwidth drop more promptly as the bandwidth samples follow the real bandwidth change (the red line) in ~2 seconds. BBR only summarizes a more accurate bandwidth estimate after ~6 seconds because the high bandwidth estimate not only expires after 10 RTTs but also prolongs the latest RTT samples to ~600 milliseconds. While BBR sends in-flight data exceeding the bottleneck buffer, packet losses happen. Figure 9 also shows that BBR spends 2.09× more bandwidth than oBBR on retransmitting lost data while both of them achieve almost the same goodput in the transmission session.

5.2.3 Realistic Network Traces

We also test various CCAs in our lab by emulating the real network conditions following publicly available traces [41], which are collected from a major mobile operator in Ireland. Four traces are selected: *static1*, *static2*, *car1*, and *car2*. *static** means the trace is collected from a static object, probably a

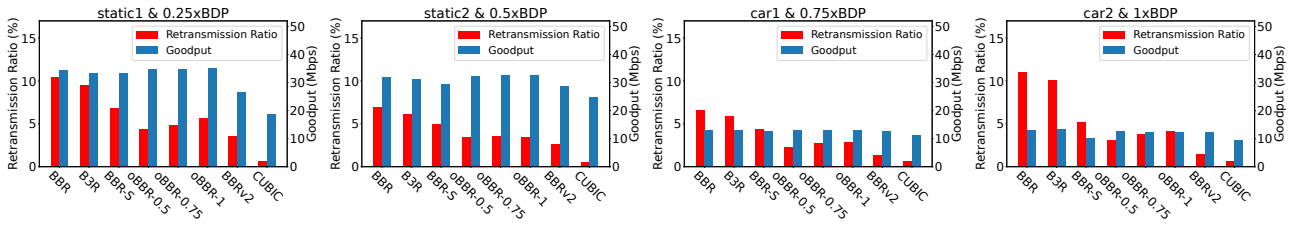

Figure 11: Performance of various CCAs in the testbed emulating the realistic network

Table 1: Characteristics of the realistic network traces

	avg. bandwidth	avg. RTT	duration
static1	45±62 Mbps	80±47 ms	3,137 s
static2	70±80 Mbps	69±6 ms	3,322 s
car1	32±64 Mbps	78±18 ms	1,645 s
car2	10±15 Mbps	118±78 ms	1,155 s

PC, and *car** means the trace is collected from a moving object, probably a car. Table 1 characterizes the traces and Figure 10 shows how the bandwidth and RTT vary over time.

We set R to different values for these traces. It is worth noting that no random packet losses are introduced in the emulations. We record retransmission ratios and average goodput of various CCAs. The results are reported in Figure 11. We can see that BBRv2 and CUBIC still have the lowest retransmission ratios in all cases, and more interestingly, they have lower goodput when compared to the oBBR schemes because oBBR reacts to the network dynamics more timely. Other performance trends are similar to those in stable network environments: BBR and B3R have the highest retransmission ratios. BBR-S has lower retransmission ratios but is still worse than oBBR. oBBR achieves the highest goodput in three out of four traces (35 Mbps of oBBR-1 in *static1*, 32 Mbps of oBBR-1 in *static2*, and 13 Mbps of oBBR-0.75 in *car1*).

5.2.4 Competitiveness

In this section, we measure how oBBR competes with other CCAs. We compare oBBR to BBR, CUBIC, and BBRv2, respectively. We also set μ to {0.5, 0.75, 1} for observing how this parameter affects oBBR's competitiveness. In experiments, the bandwidth is 40 Mbps and the latency is 100 ms. R is set to 0.5 or 1.0. For a transmission session, two flows, where one must be an oBBR flow, are launched simultaneously. We record the goodput of each flow and terminate both flows once the 1 GB data file has been fully delivered.

The results are shown in Figure 12. When competing with BBR, oBBR can hardly gain bandwidth when the buffer is as shallow as 0.5×BDP because BBR sends more in-flight data. This can be alleviated by increasing μ. Setting μ to 1 helps oBBR share 33% bandwidth. When the buffer size increases to 1×BDP, BBR performs less aggressively and even setting μ to 0.5 lets oBBR take 40.5% bandwidth. When competing with CUBIC, oBBR is aggressive in shallower buffers. But oBBR yields more bandwidth to CUBIC than BBR which takes almost all bandwidth in a 0.5×BDP buffer. In a buffer of 1×BDP, CUBIC takes up to 46.6% bandwidth share. When competing with BBRv2 in a 0.5×BDP buffer, the trend of bandwidth shares is similar to CUBIC because both of them react to packet losses. But since BBRv2 probes RTT more frequently, it takes more bandwidth in a 1×BDP buffer.

5.2.5 Internet

We further carry out the data delivery experiments in the Internet environment. We deploy the server in a data center in Virginia, USA, and the client in Shandong, China. The server is equipped with a 2-core CPU @ 2.5 GHz and 4 GB RAM, and its maximum egress bandwidth is 80 Mbps. The operating system is Ubuntu 20.04 LTS. The average link latency is about 270 ms. We experiment with data transmission in the morning, afternoon, and midnight. The results are shown in Figure 13. From the figure, CUBIC has the lowest retransmission ratio at 0.16% because it is the most sensitive algorithm to packet losses, and it also has the lowest goodput of 6.30 Mbps. BBRv2 has a retransmission ratio of 6.71% which is higher than the oBBR schemes because it fails to adjust its behavior timely in such a complex network environment, and its average goodput is 17.66 Mbps since the unavoidable packet losses in long Internet links. By setting μ to 0.75, oBBR achieves the highest goodput of 27.17 Mbps, which is 1.54× higher than BBRv2. Our oBBR schemes also have low retransmission ratios at 6.30% (μ=0.5), 6.58% (μ=0.75), and 6.85% (μ=1), which means 39.48%, 36.79%, and 36.11% fewer data are retransmitted compared to BBR-S, another BBR variant reaching a high goodput (26.94 Mbps) and a low retransmission ratio (10.41%) in the Internet experiments. These experiments indicate that oBBR could fully exploit the Internet link capacity while suppressing the retransmissions effectively.

5.3 Video Streaming

We also evaluate oBBR in video streaming, which is the dominant data delivery service on the Internet today.

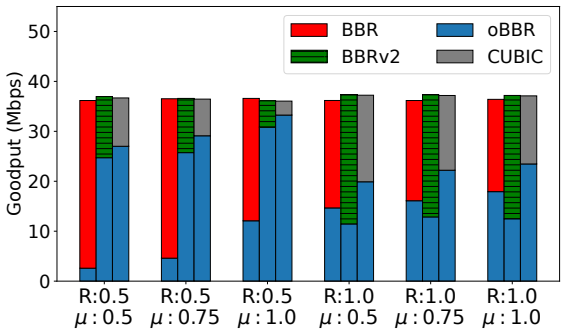

Figure 12: Competitiveness of oBBR against other CCAs

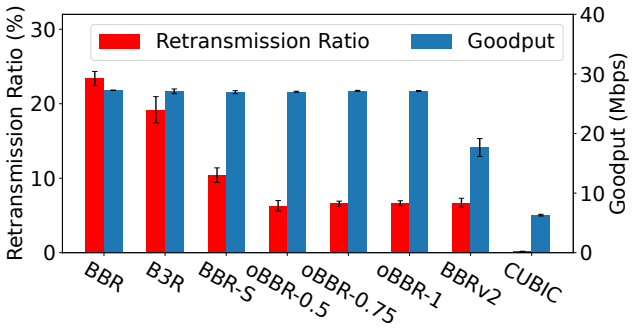

Figure 13: Performance of various CCAs on the Internet

5.3.1 Experimental setup

We build a video streaming system based on dynamic adaptive streaming over HTTP (DASH) [47], which uses HTTP as the vehicle for delivering video data. On the server, the test video is encoded into multiple bitrates and is further separated into segments of fixed length. Each of the segments is identified by a uniform resource locator (URL). We use *dash.js* [2] as the video player that fetches video segments to the client. In the player, the adaptive bitrate (ABR) algorithm dynamically switches between a buffer-based one and a throughput-based one to determine the quality of the next segment to download [46].

We use a 10-min video Big Buck Bunny as the test video, which is encoded into 10 bitrates of {254, 507, 759, 1013, 1254, 1883, 3134, 4952, 9914, 14931} Kbps. [3] For each bitrate level, the video is chunked into segments of 4 seconds. We put the server in Virginia and the client in Shandong, China. The experiments are carried out on the real-world Internet.

5.3.2 Metrics

Three metrics are used in the evaluation: average quality (AQ), quality switches (QS), and rebuffering ratio (RB).

Average quality: the average quality level (from 0 to 9) of all played segments. We expect the viewer to have a better quality of experience (QoE) with a greater AQ.

Quality switches: the number of segments with a lower quality than the previous one. A low QS means the visual quality does not fluctuate in playback, also indicating better QoE.

Rebuffering ratio: the proportion of time consumed in rebuffering. The viewers will stop watching if the rebuffering time is long. RB is calculated as $(\text{playback time} - \text{video length})/\text{video length}$.

5.3.3 Results and analysis

Figure 14 shows the performance of different CCAs in real-world video streaming sessions. For the retransmission ratio, BBR-S, BBRv2, CUBIC, and the oBBR schemes have similar performance, which is much lower than BBR and B3R. However, the low retransmission ratio of BBR-S, BBRv2, and CUBIC comes at the cost of low throughput, i.e., these algorithms fail to support the application layer to deliver high-quality videos. They have the lowest average quality, the highest quality switches, and the highest rebuffering ratio. For CUBIC, as it is too sensitive to packet loss, its throughput is suppressed at the lowest level, and the client almost selects the lowest quality level to fetch. This also decreases the rebuffering ratio of the CUBIC session. The oBBR also has low retransmission ratios (<4%) in the streaming sessions, but the user's QoE is not sacrificed. For example, by setting μ to 0.5, oBBR achieves the average quality of 6.37, the quality switches of 4, and the rebuffering ratio of 0.28%. Thus, the experiments show that oBBR benefits video streaming applications. It improves the QoE without incurring high retransmissions as BBR, which is friendly to content providers.

6 Related Work

BBR. BBR has been well-studied since it was proposed. It has been deployed in various networking scenarios, including mobiles [51], Wireless LANs [16], and clouds [17], and these research point out that the pacing mechanism in BBR may lead to poor performance. BBR is also implemented in MPTCP on Linux and the superior performance over other congestion control algorithms is observed [5]. The BBR-based MPTCP is further improved with respect to fairness and throughput in following studies [20, 35]. The performance of BBR against most existing CCAs has been extensively evaluated [31]. Such a wide range of research uncover that BBR still has problems.

Bandwidth overestimation in BBR. Since BBR selects the maximum of delivery rate samples within the latest 10 RTTs as the estimated bandwidth [56], it is easy to overestimate the bandwidth, which could result in network congestion. Chiariotti et al. [13] adopt the Adaptive Tobit Kalman Filter instead of the maximum filter for estimating bandwidth more accurately. Another study [19] suggests using Kalman Filter at

[3] Available at https://dash.akamaized.net/akamai/bbb_30fps/

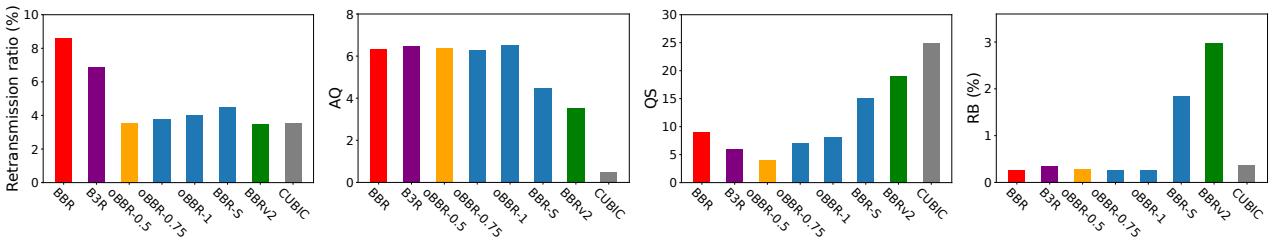

Figure 14: Performance of various CCAs in an Internet video streaming session

the receiver side and to communicate with the sender with the newly defined feedback frame of QUIC. A delayed bandwidth update strategy [48] also helps, which does not update the bandwidth estimate unless consecutive rate samples are received. BBRx [24] adjusts the estimated bandwidth based on the RTT deviation in an online learning manner. Different from these studies, we use a utility function to evaluate the delivery before and after the bandwidth update and revert to the old value if the throughput degrades.

High retransmissions in BBR. The high retransmission rates of BBR in shallow buffers have been recognized in prior studies [6, 14, 22]. To reduce the retransmissions, BBR-ACD [34] halves its congestion window when three consecutive identical RTT samples are received or the latest RTT sample is greater than 2×RTT estimate. BBR-A [33] is an extension to BBR-ACD that additionally decreases its pacing rate while the congestion window is reduced. In another study [45], the accurate propagation latency is detected when competing with CUBIC flows, and it cuts the congestion window to 1/3 of the in-flight data once there is packet loss. The existing optimizations for reducing high retransmissions in BBR flows apply loss-based multiplication to reduce the congestion window. oBBR sets the congestion window as BDP plus a proportion of bottleneck buffer so that the in-flight data will not keep decreasing even in a complex network, effectively guaranteeing the transmission throughput.

Unfairness of BBR. BBR has also been criticized for its unfairness when competing with loss-based CCAs [23, 42, 55]. Models [37, 52] are proposed for dissection. Researchers have found that a BBR flow occupies the same share of bandwidth regardless of how many loss-based flows coexist [52]. Furthermore, if too many BBR flows coexist, their advantage in throughput diminishes [37]. A learning-based model [27] has been proposed for determining the type of competing flows and mitigating the BBR's aggressiveness once the competitors are loss-based. Besides, a BBR flow gains a competitive advantage against another BBR flow if its propagation time is longer [32, 39, 40, 43, 49]. BBQ [32] enforces a cap to the span of the period that BBR pours more data for bandwidth probing. This bounds the advantage that a BBR flow with a long delivery latency can gain. BBR-E [28] reduces the in-flight data cap when the recent RTTs exceed a threshold. In another work [26], a factor γ is designed to compensate for the impacts of different RTTs, which makes the in-flight data from various flows almost the same. The fairness of BBR is out of the scope of this paper, but this is important and worth further exploring in future work.

BBRv2. To address these problems, Google introduced BBRv2 [11], which has been tested in a few studies [15, 25, 38, 54]. BBRv2 improves the fairness between flows with different RTTs and behaves less aggressively against loss-based CCAs [15, 38]. BBRv2 also reduces the high retransmission rates in BBR but at the cost of weakened resistance to packet losses [25]. In a network with bandwidth fluctuations, BBRv2 performs poorly [54]. In this work, we strive to solve the problems, i.e., degrading throughput and low responsiveness towards network dynamics, that still exist in BBRv2.

7 Conclusion

In this work, we carefully analyze the reasons for high retransmissions in BBR flows. We notice that the packet losses in shallow-buffered links are closely correlated to the in-flight data cap and the buffer size. Additionally, the slow reaction to bandwidth drops also makes BBR send excessive data to the transmission channel, thus leading to high retransmissions. To solve the problems, we design oBBR, which intelligently detects the bottleneck buffer size and scales the in-flight data cap accordingly, avoiding packet losses in the shallow-buffered links. oBBR also detects the bandwidth drop in an accurate and timely manner and tweaks its sending rate to avoid congestion. Extensive experiments in both a lab environment and the Internet have shown that oBBR significantly reduces retransmissions while still reaching a high data delivery rate.

Abstract

To improve the user experience of mobile web services, various congestion control algorithms (CCAs) have been proposed, yet the performance of the application is still unsatisfactory. We argue that the suboptimal performance comes from the gap between what the application needs (i.e., Quality of Experience (QoE)) and what the current CCA is optimizing (i.e., Quality of Service (QoS)). However, optimizing QoE for CCAs is extremely challenging due to the convoluted relationship and mismatched timescale between QoE and QoS. To bridge the gap between QoE and QoS for CCAs, we propose Floo, a new QoE-oriented congestion control selection mechanism, as a shim layer between CCAs and applications to address the challenges above. Floo targets request completion time as QoE, and conveys the optimization goal of QoE to CCAs by always selecting the most appropriate CCA in the runtime. Floo further adopts reinforcement learning to capture the complexity in CCA selection and supports smooth CCA switching during transmission. We implement Floo in a popular mobile web service application online. Through extensive experiments in production environments and on various locally emulated network conditions, we demonstrate that Floo improves QoE by about 14.3% to 52.7%.

1 Introduction

Last decade has witnessed a dramatic increase in the use of mobile web services. The latest statistics demonstrate that more than 60% of global Internet users access web services with mobile devices [4]. Mobile web services are built on the transport layer, which typically employs a congestion control algorithm (CCA) that determines the data sending behavior and significantly affects the user experience. However, unsatisfactory performance of mobile web services has still been reported [40, 43, 49]. A recent measurement in 2020 shows that some web service users are still suffering from multi seconds request completion time [54], which also corroborates our observation in our web service in production (§5.3).

Our observation is that the key issue of the unsatisfactory performance in mobile web services is the mismatch between *what CCAs are optimizing* and *what the applications need*. Normally, CCAs optimize the Quality of Service (QoS) metrics describing the transport layer protocol delivery capabilities, i.e., delay, throughput, loss rate [22, 31], or a combination of these metrics [7, 19], in different network conditions. However, the applications do not really need an optimized QoS. Instead, they need a high quality of experience (QoE) for users. Specifically, for mobile web services, they have no idea what is *throughput* but only care about *request completion time (RCT)*[1]. The mismatch between QoE and QoS for current CCAs leads to their suboptimal performance.

However, optimizing QoE for CCAs is extremely challenging due to the following reasons. First, in terms of causality, the relationship between QoE and QoS is convoluted. For example, for small requests in web services, the increase of RTT will result in the degradation of the RCT. However, for large bulk requests, the effect of the increase of RTT on RCT is negligible. Therefore, without clearly understanding the relationship between QoE and QoS, directly optimizing the QoS may not be able to improve the QoE for the application. Second, in terms of timeliness, network conditions in QoS such as RTT and throughput are usually measured on a fine timescale (e.g., per packet). With this, CCAs can also make decisions on a short timescale. However, QoEs are usually perceived in a much longer timescale. RCTs in web services can only be calculated after the request completes, which usually takes seconds, during which, the CCA has already made numerous decisions. Thus, it is challenging for CCA to know which decisions are right and further correct its decisions (§2.1).

Our insight in this paper is not to directly optimize the CCA

[1]There are various QoE metrics of mobile web service, such as page load time. In this paper, we focus on the request completion time, i.e., the time interval between the request sent and the response fully received.

itself, but to introduce a shim layer between the application layer and transport layer to *select* the appropriate CCA for a better QoE. After decades of evolution of CCA, although there may not exist one CCA to fit all scenarios, we believe that there should always be at least one CCA that behaves well in a certain scenario. Selecting the CCA addresses the challenges above in two ways: First, instead of blindly optimizing those low-level instructions for CCAs with QoS, we could select the appropriate CCA based on the QoE. Second, we can perform the CCA selection at the same or longer timescale to fully and accurately utilize the information from QoE. Therefore, if we could always select and switch to the best CCA in the runtime, we will have the QoE directly optimized (§2.2).

However, it is challenging to propose a CCA selection mechanism for large-scale mobile web service due to the following reasons (§2.3).

- **Generating an optimal CCA selection policy is challenging.** The CCA selection policy, or in other words, mapping from the observed network conditions and application QoE metrics to the appropriate CCAs, is complicated. (1) The mobile network conditions can fluctuate, and are not easy to capture from the metrics observed on endpoints. (2) It is very difficult to model and characterize the CCAs, especially the recent proposed complicated CCAs [9, 19].
- **Switching between CCAs is nontrivial.** Different CCAs maintain different states. For example, BBR maintains the maximum delivery rate in the last 8 RTTs, but Cubic does not. If we need to switch between CCAs in the runtime, we should handle the states for a seamless switch carefully. Otherwise, if each CCA starts with the slow start, the QoE might be severely impaired during each switching.

To address the above challenges and provide better performance to the real applications, we propose Floo, a QoE-oriented mechanism for congestion control selection in large-scale mobile web services. Our key ideas are (1) to design *a QoE-oriented CCA selection mechanism*, and (2) to support *seamless CCA switching* during transmission. To turn our ideas into reality, we design several building blocks in Floo. First, we propose a reinforcement learning (RL)-based framework (to understand CCAs) that uses QoE as the selection criterion, and carefully selects both transport layer and application layer metrics (against network dynamic) to be jointly used in CCA selection (§3.2 and §3.3). Second, we devise a CCA switching mechanism to ensure the smoothness of switching by migrating the CCA phases and variables. The switching mechanism can be applied to traditional non-learning CCAs, and it is implemented with multiple classical CCAs in this paper (§3.4). Briefly speaking, Floo selects the optimal CCA for each connection according to QoE, and switches to a new, better CCA when the network condition changes (§3.1).

We implement Floo atop QUIC in the production environment of one Meituan's popular mobile web service application, Dianping, with O(10M) daily active users (§4.1). To make Floo work for real application scenarios, we collect real-world application traces for 14 days, including 35 million request logs. The traces are employed for analysis and training to reduce the gap between emulated environments and real world scenarios, enabling Floo to directly serve the real applications (§4.2). Extensive experiments demonstrate that Floo reduces the RCT by about 14.3% to 52.7% on average compared to using a static CCA. Further evaluation also shows that Floo is able to achieve satisfactory performance in the real world in different scenarios (§5).

In summary, our key contributions in this paper are:

- By demonstrating the difficulty of optimizing QoE for CCAs, we reveal the need for a practical QoE-oriented CCA selection mechanism (§2).
- We propose Floo, a QoE-oriented mechanism for CCA selection, which supports seamless switching on the fly for large-scale deployment of mobile web services (§3, §4).
- We deploy and evaluate Floo with Dianping service of Meituan. Our extensive experiments showed that Floo achieves consistent high performance under dynamic mobile networks (§5).

2 Motivation and Challenge

In this section, we use real-world mobile web service traces to demonstrate optimizing QoE for CCAs is extremely challenging in §2.1. Then, we present our design choices in §2.2 to address the mismatch between QoS and QoE. Finally, we elaborate on the challenges of designing the QoE-oriented CCA selection mechanism in §2.3.

2.1 Optimizing QoE for CCAs is extremely challenging

Convoluted relationship between QoS and QoE. QoE metrics are defined by applications. In contrast, QoS metrics focus on the descriptions of transport layer performance. The optimization of QoS is not consistent with that of QoE. For example, for large bulk requests, a reduction in RTT does not imply a QoE improvement [37]. Small request-intensive web pages are not that sensitive to throughput increase, since their total bandwidth need may still be small. As for the applications that apply recovery techniques such as FEC [32], packet loss also does not have a significant impact on QoE [25]. CCA has no idea what goal the application optimizes towards and whether application layer techniques are used. Therefore, the relationship between QoE and QoS is convoluted.

We conduct emulated experiments to demonstrate the convoluted relationship. Four well-known CCAs are considered: Cubic [23], BBR [12], Copa [9], and Westwood [14]. We use real-world traces extracted from Dianping to generate request-response messages (detailed in §4.2) on Mahimahi [41] emulated network paths. The WSP algorithm [44] is employed to compute the configurations of 100 different network path conditions (detailed in §4.3.1). Each CCA runs on each network path condition for 2 minutes. We calculate the metrics of Thpt, RTT, Power [27], etc., periodically at the sender according to transport layer acknowledgments. The results are presented

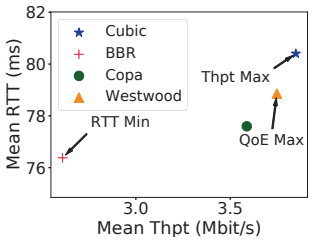

Figure 1: The mean throughput and RTT of the four CCAs achieved on a network path.

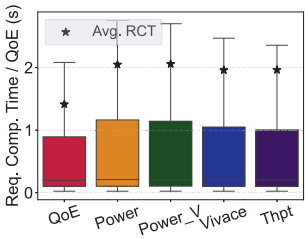

Figure 2: The RCT for all network path conditions following different CCA selection metrics.

Metrics	Definition
QoE	*Request completion time*
Power [27]	$Power = \frac{Throughput}{Delay}$
Power_V [28]	$Power\_V = \frac{Throughput*(1-LossRate)}{Delay}$
Vivace [19]	$Vivace = rate^t - b*rate*\frac{dRTT}{dT} - c*loss*rate$
Thpt	*Delivery rate*

Table 1: A QoE metric and four QoS metrics. QoE is calculated as the average RCT after the CCA convergence (20s after connection establishment). Power is the most common metric used for transport layer evaluation [7, 22, 31, 57]. Power_Variant [28] is one variant of Power, which also considers the packet loss rate. Vivace is used by an online learning CCA, and it is in form of utility function [19, 20].

in Fig. 1 and 2.

Fig. 1 shows the performance of the CCAs on a specific network path. Among the four CCAs, the CCA that achieves the highest throughput or the lowest RTT does not reach the best QoE (defined in Tab. 1). Then we consider the relationship between QoS and QoE on multiple network paths. For each network path condition, we select the best CCA following different metrics listed in Tab. 1. For each metric, we obtain all the RCT of the requests running the selected CCA for all network path conditions. Fig. 2 shows the Tukey boxplot for each metric. Results show that if the CCA is selected following the QoE metric, the RCT can be reduced by at least 27% on average, and none of the popular QoS metrics can achieve similar RCT to the QoE metric. This well demonstrate the convoluted relationship between QoS and QoE.

Mismatched timescale between QoE and QoS. The mismatch also exists in the time scale of the CCA and application optimization. CCAs collect fine-grained ACK information and make decisions at a granularity of packet-level or RTT-level. In contrast, QoE is measured and evaluated at a coarse granularity of the request level, usually around hundreds of milliseconds or even longer [9, 54]. As a result, it is difficult to map high time scale QoE to low time scale CCA behavior.

2.2 Design Choices

Instead of optimizing QoE for CCAs, we decide to design a shim, which selects an appropriate CCA aiming for better QoE. The QoE-oriented CCA selection approach addresses the mismatch between QoS and QoE:

- **Optimizing the real goal.** It is hard to make QoS-oriented CCAs optimize the QoE, because of the mismatch between QoE and QoS. However, with QoE metrics as the basis, the CCA selection shim allows the transport layer behavior to be optimized toward application layer objectives. As discussed in §2.1, the QoE is hard to be replaced by existing transport capability-oriented QoS metrics. Therefore, QoE is regarded as the real goal of our approach.
- **Time scale.** The CCA selection approach works above the transport layer to make decisions at a coarser granularity, understanding the QoE, and deciding which CCA to use. Specific sending rate/CWND increase or decrease decisions of the CCAs' are not necessarily closely coupled with QoE. Thus, the time scale mismatch is solved. The CCAs do not need to interact with the application layer and do not need to be modified.

2.3 Challenges

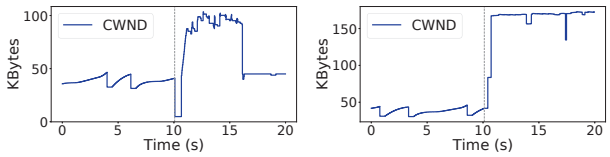
However, designing and implementing a CCA selection mechanism is non-trivial in a large-scale real-world deployment of mobile web service.

CCA Selection. Creating a mapping from the observed network conditions and QoE metrics to CCAs, or in other words, generating a CCA selection policy is challenging.

- **Fluctuating network conditions.** Under mobile networks, network conditions fluctuate due to wireless channel fading, user movement, or network congestion. Adapting to the dynamic network condition is challenging.
- **Empirical CCA characteristics.** The existing knowledge of the applicable scenarios of CCA is usually empirical [11, 15]. It is very difficult to model and characterize the CCAs, especially the recent proposed CCAs [9, 19]. Adapting to the complicated CCAs is challenging.

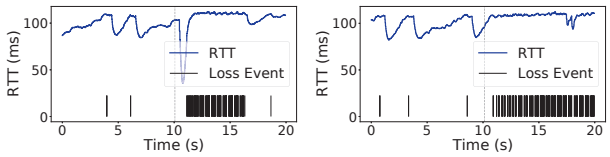
Smooth switching on the fly. Due to dynamic network conditions, CCA switching may occur during transmission. We consider two kinds of switching: Part Switching and Full Switching. While Full Switching makes the new CCA inherit all CCA-related variables, including connection-level variables (e.g., CWND/sending rate and RTT-related values), and CCA private state variables (e.g., fulled_pipe in BBR), Part Switching only inherits connection-level variables, and the private state variables of the new CCA are initialized from default values. To demonstrate their differences, we build a small testbed including two hosts and one switcher. The two hosts establish a QUIC connection, which continues to send massive data. One CCA switch event happens at the 10th second. As shown in Fig. 3, the switching without CCA state migration (Part Switching) has two problems:

- **Longer convergence time and performance deterioration.** Without CCA state migration, the new CCA starts at the slow start phase and the CWND or sending rate increases exponentially from the steady state of the previous CCA until it converges again. The path condition information required for the new CCA still needs time to be col-



(a) Cubic switches to BBR.

(b) Cubic switches to Copa.



(c) Cubic switches to BBR.

(d) Cubic switches to Copa.

Figure 3: Two demonstrations of Part Switching. The switch event happens at the 10th second. (a) and (b) show the CWND change over time. (c) and (d) show the smooth RTT changes over time and when loss events happen. Part Switching from Cubic to BBR leads to longer convergence time and performance deterioration. Part Switching from Cubic to Copa leads to distorted path estimation collected and results in abnormal behavior of the new CCA.

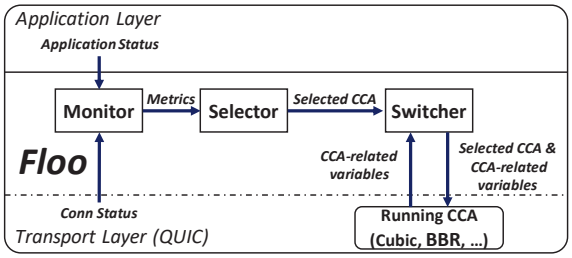


Figure 4: Floo Overview

Characteristic	Metric	Description
Btlbw	$Thpt\_max$	The maximum delivery rate
RTProp	RTT_min	The minimum RTT
Random Loss	$Loss\_rate$	|Lost Packet| / |Sent Packet|
Buffer	RTT_rate	Smooth RTT / Min RTT
RTT Variety	RTT_{var}	The variance of RTT samples
CCA	CCA_name	Current CCA
	$CWND/SendRate$	CWND or pacing rate
App-level	$Goodput$	The average Size / Duration of past responses
	$Unsent\_size$	Total bytes of the response waiting for writing to Send Buffer
	Qws	The average duration the response wait for writing to Send Buffer
	$Qws_{gradient}$	The gradient of the Qws samples
	$Bytes\_interval$	Bytes sent in the last SP

Table 2: The metrics collected by Monitor module.

lected and estimated. Worse still, since the previous CCA has converged basically, the new CCA's re-convergence will cause a lot of packets lost (about 14.8% within 2s after switching in Fig. 3c).

- **Distorted path estimation results in abnormal behavior of new CCAs.** The network condition observed by the new CCA reflects the condition after the previous CCA converged. It may not be consistent with the real path condition. For example, as shown in Fig. 3d, there is already a queue buildup in the buffer by Cubic when the switching occurs. Therefore, the *minRTT* observed by Copa is biased after the switching. In such a case, Copa is unable to make proper decisions to reduce the RTT or drain the queue. Fig. 3d shows that the high RTT may last for tens of seconds or even longer, which completely conflicts with Copa's design goal of low latency.

Therefore, smooth switching is necessary. Ideally, the new CCA should inherit all the CCA-related variables and continue to update them according to the newly observed network conditions after the switching. However, considering the more complex state design of emerging CCAs, and the personalized state variables, mapping the state of a certain CCA to a new one is much more challenging.

3 Design

3.1 Design Overview

Fig. 4 shows the overall architecture of Floo. We build the main building blocks of Floo atop QUIC, including Monitor module, Selector module and Switcher module. Monitor module collects information from both the transport layer and application layer. According to the state variables saving application statistics and connection statistics, Monitor module computes the metrics of interest in consecutive time intervals and feeds them to Selector module every selection period (SP) (§3.2). According to the metrics fed by the Monitor module, Selector module selects a CCA based on a pre-trained selection policy, which maps the metrics from Monitor module to appropriate CCAs. With the help of that policy, an appropriate CCA is selected to maximize the application QoE. The selection policy is pre-trained offline with RL methods (§3.3). After getting informed of the new optimal CCA, Switcher module conducts CCA state migration to complete a smooth switching from the current CCA to the new CCA (§3.4). Thus, an accurate and smooth switching of CCA is completed.

For a QoE-oriented CCA selection mechanism, one key design decision of Floo is how to incorporate QoE metrics into the mechanism. From emulated experiments in §2.1, we observe that it is difficult to replace QoE with QoS. As Fig. 2 shows, the CCAs selected with the QoE criterion achieve the lowest RCT, while the other four QoS metrics, Power, Power_V, Vivace and Thpt, have 31.01%, 31.34%, 27.87%, 28.01% higher RCT on average respectively. Therefore, our answer is to directly set QoE as the selection criterion.

3.2 Monitor

Monitor module gathers collectible statistics that can be measured and monitored, including the transport layer and application layer statistics. The transport layer statistics are collected from the information provided by ACK packets or the connection maintained state variables. As for the application layer statistics, we collect them from mobile web applications.

We consider the metrics shown in Tab. 2. The CCA selection mechanism is to select the optimal CCA for different network conditions. Therefore, we first consider the characteristics describing the network path conditions. They are

the former 5 rows of the table. We use bottleneck link bandwidth ($BtlBw$), round-trip propagation time ($RTProp$), RTT variety (RTT_{var}), packet loss rate ($RandomLoss$) and buffer size ($BufferSize$) to describe a network path. We estimate these objective network path conditions with the following collectible metrics: the maximum delivery rate ($Thpt_{max}$), minimum RTT (RTT_{min}), average loss rate ($Loss\_rate$), relative value of buffer size v.s. BDP (RTT_rate) and the RTT variety (RTT_{var}). The calculation of the metrics occurs in a slicing time window of 10s.

Note that the above metrics are only the observed metrics of the network paths and not the objective network path conditions. The relationship between the observed and objective values can be affected by the current running CCA. In order to accurately reflect the objective values of the network path, two additional types of information are collected. On the one hand, we record the current CCA, and $CWND$/$SendRate$ if applicable. On the other hand, we collect the information from the application layer, specifically the $Goodput$, $Unsent\_size$, Qws, $Qws_{gradient}$, $Bytes\_interval$ (defined in Tab. 2). It is worth noting that Qws is the response waiting time, which is the time between the response is generated on the server and the response data is written to the send buffer of the transport layer. Qws reflects the growth and drain of the queue in the send buffer. When the network condition worsens, the queue in the send buffer will pile up rapidly, making the rise in Qws. The calculation of these app-level statistics occurs every SP.

3.3 RL-based Selector

Selector module selects the optimal CCA based on the metrics passed by Monitor module. The selection policy, or the mapping from the Monitor module metrics to the optimal CCA, is pre-trained and saved in Selector module. We utilize an RL approach to build a prediction model as the selection policy, because RL and CCAs are similar, i.e., both of them continuously make decisions according to the changes of environment. In this section, we describe the RL system. The process and method of offline training are shown in §4.3.

State & Action. We use the metrics passed by Monitor module as the state of RL system, which is used to select the optimal CCA. We use normalized metrics instead of the exact values. This avoids exaggerating the impact of an input metric with very large values on the final model. Further, normalization helps Selector module generalize the network conditions it observes during the training phase to unseen network conditions and achieve better performance. As for the action, the RL system uses CCA candidates as the possible action values.

Reward. Reward is an important factor affecting the RL system's performance. Specifically, the rewards the RL agent gains at each step quantify its performance to improve its subsequent action. Numerous RL-based congestion control-related solutions adopt Power or its variants as reward [7, 28, 31, 42, 57]. However, our experiment results show that application-layer metrics are more appropriate reward indices than QoS-oriented transport layer metrics (§2.1). Therefore, we directly utilize the gradient of QoE as the reward for our RL system.

We regard the RCT as the QoE of web services, which is also a common QoE choice for such services. RCT is the time taken from sending the request to receiving the last byte of the response, recorded on the client side. RCT mainly includes the transmission elapsed time within the network (transmission time) and the response queuing time on the sender (i.e., Qws in Tab. 2). For web services, we employ this value as the RL system reward for the following reasons:

- When the sending rate is high, the response queuing time is much smaller than the transmission time. Therefore, RCT is approximately equal to the transmission time, which reflects the current transmission efficiency, and thus can evaluate the current action (i.e., CCA).
- When the sending rate is low, or is lower than the delivery rate from the sender application layer to the sender transport layer, RCT mainly includes the response queuing time. In this case, RCT reflects the growth and drain of the queue within the send buffer. If the current action is better than the previous action, it will suppress the queue growth or accelerate the queue draining. The change of the queue will be reflected in the change of RCT, and will further evaluate the merit of actions in one training round.

Specifically, we use the gradient of RCT as the reward: $R = \ln \frac{Last\ RCT_{avg}}{Current\ RCT_{avg}}$. In each step, we record the average RCT in time units and compare it with that of the last step. After one entire training episode, we normalize all the rewards uniformly.

Learning algorithm. Floo adopts actor-critic RL, and is trained using the Proximal Policy Optimization (PPO) algorithm [45]. PPO is an advanced RL algorithm that is adept at exploring policies with continuous features. PPO addresses the issues of the traditional policy gradient philosophy and improves the utilization of data and the model stability by the design of importance sampling and clipping. Appendix A details how PPO is utilized in Floo.

3.4 CCA State Migration

To deal with the challenges described in §2.3, our design goals are: (1) Inherit the network path estimation to speed up CCA convergence and avoid performance degradation. (2) Retain the characteristics of new CCAs consistent with the original design goals. In our design, the CCA state migration mechanism considers all the CCA-related variables, i.e., the CCAs' phase and the variables used in CCAs. This mechanism can be applied to non-learning CCAs, e.g. Cubic, BBR and Copa.

CCA Phase Migration. CCA phase migration is concerned with the state transition within the CCAs. With packet loss no longer the only congestion signal, the emerging CCA phases become more complex. However, a common feature of non-learning CCAs is that they all probe the path and estimate

Variable Type	Description
Sending rate variables	Variables that directly determine the sending rate, e.g. CWND, Pacing rate, etc.
Observation variables	Observations of the connection, e.g. smooth RTT, max delivery rate, etc.
Parameter variables	Variables related to CCA design, e.g. β=0.8 in Cubic when packet loss.
Other variables	Variables that maintain CCA's current state, e.g. *fulled_pipe* in BBR, and *velocity* in Copa.

Table 3: Four types of CCA-related variables.

their occupancy of the path based on the feedback. Therefore, we coarsely classify CCA phases into two categories based on how well the CCA probes the path.

The first category is the non-converged phase, i.e., where CCA has not formed a complete awareness of the path or does not fully utilize the available capacity. The non-converged phase includes both the slow start phase and the situation where the CCA would not fill the pipe for other purposes, such as ProbeRTT in BBR. The second category is the converged phase, i.e., where CCA adjusts the sending behavior based on the observations of the path after the slow start, including the congestion avoidance phase of traditional CCAs, the ProbeBW phase of BBR, and the moving phase of Copa.

We adopt different measures to migrate different phases. If the switching happens at the converged phase of the old CCA, Floo makes the new CCA directly enter the converged phase.This avoids massive packet loss caused by the slow start phase after switching. We do not perform switching at the non-converged phase. On the one hand, the statistics collected during the non-converged phase are unreliable. On the other hand, the non-converged phase usually does not last too long, so it will not cause much damage even if the switch is not made immediately. Note that there is one exception: if the new CCA is BBR, Floo makes the BBR enter the ProbeRTT phase first. Though the ProbeRTT phase is not converged, it will affect the performance of the converged phase.

CCA Variable Migration. CCA variable migration is mapping variables from the prior CCA to the new CCA. The variables maintained by various CCAs are different and affect CCA switching performance differently. Therefore, we group all variables into four types, as shown in Tab. 3. According to our two design goals, we adopt the corresponding migration methods for each type.

- **Sending rate variables.** Sending rate variables, such as CWND and pacing rate, directly determine the sending rate. Therefore, they need to inherit the prior rate, thus ensuring smooth switching. The key issue here is the conversion between the rate-based CCAs and window-based CCAs. We use the relationship that $CWND = pacing\ rate * RTT$ to calculate the migrated values.
- **Observation variables.** Observation variables are estimated statistics for the network path. The observation variables collected in the converged phase can directly follow the new CCA. Considering that some important observation variables are not preserved by all CCAs, we additionally preserve the bottleneck bandwidth and minimum RTT at the granularity of the connection.
- **Parameter variables.** Parameter variables are related to the design of the CCA, which are basically fixed values and will determine the performance. Therefore, we do not perform any manipulation on these variables.
- **Other variables.** Other variables maintain CCA's current states, most of which are computed from observation variables. We migrate them based on the phase migration methods. The left ones are simply initialized to default values.

4 Implementation and Training

We implement Floo atop QUIC in the production environment of Dianping service with O(10M) daily active users. We first introduce the implementation of Floo (§4.1). Then, in order to make our model applicable to real applications, we conduct a large scale passive measurement on Dianping application from Meituan, analyze the traffic patterns of the application and use the collected application traces for training (§4.2). Also, we train the RL-based CCA selection model with the numerous newly collected real application traces and wireless network traces (§4.3) to make Floo Selector module suitable for real application scenarios.

4.1 Implementation

We implement Floo based on QUIC [29][2] in user space. Floo only requires modification on the sender side. For the training phase, we implement Floo's RL-Agent on top of Tensorflow [6]. After the training phase, we obtain the trained model, which is used in Floo's Selector module. The training phase is well presented in §4.3.

As for the applications, we slightly modify Dianping to support Monitor module of Floo, then the modified Dianping can run on top of Floo. We use it in real-world experiments (§5.3). Additionally, we also implement a simple request-response messaging application (Application S) atop Floo, which is used in the training phase of Floo and all the emulated experiments in §5. Application S generates requests and responses according to the application traces introduced in §4.3.1. In the training phase of Floo, Application S negotiates with RL agent about the information of state, action, reward, etc. For all the emulated experiments in §5, Application S employs the well-trained model. The sender of Application S selects CCA dynamically according to Floo's Selector module.

CCA Candidates. We consider the CCAs that have been deployed in real Internet environments as candidates for our CCA selection policy. Firstly, for deployability, we mainly consider widely-deployed CCAs, and thus choose the most two widely-deployed [36] CCAs, Cubic and BBR. Secondly, for effectiveness, CCA candidates should cover diverse QoS metrics. Therefore, we also use the loss-resilient Westwood

[2]We use an IETF QUIC implementation, ngtcp2 [2].

and latency-sensitive Copa. These four CCAs have different preferences for QoS targets (§2.1).

4.2 Application Dataset

We measure the traffic patterns of a real mobile application in production environments. These measurements illuminate the nature of request-response messaging traffic and provide the basis for constructing CCA selection policies that can be used for real applications.

We perform a large-scale passive measurement on Dianping from Meituan. Users can make purchases through this application, and the main user actions include searching, viewing images, etc. When the users are using the application, the client establishes a persistent connection with a frontend server, through which the application sends requests to the frontend server. We instrument the mobile APP client of that application, and after each request is completed, the instrumentation collects application-level logs and connection-level logs describing the finished transport process. We collected the logs of about 35 million request-response messages over two weeks.

First, we found that the connections of the application are persistent and would last 206s on average, which is much longer than the SP, supporting Floo's CCA selection. Then, we present the characteristics of the mobile web service, i.e. size and frequency of requests and responses sent through the persistent connections between the client APP and the frontend servers in Fig. 5. Fig. 5a shows the CDF of the request size. As we can see, over 80% of the requests are less than 10 KB, indicating that most of the upstream traffic is small and generally not the performance bottleneck. Fig. 5b shows the CDF of the response size. The responses have a diverse mix of small and large sizes with heavy-tailed characteristics. For the response workload, more than 70% of the responses are less than 10KB, but more than 60% of all bytes are in the 3.4% of responses.

Fig. 5c shows the time interval between the two consecutive sending of requests from the client. The inter-sending time between requests reflects the density and diversity of requests initiated by the application. Since this interval is influenced by both user behavior and application characteristics, we filter out the request initiation due to the user behavior. Specifically, the two requests with an inter-sending time greater than 1 second are considered two clicks of the user behavior. After filtering, as shown in Fig. 5c, 80% of the request inter-sending intervals are less than 44ms, and 38.4% of them are concurrent (0ms). *Therefore, although most of the requests and responses are tens to hundreds of kilobytes in size, the bandwidth needs of the application are still high.*

4.3 Training

Floo's training goal is to learn one policy that can select an appropriate CCA to achieve good QoE in diverse network environments. That policy should be applicable to real applications over real network environments. For this purpose, we use real application traces and real wireless traces for training in a controlled emulated environment (§4.3.1). Further, we use real QUIC implementations and Application S, instead of network simulators (§4.3.2). This allows the RL agent to have an experience close to that in real-world scenarios.

Parameter	Value Range (Min - Max)
RTT(ms)	10 - 50, 50 - 100, 100 - 150, 150 - 300
RTT Jitter / RTT	0 - 0.2, Jitter max = 20ms
Loss rate(%)	0 - 0, 0 - 0.1, 0.1 - 5
Buffer / BDP	0.3 - 0.9, 0.9 - 1.1, 1.1 - 1.5

Table 4: Network condition parameters.

4.3.1 Trace and Training Settings

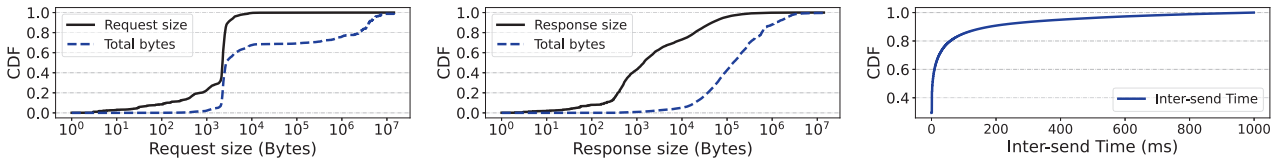
Application traces. We generate training application traces based on the distribution of the statistics collected from the measurements(§4.2). Specifically, we generate each request and response based on the CDF of the request and response size (Fig. 5a and 5b). The sending time of each request is determined based on the CDF of the inter-sending intervals (Fig. 5c). The server of Application S generates a corresponding response and delivers it down to the transport layer immediately after receiving a request. We train the RL model with many episodes, and each episode lasts 10 minutes. We generate a separate application trace for each training episode.

Network condition parameters. We use Mahimahi to emulate network paths and Traffic Control (TC) [8] to emulate RTT jitter. We adopt the network traces collected and used in previous works [3, 7, 30, 34, 38, 39, 47, 50], as listed in Tab. 6. These traces are employed to emulate the time-varying network path rate upper limit. They can be used to emulate various network conditions including 4G and 5G in both stationary and mobile scenarios.

Besides rate upper limit, RTT, RTT jitter, packet loss rate, and buffer size are also common network condition parameters [17, 52]. We select the values of these parameters using the space-filling WSP algorithm [17, 44] over the ranges listed in Tab. 4. WSP algorithm could generate multiple sets of network conditions based on the range of each parameter in order to emulate network conditions as diverse as possible. We generate 20,000 sets of network condition parameters. At the beginning of each training episode, we randomly select a network trace with one set of network condition parameters.

4.3.2 Training Method

We construct a training architecture consisting of learning agents, Application S clients and Application S servers. The client and server connecting to the same agent also establish a QUIC connection through Mahimahi. We set the episode to 10 minutes, which is long enough for CCAs to converge. For each training episode, the agent selects and configures the network condition parameters of Mahimahi and the application traces to be applied, as described in §4.3.1. The detailed training method is depicted in Appendix C.



(a) Distribution of the request size. **(b)** Distribution of the response size. **(c)** Distribution of the inter-sending interval.

Figure 5: Distributions of request and response characteristics from the measurements depicted in §4.2.

5 Evaluation

We first introduce our experimental setup in §5.1. We then evaluate Floo in the following aspects:

- **Consistent high performance.** We evaluate Floo over different scenarios. Evaluation shows that Floo achieves the highest throughput and lowest delay under different network conditions. Floo can reduce the application RCT by up to 52.7% on average, and up to 78.16% at the tail (§5.2).
- **Performance in the real world.** We implement Floo in a popular mobile web service and measure the performance for 96 hours. Experiments with real users show that Floo can reduce RCT by about 14.26% in the real world (§5.3).
- **Overhead.** Floo has acceptable overhead, with about 1.4% additional CPU utilization and sub-ms magnitude of additional time consumption (§5.4).
- **Improvement deep dive.** Finally, we evaluate the effectiveness of the design of Floo (§5.5).

5.1 Setup

We evaluate Floo in both emulated networks (§5.2, §5.4, §5.5) and large scale production environment (§5.3).

Emulated environment. We evaluate Floo in a controlled environment by emulating different network conditions with Mahimahi and generating new application traces. In our testbed evaluation, we implement Application S atop Floo, which sends requests and responses with application traces, and collects statistics for evaluation. We conduct experiments under 60 scenarios, including 10 stationary WiFi traces, 20 stationary cellular traces, and 30 mobile cellular traces. We also use the WSP algorithm to select 60 sets of other parameters, using the same method as §4.3.1, and importantly, the combinations of trace and parameter sets are different from those traces used in training. We compare the performance of Floo respectively with Cubic, BBR, Copa, Westwood and Vivace [19]. In each scenario, we send requests and receive responses using different algorithms for 3 minutes with the newly generated application traces.

Large scale production environment. We implement Floo in Dianping, with O(10M) daily active users. Our experiments are conducted in production environment where clients are heterogeneous including different OS, HTTP versions, etc. We manually enable Floo for a fraction of users, measure the performance for four days and collect 35 million request logs. In the experiments, we set the selection period (SP) as 12s. A further analysis of the impact of different SP values is detailed in Appendix F.

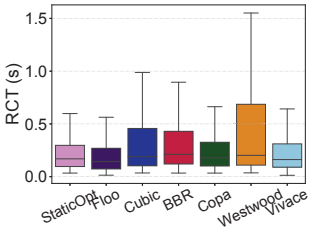


Figure 6: Floo achieves lower RCT than QoS-oriented CCAs.

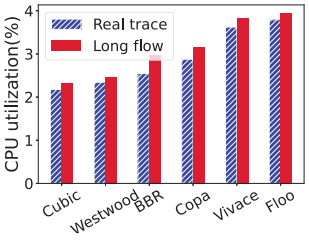

Figure 7: CPU utilization.

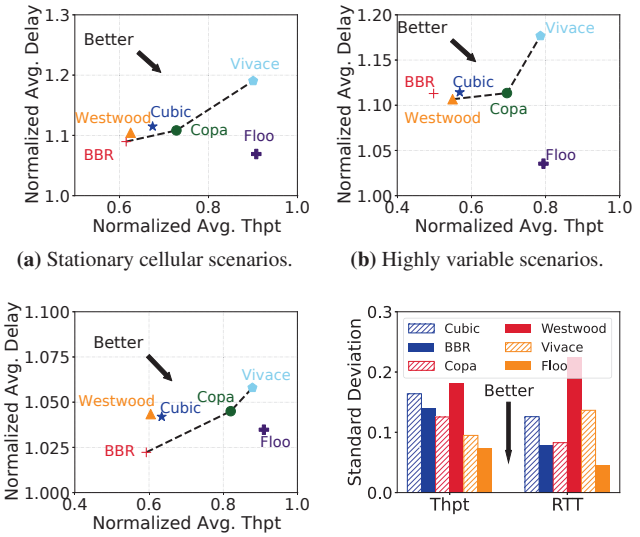
5.2 Consistent high performance

Here, we demonstrate that Floo achieves consistent high performance over different network scenarios.

Overall performance. We evaluate Floo under different scenarios, with 60 real-world traces. We record the RCT and show the performance of all scenarios in Fig. 6. For each scenario, we compare the four CCA candidates, and select the optimal CCA which achieves the lowest average RCT. The aggregated best choices for all scenarios is presented as Static_Opt. Floo achieves the lowest RCT, and reduces the overall RCT by a median of 20.11% to 32.54% and 21.18% to 78.16% in the 90^{th} percentile. The average RCT was reduced by 14.3% to 52.7% compared with QoS-oriented CCAs.

Remark 1 (Cubic and Westwood): Floo reduces the average RCT by 52.7% compared to Cubic and 50.8% to Westwood. For the 90 percentile (the tail) RCT, Floo shows great improvement, and has a 74.6% reduction compared to Cubic and 78.18% to Westwood. This is because that different types of CCA have different scopes of application. Empirically speaking, the performance of loss-based CCAs (i.e. Cubic and Westwood) degrades with high RTT and random packet loss, and will suffer longer tail latency. The improvement of Floo in the tail RCT demonstrates its selection accuracy to not use Cubic/Westwood when the network condition is poor.

Remark 2 (Copa and BBR): Compared to Copa and BBR, Floo reduces the average RCT by 20.53% and 14.3% respectively. For the 90 percentile (the tail) completion time, Floo has a 21.18% reduction compared to Copa and 21.57% to BBR. The improvement of Floo over the four CCA candidates validates the accuracy of our Selector module.



(a) Stationary cellular scenarios. **(b)** Highly variable scenarios.

(c) Wifi scenarios. **(d)** SD. of all scenarios.

Figure 8: A set of transport layer results for the three scenarios. (a)(b)(c) present the normalized avg. delay, and avg. throughput, where the dashed line represents the Pareto front of baselines. (d) presents the standard deviations of the overall results.

Remark 3 (Static_Opt): Floo can adapt to variable and dynamic network scenarios, and switch to a better CCA during the connection whenever the network condition changes. Therefore, Floo obtains better performance than statically optimal selection (9.6% reduction in avg. RCT). The advantage of Floo over Static_Opt demonstrates the need for CCA switching during the connection.

Remark 4 (Vivace): Vivace is also designed for performance. Therefore, we adopt Vivace as a baseline to evaluate Floo's ability to improve application QoE. Results show that Floo achieves 17.72% lower RCT on average than Vivace, and 25% reduction in the 90^{th} RCT. This is because Vivace still focuses on transport layer metrics and the utility function of Vivace is not consistent with the QoE. In addition, the penalty for packet loss and latency in the utility function makes Vivace less resistant to random packet loss.

Transport layer performance under different scenarios. In our emulated experiments, we consider three scenarios, including stationary cellular scenario, highly variable scenario and unseen WiFi scenario. We analyze the transport layer metrics under different scenarios. We consider two performance metrics: average smooth RTT and average throughput. For each scenario, we normalize the RTT and throughput performance of all CCAs (including Floo) to the minimum delay and maximum throughput achieved on that scenario, respectively. Then, we average all normalized values over all scenarios and show the results in Fig. 8. More detailed results are presented in Appendix E.

- **Stationary cellular scenarios.** In our evaluations, there are 20 traces of the stationary cellular network, including indoor [34] and outdoor [7] traces (Fig. 8a).
- **Highly variable scenarios - mobile cellular.** Similarly, we tested 30 mobile cellular traces, which are highly variable scenarios (Fig. 8b). These traces are collected when walking and driving under 4G [7] and 5G mmWave [38]. We also adopt the 4G measurements on high-speed rails [30] to construct a scenario with violently fluctuating bandwidths.
- **Unseen scenarios - WiFi.** To evaluate the behavior of Floo in unseen scenarios (Fig. 8c), we use WiFi traces that have not been employed in the training, We used 10 WiFi traces from [35], including traces from office and a public WiFi provided by a crowded restaurant during dinner hours.

Results show that Floo generally achieves the highest throughput with the lowest latency under different scenarios. Even in unseen scenarios, Floo shows advantages, demonstrating Floo's generalization capability. The improvement of Floo demonstrates that, besides QoE improvements, directly optimizing the application QoE through CCA selection approach can further improve transport layer capabilities.

We also present the stability of throughput and RTT (i.e., the standard deviation of the normalized average throughput and RTT) of each CCA under all scenarios in Fig. 8d. Results show that Floo could almost achieve stable high performance in all three scenarios, especially in terms of latency.

5.3 Real-world performance

We implement Floo in Dianping with O(10M) daily active users. We manually enable Floo for a fraction of users. Specifically, we deployed Floo on the front-end server to serve the persistent connection between the front-end server and the client. We enabled Floo for 5% of the users for evaluation. Besides Floo, we also implement a Floo with Part Switching (P-Floo), enable P-Floo for another 5% users and evaluate the effectiveness of switching algorithms. As a comparison, we set up another 5% of the users to use Cubic, BBR, Copa, Westwood and Vivace respectively. We collect logs for 96 hours, resulting in more than 35 million request logs, covering users from more than 50 countries and regions. We collect RCT from client side and the results are shown in Fig. 9 and Fig. 10.

Floo is still able to reduce the RCT and obtain optimal performance in real-world scenarios. Floo achieves a QoE improvement of 8.07% to 14.26% in real scenarios, with a reduction of about 25.5% for tail RCT. The difference in RCT between the real scenario and the emulated evaluation mainly comes from the different distribution of network conditions. For emulated evaluation, we aim to cover various network conditions by selecting as diverse network environments as possible. In contrast, the network states in the real scenario are not uniformly distributed. We found that there are about 57.89% of scenarios are under better network conditions (i.e., packet loss rate is 0% and min RTT is less than 44ms). Therefore, unlike the significant advantage of Copa in the emulated

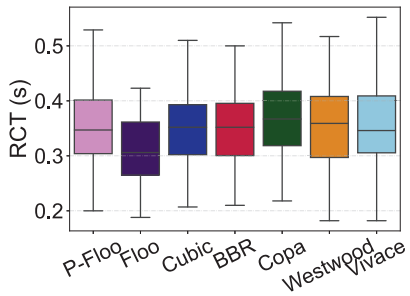


Figure 9: In real world experiments, Floo brought 12.9% reduction on average RCT.

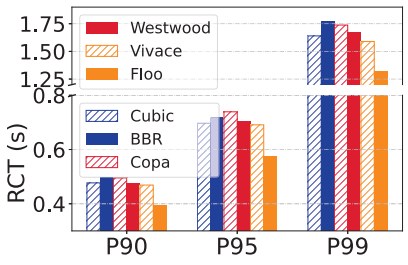

Figure 10: Floo reduces 25.5% of the 99^{th} percentile (the agestail) completion time.

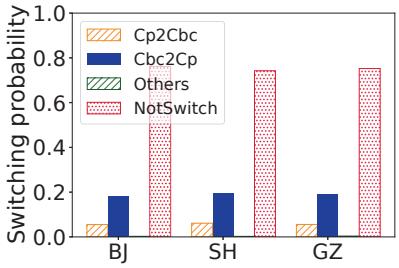

Figure 11: The probability of switching types of different user groups.

Part	CPU utilization (%)	Time Consumed (μs)
Network Monitor	0.784 (3.109)	47.4375
Selector	0.431 (3.540)	66.1875
Switcher	0.233 (3.773)	19.5625

Table 5: CPU overhead and time consuming of Floo.

scenario, Cubic and Westwood obtains a lower average RCT in the real world. As a result, the improvement brought by Floo in real world is a little lower.

We count the switching frequency and types in the real world in Fig. 11. With the SP of 12s, the probability of a CCA switching occurring at selecting is 25.76%, which implies an average switching interval of about 47s. Among the switching, the mutual switching between Copa (Cp) and Cubic (Cbc) is the most frequent, with more than 74% of the switching being Cubic to Copa and more than 23% being Copa to Cubic. We group users based on the location of CDN nodes they access. The results of switching frequency and actions in different groups are similar.

5.4 Overhead

We report the CPU utilization and runtime overhead of Floo.

CPU utilization. We measure the system overhead of Floo and compare it with other state-of-the-art CCAs. We performe experiments on an emulated network (with 48Mbps bottleneck link and 20ms RTT) for 6 minutes. We measure the average CPU utilization with real application traces and a long flow separately and show the results in Fig. 7. All algorithms are implemented atop QUIC in user space. Although Floo has a higher overhead compared to classical CCAs, however, compared to Cubic, which has the lowest overhead, the additional overhead is only 1.4%.

We measure the CPU utilization of each part by incremental experiments. Specifically, we separately measure the CPU utilization of only Monitor module, Monitor module with Selector module, and the complete Floo. We define the computed overhead of each part as the difference in CPU utilization (%) between two measurements. The results are shown in Tab. 5.

Time consuming. We show the time consumed by recording the time spent for each module. Tab. 5 presents the results taken as an average across 16 runs. We see that the additional consumed time introduced by Floo is at the sub-millisecond level, which is much less frequent than that of CCA selection (about 38.9s on average in our testbed experiments). Specifically, Selector module takes the most time (about 66μs) because of the complex calculations for CCA selection. Monitor module also consumes about 47μs to collect the additional information. Switcher module executes the state migration mechanism, which consumes about 19us.

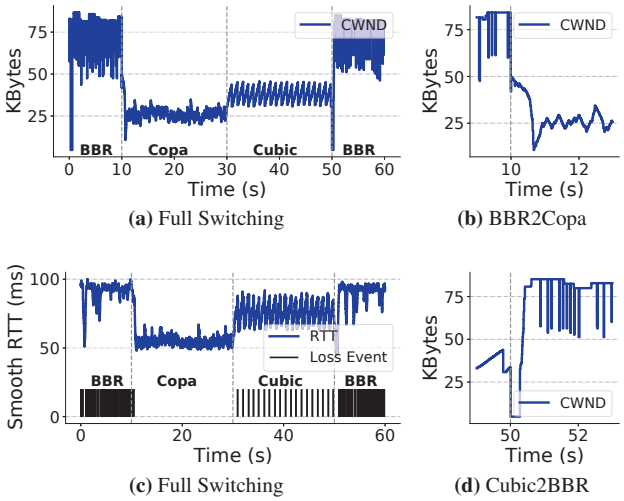
5.5 Floo deep dive

Here, we evaluate the effectiveness of Floo's design of state migration, generalizability to other QoE metrics and resilience to stochastic packet loss.

5.5.1 Effectiveness of state migration

Functional validation. Floo encounters situations where the path conditions change during transmission and switching-on-fly is required. To evaluate the effectiveness of Floo's state migration algorithm, we manually set the CCA switching every 20s and switch between all CCAs in an emulated environment. We compare Full Switching and Part Switching under 60 different scenarios.

Fig. 12 shows the details of the congestion control switching process. We show the performance of switching from BBR to Copa, and to Cubic. We do not show additional details of Westwood, since Westwood is basically similar to Cubic in terms of algorithm design. As described in §2.3, packet loss occurs under Part Switching when switching occurs without convergence. In addition, Copa maintains a high CWND and thus experiences a high RTT with packet loss due to the distortion of estimation of path conditions. Full Switching, as shown in Fig. 12, avoids these problems and maintains the CCA characteristics consistent with their design. Specifically, when switching to Copa (Fig. 12b), Floo is able to decrease the CWND within 1 second, thus quickly emptying the queue built by BBR and maintaining low latency. When switching to BBR (Fig. 12d), Floo first enters the ProbeRTT phase so as to obtain the RTProp, which the prior CCA did not maintain earlier. After that, BBR does not enter the Startup phase, but gradually converges with the ProbeBW phase.



(a) Full Switching **(b)** BBR2Copa

(c) Full Switching **(d)** Cubic2BBR

Figure 12: Details of Full Switching. (a)(c) Full Switching statistics of CWND, smooth RTT and loss event. (b) Detailed CWND of Full Switching from BBR to Copa. (d) Detailed CWND of Full Switching from Cubic to BBR.

Performance analysis. We compare the performance of Full Switching and Part Switching in both emulated and production environments. Fig. 13 shows the distribution of packet loss rate within 1 second after the switching in the emulated environment. Part Switching leads to more packet loss, while Full Switching significantly reduces the packet loss rate, especially when switching from Cubic to the low-latency algorithms, i.e. BBR and Copa. For real-world experiments, Fig. 9 shows that the average RCT is reduced by about 7.59% with Full Switching compared to Part Switching.

5.5.2 Generalizability to other QoE metrics

We change QoE to tail RCT in order to analyze Floo's ability to generalize to other QoE metrics. Accordingly, we set Reward as $R = \ln \frac{Last\ RCT_{p90}}{Current\ RCT_{p90}}$ and retrain a new RL model. We evaluate Floo-P90 under the same 60 scenarios as §5.2. For each scenario, we record the RCT of total requests, the RCT at the 50th percentile, and the RCT at the 90th percentile[3], respectively. We gather the value of all scenarios in Fig. 14.

Floo-P90 is not as good as Floo in terms of total performance of all requests. However, for the 90th percentile RCT, Floo-P90 has a significant improvement, with a reduction of 21.78% on average. Compared to Floo, Floo-P90 selects Cubic less frequently by 6.03%, while the frequency of using BBR, Copa and Westwood increased by 4.02%, 1.0% and 1.0%, respectively. This is because the loss caused by Cubic when filling the buffer can result in a long RCT, while BBR are relatively conservative. As a comparison, Floo reduces RCT at the 50th percentile by about 19.49% compared to Floo-P90. The above results show that with our mechanism, there can be a significant improvement on the target QoE metric. See §7 for more analysis on generalization ability.

[3]We do not compare the 90th percentile RCT of all secnarios because it represents the performance under poor network scenarios.

5.5.3 Resilience to stochastic packet loss

We also analyze Floo's resilience to stochastic packet loss. Stochastic packet loss often occurs under cellular networks due to channel interference, mobility, etc [24, 51]. We evaluate the performance of Floo with a single flow on a link with 4 Mbps bandwidth, 20 ms RTT, 10 KB buffer, and varying random loss rate from 0% to 10%. As shown in Fig. 15, Floo still maintains a low RCT when the stochastic loss rate is set to 10%. It is worth mentioning that Vivace maintains a low RCT until a loss rate of about 4%. After that, corresponding to the 5% loss resistance in the utility function [19], the average RCTs increase dramatically, even up to 9.5 times of the no packet loss case. In addition, the performance of Vivace suffers uncertainty and instability with random packet loss.

6 Related Work

QoE-oriented transport-layer optimization. There are many other ways to conduct QoE-oriented transport optimization [18, 19, 33], while conveying QoE to transport layer by CCA selection is more appropriate. QoS, the target of transport optimization, is reflected in the behaviors in the network, e.g. how to utilize the bottleneck queue, where CCA is the most effective procedure to control. For example, better packet scheduling could improve the host queueing time through reordering the packets [16]. However, packets from one application always have the same QoE, leaving little optimization space for packet scheduling. And flow control schemes could also decide the sending rate, while it is not aware of network behaviors. Therefore, conveying QoE through CCAs is more appropriate.

QoE-oriented CCAs. We are not the first to observe that CCAs should be optimized towards application QoE. One line of solution is to integrate application design and the transport layer behavior [13, 21]. However, these works are designed for specific applications and redesign is needed if designers want to migrate their good performance to other applications. There are also proposals to use application requirements, such as deadline [55] and priorities [56], to guide the design of CCA at the transport layer. However, they can only be used for application requirements that can be directly understood by the transport layer. For example, deadline can be identified as the data delivery time, which the transport layer can estimate and optimize directly from RTT and packet loss events. For the complex QoE metrics, a possible solution is to adopt mature algorithms, such as reinforcement learning, yet we found it impractical. If we put translated QoS as the goal of RL [7, 26], the gap between QoE and QoS remains. If we put QoE as the goal of the RL, the indirect and distant connection between QoE and cwnd/rate decisions makes the training extremely hard to converge. RL-based CCAs also

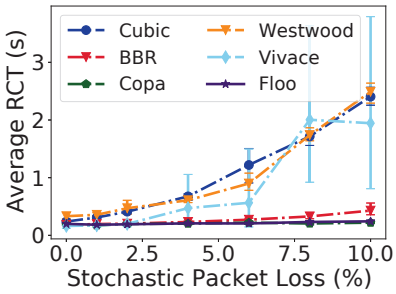

Figure 15: Impact of stochastic loss on RCT.

have interpretability issues in the wild. Therefore, Floo adopts CCA selection mechanism to bridge the gap between the complex, application-oriented QoE and the direct, transport capability-oriented QoS.

CCA-selection methods. There has been some work that adopts CCA selection methods [15,20,42,57]. Existing works still aim to optimize transport layer performance. However, as stated in §2.1, QoS-driven CCA-selection methods will suffer performance degradation when selection criteria are not entirely consistent with QoE. In addition, existing schemes cannot address the two challenges (§2.3) well. Their selection policy generation methods do not consider QoE, and they could not support seamless switching either.

Advanced CCAs for mobile web service. In recent years, many advanced CCA schemes have been proposed, including CCAs specifically designed for wireless network, such as Sprout [50], Verus [53], and emerging learning-based CCAs [7, 19]. However, these CCAs are still oriented to optimize the transport layer performance and do not address the QoS and QoE mismatch. Moreover, considering the practical issues [7, 15] and unproven performance in production environments, we did not consider them as CCA candidates.

7 Discussion

Generalization to heterogeneous applications and scalability to various CCAs. In this paper, we propose a solution for mobile web service, aiming to reduce RCT, and using four classical CCAs as candidates. In fact, Floo could be applied to heterogeneous applications and various CCAs. For example, for streaming applications, Floo can be reused by considering a chunk as a request. For complex QoE, as long as we could extract the traces, characteristics, and the QoE metric of the application, Floo can theoretically be used for any application without any idea of the implementation details and optimization techniques of the application. For CCAs, Floo can incorporate various CCAs into the selection mechanism. Nevertheless, CCA state migration has to be considered. Our design in §3.4 can be extended to all non-learning algorithms. However, generalizing to complex applications and switching between complex CCAs are not designed and verified in this paper, and are future work.

Fairness and friendliness. Floo selects among various CCAs, and the fairness and friendliness of Floo is consistent with that of the CCA candidates. In this paper, we select from the deployed CCAs, which already has had theoretical and experimental analysis of fairness and friendliness [9, 11, 48].

Portability to TCP in Linux kernel. Although Floo is implemented atop QUIC, Floo can still be applied to TCP implementation in Linux kernel. Firstly, eBPF technique [1, 10] provides a safe and convenient way to interact between user space and kernel. One can imagine that Floo works in user space, extracts information from the kernel and delivered the selected CCA to the kernel. The state migration mechanism, on the other hand, requires further modifications to the kernel. Secondly, as for the integration with mechanisms specific for TCP or QUIC, e.g., multi-streaming in QUIC, Floo is orthogonal to pre-CCA optimizations. Therefore, for implementing Floo over TCP without pre-CCA optimizations, Floo can also select the appropriate CCAs in respective situations.

8 Conclusion

We propose Floo, a QoE-oriented CCA selection mechanism for mobile web service. Floo uses QoE as the selection criterion and employs RL techniques to construct the mapping from the transport layer and application layer metrics to CCAs. Floo switches smoothly during the transmission. We implement Floo in a popular mobile web service, and evaluate Floo in both emulated and production environments. Experiments show that Floo reduces the RCT by 14.3% to 52.7% in different scenarios.

This work does not raise any ethical issues.

A Learning Algorithm of Floo

Floo's agent interacts with the environment, gets a series of trajectories ((state, action, reward) or (s, a, r) for short), and updates the policy according to the information of its interaction. Upon receiving state (s_t), Floo's agent needs to choose a corresponding action (a_t), i.e. one CCA, and will get the reward(r_t) in the next step. The policy that Floo's agent used to choose an action, is defined as the probability distribution of actions: $\pi(s_t, a_t) \rightarrow [0,1]$. $\pi(s_t, a_t)$ is the probability of taking action a_t in state s_t. Then the agent uses the PPO algorithm to update the parameter θ of the policy π. The PPO algorithm is optimized from the policy gradient methods [46], which estimates the gradient of the expected total reward by observing the trajectories obtained by following the policy. The gradient of Policy Gradient can be computed as:

$$\nabla_\theta J(\theta) = \mathrm{E}_{(s_t,a_t)\sim\pi_\theta}\left[\mathrm{A}^\theta(s_t,a_t)\nabla\log\pi_\theta(a_t^n \mid s_t^n)\right] \quad (1)$$

$\mathrm{A}^\theta(s_t,a_t)$ is the Advantage Function, which represents the difference in the expected total reward when we choose action a_t in state s_t, compared to the expected total reward for the action drawn from policy π_θ.

Policy Gradient is an on-policy method where the collected sample (s_t, a_t, r_t) is used only once. In order to make full use of the training data and improve the learning efficiency, PPO extends the Policy Gradient method. The original policy is denoted as π_θ, and when the gradient $\nabla_\theta J(\theta)$ is applied to the original policy π_θ, the new policy is denoted as $\pi_{\theta'}$. At this point, if we want to reuse the data generated by the policy π_θ to update $\pi_{\theta'}$, considering the different distributions of trajectories in $\pi_{\theta'}$ and π_θ, an importance sampling method is needed:

$$E_{x\sim p}[f(x)] = E_{x\sim q}\left[f(x)\frac{p(x)}{q(x)}\right] \quad (2)$$

Therefore, the gradient of the off-policy is calculated as follows, with the parameters before and after the update denoted as θ and θ':

$$\nabla_\theta J(\theta) = \mathrm{E}_{(s_t,a_t)\sim\pi_{\theta'}}\left[\frac{\pi_\theta(a_t \mid s_t)}{\pi_{\theta'}(a_t \mid s_t)}\mathrm{A}^{\theta'}(s_t,a_t)\nabla\log\pi_\theta(a_t^n \mid s_t^n)\right] \quad (3)$$

Trace	Year	Type (Num)	Stationary / Mobile	Description
Lumos [38, 39]	2020	4G (166), 5G mmWave (121)	Stationary, Mobile (walking, driving)	Verizon's 4G and 5G service in Minneapolis.
NYC [7]	2019	4G LTE (23)	Stationary, Mobile (bus, taxi)	Cellular traces gathered in NYC.
PiTree [34]	2019	4G(61)	Stationary	Measurement of indoor 4G bandwidth.
HSR [30]	2018	4G (33)	Mobile (high-speed rails)	4G measurements on high-speed rails.
FCC18 [3]	2018	4G (397)	Stationary	The broadband network in 2018 provided by FCC.
Ghent [47]	2016	4G (40)	Mobile (foot, bicycle, bus, tram, train, car)	4G measurements in 2016 by Ghent University.

Table 6: The description of the real network traces.

The objective function is calculated as Eq. (4). To ensure that the difference between the policy before and after the update is not too large, PPO adds a constraint to the objective function. The clip function forces $\frac{\pi_{\theta(a_t|s_t)}}{\pi_{\theta'(a_t|s_t)}}$ between $1-\varepsilon$ and $1+\varepsilon$, and finally takes the minimum value among the rewards that have been clipped and those that have not been clipped.

$$J^{\theta'}(\theta) = \sum_{(s_t,a_t)} min(\frac{\pi_\theta(a_t \mid s_t)}{\pi_{\theta'}(a_t \mid s_t)} A^{\theta'}(s_t,a_t), \\ \text{clip}(\frac{\pi_{\theta(a_t|s_t)}}{\pi_{\theta'(a_t|s_t)}}, 1-\varepsilon, 1+\varepsilon) A^{\theta'}(s_t,a_t)) \tag{4}$$

The detailed derivation and sample code can be found in [5, 45].

B Real Network Traces

Tab. 6 shows the traces used in Section 4.3.1.

C Detailed Training Method

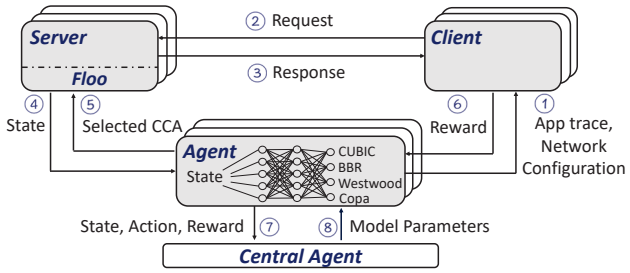

Figure 16: The workflow of the training phase of Floo. Multiple (Agent, Server, Client) sets run simultaneously.

We construct a training architecture as shown in Fig. 16. Each learning agent (Agent in Fig. 16) establishes two connections with an Application S client (Client in Fig. 16) and an Application S server (Server in Fig. 16) respectively, communicating about the experimental configurations and training trajectories. Each server/client only connects to one agent. The client and server connecting to the same agent also establish a QUIC connection through Mahimahi. For each training episode (10 min), the agent selects and configures the network condition parameters of Mahimahi and the application traces to be applied, as described in §4.3.1. During the interaction between the client and the server, the agent receives the states and rewards from the server and client respectively, and selects the corresponding action (i.e., CCA) based on the acquired state. The selected CCA is switched smoothly by Floo on the server.

To accelerate the training and improve the generalization performance of the RL model, we employ a distributed framework. We distribute 10 (Agent, Server, Client) sets. All the agents, servers, and clients are deployed in a cluster. These servers/clients are connected to the agents with high-speed links. Each agent observes a series of trajectories, and continuously sends the tuples (state, action, reward) to the central agent. The central agent then uses the PPO algorithm to compute the gradients (Eq. (3)) and updates the parameters in the selection model (Eq. (4)). The updated model will be pushed to each agent and will be used for the next episode. Tab. 7 in Appendix D shows the detailed model and parameters used during the training.

D Training Setting

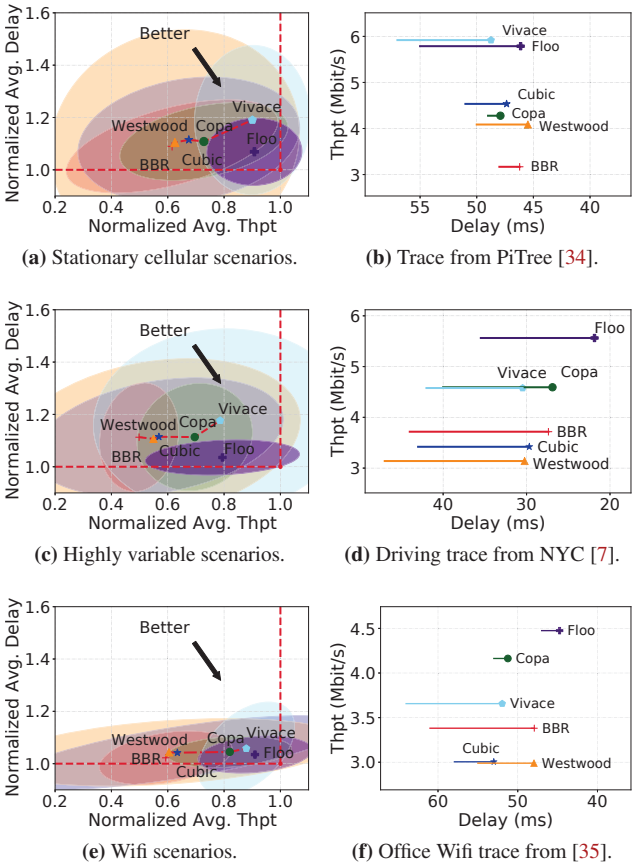
Floo uses an actor-critic architecture. Floo's actor, taking state and outputting action, use one hidden layer with 200 units. The output layer is a softmax layer to map to probabilities of actions. The critic networks, taking state and outputting V values, have one hidden layer with 200 units. The output layer is a linear unit representing the V function. All hidden layers in actor and critic networks are followed by Leaky ReLU nonlinearity. Tab. 7 shows other parameters used during the training of Floo.

Parameter	Value
Optimizer	Adam
Episode duration	10min
Actor's Learning Rate	0.0001
Critic's Learning Rate	0.0002
Discount Factor	0.99
ε in clip function	0.2

Table 7: Parameters used for the training.

E Detailed Results in Emulated Experiments

Our emulated experiments involve three scenarios: stationary cellular scenario, highly variable scenario and unseen WiFi scenario. We analyze the transport layer metrics, including average smooth RTT and average throughput. For each scenario, we normalize the RTT and throughput performance of all CCAs (including Floo) to the minimum delay and maximum throughput achieved on that scenario, respectively. We show the normalized results in Fig. 17a, Fig. 17c and Fig. 17e. The ellipse indicates the standard deviations from the average



(a) Stationary cellular scenarios. **(b)** Trace from PiTree [34].

(c) Highly variable scenarios. **(d)** Driving trace from NYC [7].

(e) Wifi scenarios. **(f)** Office Wifi trace from [35].

Figure 17: The detailed transport layer results for the three scenarios. (a)(c)(e) presents the normalized avg. delay, and avg. throughput. The center of each ellipse shows the average value of each CCA, while the ellipse indicates the standard deviations from the average values and their covariance. (b)(d)(f) shows the avg. delay (icons), 90% tile delay (end of lines), and avg. throughput of a sample.

values of the RTT and the throughput and their covariance[4]. Floo can not only achieve lower latency and higher throughput, but also obtain a smaller ellipse than other CCAs, which denotes better stability and consistency. In Fig. 17b, Fig. 17d and Fig. 17f we also depict the avg. delay (icons), 90% tail delay (end of lines), and avg. throughput of three typical sample traces. Under all three scenarios, Floo achieves excellent performance both in delay and throughput.

F Analysis of Selection Period.

Here, we investigate the impact of SP value on the performance and overhead of the mechanism. Intuitively, the SP determines the frequency of Floo monitoring network and application states, and selecting CCAs. SP should be consistent with the granularity of the application QoE and should also consider the network fluctuation. To this end, we vary the SP and record its impact on application performance. We

[4]Note that RTT/RTT_Min $\in [1,\infty)$, and Thp/Thp_Max $\in [0,1)$. The ellipse may exceed the range, but the outlier part is actually not sampled.

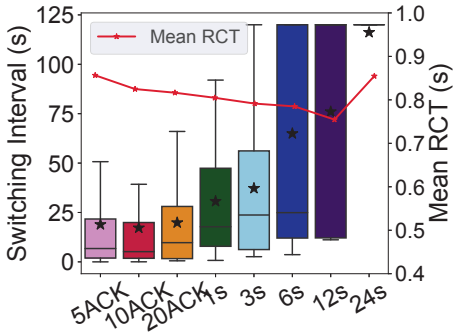


Figure 18: Avg. RCT (red line) and switching intervals distribution across diff. SPs

vary the SP from the fine-grained ACK level to the coarse-grained second-level. To report the performance, we conduct experiments in 60 scenarios and record the RCT and CCA switching interval. Note that if no switching has occurred in one scenario, the switching interval is counted as the duration of that experiment (120s).

Fig. 18 depicts the results. QoE gradually improves with the growth of the SP. The performance of ack-level selection is worse. We find that even for fine-grained ack-level SP, the granularity of CCA switching interval is at the second-level, with a median of about 5 to 10 seconds and an average value of more than 16 seconds. The QoE results are consistent with the frequency of CCA switching. This is because the fine-grained data estimation is susceptible to outliers, and cannot reflect the real path condition and application performance. On the other hand, the frequency of CCA selection is higher than that of request sending, which could lead to meaningless CCA switching. However, long SP, such as 24s, is challenged to capture and react to the instant changes in network conditions and application performance. In 96% of the scenarios, the SP of 24s does not switch during the connection. Therefore, long SP could not achieve good performance. As for the CPU utilization, experiments show that SP has little impact on the overhead. The difference in CPU utilization between different SPs is less than 0.28%. To have a balanced performance and overhead, we set a fixed SP of 12s in this paper, which represents the minimum switching period.

FarReach: Write-back Caching in Programmable Switches

[1]*The Chinese University of Hong Kong* [2]*Peking University* [3]*Xiamen University*

Abstract

Skewed write-intensive key-value storage workloads are increasingly observed in modern data centers, yet they also incur server overloads due to load imbalance. Programmable switches provide viable solutions for realizing load-balanced caching on the I/O path, and hence implementing write-back caching in programmable switches is a natural direction to absorb frequent writes for high write performance. However, enabling in-switch write-back caching is non-trivial, as it not only is challenged by the strict programming rules and limited stateful memory of programmable switches, but also necessitates reliable protection against data loss due to switch failures. We propose FarReach, a new caching framework that supports fast, available, and reliable in-switch write-back caching. FarReach carefully co-designs both the control and data planes for cache management in programmable switches, so as to achieve high data-plane performance with lightweight control-plane management. Experiments on a Tofino switch testbed show that FarReach achieves a throughput gain of up to 6.6× over a state-of-the-art in-switch caching approach under skewed write-intensive workloads.

1 Introduction

Key-value stores have been widely deployed in modern data centers to manage structured data (in units of *records*) for data-intensive applications, such as social networking [1, 33, 41], web indexing [7], and e-commerce [11]. Practical key-value storage workloads are traditionally read-intensive (e.g., up to a read-to-write ratio of 30:1 at Facebook's Memcached [1]). Recent field studies of production key-value stores show the dominance of *write-intensive workloads*; for example, more than 20% of Twitter's Twemcache clusters have more writes than reads [41], and the AI/machine-learning services at Facebook's RocksDB production have 92.5% of read-modify-writes [6]. Also, write-intensive workloads are *skewed*; for example, 25% of frequently accessed (i.e., *hot*) records dominate in the write workloads at Twitter's Twemcache clusters [41].

Enabling high write performance for key-value stores in data centers is challenging. Write requests issued from a client to a key-value storage server often suffer from long round-trip times (RTTs) due to switch-to-server transmissions and server-side processing. In particular, if the server is overloaded, I/O requests will have long queuing delays or even be dropped. Also, in distributed key-value stores that span multiple servers, a small portion of servers may be bottlenecked by substantial requests for hot records under skewed workloads, thereby leading to load imbalance [17, 21].

Programmable switches [5] offer an opportunity to improve the write performance of key-value stores. By deploying a programmable switch on the I/O path (e.g., as a top-of-rack switch in a rack-based data center), it can inherently intercept the I/O requests for all servers within the rack and provide stateful memory that can be programmed to cache frequently accessed records. For each request issued by a client, the switch can read or write any of its cached records and directly respond to the client, thereby eliminating the long RTT to access the server-side record. It is also proven that load balancing is achievable by keeping only $O(N \log N)$ records, where N is the number of servers [14]. Recent studies have demonstrated the effectiveness of load-balanced in-switch caching [20, 27–29] for high throughput and sub-RTT latencies. However, existing in-switch caching approaches [20, 27–29] target read-intensive workloads and implement *write-through* caching (i.e., write requests update records both in the in-switch cache and the server side). Thus, they do not provide write performance gains compared with no caching under skewed write-intensive workloads.

To address skewed write-intensive workloads, it is desirable to implement in-switch *write-back* caching (i.e., write requests update records in the in-switch cache only without immediately updating the server side) to absorb frequent writes to hot records. However, enabling write-back caching in programmable switches is subject to several challenges. First, in-switch write-back caching raises an issue of synchronizing records in both the in-switch cache and server-side storage. Without proper synchronization, the latest records may become unavailable to clients during cache eviction. Second, since the in-switch cache keeps the latest records under the write-back policy, protecting against data loss in the in-switch cache during switch failures is critical. However, providing fault tolerance guarantees for the in-switch cache is challenged by the limited switch resources (e.g., limited stages with only tens of megabytes for stateful memory) [5, 31]. Finally, the strict pipeline programming model and limited resources in programmable switches necessitate a design of simple but efficient caching mechanisms. While programmable switches can be managed with a software controller to relax switch resource constraints [20, 29], the control-plane interaction between the controller and programmable switches can incur long delays and slow down the data-plane I/O performance. Even worse, the synchronization and fault tolerance issues complicate cache management with extra control-plane overhead, thereby further degrading I/O performance.

In this paper, we propose FarReach, a fast, available, and reliable in-switch write-back caching framework to improve the I/O performance of key-value stores under skewed write-intensive workloads. FarReach exploits a careful co-design of the control and data planes, such that it offloads cache management to a centralized controller in the control plane, while achieving high data-plane performance with lightweight control-plane management. It comprises the following design features: (i) fast cache admission that admits hot records into the in-switch cache without blocking data-plane I/O traffic; (ii) available cache eviction that ensures that the latest records evicted from the in-switch cache remain available to read requests; and (iii) reliable snapshot generation and zero-loss crash recovery for the protection against data loss during switch failures. To the best of our knowledge, this is the first work that specifically addresses the availability and fault tolerance issues of in-switch caching.

We implement FarReach and compile the in-switch cache prototype (written in P4 [4]) into the Tofino switch chipset [39]. We evaluate FarReach with YCSB [42] and synthetic workloads. Compared with NetCache [20], a state-of-the-art in-switch caching framework that targets read-intensive workloads and implements write-through caching, FarReach achieves a throughput gain of up to 6.6× across 128 simulated servers under skewed write-intensive workloads. FarReach also has low access latencies, fast crash recovery, and limited switch resource usage.

We now release the source code of our FarReach prototype at **http://adslab.cse.cuhk.edu.hk/software/farreach**.

2 Background and Motivation

2.1 Programmable Switches

Figure 1 shows the programmable switch architecture, which consists of both a data plane and a control plane. The data plane processes packets with a stringent timing requirement for line-rate forwarding. It contains multiple *ingress* and *egress* pipelines. When a packet arrives at the switch through an ingress port, the packet first enters the corresponding ingress pipeline, which specifies an egress port. Then the *traffic manager*, which interconnects between the ingress and egress pipelines, transfers the packet to the egress pipeline corresponding to the specified egress port. Finally, the packet leaves the switch through the egress port. On the other hand, the control plane contains an operating system within the switch, called the *switch OS*, to manage the forwarding rules of the data plane. The switch OS of each switch interacts with a centralized *controller*, which manages the packet processing of all switches in a network-wide manner.

Each ingress/egress pipeline follows a reconfigurable match tables (RMT) model [5]. When a packet enters an ingress/egress pipeline, it is first processed by a *parser*, which extracts packet header fields into the packet header vector (PHV). The pipeline transfers the PHV across a number of

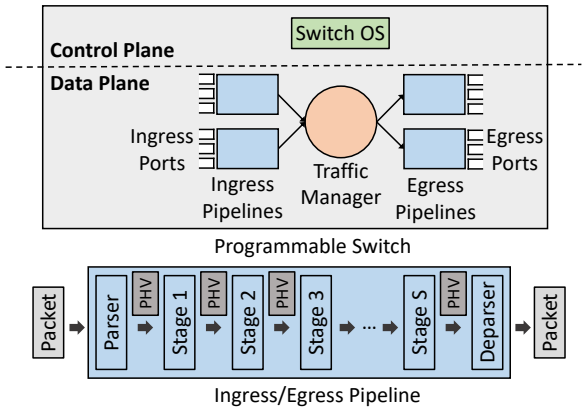

Figure 1: Programmable switch architecture.

stages with multiple *match-action tables* each. Each stage also keeps a limited amount of SRAM, composed of tens of memory blocks, for tracking stateful information that is accessible by the match-action tables. A match-action table can use an ALU to perform arithmetic or logical operations and store the results into the PHV. It matches the fields in the PHV from the previous stage and performs the corresponding action to update the PHV for the next stage, while the match-action rules can be configured by the switch OS. A match-action table can also use a special kind of ALU, called stateful ALU, to store the results into on-chip memory. To fulfill the stringent timing requirement, the memory blocks associated with a stage cannot be accessed from other stages, while the processing of a packet within a stage can only access a limited number of memory blocks associated with the stage and each memory block can only be accessed at most once. After being updated by all stages, the PHV is processed by a *deparser*, which reconstructs the new packet header fields. The header fields are combined with the original payload to form the packet to be forwarded.

2.2 Challenges

Write caching policies can be classified into *write-through* and *write-back*. Write-through synchronously updates the records both in the cache and on the server side; in contrast, write-back (a.k.a. delayed-write) updates only the records in the cache, and later reflects the updates on the server side. Existing in-switch caches [20, 27–29] mainly implement write-through caching. In this work, we focus on write-back caching, as it improves the write performance over write-through caching by delaying server-side updates. However, managing write-back caching is non-trivial, and is subject to three unique challenges in programmable switches.

Performance challenge. Since a programmable switch has a restricted pipeline programming model (i.e., it can only access a limited number of memory blocks) and scarce hardware resources (i.e., it only has a limited number of stages and stateful ALUs) [5], it is necessary to offload switch-level cache management (including cache admission and eviction) to a

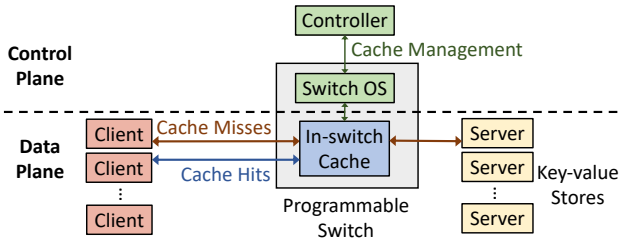

Figure 2: FarReach's architecture.

centralized controller [20, 29], while the switch only updates the cached records in the data plane under the write-back policy. However, due to the high controller-to-switch latency, control-plane processing is much slower than data-plane processing in a programmable switch, thereby bottlenecking the I/O performance.

Availability challenge. Under write-back caching, both cache admission and eviction algorithms need careful coordination between the control and data planes, so as to correctly maintain the latest records in either the in-switch cache or server-side storage; otherwise, the outdated records may be returned to the client. Such an issue does not exist in write-through caching [20, 29], as it always keeps the latest records on the server side. The availability issue is even more challenging in programmable switches, since the controller needs to manage both the cache and server updates, but incurs high overhead. Also, the controller is not on the packet forwarding path and has no view about the traversed packets in the data plane.

Reliability challenge. Under write-back caching, the latest records may only be kept in the in-switch cache and may have their updates to the server-side storage delayed. If the switch crashes, all latest records are lost. Such an issue again does not exist in write-through caching, as the latest records can be persistently kept in server-side storage [20, 29].

3 FarReach Design

3.1 Design Overview

Architecture. FarReach is a fast, available, and reliable in-switch write-back cache architecture for improving the I/O performance and load balancing of server-side key-value stores. Figure 2 shows FarReach's architecture, in which clients are connected via the in-switch cache to multiple servers for key-value storage, while the controller is responsible for cache admission and eviction. Recall that the controller has no view about the data plane (§2.2). Thus, the cache management decisions are triggered by the switches (in the data plane) based on the workload patterns.

Goals. FarReach's core idea is a careful co-design of the control and data planes. Table 1 summarizes our design features. FarReach aims for three design goals:

- *Fast access* (§3.2). FarReach supports non-blocking cache admission for admitting hot records into the in-switch cache, so as to achieve high write performance. It also ensures atomicity in cache admission under the multi-pipeline setting of programmable switches.
- *Availability* (§3.3). FarReach ensures that any latest record that is evicted from the in-switch cache remains available to clients.
- *Reliability* (§3.4). FarReach protects against data loss during switch failures. It uses a crash-consistent snapshot generation algorithm for making snapshots of the in-switch cache state. It also ensures atomicity of snapshot generation in the multi-pipeline setting. It further couples snapshot generation with upstream backup [18] to achieve zero-loss crash recovery.

Table 1: Summary of design features of FarReach.

Design features	Design details
Non-blocking cache admission (§3.2)	FarReach tracks the "outdated" or "latest" state of each cached record to limit conservative reads. It also associates a validity register with each cached record for atomicity.
Available cache eviction (§3.3)	FarReach uses a "to-be-evicted" flag to make each evicted record available. It identifies latest records by sequence numbers and handles packet loss by record embedding.
Crash-consistent snapshot generation (§3.4)	FarReach reports original cached records to the controller. It recirculates writes for atomicity, and exploits client-side record preservation for zero-loss recovery.

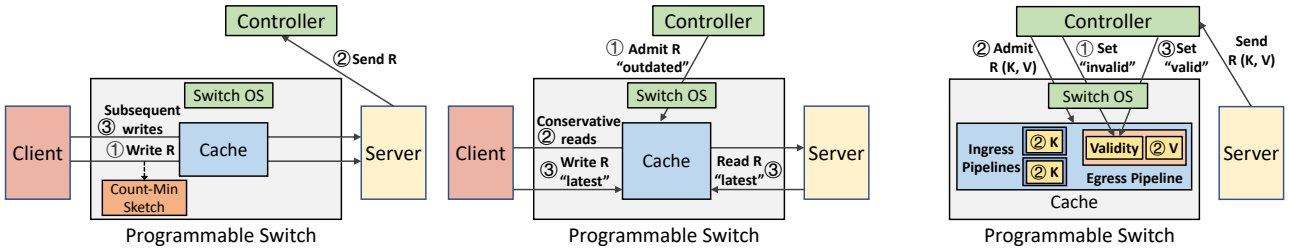
Design assumptions. FarReach currently supports a fixed key length of 16 bytes and a variable value length of up to 128 bytes due to limited switch resources; the same constraint is also assumed in NetCache [20] and DistCache [29]. Thus, FarReach is suitable for workloads dominated by small records (e.g., ZippyDB and UP2X in Facebook's RocksDB production [6]). For large records, FarReach simply relays them between clients and servers without caching.

FarReach currently does not support range queries, since programmable switches cannot feasibly maintain sorted structures with the memory access limitations (§2.1) and servers are unaware of the latest in-switch records under the write-back policy. In this work, we focus on skewed write-intensive workloads without range queries.

FarReach guarantees reliability for switch failures. We assume that the durability of server-side records is addressed by the persistence feature of key-value stores [25, 30, 37].

3.2 Non-blocking Cache Admission

Problem of cache admission. A naïve design of cache admission in programmable switches can introduce *blocking* to write requests. Due to limited switch resources, the controller is responsible for cache management (§2.2). Suppose that the controller is about to admit a new hot record into the in-switch cache. As control-plane processing is slower than data-plane packet forwarding (§2.2), the switch may receive subsequent



(a) Before cache admission (b) After cache admission

Figure 3: Non-blocking cache admission in FarReach. Before admitting a record R, the switch forwards subsequent writes to the server in a non-blocking manner. After admitting R, the switch conservatively forwards reads for R to the server until it receives a new write from the client or a read from the server; it also marks R as "latest".

Figure 4: Atomic validity control in FarReach. For a record R with a key K and a value V, the controller maintains an egress validity register for atomicity of cache admission.

writes for the same key before the record from the first write is admitted to the cache. In this case, such subsequent writes need to be *blocked* until the record is admitted; otherwise, the admitted record may overwrite the newer records from the subsequent writes that arrive earlier at the switch, due to the write-back policy.

Cache admission policy. Before proposing our cache admission design, we first describe the cache admission policy in FarReach. FarReach currently triggers cache admission for the hot records with high access frequencies. It follows the design of NetCache [20] and deploys space-efficient in-switch data structures for frequency tracking, due to the limited in-switch SRAM. Specifically, FarReach maintains a Count-Min Sketch [10] to track the access frequencies of uncached records for cache admission, as well as a counter array to track the access frequencies of cached records for cache eviction (§3.3), within the switch. A Count-Min Sketch is a fixed-size, error-bounded summary data structure composed of multiple rows with a fixed number of counters each. FarReach samples incoming requests for frequency monitoring to reduce processing overhead. For each sampled request to an uncached key, FarReach updates the Count-Min Sketch and estimates the access frequency. If the frequency exceeds a pre-defined threshold, FarReach identifies the key as hot. It triggers the controller to admit the hot record into the in-switch cache, and also tracks the frequency of the cached record in the counter array. To avoid counter overflow, FarReach periodically resets all counters of the Count-Min Sketch and the counter array to zero. Note that we do not claim the novelty of this design.

Our cache admission design. We propose a non-blocking cache admission algorithm for FarReach, as shown in Figure 3. Suppose that a client issues a write request of a record (say, R) to a server. If R is not yet cached and is identified as hot based on the Count-Min Sketch, the switch forwards R to the server (① in Figure 3(a)). The server forwards R to the controller for cache admission (② in Figure 3(a)). Note that a read request issued by a client can also trigger cache admission, except that the server will send the server-side latest record R to the controller (② in Figure 3(a)). Before the controller admits R into the in-switch cache, the switch forwards subsequent writes for the same R's key (i.e., cache misses) to the server without updating the cache (③ in Figure 3(a)). The server directly processes the writes without blocking. Thus, the server now keeps the latest record.

After R is admitted, FarReach temporarily marks the admitted R as "outdated" (① in Figure 3(b)). For any read request to R's key (which is "outdated"), FarReach *conservatively* forwards the read request to the server to obtain the latest record (② in Figure 3(b)).

Conservative reads increase read latencies due to server-side processing. To limit conservative reads, our insight is that all requests and responses must traverse the switch, so FarReach can monitor all traversed requests and responses to mark the "outdated" cached record as "latest" as early as possible. Specifically, FarReach marks the "outdated" record as "latest" (③ in Figure 3(b)) if it sees: (i) a write request from a client for the same key (which carries the latest record), or (ii) a read response from the server for the same key (which carries the latest record while the cached record remains outdated). When a cached record is marked as "latest", it can be directly updated by subsequent writes based on the write-back policy. Under skewed write-intensive workloads, an "outdated" cached record can soon be marked as "latest" by a subsequent write for the same key, so conservative reads are limited.

Recall that a server in FarReach is responsible for sending a record to the controller for cache admission (i.e., ② in Figure 3(a)). Thus, it can determine whether any record of the same key has been sent to the controller and avoid sending duplicate records of the same key, thereby keeping limited control-plane bandwidth usage (e.g., up to 1.41 MiB/s; see §5.4). This is in contrast to NetCache [20], in which a switch sends records to the controller for cache admission and needs an in-switch Bloom Filter [3] to avoid duplicate submission; FarReach removes the need of maintaining an in-switch Bloom Filter and hence saves switch resource usage for implementing in-switch write-back caching.

Atomic validity control. FarReach stores the keys and values of records in the ingress and egress pipelines, respectively, to accommodate the limited number of stages of a single pipeline. However, it is critical but non-trivial to provide atomicity for

cache admission under the multi-pipeline setting. Specifically, a switch can only provide atomicity within a single pipeline rather than multiple pipelines, yet the requests for the same key can arrive from different ingress pipelines. Without the atomicity of cache admission, the write requests to the same key arriving from different ingress pipelines may have inconsistent views on the key: cached or uncached. For the former, the cached record is updated directly by the write-back policy; for the latter, the requests are forwarded to the server based on our non-blocking cache admission design. Thus, the key may be updated with an inconsistent value.

Our insight is that although the requests for the same key can enter a switch from different ingress pipelines, FarReach can forward them to the same egress pipeline corresponding to the same server. Note that such forwarding does not incur cross-pipeline imbalance, as the bottleneck lies in server-side storage (including both CPU processing and disk I/O) instead of line-rate switches. The server-side bottleneck is shown in our evaluation, where the system throughput is up to 12.1 MB/s under 128 simulated servers (§5.2), significantly lower than the maximum throughput 3.2 Tbps of a two-pipeline Tofino switch [39]. Thus, FarReach can provide atomicity for each record being admitted, with the aid of the single egress pipeline that is connected to the corresponding server, while incurring limited performance degradation.

We propose *atomic validity control* for cache admission in FarReach (Figure 4). Specifically, programmable switches provide atomic primitives for each register within a single pipeline. FarReach introduces a *validity register* for each cached key in an egress pipeline. Before admitting a record R with key K and value V sent by a server, FarReach first sets the validity register for R as "invalid" (① in Figure 4). It then admits, via the switch OS, V into the egress pipeline and K into all ingress pipelines (the latter is to ensure consistency across all ingress pipelines) (② in Figure 4). Finally, it changes the validity register to "valid" (③ in Figure 4). Based on the validity register, FarReach treats a record as a cache hit only if the key is cached in an ingress pipeline and the validity register is "valid" in the single egress pipeline; or as a cache miss otherwise. Thus, if a key has not been admitted into all ingress pipelines, its record is treated as a cache miss as its validity register remains "invalid".

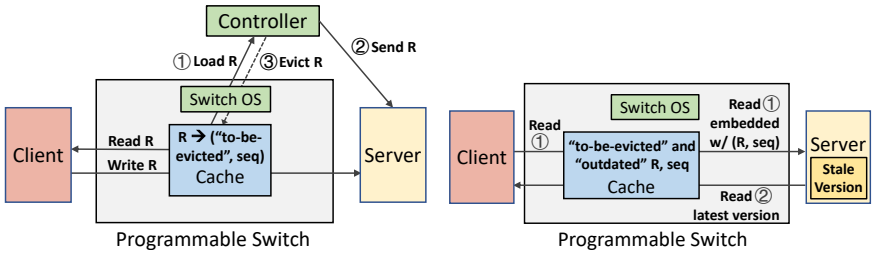
3.3 Available Cache Eviction

Problem of cache eviction. If the in-switch cache is full for cache admission, FarReach selects a cached record to evict, by sampling multiple cached records and selecting the one with the least access frequency from the counter array (§3.2). It then triggers the controller to perform cache eviction on the selected record. Under the write-back policy, the evicted record may also be the latest record and has not yet been updated in the server. It is critical to keep any latest record to be evicted available during cache eviction. To achieve this goal, the controller needs to synchronize the views of both the switch and the server on the evicted record during cache eviction, especially when there also exist read/write requests for the evicted record. However, the controller is constrained by slow control-plane processing, which leads to high synchronization overhead.

Our cache eviction design. We propose a cache eviction algorithm for FarReach that ensures availability, whose workflow is shown in Figure 5(a). Our idea is to associate additional metadata with each cached record in the in-switch cache, so as to maintain the availability of any evicted record, while incurring limited synchronization overhead to the controller. Specifically, when a cached record (say, R) is to be evicted, the controller first marks R as "to-be-evicted" and loads R from the in-switch cache (① in Figure 5(a)). It then sends R to a server for storage (② in Figure 5(a)). If there is any write request to the "to-be-evicted" R, FarReach simply forwards the write request to the server (instead of updating the record in the cache under the write-back policy) and marks the evicted record as "outdated". If there is any read request to the "to-be-evicted" R and R is "latest" (marked in cache admission (§3.2)), the cache returns R to the client; otherwise, if R is "outdated" (i.e., it has been updated), FarReach forwards the read request of R to the server, which holds the latest record. Thus, we ensure that any evicted cached record that is also the latest record remains available. After the server has stored the latest "to-be-evicted" cached record, the controller acknowledges the cache to actually evict the "to-be-evicted" R (③ in Figure 5(a)). Note that all writes to the "to-be-evicted" R must be forwarded to the server no matter with the view of cached or uncached, so FarReach does not have any atomicity issue when evicting R in the multi-pipeline setting.

Identifying latest records. One subtlety is that a server may receive the request of storing a record from two possible paths: (i) the eviction of a record from the cache and (ii) the write request of the record issued by a client. It is critical to differentiate the latest version of a record that is finally stored in the server. To resolve this issue, recall that FarReach forwards the write requests of the same record to the same egress pipeline corresponding to the server (§3.2). As programmable switches can provide atomicity and serialize packets in a single pipeline (§3.2), FarReach associates a *sequence number* with each cached record atomically. It increments the sequence number for each write request of the key in the egress pipeline based on the serialized order of accessing the cache, and embeds the sequence number into the write request. When the server receives a request of storing a record, it overwrites the existing record only if the received record has a higher sequence number than the existing record; otherwise, the received record will be discarded.

Handling packet loss. Packet loss in switch-to-server transmissions can break the availability of cache eviction. To elaborate, recall that an in-switch record can be the latest version under the write-back policy. During cache eviction, FarReach



(a) Cache eviction workflow (b) Record embedding

Figure 5: Available cache eviction in FarReach. For a record *R* to be evicted, it is marked as "to-be-evicted" and is made available to the client's read if it is also the latest record. To handle switch-server packet loss, if *R* is "outdated", the switch embeds the "outdated" evicted record into any read and forwards the read to the server. The server compares the received read with the server-side version and keeps the latest version.

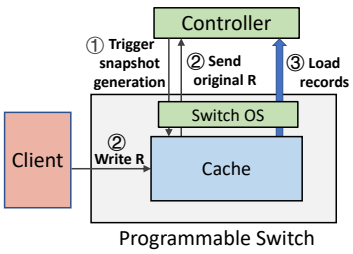


Figure 6: Crash-consistent snapshot generation in FarReach. If the switch receives the first write to a cached record *R* during snapshot generation, it forwards the original *R* to the controller before *R* is updated.

forwards the write request to a "to-be-evicted" record to the server and marks the evicted record as "outdated". If the write request is lost during its transmission (e.g., due to server-side congestion or packet corruption), the server is not updated with the latest version, but still keeps the stale version. As the in-switch cache marks the evicted record as "outdated", it forwards all subsequent reads to the server and receives the stale version. Note that such an issue does not exist in cache admission, as a write request updates either the server (before the record is admitted to the in-switch cache) or the in-switch cache (after the record is admitted to the in-switch cache), instead of changing both of them.

To maintain availability under packet loss, FarReach employs *record embedding* during cache eviction, as shown in Figure 5(b). Our insight is that even though an evicted record is marked as "outdated" during cache eviction, it can still be the latest version that can be used for serving read requests. Specifically, before forwarding a read to the server, the in-switch cache embeds the "outdated" evicted record (if such a record exists) into the read; the embedded record includes the value and sequence number assigned by the switch (① in Figure 5(b)). FarReach ensures that the latest version is available to any client-issued read by comparing the embedded record with the server-side version (② in Figure 5(b)): if the sequence number embedded into a read request is larger than that stored in the server (i.e., the embedded record is the latest version), FarReach directly returns the embedded record to the client; otherwise, FarReach returns the record stored in the server (which is the latest version) to the client.

3.4 Crash-consistent Snapshot Generation

We now address the reliability challenge (§2.2) through a consistency model that incurs zero data loss after switch failures. At a high level, FarReach periodically generates snapshots to protect against data loss of in-switch cached records. It also lets each client preserve the cached records generated after the latest snapshot for recovery. Note that the uncached records are protected by server-side persistent key-value stores (§3.1).

Problem of snapshot generation. Since the in-switch cache keeps the latest records under the write-back policy, we need to protect against data loss in switch failures. We propose to generate a snapshot for all cached records in the in-switch cache at regular time points (called *snapshot points*), so that the switch can restore from the latest snapshot when recovering from a switch failure. However, the design of such snapshot generation is non-trivial. Since programmable switches have limited stages for cache backup and limited on-chip memory for snapshot storage, they need to offload all cached records to the controller. Note that the snapshot overhead is limited for the controller, as the controller only needs to store the latest snapshot for crash recovery (e.g., 1.5 MB for 10K records with 16-byte keys and 128-byte values). When the cached records are loaded to the controller during snapshot generation, some cached records may be updated under the write-back policy. The final snapshot will become inconsistent with the in-switch cache state at the snapshot point. Blocking cache updates during snapshot generation can avoid such inconsistencies, yet it also degrades the I/O performance.

Our snapshot generation algorithm. We propose a two-phase snapshot generation algorithm for FarReach to maintain crash consistency in snapshot generation, without blocking cache updates. Our insight is that whenever FarReach receives the first write request to a cached record during snapshot generation, it can send the original cached record (i.e., after the snapshot point but before the first write) to the controller. This allows the controller to keep the backups for all original cached records that are to be overwritten. At the end of snapshot generation, the controller replaces the overwritten cached records by their backups of the original cached records, so that the snapshot is crash-consistent with the in-switch cache state at the snapshot point. Under the skewed write-intensive workloads where most writes are issued to a small fraction of hot records, FarReach only needs to send limited original cached records to the controller (without the need to send the cached record for the subsequent writes after the first write). Thus, the bandwidth overhead in the controller is limited.

Based on the insight, FarReach generates a crash-consistent snapshot in a two-phase manner (i.e., triggering snapshot gen-

eration and making a consistent snapshot) at each snapshot point, as shown in Figure 6. In the first phase, the controller notifies the in-switch cache to trigger snapshot generation (① in Figure 6). The cache monitors each traversed write request to identify whether the write request is the first write to a cached record during snapshot generation. If so, the cache sends the original cached record to the controller (② in Figure 6). In the second phase, the controller loads all cached records from the cache for snapshot generation (③ in Figure 6). Note that if a cached record has been loaded to the controller and later receives the first write, the cache no longer needs to send the original cached record, which has already been loaded. Once the controller loads all cached records, it notifies the cache about the completion of snapshot generation (i.e., the cache no longer needs to monitor the writes to cached records), reverts any overwritten cached record with the original one, and finally obtains a crash-consistent snapshot.

FarReach carefully updates the snapshot to address two corner cases. If a new record is first admitted to the cache after the snapshot point, the controller will not include the record into the snapshot. If a cached record is evicted after the snapshot point, the controller saves the evicted record during cache eviction (§3.3), and replaces the updated record with the evicted record in the snapshot after the second phase of snapshot generation.

Atomic triggering of snapshot generation. As the write requests of a record can arrive from multiple ingress pipelines, FarReach needs to trigger snapshot generation in multiple pipelines at the same time; otherwise, the ingress pipelines may set a snapshot point at different times and generate inconsistent snapshots. We propose a coordination mechanism to support simultaneous snapshot generation in multiple ingress pipelines. Specifically, FarReach selects one of the ingress pipelines, and recirculates all write requests from other ingress pipelines to the selected ingress pipeline; in other words, all write requests are processed as if they arrive at a single ingress pipeline. The controller first notifies the selected ingress pipeline to trigger snapshot generation, such that the selected ingress pipeline notifies the egress pipelines to send any original cached record that receives the first write to the controller. It then notifies the remaining ingress pipelines to trigger snapshot generation. After all ingress pipelines trigger snapshot generation, FarReach disables the recirculation, and now the controller can perform snapshot generation with all ingress pipelines in parallel. Thus, we ensure that snapshot generation is applied to all ingress pipelines at the same snapshot point. Note that the recirculation overhead is limited, due to the short duration for notifying all ingress pipelines to trigger snapshot generation (e.g., $\approx$6 ms from our evaluation).

Zero-loss crash recovery. Our snapshot generation only guarantees crash consistency for switch failures, but the cached records that are newly added or updated after the latest snapshot point remain unprotected and can be lost during a switch failure. Unfortunately, switches do not have external storage for keeping cached records reliably. To achieve zero-loss crash recovery, we propose *client-side record preservation* based on the idea of upstream backup [18] in stream processing, by keeping the copies of cached records after the latest snapshot point on the client side. Specifically, after a client sends a write request of a cached key and receives the response from the in-switch cache, it keeps locally the value and sequence number assigned by the in-switch cache (§3.3) for the cached key. After the completion of snapshot generation at each snapshot point, the controller notifies each client with the cached keys and the corresponding sequence numbers at the snapshot point. Each client then releases its preserved records whose sequence numbers are no larger than those notified by the controller. Since the in-switch cache only keeps a limited number of hot records, FarReach incurs low client-side overhead for record preservation.

FarReach exploits a *replay-based approach* to achieve zero-loss crash recovery after a switch failure. It first replays the write requests of the latest cached records to update the servers for persistent storage. Specifically, FarReach collects both the latest in-switch snapshot (from the controller) and the client-side preserved records (from all clients), and selects the record with the largest sequence number for each cached key. If the sequence number of each selected record is larger than that stored in a server, FarReach replays the write request to store the selected record in the server for persistent storage. After all latest records are persisted, the clients can then release their preserved records.

FarReach next recovers the in-switch cache, by replaying the cache admission for each record of the latest in-switch snapshot, and marks each cached record as "outdated". The "outdated" records of the in-switch cache are expected to be quickly marked as "latest" under skewed write-intensive workloads (§3.2). Note that we do not simply start with an empty in-switch cache from scratch, as it incurs large overhead to admit all records through the controller.

Client crashes. One limitation of FarReach is that data loss can occur if both a client and the switch crash simultaneously. If any client crashes before replay-based recovery, the cached records preserved by the client, which are not yet protected by the latest in-switch snapshot, will be lost after a switch failure. We can reduce the snapshot period to a smaller window for less vulnerability, at the expense of incurring larger snapshot generation overhead. Nevertheless, the snapshot generation overhead remains still limited (e.g., up to 1.41 MiB/s of control-plane bandwidth when the snapshot period is 2.5 s; see §5.4). We leave how to completely prevent data loss from client crashes as future work.

3.5 Discussion

Novelty. While FarReach borrows ideas from NetCache [20] (e.g., cache admission based on a Count-Min Sketch), it has other novel design elements: (i) non-blocking cache admission for fast access, with atomic validity control to address

the atomicity issue (§3.2); (ii) available cache eviction for the availability of records, with record embedding to handle packet loss (§3.3); and (iii) crash-consistent snapshot generation with zero-loss recovery (§3.4). Note that the last two elements are tailored for write-back caching and are not found in NetCache for write-through caching.

Trade-offs. FarReach makes two trade-offs in its design. First, FarReach trades extra switch resources for in-switch caching for higher key-value storage performance under skewed write-intensive workloads, yet we show that the extra switch resource usage of FarReach for supporting the write-back policy is similar to that of NetCache (§5.5). Second, FarReach trades extra client-side storage capacity for zero-loss recovery. Nevertheless, since the clients only keep the copies of cached records after the latest in-switch snapshot, the client-side storage overhead is limited (e.g., 1.5 MB for 10K cached records with 16-byte keys and 128-byte values).

Future work. We pose two open issues as future work. First, in addition to reducing vulnerability window from client crashes (§3.4), FarReach should collect the preserved records from all clients during crash recovery, and it may limit scalability as the number of clients increases. One possible solution is to extend FarReach with multiple switches and partition clients among them, such that FarReach can collect the preserved records through multiple switches in parallel. Second, FarReach offloads cache management (including cache admission and eviction) to a centralized controller, which may be overwhelmed by extensive cache admission and eviction decisions. One possible solution is to rate-limit admission and eviction operations to avoid overloading the control plane.

4 Implementation

We prototyped FarReach with both the control and data planes. The control plane includes the switch OS and the controller, while the data plane includes multiple clients and servers as well as the in-switch cache. All communications among different components are based on UDP with a timeout-and-retry mechanism for low-latency yet reliable transmissions.

4.1 Control Plane

We implement both the switch OS and the controller in C++, with 2.2K and 1K LoC, respectively, and compile the programs by `g++` (v5.4.0) with the `-O3` optimization. The switch OS provides interfaces for: (i) cache admission/eviction by configuring match-action tables and setting registers, and (ii) snapshot generation by loading in-switch records and sending original cached records. The controller manages the in-switch cache through the interfaces provided by the switch OS and coordinates snapshot generation by communicating with the switch OS and all key-value storage servers.

4.2 Data Plane

Client implementation. We evaluate our prototype with the YCSB benchmark [42] (§5), which is written in Java. We implement a client application in Java that supports YCSB, with the common key-value storage interfaces including `get`, `put`, and `delete` to access records stored in both the in-switch cache and key-value storage servers. The client application also provides a shim layer to manage client-side record preservation for zero-loss recovery under switch failures (§3.4).

Server implementation. We deploy RocksDB (v6.22.1) [37] in each server; RocksDB is a log-structured merge-tree (LSM-tree) persistent key-value store [34] that is suitable for write-intensive workloads. To support multiple servers, we distribute records across servers using consistent hashing [22].

In-switch cache. We implement the in-switch cache in P4 [4] and compile it into the Tofino switch chipset [39]. The cache implementation includes both ingress and egress pipelines. In each ingress/egress pipeline, the Tofino switch provides 12 stages for pipeline programming. Each stage has 4 stateful ALUs to support at most 4 register arrays, and each register can store 4 bytes of data.

In each ingress pipeline, we deploy multiple match-action tables for egress processing. We implement a match-action table for cache lookup, which matches the key (currently of size 16 bytes) in the packet header to obtain the record location in the egress pipeline. We also deploy a match-action table to trigger snapshot generation, such that each egress pipeline can send the original cached records to the controller (§3.4). As the Tofino switch currently does not support cross-pipeline recirculation, we connect the selected ingress pipeline with each of the other ingress pipelines with a physical wire, so as to recirculate the write requests from the other ingress pipelines to the selected ingress pipeline during snapshot generation in the multi-pipeline setting (§3.4). Furthermore, we pre-compute the hash results for the Count-Min Sketch in the ingress pipeline and send them to the egress pipeline by each packet header, so as to save the stages in the egress pipelines.

In each egress pipeline, we store the statistics, metadata, and cached values. In the first stage, we deploy a Count-Min Sketch and configure it with 4 rows as suggested in [20]. Each row corresponds to a register array with 64K registers. We use part of the second stage to maintain a counter array (as a register array) to track the access frequencies of cached records (§3.2). To support write-back caching and snapshot generation, we use the remaining part of the second stage and the third and fourth stages to maintain the required metadata. We use the remaining 8 (out of 12) stages to provide 32 register arrays of 4-byte registers in total for supporting a value size of up to 128 bytes.

We need to address two subtle issues in the egress pipeline implementation. First, to support write-back caching, the in-switch cache needs to directly respond to a write request with a cache hit. However, the Tofino switch cannot directly change the egress port in the egress pipeline. Thus, we drop the original write request and send a response to the client by cloning. Second, to assign a sequence number for each write request, we can maintain a global counter to track the latest

sequence number, but this easily leads to overflow. Instead, we use multiple global counters to reduce the likelihood of overflow. Specifically, we maintain a register array with 32K registers. We map the write requests of different keys into different registers by hashing, and then increment the hashed register to assign a sequence number for each write request.

5 Evaluation

5.1 Methodology

Testbed. We conduct evaluation on a testbed composed of a 3.2 Tbps two-pipeline Tofino switch [39] and four physical machines. Each machine has four 12-core CPUs (Intel E5-2650 v4), 64 GiB DRAM, and 2 TB hard disk (HGST Ultrastar), and is connected with the switch by a 40 Gbps NIC (Intel XL710). We use two physical machines as clients and another two as key-value storage servers. We connect one client and one server with one pipeline of the switch, and connect the other machines with another pipeline.

Setup. We evaluate FarReach using both YCSB [42] and synthetic workloads (see §5.2 and §5.3, respectively). Since our testbed comprises only two servers, we exploit server rotation [20] to simulate a much larger number of servers. Specifically, let N be the number of simulated servers. Given a workload, we issue the requests to N logical partitions via consistent hashing [22] (§4). We find the partition (called the *bottleneck partition*) that receives the most requests among all N partitions. We run each experiment over N iterations. In the first iteration, we deploy the bottleneck partition in a physical server and send sufficient requests to saturate the bottleneck to measure its performance. In the subsequent $N-1$ iterations, we deploy the bottleneck partition in a physical server and each of the $N-1$ non-bottleneck partitions in another physical server, and measure the performance of the non-bottleneck partition. After N iterations, we add all per-partition performance to obtain the aggregate performance. By default, we simulate 16 servers, and increase the number of simulated servers for scalability evaluation (Exp#3). Note that server rotation is only applied to static workloads without the dynamics in key popularity, and we also study the impact of dynamic workloads (Exp#7).

We compare FarReach against two baselines: NoCache (i.e., no in-switch caching) and NetCache [20] (i.e., the in-switch cache that implements write-through caching). Before each experiment, we pre-load 100M records, each of which contains a 16-byte key and 128-byte value, into each server that is initially empty. For FarReach and NetCache, we fix the in-switch cache size as 10,000 records and pre-load the hottest records into the cache. We also set the sampling rate as 0.5 and the pre-defined threshold as 20 requests for the Count-Min Sketch. For FarReach, we set the snapshot period as 10 s by default. We run all experiments with 5 times, and plot the average results with the 95% confidence levels based on the Student's t-distribution.

Summary of results. We summarize the results as follows:

- Under YCSB workloads, FarReach increases the I/O throughput by up to 91% and 84% (for workload A with 50% reads and 50% writes) compared with NoCache and NetCache, respectively (Exp#1). FarReach also achieves sub-RTT latency with up to 72% reduction of average latency (Exp#2) and scales to an increasing number of servers with up to 6.6× throughput gain (Exp#3).
- Under synthetic workloads, FarReach achieves higher throughput gains over NoCache and NetCache for more write-intensive and more skewed workloads (Exp#4 and Exp#5, respectively), while maintaining similar throughput gains for different value sizes and dynamic workloads (Exp#6 and Exp#7, respectively).
- FarReach's snapshot generation incurs limited overhead on throughput and control-plane bandwidth (Exp#8). Its recovery time is within 2.35 s (Exp#9).
- FarReach incurs similar switch resource overhead as NetCache (Exp#10).

5.2 Performance under YCSB Workloads

(Exp#1) Throughput analysis. We first evaluate the end-to-end throughput using YCSB workloads, namely Load (inserting records), A (50% reads, 50% writes), B (95% reads, 5% writes), C (100% reads), D (95% reads, 5% writes), and F (50% reads, 50% read-modify-writes); we do not consider range queries (i.e., Workload E) due to switch limitations (§3.1). For each workload, we generate requests with 16-byte keys and 128-byte values. The Load workload follows the uniform distribution, workload D follows the read-latest distribution, and workloads A, B, C, and F are skewed and follow the Zipf distribution with the Zipfian constant 0.99 (default in YCSB). We verify that under NoCache, the load throughput to a RocksDB instance can reach 0.06 MOPS, which is consistent with prior findings [2, 35].

Figure 7 shows that FarReach increases the throughput of NoCache by 91%, 55%, 85%, and 72% in the four skewed workloads A, B, C, and F, respectively, by reducing and balancing the server-side load with in-switch write-back caching. FarReach also increases the throughput of NetCache by 84%, 20%, and 61% in workloads A, B, and F, and achieves similar throughput as NetCache in workload C (which is read-intensive). In NetCache, the writes of the cached keys keep invalidating the in-switch write-through cache, especially in write-intensive workloads A and F, and hence limit the throughput of NetCache. NetCache only achieves high throughput in read-intensive workloads B and C. In the non-skewed workloads Load and D, both FarReach and NetCache have similar throughput as NoCache due to limited cache hits.

(Exp#2) Latency analysis. We next evaluate the request latencies. We focus on YCSB workload A, which is skewed and most write-intensive. In particular, we examine the trade-off between the latency and target throughput (i.e., configured by a given sending rate) as in prior studies [8, 12, 20]. We

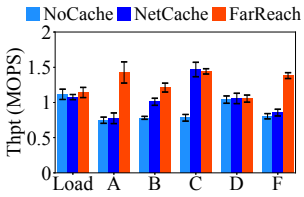

Figure 7: (Exp#1) Throughput analysis.

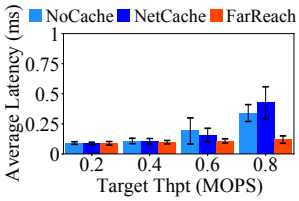

Figure 8: (Exp#2) Latency analysis.

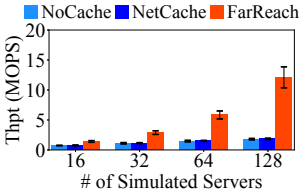

Figure 9: (Exp#3) Scalability analysis.

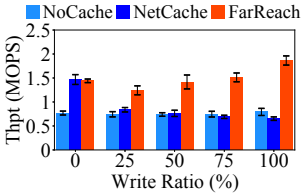

Figure 10: (Exp#4) Impact of write ratio.

only show the average latency results, while the results of other latency statistics (e.g., medium and 95th-percentile) are similar and hence omitted for brevity.

Figure 8 shows that all schemes have small average latencies under low target throughput, as the servers do not have heavy loads and can quickly process requests. FarReach reduces the average latencies of NoCache and NetCache by 65% and 72% when the target throughput is 0.8 MOPS, respectively. For high target throughput, both NoCache and NetCache are bottlenecked by an overloaded server and hence incur large queuing delays. NetCache has a larger latency than NoCache, as NetCache needs extra server-side overhead to update the in-switch write-through cache for the write requests. FarReach effectively reduces and balances the server-side load and hence achieves a small latency. Note that NoCache and NetCache show larger confidence intervals than FarReach, especially for high target throughput. The reason is that the server-side queuing latency can vary significantly for highly overloaded bottleneck server across different runs, while FarReach maintains a low latency due to load balancing.

(Exp#3) Scalability analysis. We evaluate the scalability of different schemes by varying the number of simulated servers. We focus on YCSB workload A. Figure 9 shows that the throughput gains of FarReach are 1.9×, 2.5×, 3.9×, and 6.6× those of NoCache and NetCache (both of which have very similar throughput) under 16, 32, 64, and 128 servers, respectively. As the number of simulated servers increases, the throughput of FarReach also increases due to load balancing across all servers, while the throughput of both NoCache and NetCache is limited by the overloaded servers due to load imbalance. Our results show that FarReach scales to a large number of servers under skewed write-intensive workloads.

5.3 Performance under Synthetic Workloads

We generate different synthetic workloads with YCSB for varying write ratios (over all reads and writes), key distributions, value sizes, key popularities. By default, we generate requests with 16-byte keys and 128-byte values, where the keys follow the Zipf distribution with the Zipfian constant 0.99, and set the write ratio as 100% (i.e., write-only requests).

(Exp#4) Impact of write ratio. We first vary the write ratio of the synthetic workload to evaluate the throughput of different schemes. Figure 10 shows that FarReach increases the throughput of NoCache by 67-135% for different write ratios,

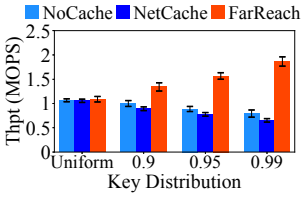

Figure 11: (Exp#5) Impact of key distribution.

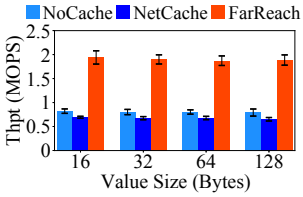

Figure 12: (Exp#6) Impact of value size.

due to load balancing in FarReach. FarReach achieves similar throughput as NetCache when the write ratio is zero (i.e., read-only requests), while increasing the throughput of NetCache by 48-186% as the write ratio ranges from 25% to 100%. The throughput gain of FarReach over NoCache and NetCache is the highest when the write ratio is 100% through in-switch write-back caching. Note that NetCache has slightly smaller throughput than NoCache, especially under the write ratio of 100%, due to the extra server-side overhead to maintain cache coherence for write requests.

(Exp#5) Impact of key distribution. We next consider synthetic workloads under the uniform key distribution as well as the Zipfian key distributions with different Zipf constants. Figure 11 shows that all schemes achieve similar throughput of ≈1 MOPS under the uniform key distribution, as most requests are from the uncached keys and will be processed by the servers, so FarReach cannot benefit from in-switch write-back caching. For the skewed workloads, FarReach increases the throughput of NoCache by 34-135% and that of NetCache by 50-186%. The throughput gain of FarReach is higher when the workload is more skewed (i.e., a larger Zipfian constant), as NoCache and NetCache becomes more imbalanced.

(Exp#6) Impact of value size. We further vary the value size of the synthetic workload from 16 bytes to 128 bytes (while the key size remains 16 bytes); note that the number of records that can be cached in both NetCache and FarReach (i.e., 10,000 records) remains unchanged. Figure 12 shows that the throughput gains of FarReach over NoCache and NetCache remain almost the same at 2.33× across different value sizes, as the caching behavior of FarReach mainly depends on the key distribution.

We also evaluate all schemes when the value size increases to 256 bytes (i.e., exceeding the maximum value size of 128 bytes). All schemes achieve similar throughput of ≈0.7 MOPS (not shown in a figure), as both NetCache and

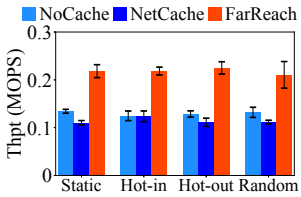

Figure 13: (Exp#7) Impact of key popularity changes.

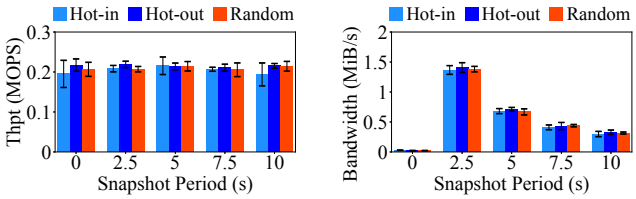

Figure 14: (Exp#8) Performance of snapshot generation, in terms of throughput (left) and control-plane bandwidth (right).

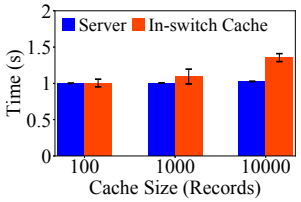

Figure 15: (Exp#9) Crash recovery time.

FarReach directly forward all records to the servers and have similar behavior as NoCache.

(Exp#7) Impact of key popularity changes. Finally, we consider dynamic key popularity patterns, in which the access frequency of a specific key may change over time, while the previous experiments thus far focus on a static key popularity pattern. We consider three dynamic patterns as used in prior work [20, 27]: (i) *hot-in*, which periodically moves the 200 coldest keys to the highest key popularity ranks and decreases the ranks of other keys accordingly; (ii) *hot-out*, which periodically moves the 200 hottest keys to the lowest key popularity ranks and increases the ranks of other keys accordingly; and (iii) *random*, which randomly replaces 200 keys of the top 10,000 hottest keys with coldest keys. As the dynamic patterns will trigger cache management decisions and hence change the system state, we cannot simulate multiple servers by server rotations as in prior experiments. Instead, we evaluate the performance on the two physical servers, each of which runs a RocksDB instance. For each dynamic pattern, we run each scheme for 70 s, and change the key popularity ranks based on each dynamic pattern every 10 s. We measure the instantaneous throughput every 1 s, and evaluate the average throughput over the entire 70 s.

Figure 13 shows that FarReach increases the average throughput of NoCache and NetCache by at least 59% under different dynamic patterns. We also run each scheme for 70 s without any key popularity change (i.e, static), and FarReach has similar throughput gains as in the dynamic patterns. The reason is that FarReach quickly reacts to the key popularity changes (typically within 1 s from our measurement), so it maintains the cache hit rate and hence the average throughput. Note that the throughput is smaller than that in prior experiments as we now use fewer servers, yet our emphasis here is to examine the adaptiveness of FarReach to key popularity changes rather than the absolute performance.

5.4 Snapshot Generation and Crash Recovery

(Exp#8) Performance of snapshot generation. We vary the period of snapshot generation to evaluate the throughput and control-plane bandwidth of FarReach on synthetic workloads. We focus on the results under dynamic patterns, in which the bandwidth costs of both snapshot generation and cache management are included, while we observe similar results under the static pattern and they are omitted for brevity.

Figure 14 shows both the throughput and control-plane bandwidth of FarReach versus the snapshot period; note that if the snapshot period is zero, it means that snapshot generation is disabled. FarReach keeps its throughput at about 0.2 MOPS for various snapshot periods under different dynamic patterns, implying that snapshot generation has a limited impact on throughput.

When snapshot generation is disabled (i.e., the snapshot period is zero), FarReach only incurs about 0.03 MiB/s of control-plane bandwidth, since it only triggers cache management decisions for new hot records and avoids sending duplicate records to the controller (§3.2). When snapshot generation is enabled and as the snapshot period increases from 2.5 s to 10 s, the control-plane bandwidth of FarReach decreases from 1.41 MiB/s to 0.33 MiB/s. Note that the control-plane bandwidth of FarReach is far smaller than the maximum bandwidth of the controller (i.e., 40 Gbps).

(Exp#9) Crash recovery time. We evaluate the crash recovery time of FarReach under a switch failure for various in-switch cache sizes. Specifically, for a given in-switch cache size, we first run the synthetic workload under the static pattern with 16 servers simulated by server rotations. We manually kill the in-switch cache and the switch OS to mimic a switch failure. We then trigger zero-loss crash recovery (§3.4), which applies a replay-based approach to update the servers and recover the in-switch cache. For multiple servers, we take the average time of updating a server as the server-side recovery time.

Figure 15 shows that the time of updating a server in FarReach stays at about 1 s as the cache size increases, as FarReach only replays a limited number of writes partitioned in each server, while taking the majority of time to collect client-side preserved records and control-plane in-switch snapshot. The time to recover the in-switch cache in FarReach increases from 1 s to 1.35 s as the cache size increases from 100 records to 10,000 records, as FarReach needs to admit more records from the latest snapshot under a larger cache size. Overall, the crash recovery time is within 2.35 s for various in-switch cache sizes.

5.5 Switch Deployment

(Exp#10) Switch resource usage. We compile the three schemes into the same Tofino switch chipset [39] to evaluate the switch resource usage. We focus on the following

Table 2: (Exp#10) Switch resource usage (percentages in brackets are fractions of total resource usage).

	SRAM (KiB)	# stages	# actions	# ALUs	PHV size (bytes)
NoCache	320 (2.08%)	4 (33.33%)	6 (nil)	0 (0%)	134 (17.45%)
NetCache	8800 (57.29%)	12 (100%)	69 (nil)	45 (93.75%)	528 (68.75%)
FarReach	8992 (58.54%)	12 (100%)	70 (nil)	45 (93.75%)	499 (64.97%)

metrics: SRAM consumption (with up to 768 KiB for stateful information and 512 KiB for match-action tables per stage), the numbers of stages (12 stages in total), actions, and ALUs (at most 4 stateful ALUs per stage) for in-switch computation, and the packet header vector (PHV) size (768 bytes in total) for cross-stage communication.

Table 2 shows the results. NoCache has the smallest hardware resource usage, as it only needs to support basic network functions (e.g., L2/L3 forwarding). NetCache and FarReach have similar switch resource usage, as both of them deploy an in-switch cache that consumes SRAM to track stateful information (e.g., key-value records and cache metadata). Also, both schemes maintain SRAM-based match-action tables, exploit the stages, actions, and ALUs to perform in-switch computations (e.g., cache lookups and updates), and use the PHV size to transmit each request across different stages.

6 Related Work

In-switch caching and storage management. Several in-switch caching designs have been proposed for high-performance storage. SwitchKV [27] caches hot keys in a software switch, which forwards the reads of cached keys to the in-memory cache nodes, instead of servers, for accessing the values. IncBricks [28] caches records in general-purpose network accelerators and implements packet parsing in programmable switches to serve the reads of cached keys. NetCache [20] implements a packet processing pipeline for an in-switch read cache based on switch ASICs. DistCache [29] implements distributed in-network caching across multiple racks. The above studies target only read-intensive workloads with write-through caching, which incurs significant overhead under write-intensive workloads (§5). PKache [15] implements in-switch caching with limited associativity and provides a general framework with different cache management policies, yet it does not address write-back caching.

Aside from caching, some studies use programmable switches for efficient storage management. AppSwitch [9] offloads hash-based routing to software switches, and its control plane dynamically updates the routing rules based on server loads for load balancing. NetChain [19] stores records in programmable switches for the coordination of the switch-based chain replication model. TurboKV [13] and Pegasus [26] keep in-switch directory information to speed up the replication protocol of in-memory key-value stores. Concordia [40] tracks the locations of host-side cache copies in programmable switches for efficient cache coherence. Mind [24] maintains in-switch memory management (e.g., address translation and cache coherence) for efficient and transparent rack-scale memory disaggregation. Such systems do not consider in-switch caching for server-side key-value storage.

Write-back caching. Prior studies propose write-back caching policies. DEFER [32] improves the reliability of write-back caching by replication and logging. FlashTier [38] deploys a write-back flash cache and ensures consistency by storing both cached data and mapping details durably in flash. Some studies propose write-back caching policies with different reliability guarantees. Examples include: (i) ordered and journaled policies [23] that provide point-in-time consistency, (ii) write-back flush and persist policies [36] that use write barriers for durable and consistent caching, and (iii) client-side buffered write policies [16] that ensure durability by replication with read-after-write consistency guarantees. However, programmable switches have restricted programming requirements and limited hardware resources for implementing such policies. How to enable new write-back caching policies with stronger reliability guarantees is our future work.

7 Conclusion

FarReach is a fast, available, and reliable in-switch write-back caching framework for load-balanced key-value stores in modern data centers under skewed write-intensive workloads. It incorporates new co-designs of control and data planes for cache admission and eviction under a write-back policy. In particular, FarReach pays special attention to crash-consistent snapshot generation and zero-loss crash recovery, so as to protect against data loss under switch failures. Evaluation under YCSB and synthetic workloads demonstrates the performance benefits of FarReach under skewed write-intensive workloads.

CXL-ANNS: Software-Hardware Collaborative Memory Disaggregation and Computation for Billion-Scale Approximate Nearest Neighbor Search

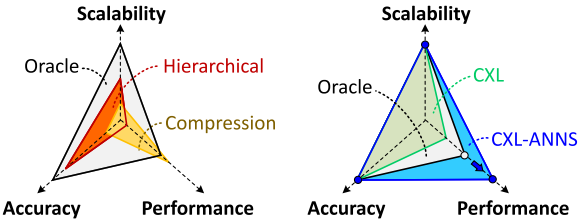
Abstract

We propose *CXL-ANNS*, a software-hardware collaborative approach to enable highly scalable approximate nearest neighbor search (ANNS) services. To this end, we first disaggregate DRAM from the host via compute express link (CXL) and place all essential datasets into its memory pool. While this CXL memory pool can make ANNS feasible to handle billion-point graphs without an accuracy loss, we observe that the search performance significantly degrades because of CXL's far-memory-like characteristics. To address this, CXL-ANNS considers the node-level relationship and caches the neighbors in local memory, which are expected to visit most frequently. For the uncached nodes, CXL-ANNS prefetches a set of nodes most likely to visit soon by understanding the graph traversing behaviors of ANNS. CXL-ANNS is also aware of the architectural structures of the CXL interconnect network and lets different hardware components therein collaboratively search for nearest neighbors in parallel. To improve the performance further, it relaxes the execution dependency of neighbor search tasks and maximizes the degree of search parallelism by fully utilizing all hardware in the CXL network.

Our empirical evaluation results show that CXL-ANNS exhibits 111.1× higher QPS with 93.3% lower query latency than state-of-the-art ANNS platforms that we tested. CXL-ANNS also outperforms an oracle ANNS system that has DRAM-only (with unlimited storage capacity) by 68.0% and 3.8×, in terms of latency and throughput, respectively.

1 Introduction

Dense retrieval (also known as nearest neighbor search) has taken on an important role and provides fundamental support for various search engines, data mining, databases, and machine learning applications such as recommendation systems [1–8]. In contrast to the classic pattern/string-based search, dense retrieval compares the similarity across different objects using their distance and retrieves a given number of objects, similar to the query object, referred to as *k*-nearest neighbor (*kNN*) [9–11]. To this end, dense retrieval embeds input information into a few thousand dimensional spaces of each object, called a feature *vector*. Since these vectors can encode a wide spectrum of data formats (e.g., images, documents, sounds, etc.), dense retrieval understands an input query's semantics, resulting in more context-aware and accurate results than traditional search [6, 12, 13].



(a) Previous studies. (b) CXL-based approaches.

Figure 1: Various billion-scale ANNS characterizations.

Even though kNN is one of the most frequently used search paradigms in various applications, it is a costly operation taking linear time to scan data [14, 15]. This computation complexity unfortunately makes dense retrieval with a billion-point dataset infeasible. To make the kNN search more practical, *approximate nearest neighbor search* (ANNS) restricts a query vector to search only a subset of neighbors with a high chance of being the nearest ones [15–17]. ANNS exhibits good vector searching speed and accuracy, but it significantly increases memory requirement and pressure. For example, many production-level recommendation systems already adopt billion-point datasets, which require tens of TB of working memory space for ANNS; Microsoft search engines (used in Bing/Outlook) require 100B+ vectors, each being explained by 100 dimensions, which consume more than 40TB memory space [18]. Similarly, several of Alibaba's e-commerce platforms need TB-scale memory spaces to accommodate their 2B+ vectors (128 dimensions) [19].

To address these memory pressure issues, modern ANNS techniques leverage lossy compression methods or employ persistent storage, such as solid state disks (SSDs) and persistent memory (PMEM), for their memory expansion. For example, [20–23] split large datasets and group them into multiple clusters in an offline time. This compression approach only has product quantized vectors for each cluster's centroid and searches kNN based on the quantized information, making billion-scale ANNS feasible. On the other hand, the hierarchical approach [24–28] accommodates the datasets to SSD/PMEM, but reduces target search spaces by referring to a summary in its local memory (DRAM). As shown in Figure 1a, these compression and hierarchical approaches can achieve the best kNN search performance and scalabil-

ity similar to or slightly worse than what an *oracle*[1] system offers. However, these approaches suffer from a lack of accuracy and/or performance, which unfortunately hinders their practicality in achieving billion-scale ANNS services.

In this work, we propose *CXL-ANNS*, a software-hardware collaborative approach that enables scalable approximate nearest neighbor search (ANNS). As shown in Figure 1b, the main goal of CXL-ANNS is to offer the latency of billion-point kNN search even shorter than the oracle system mentioned above while achieving high throughput without a loss of accuracy. To this end, we disaggregate DRAM from the host resources via compute express link (CXL) and place all essential datasets into its memory pool; CXL is an open-industry interconnect technology that allows the underlying working memory to be highly scalable and composable with a low cost. Since a CXL network can expand its memory capacity by having more *endpoint devices* (EPs) in a scalable manner, a host's *root-complex* (RC) can map the network's large memory pool (up to 4PB) into its system memory space and use it just like a locally-attached conventional DRAM.

While this CXL memory pool can make ANNS feasible to handle billion-point graphs without a loss of accuracy, we observe that the search performance degrades compared to the oracle by as high as 3.9× (§3.1). This is due to CXL's far-memory-like characteristics; every memory request needs a CXL protocol conversion (from CPU instructions to one or more CXL flits), which takes a time similar to or longer than a DRAM access itself. To address this, we consider the relationship of different nodes in a given graph and cache the neighbors in the local memory, which are expected to visit frequently. For the uncached nodes, CXL-ANNS prefetches a set of nodes most likely to be touched soon by understanding the unique behaviors of the ANNS graph traversing algorithm. CXL-ANNS is also aware of the architectural structures of the CXL interconnect network and allows different hardware components therein to simultaneously search for nearest neighbors in a collaborative manner. To improve the performance further, we relax the execution dependency in the KNN search and maximize the degree of search parallelism by fully utilizing all our hardware in the CXL network.

We summarize the main contribution as follows:

• *Relationship-aware graph caching.* Since ANNS traverses a given graph from its entry-node [10, 19], we observe that the graph data accesses, associated with the innermost edge hops, account for most of the point accesses (§3.2). Inspired by this, we selectively locate the graph and feature vectors in different places of the CXL memory network. Specifically, CXL-ANNS allocates the node information closer to the entry node in the locally-attached DRAMs while placing the other datasets in the CXL memory pool.

• *Hiding the latency of CXL memory pool.* If it needs to traverse (uncached) outer nodes, CXL-ANNS prefetches the datasets of neighbors, most likely to be processed in the next step of kNN queries from the CXL memory pool. However, it is non-trivial to figure out which node will be the next to visit because of ANNS's procedural data processing dependency. We propose a simple foreseeing technique that exploits a unique graph traversing characteristic of ANNS and prefetches the next neighbor's dataset during the current kNN candidate update phase.

• *Collaborative kNN search design in CXL.* CXL-ANNS significantly reduces the time wasted for transferring the feature vectors back and forth by designing EP controllers to calculate distances. On the other hand, it utilizes the computation power of the CXL host for non-beneficial operations in processing data near memory (e.g., graph traverse and candidate update). This collaborative search includes an efficient design of RC-EP interfaces and a sharding method being aware of the hardware configurations of the CXL memory pool.

• *Dependency relaxation and scheduling.* The computation sequences of ANNS are all connected in a serial order, which makes them unfortunately dependent on execution. We examine all the activities of kNN query requests and classify them into urgent/deferrable subtasks. CXL-ANNS then relaxes the dependency of ANN computation sequences and schedules their subtasks in a finer granular manner.

We validate all the functionalities of CXL-ANNS's software and hardware (including the CXL memory pool) by prototyping them using Linux 5.15.36 and 16nm FPGA, respectively. To explore the full design spaces of ANNS, we also implement the hardware-validated CXL-ANNS in gem5 [29] and perform full-system simulations using six billion-point datasets [30]. Our evaluation results show that CXL-ANNS exhibits 111.1× higher bandwidth (QPS) with 93.3% lower query latency, compared to the state-of-the-art billion-scale ANNS methods [20, 24, 25]. The latency and throughput behaviors of CXL-ANNS are even better than those of the oracle system (DRAM-only) by 68.0% and 3.8×, respectively.

2 Background

2.1 Approximate Nearest Neighbor Search

The most accurate method to get k-nearest neighbors (kNN) in a graph is to compare an input query vector with all data vectors in a brute-force manner [9, 31]. Obviously, this simple dense retrieval technique is impractical mainly due to its time complexity [10, 24]. In contrast, approximate nearest neighbor search (ANNS) restricts the query vector to retrieve only a subset of neighbors that can be kNN with a high probability. To meet diverse accuracy and performance requirements, several ANNS algorithms such as tree-structure based [32, 33], hashing based [11, 34, 35] and quantization based approaches [20–23] have been proposed over the past decades. Among the various techniques, ANNS algorithms using graphs [10, 19, 24] are considered as the most promising

[1] In this paper, the term "Oracle" refers to a system that utilizes ample DRAM resources with an unrestricted memory capacity.

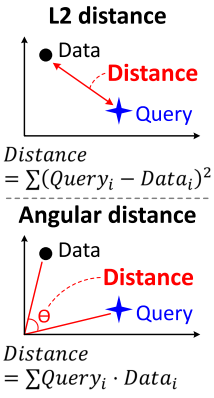


Figure 2: Distance.

Algorithm 1: Best-first Search

Input: *query*,
k := number of nearest neighbor to find

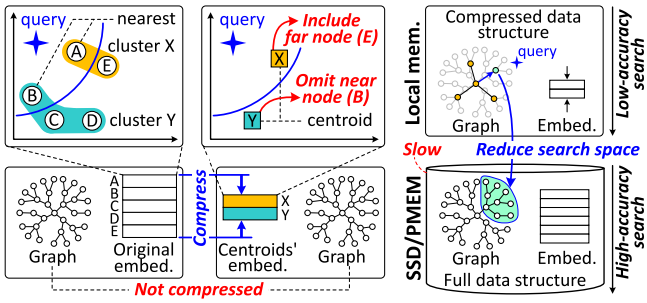
```
1  distance = calcDist(query, startNode)
2  CandidateArr = {startNode, distance}
3  curNode = startNode
4  CandidateArr.markVisited(curNode)
   /* Main iteration (line 5~10) */
5  while !candidateArr.allVisited() do
6      neighbors = Graph.neighbors(curNode)
7      distances = calcDist(query, neighbors)
8      CandidateArr.insert(neighbors, distances)
9      curNode = CandidateArr.getNextNode()
10     CandidateArr.markVisited(curNode)
11 return CandidateArr[: k]
```

solution, with great potential [2]. This is because graph-based approaches can better describe neighbor relationships and traverse fewer points than the other approaches that operate in a Euclidean space [19, 36–39].

Distance calculations. While there are various graph construction algorithms for ANNS [10, 19, 24], the goal of their query search algorithms is all the same or similar to each other; it is simply to find *k* numbers of neighbors in the target graph, which are expected to have the shortest distance from a given feature vector, called *query vector*. There are two most common methods to define such a distance between the query vector and neighbor's feature vector (called *data vector*): i) L2 (Euclidean) distance and ii) angular distance. As shown in Figure 2, these methods map the nodes that we compare into a temporal dimension space using their own vector's feature elements. Let us suppose that there are n numbers of features for each vector. Then, L2 and angular distances are calculated by $\sum_i (Query_i - Data_i)^2$ and $\sum_i (Query_i \cdot Data_i)$, respectively; where $Query_i$ and $Data_i$ are the i^{th} feature of a given query and data vectors, respectively ($i \leq n$). These distance definitions are simplified to reduce their calculation latency, which differs from the actual distances in a multi-dimensional vector space. This simplification works well since ANNS uses the distances only for a relative comparison to search kNN.

Approximate kNN query search. Algorithm 1 explains the graph traversing method that most ANNS employs [10, 19, 24]. The method, best-first search (BFS) [38, 40], traverses from an *entry-node* (line ❸) and moves to neighbors getting closer to the given query vector (lines ❺~❿). While the brute-force search explores a full space of the graph by systematically enumerating all the nodes, ANNS uses a preprocessed graph and visits a limited number of nodes for each hop. The graph is constructed (preprocessed) to have the entry-node that arrives all the nodes of its original graph within the minimum number of average edge hops; this preprocessed graph guarantees that there exists a path between the entry-node and any of the given nodes. To minimize the overhead of graph traverse, BFS employs a *candidate array* that includes the neighbors whose

[2] For the sake of the brevity, we use "graph-based approximate kNN methods" and "ANNS" interchangeably.



(a) Compression-based approach. (b) Hierarchical approach.

Figure 3: Existing billion-scale ANNS methods.

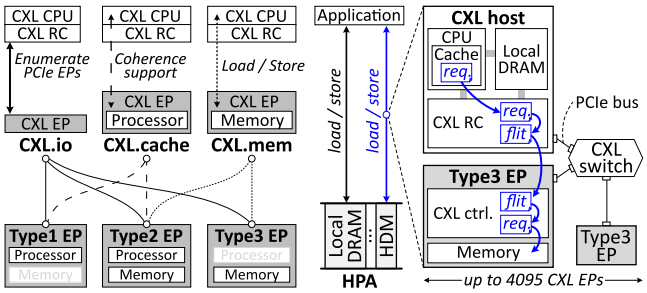
distances (from the query vector) are expected to be shorter than others. For each node visiting, BFS checks this candidate array and retrieves unvisited node from the array (line ❻, ❾). It then calculates the distances of the node's neighbors (line ❼) by retrieving their vectors from the embedding table. After this distance calculation, BFS updates the candidate array with the new information, neighbors and distances (line ❽). All these activities are iterated (line ❺) until there is no unvisited node in the candidate array. BFS finally returns the *k* number of neighbors in the candidate array.

2.2 Towards Billion-scale ANNS

While ANNS can achieve good search speed and reasonable accuracy (as it only visits the nodes in the candidate array), it still requires maintaining all the original graph and vectors in its embedding table. This renders ANNS difficult to have billion-point graphs that exhibit high memory demands in many production-level services [18, 19]. To address this issue, there have been many studies proposed [20–27], but we can classify them into two as shown in Figures 3a and 3b.

Compression approaches. These approaches [20–23] reduce the embedding table by compressing its vectors. As shown in Figure 3a, they logically split the given graph into multiple sub-groups, called *clusters*; the nodes A and E are classified in the cluster X whereas the others are grouped as the cluster Y. For each cluster, these approaches then encode the corresponding vectors into a single, representative vector (called centroid) by averaging all the vectors in the cluster. They then replace all the vectors in the embedding table with their cluster ID. Since the distances are calculated by the compressed centroid vectors (rather than original data vectors), it exhibits a low accuracy for the search. For example, the node E can be selected as one of kNN although the node B sits closer to the query vector. Another issue of these compression approaches is the limited reduction rate in the size of the graph datasets. Since they quantize only the embedding table, their billion-point graph data have no benefit of the compression or even get slightly bigger to add a set of shortcuts into the original graph.

Hierarchical approaches. These approaches [24–27] store all the graph and vectors (embedding table) to the underlying SSD/PMEM (Figure 3b). Since SSD/PMEM are prac-



(a) Types of CXL EP. (b) CXL-based memory pool.

Figure 4: CXL's sub-protocols and endpoint types.

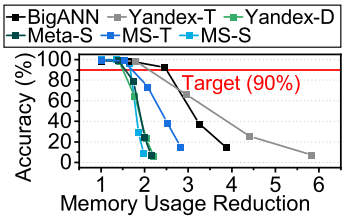


Figure 5: Accuracy.

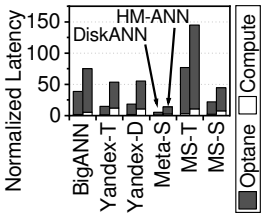

Figure 6: Latency.

tically slower than DRAM by many orders of magnitude, these methods process kNN queries in two separate phases: i) *low-accuracy search* and ii) *high-accuracy search*. The former only refers to compressed or simplified datasets, similar to the datasets that the compression approaches use. The low-accuracy search quickly finds out one or more nearest neighbor candidates (without a storage access) thereby reducing the search space that the latter needs to process. Once it has been completed, the high-accuracy search refers to the original datasets associated with the candidates and processes the actual kNN queries. For example, DiskANN [24] 's low accuracy search finds the kNN candidates using the compressed datasets in DRAM. The high-accuracy search then re-examines and re-ranks the order of kNN candidates by visiting their actual vectors stored in SSD/PMEM. On the other hand, HM-ANN [25] simplifies the target graph by adding several shortcuts (across multiple edge hops) into the graph. HM-ANN's low-accuracy search scans a candidate closer to the given query vector from the simplified graph. Once HM-ANN detects the candidate, the high-accuracy search checks its kNN by referring to all the graph and data vectors recorded in SSD/PMEM.

2.3 Compute Express Link for Memory Pool

CXL is an open standard interconnect which can expand memory over the existing PCIe physical layers in a scalable option [41–43]. As shown in Figure 4a, CXL consists of three sub-protocols: i) *CXL.io*, ii) *CXL.cache*, and iii) *CXL.mem*. Based on which sub-protocols are used for the main communication, CXL EPs can be classified as Types.

Sub-protocols and endpoint types. CXL.io is basically the same as the PCIe standard, which is aimed at enumerating the underlying EPs and performing transaction controls. It is thus used for all the CXL types of EPs to be interconnected to the CXL CPU's root-complex (*RC*) through PCIe. On the other hand, CXL.cache is for an underlying EP to make its states coherent with those of a CXL host CPU, whereas CXL.mem supports simple memory operations (load/store) over PCIe. Type 1 is considered by a co-processor or accelerator that does not have memory exposed to CXL RC while Type 2 employs internal memory, accessible from CXL RC. Thus, Type 1 only uses CXL.cache (in addition to CXL.io), but Type 2 needs to use both CXL.cache and CXL.mem. A potential example of Type 1 and 2 can be FPGAs and GPUs, respectively. On the other hand, Type 3 only uses CXL.mem (read/write), which means that there is no interface for a device-side compute unit to update its calculation results to CXL CPU's RC and/or get a non-memory request from the RC.

CXL endpoint disaggregation. Figure 4b shows how we can disaggregate DRAM from host resources using CXL EPs, in particular, Type 3; we will discuss why Type 3 is the best device type for the design of CXL-ANNS, shortly. Type 3's internal memory is exposed as a *host-managed device memory* (HDM), which can be mapped to the CXL CPU's host physical address (HPA) in the system memory just like DRAM. Therefore, applications running on the CXL CPU can access HDM (EP's internal memory) through conventional memory instructions (loads/stores). Thanks to this characteristic, HDM requests are treated as traditional memory requests in CXL CPU's memory hierarchy; the requests are first cached in CPU cache(s). Once its cache controller evicts a line associated with the address space of HDM, the request goes through to the system's CXL RC. RC then converts one or more memory requests into a CXL packet (called *flit*) that can deal with a request or response of CXL.mem/CXL.cache. RC passes the flit to the target EP using CXL.mem's read or write interfaces. The destination EP's PCIe and CXL controllers take the flit over, convert it to one or more memory requests, and serve the request with the EP's internal memory (HDM).

Type consideration for scaling-out. To expand the memory capacity, the target CXL network can have one or more switches that have multiple ports, each being able to connect a CXL EP. This switch-based network configuration allows an RC to employ many EPs (upto 4K), but only for Type 3. This is because CXL.cache uses virtual addresses for its cache coherence management unlike CXL.mem. As the virtual addresses (brought by CXL flits) are not directly matched with the physical address of each underlying EP's HDM, the CXL switches cannot understand where the exact destination is.

3 A High-level Viewpoint of CXL-ANNS

3.1 Challenge Analysis of Billion-scale ANNS

Memory expansion with compression. While compression methods allow us to have larger datasets, it is not scalable since their quantized data significantly degrades the kNN search accuracy. Figure 5 analyzes the search accuracy of billion-point ANNS that uses the quantization-based com-

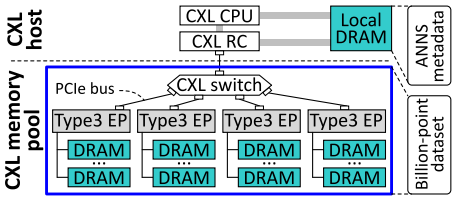

Figure 7: CXL baseline architecture.

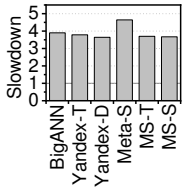

Figure 8: CXL.

pression described in §2.2. In this analysis, it reduces the embedding table by 2×∼16×. We use six billion-point datasets from [30]; the details of these datasets and evaluation environment are the same as what we used in §6.1. As the density of the quantized data vectors varies across different datasets, the compression method exhibits different search accuracies. While the search accuracies are in a reasonable range to service with low compression rates, they significantly drop as the compression rate of the dataset increases. It cannot even reach the threshold accuracy that ANNS needs to support (90%, recommended by [30]) after having 45.8% less data than the original. This unfortunately makes the compression impractical for billion-scale ANNS at high accuracy.

Hierarchical data processing. Hierarchical approaches can overcome this low accuracy issue by adding one more search step to re-rank the results of kNN search. This high-accuracy search however increases the search latency significantly as it eventually requires traversing the storage-side graph and accessing the corresponding data vectors (in storage) entirely. Figure 6 shows the latency behaviors of hierarchical approaches, DiskANN [24] and HM-ANN [25]. In this test, we use 480GB Optane PMEM [44] for DiskANN/HM-ANN and compare their performance with the performance of an oracle ANNS that has DRAM-only (with unlimited storage capacity). One can observe from this figure that the storage accesses of the high-accuracy search account for 87.6% of the total kNN query latency, which makes the search latency of DiskANN and HM-ANN worse than that of the oracle ANNS by 29.4× and 64.6×, respectively, on average.

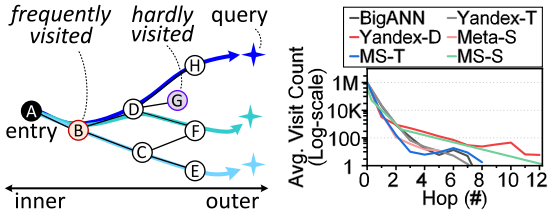
CXL-augmented ANNS. To avoid the accuracy drop and performance depletion, this work advocates to directly have billion-point datasets in a scalable memory pool, disaggregated using CXL. Figure 7 shows our baseline architecture that consists of a CXL CPU, a CXL switch, and four 1TB Type 3 EPs that we prototype (§6.1). We locate all the billion-point graphs and corresponding vectors to the underlying Type 3 EPs (memory pool) while having ANNS metadata (e.g. candidate array) in the local DRAM. This baseline allows ANNS to access the billion-point datasets on the remote-side memory pool just like conventional DRAMs thanks to CXL's instruction-level compatibility. Nevertheless, it is not yet an appropriate option for practical billion-scale ANNS due to CXL's architectural characteristics that exhibit lower performance than the local DRAM.

To be precise, we compare the kNN search latency of the baseline with the oracle ANNS, and the results are shown in Figure 8. In this analysis, we normalize the latency of the baseline to that of the oracle for better understanding. Even though our baseline does not show severe performance depletion like what DiskANN/HM-ANNS suffer from, it exhibits 3.9× slower search latency than the oracle, on average. This is because all the memory accesses associated with HDM(s) insist the host RC convert them to a CXL flit and revert the flit to memory requests at the EP-side. The corresponding responses also requires this *memory-to-flit* conversion in a reverse order thereby exhibiting the long latency for graph/vector accesses. Note that this 3.6∼4.6× performance degradation is not acceptable in many production-level ANNS applications such as recommendation systems [45] or search engines [46].

3.2 Design Consideration and Motivation

The main goal of this work is to make the CXL-augmented kNN search faster than in-memory ANNS services working only with locally-attached DRAMs (cf. CXL-ANNS vs. Oracle as shown in Figure 8). To achieve this goal, we propose CXL-ANNS, a software-hardware collaborative approach, which considers the following three observations: i) node-level relationship, ii) distance calculation, and iii) vector reduction.

Node-level relationship. While there are diverse graph structures [10, 19, 24] for the best-first search traverses (cf. Algorithm 1), all of the graphs starts their traverses from a unique, single entry-node as described in §2.1. This implies that the graph traverse of ANNS visits the nodes closer to the entry-node much more frequently. For example, as shown in Figure 9a, the node B is always accessed to serve a given set of kNN queries targeting other nodes listed in the graph branch while the node G is difficult to visit. To be precise, we examine the average count to visit nodes in all the billion-point graphs that this work evaluate when there are a million kNN query



(a) Traverse. (b) Nodes' visit count.

Figure 9: Graph traverse.

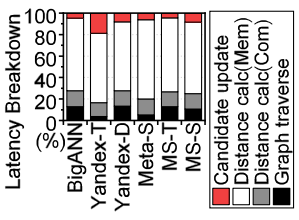


Figure 10: End-to-end breakdown analysis.

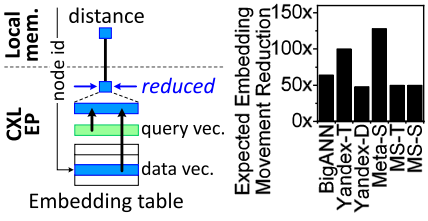

(a) Reduction example. (b) Reduction ratio.

Figure 11: Data reduction.

requests. The results are shown in Figure 9b. One can observe from this analysis that the nodes most frequently accessed during the 1M kNN searches reside in the 2∼3 edge hops. By appreciating this node-level relationship, we will locate the graph and vector data regarding inner-most nodes (from the entry-node) to locally-attached DRAMs while allocating all the others to the underlying CXL EPs.

Distance calculation. To analyze the critical path of billion-point ANNS, we decompose the end-to-end kNN search task into four different sub-tasks, i) candidate update, ii) memory access and iii) computing fractions of distance calculation, and iv) graph traverse. We then measure the latency of each sub-tasks on use in-memory, oracle system, which are shown in Figure 10. As can be seen from the figure, ANNS distance calculation significantly contributes to the total execution time, constituting an average of 81.8%. This observation stands in contrast to the widely held belief that graph traversal is among the most resource-intensive operations [47–49]. The underlying reason for this discrepancy is that distance calculation necessitates intensive embedding table lookups to determine the data vectors of all nodes visited by ANNS. Notably, while these lookup operations have the same frequency and pattern as graph traversal, the length of the data vectors employed by ANNS is 2.0× greater than that of the graph data due to their high dimensionality. Importantly, although distance calculation exhibits considerable latency, it does not require substantial computational resources, thus making it a good candidate for acceleration using straightforward hardware solutions.

Reducing data vector transfers. We can take the overhead brought by distance calculations off the critical path in the kNN search by bringing only the distance that ANNS needs to check for each iteration its algorithm visits. As shown in Figure 11a, let's suppose that CXL EPs can compute a distance between a given query vector and data vectors that ANNS is in visit. Since ANNS needs the distance, a simple scalar value, instead of all the full features of each data vector, the amount of data that the underlying EPs transfer can be reduced as many as each vector's dimensional degrees. Figure 11b analyzes how much we can reduce the vector transfers during services of the 1M kNN queries. While the vector dimensions of each dataset varies (96∼256), we can reduce the amount of data to load from the EPs by 73.3×, on average.

3.3 Collaborative Approach Overview

Motivated by the aforementioned observations, CXL-ANNS first caches datasets considering a given graph's inter-node relationship and performs ANNS algorithm-aware CXL prefetches (§4.1). This makes the performance of a naive CXL-augmented kNN search comparable with that of the oracle ANNS. To go beyond, CXL-ANNS reduces the vector transferring latency significantly by letting the underlying EPs to calculate all the ANNS distances near memory (§5.1). As this near-data processing is achieved in a collaborative manner between EP controllers and RC-side ANNS algorithm handler, the performance can be limited by the kNN query service sequences. CXL-ANNS thus schedules kNN search activities in a fine-grained manner by relaxing their execution dependency (§5.3). Putting all together, CXL-ANNS is designed for offering high-performance even better than the oracle ANNS without an accuracy loss.

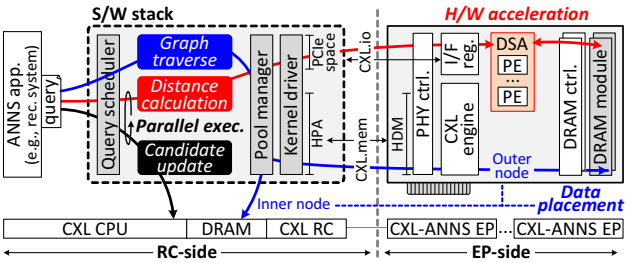

Figure 12: Overview.

Figure 12 shows the high-level viewpoint of our CXL-ANNS architecture, which mainly consists of i) RC-side software stack and ii) EP-side data processing hardware stack.

RC-side software stack. This RC-side software stack is composed of i) query scheduler, ii) pool manager, and iii) kernel driver. At the top of CXL-ANNS, the query scheduler handles all kNN searches requested from its applications such as recommendation systems. It splits each query into three subtasks (graph traverse, distance calculation, and candidate update) and assign them in different places. Specifically, the graph traverse and candidate update subtasks are performed at the CXL CPU side whereas the scheduler allocates the distance calculation to the underlying EP by collaborating with the underlying pool manager. The pool manager handles CXL's HPA for the graph and data vectors by considering edge hop counts, such that it can differentiate graph accesses based on the node-level relationship. Lastly, the kernel driver manages the underlying EPs and their address spaces; it enumerates the EPs and maps their HDMs into the system memory's HPA that the pool manager uses. Since all memory requests for HPA are cached at the CXL CPU, the driver maps EP-side interface registers to RC's PCIe address space using CXL.io instead of CXL.mem. Note that, as the PCIe spaces where the memory-mapped registers exist is in non-cacheable area, the underlying EP can immediately recognize what the host-side application lets the EPs know.

EP-side hardware stack. EP-side hardware stack includes a domain specific accelerator (DSA) for distance calculation in addition to all essential hardware components to build a CXL-based memory expander. At the front of our EPs, a physical layer (PHY) controller and CXL engine are implemented, which are responsible for the PCIe/CXL communication control and flit-to-memory request conversion, respectively. The converted memory request is forwarded to the underlying memory controller that connects multiple DRAM modules at its backend; in our prototype, an EP has four memory controllers, each having a DIMM channel that has 256GB DRAM

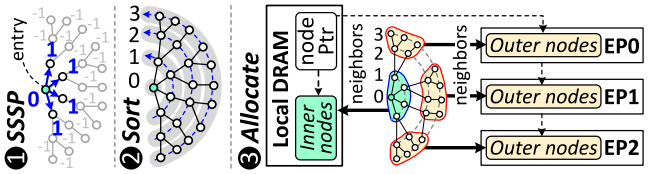

Figure 13: Data placement.

modules. On the other hand, the DSA is located between the CXL engine and memory controllers. It can read data vectors using the memory controllers while checking up the operation commands through CXL engine's interface registers. These interface registers are mapped to the host non-cacheable PCIe space such that all the commands that the host writes can be immediately visible to DSA. DSA calculates the approximate distance for multiple data vectors using multiple processing elements (PEs), each having simple arithmetic units such as adder/subtractor and multiplier.

4 Software Stack Design and Implementation

From the memory pool management viewpoint, we have to consider two different system aspects: i) graph structuring technique for the local memory and ii) efficient space mapping method between HDM and graph. We will explain the design and implementation details of each method in this section.

4.1 Local Caching for Graph

Graph construction for local caching. While the pool manager allocates most graph data and all data vectors to the underlying CXL memory pool, it caches the nodes, expected to be most frequently accessed, in local DRAMs as much as the system memory capacity can accommodate. To this end, the pool manager considers how many edge hops (i.e., calculating the number of edge hops) exist from the fixed entry-node to each node for its relationship-aware graph cache. Figure 13 explains how the pool manager allocates the nodes in a given graph to different places (local memory vs. CXL memory pool). When constructing the graph, the pool manager calculates per-node hop counts by leveraging a single source shortest path (SSSP) algorithm [50, 51]; it first lets all the nodes in the graph have a negative hop count (e.g., -1). Starting from the entry-node, the pool manager checks all the nodes in one edge hop and increases its hop count. It visits each of the nodes and iterates this process for them until there is no node to visit in a breadth-first search manner. Once each node has its own hop count, the pool manager sorts them based on the hop count in an ascending order and allocates the nodes from the top (having the smallest hop count) to local DRAMs as many as it can. The available size of the local DRAMs can be simply estimated by referring to system configuration variables (`sysconf()`) of the total number of pages (`_SC_AVPHYS_PAGES`) and the size of each page (`_SC_PAGESIZE`). It's important to mention that in this study, the pool manager uses several threads within the user space to execute SSSP, aiming to reduce the construction time

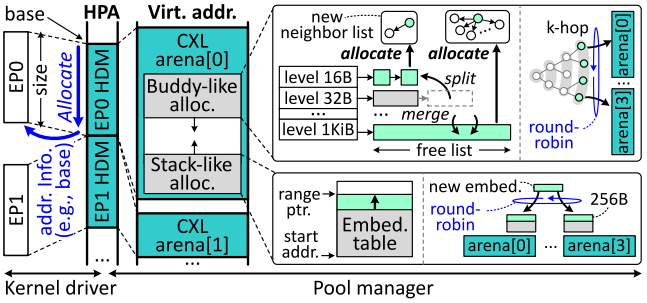

Figure 14: Memory management.

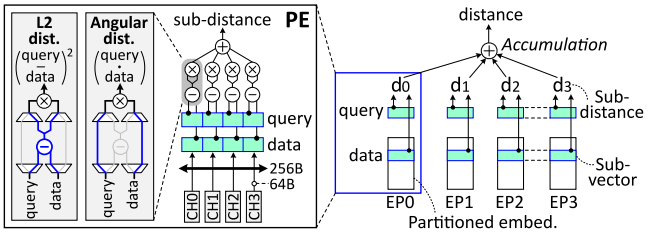
to a minimum. Once the construction is done, the threads are terminated to make sure they do not consume CPU resources when a query is given.

4.2 Data Placement on the CXL Memory Pool

Preparing CXL for user-level memory. When mapping HDM to the system memory's HPA, CXL CPU should be capable of recognizing different HDMs and their size whereas each EP needs to know where its HDM is assigned in HPA. As shown in Figure 14, our kernel driver checks PCIe configuration space and figures out CXL devices at the PCIe enumeration time. The driver then checks RC information from the system's data structure describing the hardware components that show where the CXL HPA begins (base), such as device tree [52] or ACPI [53]. From the base, our kernel driver allocates each HDM as much as it defines in a contiguous space. It lets the underlying EPs know where each of corresponding HDM is mapped in HPA, such that they can convert the address of memory requests (HPA) to its original HDM address. Once all the HDMs are successfully mapped to HPA, the pool manager allocates each HDM to different places of user-level virtual address space that the query scheduler operates on. This memory-mapped HDM, called *CXL arena*, guarantees per-arena continuous memory space and allows the pool manager to distinguish different EPs at the user-level.

Pool management for vectors/graph. While CXL arenas directly expose the underlying HDMs of CXL EPs to user-level space, it should be well managed to accommodate all the billion-point datasets appreciating their memory usage behaviors. The pool manager considers two aspects of the datasets; the data vectors (i.e., embedding table) should be located in a substantially large and consecutive memory space while the graph structure requires taking many neighbor lists with variable length (16B∼1KB). The pool manager employs stack-like and buddy-like memory allocators, which grow upward and downward in each CXL arena, respectively. The former allocator has a range pointer and manages memory for the embedding table, similar to stack. The pool manager allocates the data vectors across multiple CXL arenas in a round-robin manner by considering the underlying EP architecture. This vector sharding method will be explained in §5.1. In contrast, the buddy-like allocator employs a level pointer,



(a) PE architecture. (b) Sharding.

Figure 15: Distance calculation.

each level consisting of a linked list, which connects data chunks with different size (from 16B to 1KB). Like Linux buddy memory manager [54], it allocates the CXL memory spaces as much as each neighbor list exactly requires and merge/split the chunk(s) based on the workload behaviors. To make each EP balanced, the pool manager allocates the neighbor lists for each hop in round-robin manner across different CXL arenas.

5 Collaborative Query Service Acceleration

5.1 Accelerating Distance Calculation

Distance computing in EP. As shown in Figure 15a, a processing element (PE) of DSA has arithmetic logic tree connecting a multiplier and subtractor at each terminal for element-wise operations. Depending on how the dataset's features are encoded, the query and data vectors are routed differently to the two units as input. If the features are encoded for the Euclidean space, the vectors are supplied to the subtractor for L2 distance calculation. Otherwise, the multiplexing logics directly deliver the input vectors to the multiplier by bypassing the subtractor such that it can calculate the angular distance. Each terminal simultaneously calculates individual elements of the approximate distance, and the results are accumulated by going through the arithmetic logic tree network from the terminal to its root. In addition, each PE's terminal reads data from all four different DIMM channels in parallel, thus maximizing the EP's backend DRAM bandwidth.

Vector sharding. Even though each EP has many PEs (10 in our prototype), if we locate the embedding table from the start address of an EP in a consecutive order, EP's backend DRAM bandwidth can be bottleneck in our design. This is because each feature vector in the embedding table is encoded by high dimensional information (∼256 dimensions, taking around 1KB). To address this, our pool manager shards the embedding table in a column wise and stores different parts of the table across the different EPs. As shown in Figure 15b, this *vector sharding* splits each vector into multiple sub-vectors based on each EP's I/O granularity (256B). Each EP simultaneously computes its sub-distance from the split data vector that the EP accommodates. Later, the CXL CPU accumulates the sub-distances to get the final distance value. Note that, since the L2 and angular distances are calculated by accumulating the output of element-wise operations, the final distance is the same as the results of the sub-distance accumulation using vector sharding.

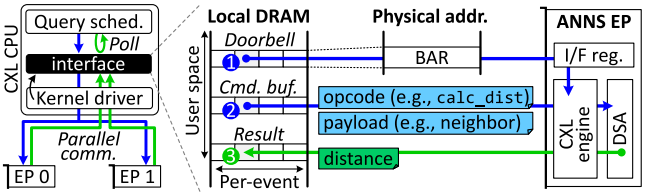


Figure 16: Interface.

Interfacing with EP-level acceleration. Figure 16 shows how the interface registers are managed to let the underlying EPs compute a distance where the data vectors exist. There are two considerations for the interface design and implementation. First, multiple EPs perform the distance calculation for the same neighbors in parallel thanks to vector sharding. While the neighbor list contains many node ids (≤200), it is thus shared by the underlying EPs. Second, handling interface registers using CXL.io is an expensive operation as CPU should be involved in all the data copies. Considering these two, the interface registers handle only the event of command arrivals, called *doorbell* whereas each EP's CXL engine pulls the corresponding operation type and neighbor list from the CPU-side local DRAM (called a command buffer) in an active manner. This method can save the time for CPU to move the neighbor list to each EP's interface registers one by one as the CXL engine brings all the information if there is any doorbell update. The CXL engine also pushes results of distance calculation to the local DRAM such that the RC-side software directly accesses the results without an access of the underlying CXL memory pool. Note that all these communication buffers and registers are directly mapped to the user-level virtual addresses in our design such that we can minimize the number of context switches between user and kernel mode.

5.2 Prefetching for CXL Memory Pool

Figure 17a shows our baseline of collaborative query service acceleration, which lets EPs compute sub-distances while ANNS's graph traverse and candidate update (including sub-distance accumulation) are handled at the CPU-side. This scheduling pattern is iterated until there is no kNN candidates to visit futher (Algorithm 1). A challenge of this baseline approach is traversing graph can be started once the all node information is ready at the CPU-side. While local caching

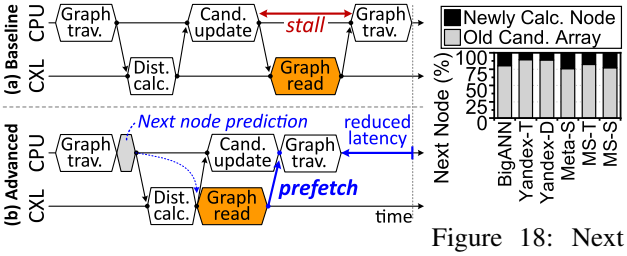

Figure 17: Prefetching.

Figure 18: Next node's source.

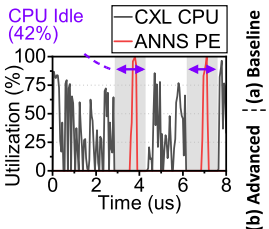

Figure 18: Resource utilization.

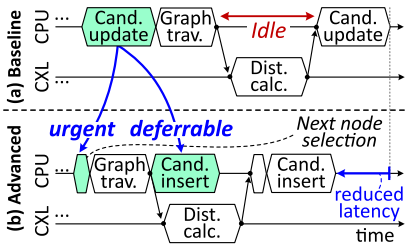

Figure 19: Query scheduling.

of our pool manager addreses this, it yet shows a limited performance. It is required to go through the CXL memory pool to get nodes, which does not sit in the innermost edge hops. As its latency to access the underlying memory pool is long, the graph traverse can be postponed comparably. To this end, our query scheduler prefetches the graph information earlier than the actual traverse subtask needs, as shown in Figure 17b.

While this prefetch can hide the long latency imposed by the CXL memory pool accesses, it is non-trivial as the prefetch requires knowing the nodes that the next (future) iteration of the ANNS algorithm will visit. Our query scheduler speculates the nodes to visit and brings their neighbor information by referring to the candidate array, which is inspired by an observation that we have. Figure 18 shows which nodes are accessed in the graph traverse of the next iteration across all the datasets that we tested. We can see that 82.3% of the total visiting nodes are coming from the candidate array (even though its information is not yet updated for the next step).

5.3 Fine-Granular Query Scheduling

Our collaborative search query acceleration can reduce the amount of data to transfer significantly and successfully hide the long latency imposed by the CXL memory pool. However, computing kNN search in different places makes the RC-side ANNS subtasks pending until EPs complete their distance calculation. Figure 18 shows how much the RC-side subtasks (CXL CPU) stay idle, waiting for the distance results. In this evaluation, we use Yandex-D as a representative of the datasets, and its time series are analyzed for the time visiting only first two nodes for their neighbor search. The CXL CPU performs nothing while EPs calculate the distances, which take 42% of the total execution time for processing those two nodes. This idle time cannot be easily removed as candidate update cannot be processed without having their distance.

To address this, our query scheduler relaxes the execution dependency on the candidate update and separates such an update into urgent and deferrable procedures. Specifically, the candidate update consists of i) inserting (updating) the array with the candidates, ii) sorting kNN candidates based on their distance, and iii) node selection to visit. The node selection is an important process because the following graph traverse requires knowing the nodes to visit (urgent). However, sorting/inserting kNN candidates maintain the k numbers of neighbors in the candidate array, which are not to be done immediately. Thus, as shown in Figure 19, the query scheduler performs the node selection before the graph traverse, but it executes the deferrable operations during the distance calculation time by delaying them in a fine-granular manner.

6 Evaluation

6.1 Evaluation Setup

Prototype and Methodology. Given the lack of a publicly available, fully functional CXL system, we constructed and validated the CXL-ANNS software and hardware in an operational real system (Figure 21). This hardware prototype is based on a 16nm FPGA. To develop our CXL CPU prototype, we adapted the RISC-V CPU [55]. The prototype integrates 4 ANNS EPs, each equipped with four memory controllers, linked to the CXL CPU via a CXL switch. The system's software for the prototype, including the kernel driver, is compatible with Linux 5.15.36. For the ANNS execution, we adjusted Meta's open ANNS library, FAISS v1.7.2 [56].

Unfortunately, the prototype system does not offer the flexibility needed to explore various ANNS design spaces. As a remedy, we also established a hardware-validated full-system simulator [29] that represents CXL-ANNS, which was utilized for evaluation. This model replicates all operational cycles extracted from the hardware prototype and is cross-validated with our real system at the cycle level. We conducted simulation-based studies in this evaluation, the system details of which are outlined in Table 1. Notably, the system emulates the server utilized in Meta's production environment [57]. Although our system by default uses 4 EPs, our system increases their count for specific workloads (e.g., Meta-S) that necessitate larger memory spaces (more than 2TB) compared to others.

Workloads. We use billion-scale ANNS datasets from BigANN benchmark [30], a public ANNS benchmark that multiple companies (e.g., Microsoft, Meta) participate in. Their important characteristics are summarized in Table 2. In addition, since ANNS-based services often need different number

Dataset	Dist.	Num. vecs.	Emb. dim.	Avg. num. neighbors	Candidate arr. size k=1	k=5	k=10	Num. devices.
BigANN	L2	1B	128	31.6	30	75	150	4
Yandex-T	Ang.	1B	200	29.0	440	900	2500	4
Yandex-D	L2	1B	96	66.9	300	700	1700	4
Meta-S	L2	1B	256	190	1200	2800	5600	8
MS-T	L2	1B	100	43.1	60	130	250	4

Table 3: Latency.

of nearest neighbors [3, 19], we evaluated our system on the various k (e.g., 1, 5, 10). We generated the graph for ANNS by using state-of-the-art algorithm, NSG, employed by production search services in Alibaba [19]. Since the accuracy and performance of BFS can vary on the size of the candidate array, we only show the performance behavior of our system when its accuracy is 90%, as recommended by the BigANN benchmark. The accuracy is defined as *recall@k*; the ratio of the exact k number of neighbors that are included in the k number of output nearest neighbors of ANNS.

Configurations. We compare CXL-ANNS with 3 state-of-the-art large-scale ANNS systems. For the compression approach, we use a representative algorithm, product quantization [20] (***Comp***). It compresses the data vector by replacing the vector with the centroid of its closest cluster (see §2.2). For the hierarchical approach, we use DiskANN [24] (***Hr-D***) and HM-ANN [25] (***Hr-H***) for the evaluation. The two methods employ compressed embedding table and simplified graphs to reduce the number of SSD/PMEM accesses, respectively. For fair comparison, we use the same storage device, Intel Optane [44], for both Hr-D/H. For CXL-ANNS, we evaluated its multiple variants to distinguish the effect of each method we propose. Specifically, ***Base*** places the graph and embedding table in CXL memory pool and lets CXL CPU execute the subtasks of ANNS. Compared to Base, ***EPAx*** performs distance calculation by using DSA inside the ANNS EP. Compared to EPAx, ***Cache*** employs relationship-aware graph caching and prefetching. Lastly, ***CXLA*** employs all the methods we propose, including fine-granular query scheduling. In addition, we compare oracle system (***Orcl***) that uses unlimited local DRAM. We will show that CXL-ANNS makes the CXL-augmented kNN search faster than Orcl.

6.2 Overall Performance

We first compare the throughput and latency of various systems we evaluated. We measured the systems' throughput by counting the number of processed queries per second (QPS, in short). Figure 22 shows the QPS of all ks, while Figure 24 digs the performance behavior deeper for k=10 by breaking down the latency. We chose k=10 following the guide from BigANN benchmark. The performance behavior for k=1,5 are largely same with when k=10. For both figures, we normalized the values by that of *Base* when k=10. The original latencies are summarized in Table 3.

As shown in Figure 22, the QPS gets lower when the k increases for all the systems we tested. This is because, the BFS visits more nodes to find more nearest neighbors. On the other hand, while Comp exhibits comparable QPS to Orcl, it fails to reach the target recall@k (0.9) for 7 workloads. This is because Comp cannot calculate the exact distance since it replaces the original vector with the centroid of a cluster nearby. This can also be observed in Figure 23. The figure shows the accuracy and QPS when we vary the size of candidate array for two representative workloads. BigANN represents the workloads that Comp does reach the target recall, while Yandex-D represents the opposite. We can see that Comp converges at low recall@10 of 0.92 and 0.58, respectively, while other systems reach the maximum recall@10.

In contrast, hierarchical approaches (Hr-D/H) reaches the target recall@k for all the workloads we tested, by re-ranking the search result. However, they suffer from the long latency of underlying SSD/PMEM while accessing their uncompressed graph and embedding table. Such long latency significantly depletes the QPS of Hr-D and Hr-H by 35.9× and 77.6× compared to Orcl, respectively. Consider Figure 24 to better understand; Since Hr-D only calculates the distance for the limited number of nodes in the candidate array, it exhibits 20.1× shorter distance calculation time compared to Hr-H, which starts a new BFS on original graph stored in SSD/PMEM. However, Hr-D's graph traverse takes longer time than that of Hr-H by 16.6×. This is because, Hr-D accesses the original graph in SSD/PMEM for both low/high-accuracy search while Hr-H accesses the original graph only for their high-accuracy search.

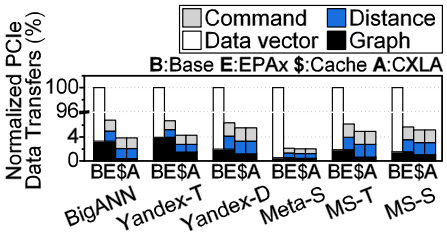

Figure 25: Data transfer.

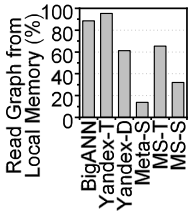

Figure 26: Local caching.

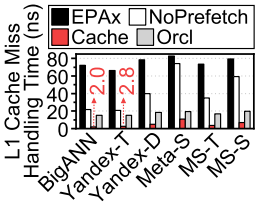

Figure 27: Cache miss handling time.

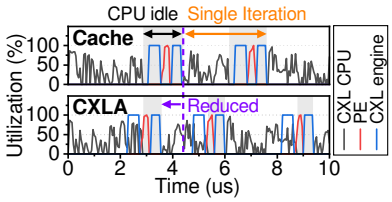

Figure 28: CPU/PE utilization (Yandex-D).

As shown in Figure 22, Base does not suffer from accuracy drop or the performance depletion of Hr-D/H since it employs a scalable memory pool that CXL offers. Therefore, it significantly improves the QPS by 9.4× and 20.3×, compared to Hr-D/H, respectively. However, Base still exhibits 3.9× lower throughput than Orcl. This is because Base experiences the long latency of memory-to-flit conversion while accessing the graph/embedding in CXL memory pool. Such conversion makes Base's graph traverse and distance calculation longer by 2.6× and 4.3×, respectively, compared to Orcl.

Compared to Base, EPAx significantly diminishes the distance calculation time by a factor of 119.4×, achieved by reducing data vector transfer through the acceleration of distance calculation within the EPs. While this EP-level acceleration introduces an interface overhead, this overhead only represents 5.4% of the Base's distance calculation latency. Hence, EPAx reduces the query latency by 7.5× on average, relative to Base. It's important to highlight that EPAx's latency is 1.9× lower than Orcl's, which has unlimited DRAM. This discrepancy stems from Orcl's insufficient grasp of the ANNS algorithm and its behaviour, which results in considerable data movement overhead during data transfer between local memory and the processor complex. Additional details can be found in Figure 25, depicting the volume of data transfer via PCIe for the CXL-based systems. The figure shows that EPAx eliminates data vector transfer, thereby cutting down data transfer by 21.1×.

Further, Cache improves EPAx's graph traversal time by 3.3×, thereby enhancing the query latency by an average of 32.7%. This improvement arises because Cache retains information about nodes anticipated to be accessed frequently in the local DRAM, thereby handling 59.4% of graph traversal within the local DRAM (Figure 26). The figure reveals a particularly high ratio for BigANN and Yandex-T, at 92.0%. As indicated in Table 2, their graphs have a relatively small number of neighbors (31.6 and 29.0, respectively), resulting in their graphs being compact at an average of 129.3GB. In contrast, merely 13.8% of Meta-S's graph accesses are serviced from local memory, attributable to its extensive graph. Nevertheless, even for Meta-S, Cache enhances graph traversal performance by prefetching graph information before actual visitation. As depicted in Figure 24, this prefetching can conceal CXL's prolonged latency, reducing Meta-S's graph traversal latency by 72.8%. While prefetching would introduce overhead in speculating the next node visit, it is insignificant, accounting for only 1.3% of the query latency. These caching and prefetching techniques yield graph processing performance similar to that of Orcl. We will explain the details of prefetching shortly.

Lastly, as depicted in Figure 22, CXLA boosts the QPS by 15.5% in comparison to Cache. This is due to CXLA's enhancement of hardware resource utilization by executing deferrable subtasks and distance calculations concurrently in the CXL CPU and PE, respectively. As illustrated in Figure 24, such scheduling benefits Yandex-T, Yandex-D, and Meta-S more so than others. This is attributable to their use of a candidate array that is, on average, 16.3× larger than others, which allows for the overlap of updates with distance calculation time. Overall, CXLA attains a significantly higher QPS than Orcl, surpassing it by an average factor of 3.8×.

6.3 Collaborative Query Service Analysis

Prefetching. Figure 27 compares the L1 cache miss handling latency while accessing the graph for the CXL-based systems we tested. We measured the latency by dividing the total L1 cache miss handling time of CXL CPU by the number of L1 cache access. The new system, NoPrefetch, disables the prefetching from Cache. As shown in Figure 27, EPAx's latency is as long as 75.4ns since it accesses slow CXL memory whenever there is a cache miss. NoPrefetch alleviates such problem thanks to local caching, shortening the latency by 45.8%. However, when the dataset uses a large graph (e.g. Meta-S, MS-S), only 24.5% of the graph can be cached in local memory. This makes NoPrefetch's latency 2.3× higher than that of Orcl. In contrast, Cache significantly shortens the latency by 8.5× which is even shorter than that of Orcl. This is because Cache can foresee the next visiting nodes and loads the graph information in the cache in advance. Note that, Orcl accesses local DRAM on demand on cache miss.

Utilization. Figure 28 shows the utilization of CXL CPU, PE, CXL engine on a representative dataset (Yandex-D). To clearly provide the behavior of our fine-granule scheduling, we composed a CXL-ANNS with single-core CXL CPU and single PE per device and show their behavior in a timeline. The upper part of the figure shows the behavior of Cache that does not employ the proposed scheduling. We plot CXL CPU's utilization as 0 when it polls the distance calculation results of PE, since it does not perform any useful job during that time. As shown in the figure, CXL CPU idles for 42.0% of the total time waiting for the distance calculation result. In

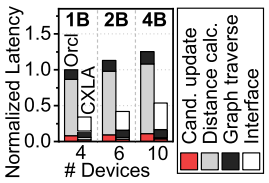

Figure 29: Device scaling (Yandex-D).

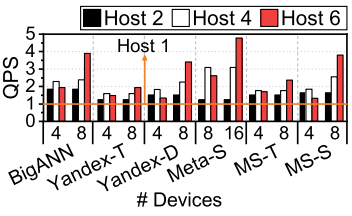

Figure 30: Host Sensitivity.

contrast, CXLA reduces the idle time by 1.3×, relaxing the dependency between ANNS subtasks. In the figure, we can see that the CXL CPU's candidate update time overlaps with the time CXL engine and PE handling the command. As a result, CXLA improves the utilization of hardware resources in CXL network by 20.9%, compared to Cache.

6.4 Scalability Test

Bigger Dataset. To evaluate the scalability of CXL-ANNS, we increase the number of data vectors in Yandex-D by 4B, and connect more EP to CXL CPU to accommodate their data. Since there is no publicly available dataset that is as large as 4B, we synthetically generated additional 3B vectors by adding noise to original 1B vectors. As shown in Figure 29, we can see that the latency of Orcl increases as we increase the scale of dataset. This is because larger dataset makes BFS visit more nodes to maintain the same level of recall. On the other hand, we can see the interface overhead of CXLA increases as we employ more devices to accommodate bigger dataset. This is because the CXL CPU should notify more devices for the command arrival by ringing the doorbell. Despite such overhead, CXLA exhibits 2.7× lower latency than Orcl thanks to its efficient collaborative approach.

Multi-host. In a disaggregated system, a natural way to increase the system's performance is to employ more host CPUs. Thus, we evaluate the CXL-ANNS that supports multiple hosts in the CXL network. Specifically, we split EP's resources such as HDM and PEs and then allocate each of them to one the the CXL hosts in the network. For ANNS, we partition the embedding table and make each host responsible for finding kNN from different partitions. Once all the CXL hosts find the kNN, the system gathers them all and rerank the neighbors to finally select kNN among them.

Figure 30 shows the QPS of multi-host ANNS. The QPS is normalized to that when we use single CXL host with the same number of EPs that we used before. Note that we also show the QPS when we employ more number of EPs than we used before. When the number of EPs stays the same, the QPS increases until we connect 4 CXL hosts in the system. However the QPS drops when the number of CXL hosts is 6. This is because the distance calculation by limited number of PEs became the bottleneck; the commands from the host pends since there is no availabe PE. Such problem can be addressed by having more EPs in the system, thereby distributing the computation load. As we can see in the figure, when we double the number of EPs in the network, we can improve the QPS when we have 6 CXL hosts in the system.

7 Discussion and Acknowledgments

GPU-based distance calculation. Recent research has begun to leverage the massive parallel processing capabilities of GPUs to enhance the efficiency of graph-based ANNS services [58, 59]. While GPUs generally exhibit high performance, our argument is that it's not feasible for CPU+GPU memory to handle the entirety of ANNS data and tasks, as detailed in Section 1. Even under the assumption that ANNS is functioning within an optimal in-memory computing environment, there are two elements to consider when delegating distance computation to GPUs. The first point is that GPUs require interaction with the host's software and/or hardware layers, which incurs a data transfer overhead for computation. Secondly, ANNS distance computations can be carried out using a few uncomplicated, lightweight vector processing units, making GPUs a less cost-efficient choice for these distance calculation tasks.

In contrast, CXL-ANNS avoids the burden of data movement overhead, as it processes data in close proximity to its actual location and returns only a compact result set. This approach to data processing is well established and has been validated through numerous application studies [48, 60–66]. Moreover, CXL-ANNS effectively utilizes the cache hierarchy and can even decrease the frequency of accesses to the underlying CXL memory pool. It accomplishes this through its CXL-aware and ANNS-aware prefetching scheme, which notably enhances performance.

Acknowledgments. The authors thank anonymous reviewers for their constructive feedback as well as Panmnesia for their technical support. The authors also thank Sudarsun Kannan for shepherding this paper. This work is supported by Panmnesia and protected by one or more patents. 8 Conclusion

We propose CXL-ANNS, a software-hardware collaborative approach for scalable ANNS. CXL-ANNS places all the dataset into its CXL memory pool to handle billion-point graphs while making the performance of the kNN search comparable with that of the (local-DRAM only) oracle system. To this end, CXL-ANNS considers inter-node relationship and performs ANNS-aware prefetches. It also calcualate distances in its EP while scheduling the ANNS subtasks to utilize all the resources in the CXL network. Our empirical results show that CXL-ANNS exhibits 111.1× better performance compared to the state-of-the-art billion-scale ANNS methods and 3.8× better performance than oracle system, respectively.

Abstract

This paper investigates the feasibility of using inexpensive flash memory on new interconnect technologies such as CXL (Compute Express Link) to overcome the memory wall. We explore the design space of a CXL-enabled flash device and show that techniques such as caching and prefetching can help mitigate the concerns regarding flash memory's performance and lifetime. We demonstrate using real-world application traces that these techniques enable the CXL device to have an estimated lifetime of at least 3.1 years and serve 68–91% of the memory requests under a microsecond. We analyze the limitations of existing techniques and suggest system-level changes to achieve a DRAM-level performance using flash.

1 Introduction

The growing imbalance between computing power and memory capacity requirement in computing systems has developed into a challenge known as the memory wall [23, 34, 52]. Figure 1, based on the data from Gholami et al. [34] and expanded with more recent data [11, 30, 43], illustrates the rapid growth in NLP (natural language processing) models (14.1× per year), which far outpaces that of memory capacity (1.3× per year). The memory wall forces modern data-intensive applications such as databases [8, 10, 14, 20], data analytics [1, 35], and machine learning (ML) [45, 48, 66] to either be aware of their memory usage [61] or implement user-level memory management [66] to avoid expensive page swaps [37, 53]. As a result, overcoming the memory wall in an application-transparent manner is an active research avenue; approaches such as creating an ML-centric system [45, 48, 61], building a memory disaggregation framework [36, 37, 52, 69], and designing new memory architecture [23, 42] are actively pursued.

We question whether it is possible to overcome the memory wall using flash memory — a memory technology that is typically used in storage due to its high density and capacity scaling [59]. While DRAM can only scale to gigabytes in capacity, a flash memory-based solid-state drive (SSD) is

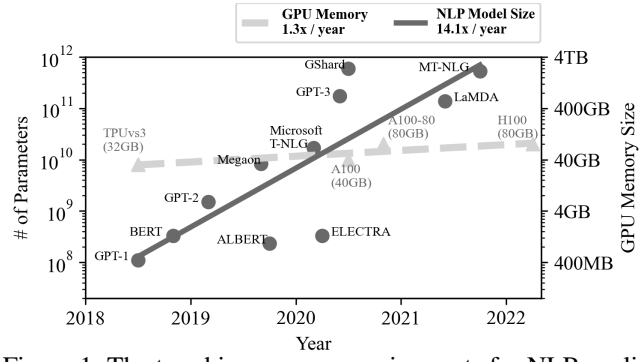

Figure 1: The trend in memory requirements for NLP applications [11, 30, 34, 43]. The number of parameters increases by a factor of 14.1× per year, while the memory capacity in GPUs only grows by a factor of 1.3× every year.

in the terabyte scale [23], a sufficiently large capacity to address the memory wall challenge. The use of flash memory as main memory is enabled by the recent emergence of interconnect technologies such as CXL [3], Gen-Z [7], CCIX [2], and OpenCAPI [12], which allow PCIe (Peripheral Component Interconnect Express) devices to be accessed directly by the CPU through load/store instructions. Furthermore, these technologies promise excellent scalability as more PCIe devices can be attached across switches [13] unlike DIMM (Dual Inline Memory Module) used for DRAM.

However, there are three main challenges to using flash memory as CPU-accessible main memory. First, there is a granularity mismatch between memory requests and flash memory. This results in a significant traffic amplification on top of the existing need for indirection in flash [23, 33]: for example, a 64B cache line flush to the CXL-enabled flash would result in 16KiB flash memory page read, 64B update, and 16KiB flash program to a different location (assuming a 16KiB page-level mapping). Second, flash memory is still orders of magnitude slower than DRAM (tens of microseconds vs. tens of nanoseconds) [5, 24]. As a consequence, while the peak data transfer rate between the two technologies is similar [4, 15], the long flash memory latency hinders sustained performance as data-intensive applications can only endure

latency within the microsecond range at most [53]. Lastly, flash memory has limited endurance and wears out after repeated writes [24, 44]. This limits the usability of the memory technology as flash memory blocks beyond their endurance limit exhibit unreliable behavior and high levels of errors [44].

We address the above flash memory challenges by exploring design options, particularly those related to caching and prefetching, so that a CXL-enabled flash device (or CXL-flash) can be used to overcome the memory wall. Even though prior works have explored the scalability aspects of multiple CXL devices [36, 42] and have proven the feasibility of CXL-flash [9, 42], to the best of our knowledge, we are the first open-sourced in-depth study on the design choices of a CXL-flash device and on the effectiveness of existing optimization techniques. Due to the large design space, we first explore the CXL-flash hardware design in § 4 and then evaluate and analyze detailed policies and algorithms in § 5. We discover that it is possible to design a CXL-flash with 68–91% of its requests achieving less than a microsecond latency and an estimated lifetime of at least 3.1 years using memory traces of real applications. While exploring various designs and policies, we make seven observations which collectively indicate that modern prefetching algorithms are ill-suited to predict memory access patterns for the CXL-flash. More specifically, the virtual to physical address translation obfuscates access patterns for existing prefetchers to perform adequately. To counter this, we explore passing memory access hints from the kernel to the CXL-flash to further improve performance.

We make the following contributions with this work.

- We develop a novel tool that collects physical memory traces of an application, and we simulate the behavior of a CXL-flash with these traces. Both the memory tracing tool and the CXL-flash simulator (§ 3) are available at https://github.com/spypaul/MQSim_CXL.git
- Through synthetic workloads, we demonstrate the potential to effectively reduce the latency of a CXL-flash by integrating various system design techniques such as caching and prefetching, highlighting optimization opportunities. (§ 4)
- Using real-world workloads, we analyze the limitations of the current prefetchers and suggest system-level changes for future CXL-flash to achieve near-DRAM performance, specifically sub-µs latencies for the device. (§ 5)

2 Background

In this section, we first describe the opportunities presented by CXL (Compute Express Link) [3] as a representation of PCIe-based memory coherent interconnect technologies (which also include Gen-Z [7], CCIX [2], and OpenCAPI [12]). We then discuss the challenges of using flash memory with CXL.

2.1 Opportunities presented by CXL

CXL is a new interconnect protocol built on top of PCIe that integrates CPUs, accelerators, and memory devices into a single computing domain [42]. The main benefits of this integration are twofold. First, it allows coherent memory access between CPUs and PCIe devices. This reduces the synchronization overheads that are typically required for data transfers between the CPU and the device. Second, it is easy to scale the number of CXL devices: through a CXL switch, another set of CXL devices can be connected to the CPU.

Among the three types of devices that CXL supports, the Type 3 device for memory expansion is of interest to this work. Type 3 devices expose host-managed device memory (HDM), and the CXL protocol allows the host CPU to directly manipulate the device memory via load/store instructions [3]. While CXL currently only considers DRAM and PMEM as the primary memory expansion devices, it is possible to use SSDs, thanks to CXL's coherent memory access [42]. Moreover, the high capacity and better scaling of flash-based SSDs, enabled by stacking in 3D [59] and storing multiple bits in a cell [24], can effectively address the memory wall that modern data-intensive applications face. Inspired by previous works on CXL [36, 42], this paper studies the feasibility of using flash memory as a CXL memory expansion device.

2.2 Challenges with flash memory

We discuss the following three peculiarities of flash that make it challenging to use it as the system's main memory.

Granularity mismatch. Flash memory is not randomly accessible: its data are written and read at page granularity whose size is in the order of kilobytes [33], resulting in a large traffic amplification. Furthermore, a page cannot be overwritten. Instead, a block, which consists of hundreds of pages, must be erased first, and data can be written to only erased pages [33]. This restrictive interface causes any 64B cache line flush to incur a large write amplification through read-modify-writes. An SSD, as a block device whose access granularity is much larger (4KiB), has far less overhead.

Microsecond-level latency. Flash memory is orders of magnitude slower than DRAM, whose latencies are in the range of tens to hundreds of nanoseconds. The relatively faster flash memory read is still in the tens of microseconds, while the slower program and erase operations are in the hundreds and thousands of microseconds. Moreover, the flash memory latency also depends on their cell technology [24]. As outlined in Table 1 as an example, as more bits are stored per cell, the latency increases, from SLC (single-level cell) to TLC (triple-level cell). The ultra-low latency (ULL) flash is a variant of SLC that improves performance at the expense of density [46, 76]. Even the ULL technology, however, is orders of magnitude slower than DRAM. As a block device, microsecond-level latencies are tolerable due to the software

Table 1: Overview of memory technology characteristics.

Technology	Read latency	Program latency	Erase latency	Endurance limit
DRAM [50]	46ns	46ns	N/A	N/A
ULL [46, 76]	3μs	100μs	1000μs	100K
SLC [24]	25μs	200μs	1500μs	100K
MLC [24]	50μs	600μs	3000μs	10K
TLC [24]	75μs	900μs	4500μs	3K

overhead in the storage stack. However, for a memory device that is directly accessed using load/store instructions, microsecond-level latencies become a challenge.

Limited endurance. The high voltages applied to flash memory during the program and erase operations slowly wear out the cells, making them unusable over time [44, 72]. The memory manufacturers specify an endurance limit as a guide to how many times the flash memory block can be erased. This limit also depends on the flash technology, as shown in Table 1. While this is nevertheless a soft limit and flash memory can still be used beyond the limit [72], worn-out blocks exhibit unreliable behavior and are not guaranteed to correctly store data [44]. Due to application-level and kernel-level caching and buffering, the amount of writes to a block-interfaced SSD is reduced, and the current endurance limit is often sufficient during the SSD's lifetime. As a memory device, however, flash memory will quickly become unusable with frequent memory writes.

We note that while these challenges for flash also exist in the storage domain, they are handled by the SSD-internal firmware. For CXL-flash, however, they should be addressed by hardware due to the much finer timescale, making it difficult to implement flexible and optimal algorithms. Thus, we expect these challenges to exacerbate when moving flash memory from the storage domain to the memory domain.

3 Tool and Methodology

To understand the behavior of physical memory accesses from the CPU to the CXL device, we build a physical memory tracing tool using page fault events (§ 3.1). We then demonstrate the necessity of this tool by comparing it with a set of virtual memory traces (§ 3.2). The tools and artifacts generated in this work are publicly available.

3.1 Tracing memory accesses

Main memory and CXL-flash are accessed via physical memory addresses. Unfortunately, to the best of our knowledge, no publicly available tool traces the physical memory transactions between the last level cache (LLC) and the memory controller without hardware modifications. Tracing the load/store instructions in the CPU is not sufficient as (1) it collects the virtual address accesses, and (2) the eventual accesses to the CXL-flash are filtered by the cache hierarchy.

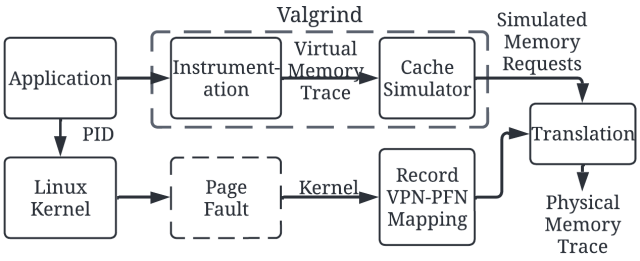

Figure 2: Workflow for collecting physical memory traces. We collect the virtual memory trace using Valgrind and simulate its behavior in the cache. Simultaneously, we capture page fault events to trace the updates to the page table, and use this to generate physical memory traces.

Table 2: Synthetic workload characteristics.

Workload	Inter-arrival time (ns)	Read-write ratio	Footprint (GiB)
Hash map	329	53:47	<1
Matrix multiply	38	55:45	<1
Min heap	72	50:50	1
Random	76	50:50	4
Stride	146	50:50	8

We trace physical memory accesses by combining memory tracing from Valgrind [19, 57] and information from page fault events. Figure 2 illustrates this workflow. As shown in the top path, we instrument the application with Valgrind for load/store instructions and use its cache simulator (Cachegrind) to filter accesses to memory. More specifically, we modify Cachegrind to collect memory accesses caused by LLC misses or evictions. However, these memory accesses from Cachegrind are still addressed virtually, and the virtual-to-physical (V2P) mapping information is needed to generate the physical memory trace. For this, as shown in the bottom path of Figure 2, we collect updates to the page table caused by page faults while the application is running. We modify kernel functions that install page table entries (`do_anonymous_page()` and `do_set_pte()`) and store the V2P translations for the target application's PID in the `/proc` file system. This captures the dynamic nature of page table updates during the execution of the application with minimal overhead. We combine the virtual accesses from Valgrind and the page table updates to generate the physical memory trace.

3.2 Virtual vs. physical memory accesses

We demonstrate our physical memory tracing tool using five synthetic applications based on prior work on prefetching [25, 56]. The characteristics of collected traces are summarized in Table 2. We collect the first 20 million memory accesses:

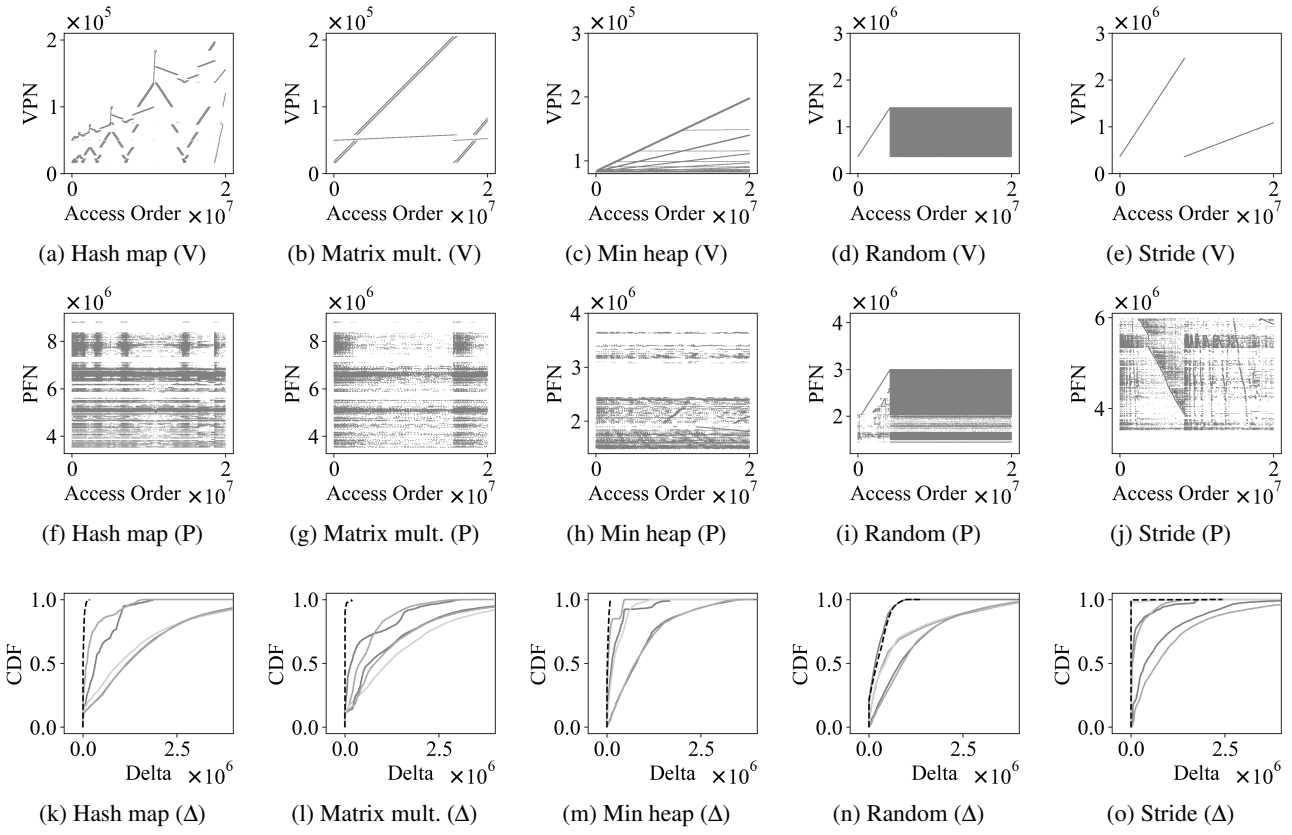

Figure 3: The scatter plots showing access patterns for five synthetic applications: hash map, matrix multiply, min heap, random, and stride. The top row (Figures 3a–3e) shows the virtual address accesses; the second row (Figures 3f–3j), the physical accesses. The last row (Figures 3k–3o) shows the CDF of the difference between consecutive accesses. We observe that the physical memory accesses appear different from the virtual ones due to address translation.

note these are not load/store instructions, but the memory transactions between the LLC and memory.

Figures 3a–3e (first row of Figure 3) plot the accessed virtual page number (VPN) for the five synthetic traces. We can observe that the virtual address access pattern matches our expectations for the application. However, as shown in Figures 3f–3j (second row of Figure 3), the corresponding physical frame number (PFN) does not resemble the VPN. We show the difference between consecutive accesses (Δ, delta) in Figures 3k–3o (last row of Figure 3). The black dashed line is the delta for the virtual address while the grey solid lines are the deltas for the physical addresses across five iterations, with the two of the iterations running while other applications are running to inflate the memory utilization. We make two observations. First, the virtual access patterns (black dashed lines) have much smaller delta values on average. However, the physical access patterns (grey solid lines) may have very large delta values due to virtual-to-physical address translation. Second, the grey solid lines rarely overlap with each other, highlighting that the physical memory pattern is dynamic and depends on various runtime factors that affect memory allocation. To this end, the observed mismatch between the physical and virtual addresses may be influenced by dynamic factors, such as memory utilization of the system.

To demonstrate that it is necessary to capture the physical memory trace, we measure the performance of a CXL-flash using the virtual and physical address traces as inputs. The CXL-flash is configured to have a flash memory backend of 8 channels and 8 ways per channel and a 512MiB DRAM cache, and implements a Next-N-line prefetcher [41] (more details in § 4). We measure the percentage of memory requests with less than a microsecond latency for the five synthetic applications and report the results in Table 3. Using virtual memory traces generates an *overly optimistic* result with far more requests completing under a microsecond compared to the result from running physical memory traces. The error between the running with virtual address and physical address is significantly high: all the matrix multiply experiments have errors over 25%. The random and stride access workload have low error rates, making it either too difficult or too easy to predict access patterns regardless of virtual or physical addressing.

One technique to mitigate the change of information during

Table 3: Percentage of sub-μs latencies for a CXL-flash using virtual and physical address traces for the five synthetic applications. We repeat the physical trace generation five times with iterations 4 and 5 having a higher system memory utilization (thus, a more fragmented memory layout). We compute the errors for the virtual trace performances in relation to those of the physical traces, and highlight errors over 10% in yellow (), and over 25% in red ().

Workload	% of sub-μs latency (virtual)	% of sub-μs latency (physical)					Error (%)				
		1	2	3	4	5	1	2	3	4	5
Hash map	96.9%	86.7%	88.3%	74.5%	63.8%	63.9%	10.2%	8.6%	22.4%	33.1%	33.0%
Matrix mult.	98.2%	72.7%	57.4%	59.2%	48.1%	47.9%	25.5%	40.8%	39.0%	50.1%	50.3%
Min heap	97.8%	92.1%	96.0%	75.6%	69.1%	69.4%	5.7%	1.8%	22.2%	28.7%	28.4%
Random	32.2%	26.4%	27.1%	28.0%	22.4%	21.8%	5.8%	5.1%	4.2%	9.8%	10.6%
Stride	64.7%	64.3%	59.4%	64.5%	51.9%	52.0%	0.4%	5.3%	0.2%	12.6%	12.7%

address translation is to utilize huge pages, which can significantly reduce the number of address translations [54, 58] to preserve memory access patterns. However, such a method can only reduce its impact on the system partially, and the address translation is inevitable. With the rapid growth of memory requirements of applications (14.1 × per year from Figure 1), within a few years, huge pages would exhibit the same challenges that the smaller pages face. Therefore, we decide to keep the configuration general to explore the design options for a CXL-flash.

4 Design Space for CXL-flash

We explore the design space for building a CXL-flash, specifically on the hardware modules inside it; we later evaluate algorithms and policies in § 5. To model the hardware, we build a CXL-flash simulator based on MQSim [68] and its extension MQSim-E [49], and use the physical memory traces of the five synthetic applications (Table 2) to evaluate the effects of design options. The overall architecture of our CXL-flash is depicted in Figure 4 with starting configuration in Table 4.

We answer the following research questions in this section.

- How effective is caching in improving performance? (§ 4.1)
- How can we effectively reduce flash memory traffic? (§ 4.2)
- How effective is prefetching in hiding the long flash memory latency? (§ 4.3)
- What are the appropriate flash memory technology and parallelism for CXL-flash? (§ 4.4)

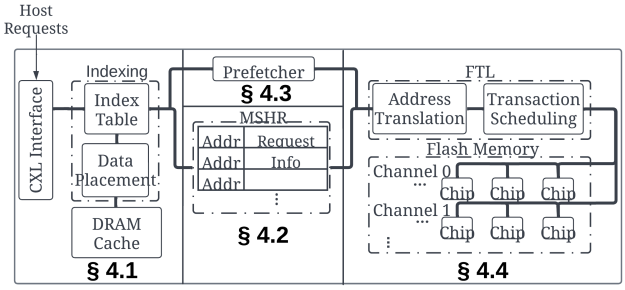

Figure 4: Architecture of the CXL-flash

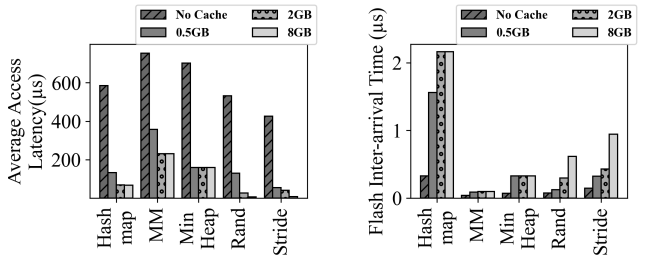
Table 4: Initial configuration for the CXL-flash in § 4.

Parameters	Value
DRAM latency	46ns
Cache replacement	FIFO
Flash parallelism	32 × 32
Flash technology	SLC (Table 1)

4.1 Caching for performance

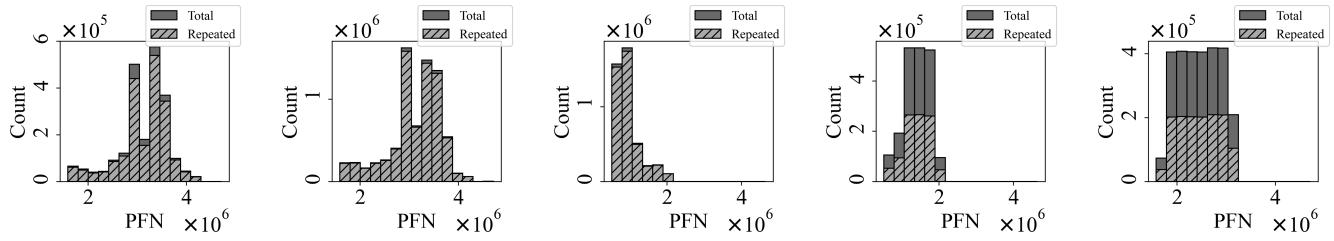
We first explore the effect of adding a DRAM cache in front of flash memory. The cache mainly serves two purposes. First, it improves the performance of the CXL-flash by serving frequently accessed data from the faster DRAM. Second, it reduces the overall traffic to flash memory on a cache hit.

Figure 5 quantitatively shows the benefit of using a cache. We vary the cache size from 0 to 8GiB and measure the average latency for the physical memory accesses (Figure 5a) and the inter-arrival time of flash memory requests to the backend. (Figure 5b). When there is no cache, the average latency is much higher than the flash memory read and program latencies because of queuing delays. This is even though the flash memory backend is configured to have an ample amount of



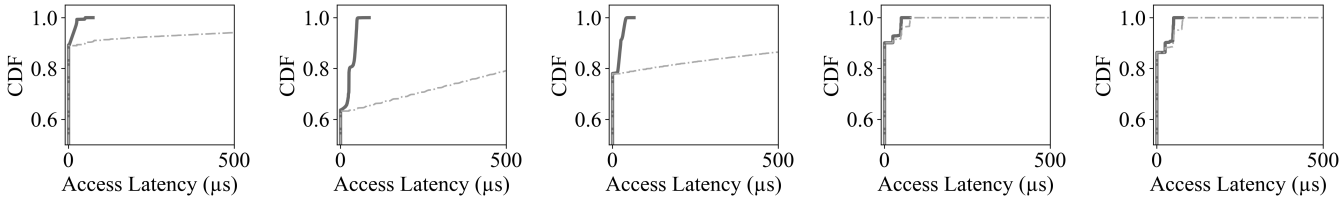
(a) Average access latency (b) Flash memory traffic

Figure 5: Average access latency (Figure 5a) for both 64B read and write requests and flash memory traffic (Figure 5b) as the DRAM cache size varies. In general, the cache improves performance and reduces the amount of traffic to flash. However, even with a sufficiently large cache, the average latencies are still much higher than that of DRAM due to the high intensity of memory accesses.



(a) Hash map (b) Matrix mult. (c) Min heap (d) Random (e) Stride

Figure 6: Flash memory read count for physical memory frames. The solid bar represents the total number of reads, while the shaded bar, the number of repeated reads. A repeated read is a read request to an outstanding read request.



(a) Hash map (b) Matrix mult. (c) Min heap (d) Random (e) Stride

Figure 7: The latency distribution with (solid lines) and without (dashed lines) MSHR.

parallelism at 32 channels and 32 ways per channel, it is insufficient to process the memory requests with short inter-arrival times. Adding a cache significantly reduces the traffic to the flash memory backend and improves the overall performance. However, we observe in Figure 5a that the average latencies for matrix multiply and min heap are still much higher than the DRAM latency, even though the memory footprints for these workloads are smaller than the cache. This is due to the short inter-arrival time of requests that overwhelm the flash memory backend for fetching data (Figure 5b). This experiment shows that caching alone is insufficient in reducing the latency of a CXL-flash, and we need additional auxiliary structures to reduce the traffic to flash memory.

4.2 Reducing flash memory traffic

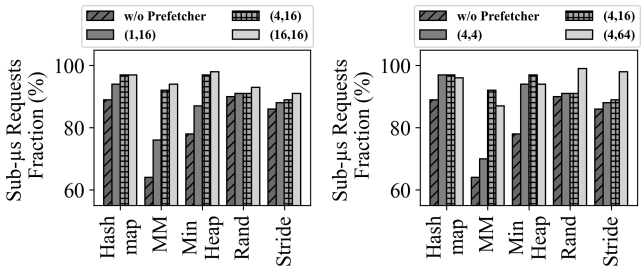
Memory accesses are at 64B granularity while the flash memory backend is addressed at 4KiB units. Thus, upon a cache miss, 4KiB of data will be fetched from flash, and subsequent 64B cache misses that belong to the same 4KiB will generate additional flash memory read requests even when the flash memory read is in progress. This scenario is very likely for memory accesses with high spatial locality, and exacerbated by the much longer flash memory latency. We call these *repeated reads*, and Figure 6 illustrates the severity of repeated reads in the hash map, matrix multiply, and heap workloads: over 90% of flash memory reads are repeats!

Inspired by CPU caches, we add a set of MSHRs (miss status holding registers) [29, 47] to the CXL-flash, as shown in Figure 4. MSHR tracks the current outstanding flash memory requests and services multiple 64B memory accesses from a single flash memory read. We note that MSHRs are uncommon in SSDs: in the storage domain, the software stack merges block I/Os with overlapping addresses so there is no need for the underlying device to implement MSHRs. However, for CXL-flash, there is no software layer to perform this duty as it receives memory transactions directly from the LLC. We observe in Figure 7 that MSHRs significantly reduce long tail latencies, particularly for the three workloads with a significant number of repeated reads. We also observe small improvements to the other two workloads, random and stride, by adding MSHR. However, MSHRs only reduce flash memory traffic, and it does not actively improve the cache hit rate by bringing data into the cache before they are needed.

4.3 Prefetching data from flash

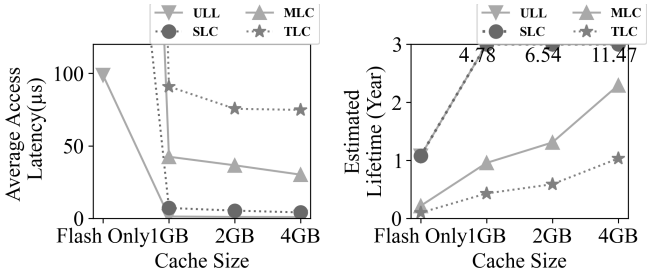
Prefetching is an effective technique for hiding the long latency of a slower technology. Typically prefetchers fetch additional data upon a demand miss or a prefetch hit. To understand the effectiveness of this technique, we implement a simple Next-N-line prefetcher [41] in our CXL-flash, as shown in Figure 4. This prefetcher has two configurable parameters: degree and offset. The degree controls the amount of additional data to fetch while the offset determines the prefetch address from the triggering one. In other words, the degree parameter represents the aggressiveness of the prefetcher, and the offset controls how far ahead the prefetcher is fetching.

Figure 8 shows the effect of varying the degree and offset for the prefetcher. For the (X, Y) notation in a unit of the



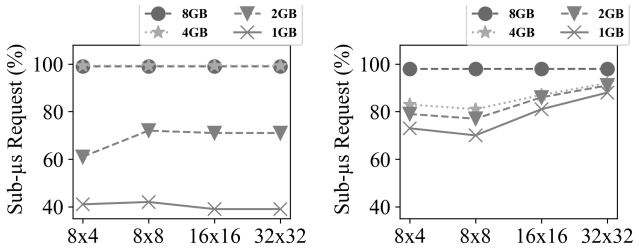
(a) Sensitivity to degree (b) Sensitivity to offset

Figure 8: The performance of the CXL-flash with different prefetcher configurations. (X, Y) represents the degree and offset for the Next-N-line prefetcher.



(a) Average access latency (b) Estimated lifetime

Figure 9: Sensitivity test to flash technology and cache size on the performance and lifetime of CXL-flash with stride.



(a) Random (b) Stride

Figure 10: Percentage of sub-μs requests when varying flash parallelism and cache size. The x-axis represents the flash memory parallelism (channels $\times$ ways). The lines represent values for different cache sizes.

number of 4KiB pages, X denotes the degree, and Y is the offset. As shown in Figure 8a, increasing the degree, or the aggressiveness of the prefetcher generally improves the performance. Even a small degree of 1 increases the portion of sub-microsecond requests from 64% to 76% for the matrix multiply workload, highlighting the necessity of prefetching for CXL-flash. However, the improvement plateaus and further increasing the degree may only pollute the cache. On the other hand, increasing the offset shows two different behaviors depending on the workload. For the hash map, matrix multiply, and min heap workloads, the performance first improves when increasing the offset from 4 to 16. However, an offset of 64 deteriorates the performance as it fetches data too far out. The random workload is insensitive to the offset unless it is large enough, while the stride workload shows gradual improvement as the offset increases.

4.4 Exploring flash technology and parallelism

In previous subsections, we examine the performance of the CXL-flash using SLC flash technology and ample flash parallelism of 32 channels and 32 ways per channel (32 $\times$ 32). In this section, we experiment with how sensitive technology (ULL, SLC, MLC, and TLC) and parallelism (8 $\times$ 4, 8 $\times$ 8, 16 $\times$ 16, and 32 $\times$ 32) are to the overall CXL-flash performance.

We first examine the effect of flash technology and cache size for the stride workload as shown in Figure 9. We use this workload as it performs well in the default configuration, thus we expect it to represent the workload with the lowest room for improvement. Figure 9a illustrates the average latency for the different memory technologies. We observe that even though ULL and SLC flash have a noticeable difference in latency (3μs vs. 25μs), the performance difference between the two is negligible with the existence of a cache. Only when there is no DRAM cache, ULL flash is outstandingly better. We also observe that using MLC and TLC technology degrades the performance significantly. Figure 9b shows the estimated lifetime of the CXL-flash based on the amount of flash write traffic. This estimation takes into consideration the endurance limit, the capacity, and the amount of data written; it optimistically assumes that the write amplification at the flash memory backend is negligible. We observe that with ULL and SLC technologies and some cache, the CXL-flash can achieve a lifetime of more than 4 years. Increasing the size of the cache further improves the lifetime due to reduced flash write traffic. For MLC- and TLC-based CXL-flash, it would only be viable with a sufficiently large cache: with only a 1GiB of cache, it would not last more than a year.

Next, we investigate the effect of varying flash parallelism and cache size on the overall performance using the random (Figure 10a) and stride (Figure 10b) workloads. We use these two as they have the largest memory footprint (8GiB and 4GiB, respectively). Flash technology here is SLC. We observe that with a sufficiently large cache, reducing parallelism to (8 $\times$ 4) does not adversely affect the performance. However, with smaller caches, the flash parallelism matters. Interestingly, the two workloads exhibit slightly different behaviors. The random workload shows high sensitivity to the cache size. On the other hand, the stride workload is less sensitive to the cache size but more to the parallelism. This is due to the prefetcher's effectiveness with stride workloads.

Table 5: Workload characteristics of real-world applications. The spatial and temporal locality values range between 0 and 1, and are computed using the stack and block affinity metrics [32]: a higher value indicates higher locality.

Workload	Category	Description	Inter-arrival time (ns)	# of accesses (M)	Read-write ratio	Footprint (GiB)	Spatial locality	Temporal locality
BERT [18]	NLP	Infers using a transformer model	297	41	73:27	0.5	0.64	0.66

4.5 Summary of findings

We briefly summarize our findings.

- Caching alone is not sufficient to hide the much longer flash memory latencies (§ 4.1), and we need auxiliary structures to reduce the flash memory traffic (§ 4.2).
- Prefetching data improves the CXL-flash's performance, but the best configuration (or even the algorithm) is workload-dependent (§ 4.3).
- The performance difference between using ULL and SLC is only marginal, and it is challenging to utilize MLC and TLC flash in terms of both performance and lifetime (§ 4.4).

5 Evaluation of Policies

Building on top of our design space exploration for the CXL-flash architecture from § 4, we evaluate advanced caching and prefetching policies in this section. We use five different real-world applications that are memory-intensive from a wide variety of domains: natural language processing [18, 70], graph processing [6, 27], high-performance computing [17, 62], SPEC CPU [16, 21], and key-value store [22, 31]. We collect the physical memory traces using our tool (§ 3) and summarize the workload characteristics in Table 5.

However, the memory footprints of the real applications are smaller than we had anticipated, even though they are collected on a machine with 64GiB of memory. Thus, we intentionally configure the cache to be small (64MiB) so that experimental results would scale up for larger workloads. We also scale down the flash parallelism to a more realistic setting and use ULL flash. The default parameters for the CXL-flash in this section are summarized in Table 6.

Table 6: Default parameters for the CXL-flash in § 5.

Parameters	Value
DRAM size	64MiB
DRAM latency	46ns
Flash parallelism	8×8
Flash technology	ULL (Table 1)

5.1 Cache replacement policy

Unlike the previous examination of cache size on performance (§ 4.1), here we fix the cache size and evaluate the effects of different cache replacement policies across different set associativities. In particular, we implement the following four.

FIFO evicts the oldest data.

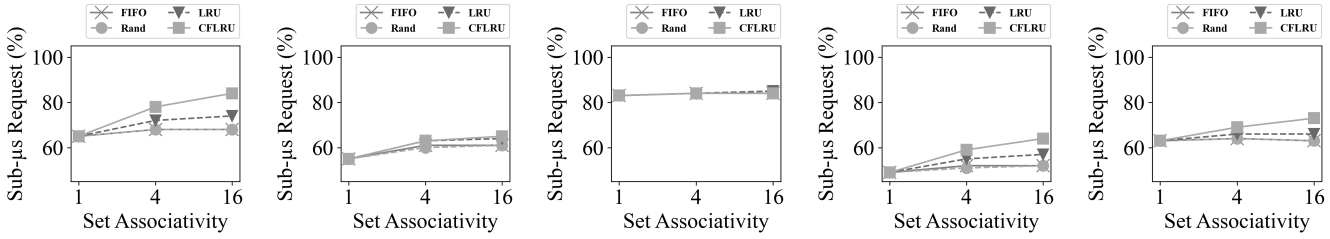
Random selects data arbitrarily to evict.

LRU kicks out the least recently used data.

CFLRU [60] prefers to evict clean data over modified ones.

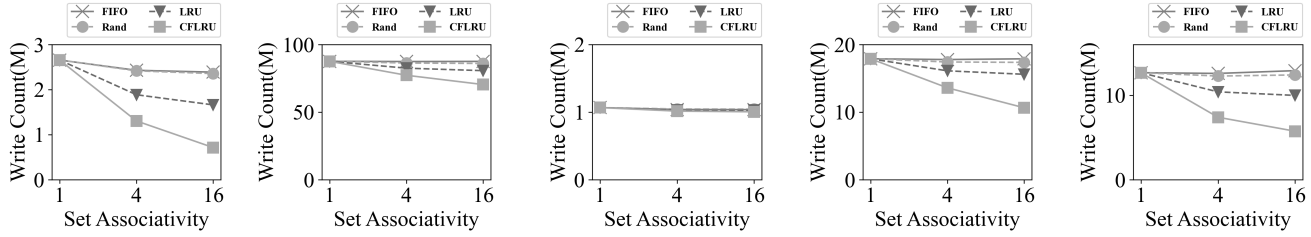
We select Random as our baseline, and FIFO and LRU are two standard CPU cache policies implementable in hardware. To further reduce traffic and extend the device's lifetime, we implement CFLRU to explore the benefits of prioritizing evicting clean cache lines to reduce flash write activities.

Figure 11 measures the percentage of memory requests to the CXL-flash with less than a microsecond latency, and Figure 12 shows the number of flash memory writes. We make five observations from these figures. First, increasing associativity improves performance as it increases the cache hit rate. For a caching system whose miss penalty is high, increasing the hit rate has a greater impact than reducing hit time. Second, CFLRU outperforms the other replacement policies, particularly in BERT, XZ, and YCSB (Figures 11a, 11d, and 11e). This is supported by the significant reduction in write traffic as shown in Figures 12a, 12d, and 12e. Third, workloads with high localities such as Radiosity are insensitive to cache replacement policies (Figures 11c and 12c): at least 83% of the request have sub-microsecond latency regardless of the policy. Four, read-dominant workloads generally perform better than write-heavy ones as the flash memory program latency is disproportionately larger than that of read. BERT and Radiosity only generate as low as 0.7M and 1.0M flash writes, respectively (Figures 12a and 12c), and in turn, their portion of sub-microsecond latencies are as high as 84% and 85%, respectively (Figures 11a and 11c). Lastly, workloads with low localities not only perform poorly but also are less sensitive to the cache policies. In particular, as shown in Figure 11b, only at most 65% of the requests achieve a sub-microsecond latency for the page rank workload due to its low localities and large footprint. The XZ trace in Figure 11d



(a) BERT (b) Page Rank (c) Radiosity (d) XZ (e) YCSB

Figure 11: Percentage of CXL-flash latencies smaller than a microsecond with respect to cache replacement policies and set associativity. In general, increasing associativity reduces the latency and CFLRU performs better than the others.



(a) BERT (b) Page Rank (c) Radiosity (d) XZ (e) YCSB

Figure 12: Number of flash memory write requests with respect to cache replacement policies and set associativity. CFLRU noticeably reduces the number of writes as the associativity increases.

also exhibits low localities but is more sensitive to CFLRU than page rank as the workload has a higher write ratio.

In the storage domain, reducing the amount of data written to the SSD is achieved by various software-level techniques, including the OS-level page cache. Cache management for CXL-flash, however, behaves similarly to CPU caches, and there may be limitations to how close it approaches optimality.

5.2 Prefetching policy

Previously in § 4.3, we measured the effectiveness of a simple Next-N-line prefetcher with a large 8GiB cache. In this section, we scale down the cache to 64MiB, set its associativity to 16, and manage it using the CFLRU algorithm, and measure the performance of the following five prefetcher settings.

NP (No prefetch) does not prefetch any data.

NL (Next-N-line) [41] brings in the next *N* data upon a demand miss or prefetch hit.

FD (Feedback-directed) [65] dynamically adjusts the aggressiveness of the prefetcher by tracking prefetcher accuracy, timeliness, and pollution.

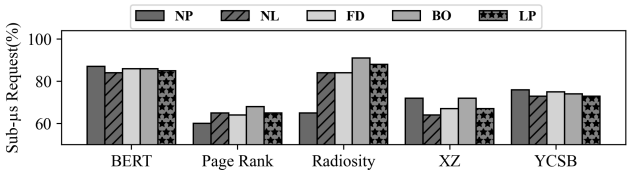
BO (Best-offset) [55] learns the deltas between consecutive accesses by tracking the history of recent requests. It also has a notion of confidence to disable prefetching.

LP (Leap) [53] implements a majority-based prefetching with dynamic window size adjustment. It also gradually adjusts aggressiveness based on the prefetcher accuracy.

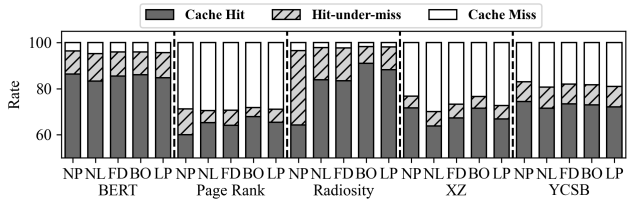
We select these algorithms as they are proven to be effective, implementable in hardware, and fit into the design space of a CXL-flash. In particular, NL, FD, and BO are prefetchers for CPU cache, where BO is an enhancement of NL, and FD utilizes performance metrics we will later discuss. LP is primarily for prefetching data from remote memory, where the latency difference between a cache hit and a cache miss can be similar to that in our design space.

Observation #1: ***Although 68–91% of requests have a latency of under a microsecond, using a prefetcher can be detrimental to the performance of real-world applications.*** As shown in Figure 13a, the state-of-the-art prefetchers degrade the performance for three workloads, BERT, XZ, and YCSB workloads, and are only helpful for the other two workloads. Radiosity, in particular, shows a 36% increase in sub-microsecond latencies when using the best-offset prefetcher. To understand why, we examine the cache hit, hit-under-miss (HUM), and miss rate in Figure 13b. A cache hit-under-miss refers to a hit in the MSHR where while the data is not in the cache yet, it is being fetched due to a previous miss. We observe that BO on Radiosity converts 25% of hit-under-miss into hits, indicating high effectiveness of prefetching on workloads with a high spatial locality factor (*cf.* Table 5). Our observation indicates that the performance of prefetchers depends on the characteristics of workloads, and they can have detrimental effects on applications.

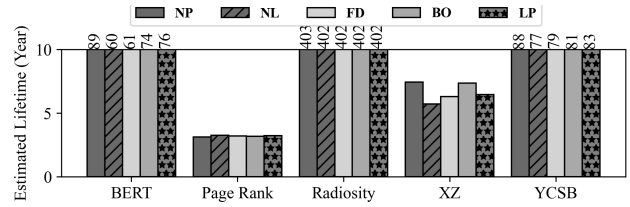
Observation #2: ***Even under high-intensity workloads, a CXL-flash has a lifetime of at least 3.1 years.*** We estimate the lifetime of the CXL-flash under real workloads based on the amount of data written to flash, endurance limit, and 1TiB capacity, as shown in Figure 13c. We observe, in the worst case, the device would last 3.1 years under Page Rank, but



(a) Percentage of sub-μs requests



(b) Cache hit, cache hit-under-miss (HUM), and cache miss



(c) Device lifetime

Figure 13: CXL-flash's performance and lifetime with different prefetchers. Figure 13a shows the portion of requests with a latency of less than a microsecond. Figure 13b shows the hit, hit-under-miss, and miss rate of the 64MiB cache inside the CXL-flash. Figure 13c plots the estimated lifetime.

under workloads such as Radiosity, it would be as much as 403 years. Three factors contribute to the lifetime: workload intensity, read-write ratio, and locality; Page rank has the highest workload intensity, a high ratio of writes, and a low locality. Even under this adverse condition, the CXL-flash provides a reasonable lifetime; hence, the durability of the CXL-flash can sustain the intensity of memory requests.

Observation #3: ***A CXL-flash has a better performance per cost than a DRAM-only device.*** While a CXL-flash falls slightly short of achieving a DRAM-like performance for sub-µs requests, our analysis reveals its potential to provide benefits for memory-intensive applications. As a CXL-flash can serve 68–91% of the memory requests under a microsecond, and the recent price point of DRAM is 17 - 100× higher than that of NAND flash [39, 64, 77], we expect an 11 - 91× performance-per-cost benefit from a CXL-flash over a DRAM-only device, as depicted in Figure 14. Although some cases may still prefer a DRAM-only device when achieving the best performance is essential, a CXL-flash can be a cost-effective memory expansion option depending on the workload.

Interestingly, we observe that while prefetchers are useful for Page Rank, their performance is overall the worst, with only at most 68% of requests completing under a microsecond. To further understand the performance of prefetchers, we measure the following four metrics.

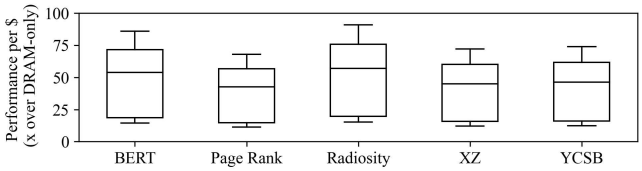


Figure 14: Performance-per-cost benefits of a CXL-flash with BO prefetcher over a DRAM-only device. The estimation is derived from the performance results in Figure 13a, the recent price point of DRAM at 5 $/GB [77], and the price range of NAND flash varying from 0.05 to 0.30 $/GB [39, 64].

Accuracy measures how much of the data brought in by the prefetcher is actually used. Higher is better.

Coverage is the portion of prefetched data cache hits among the memory requests. A high coverage means that cache hits are thanks to the prefetcher, while a low coverage indicates that the prefetcher is not contributing.

Lateness is the portion of late prefetches among all the prefetches. A prefetched data is late if it is accessed while it is being prefetched. Lower is better.

Pollution measures how many cache misses are caused by the prefetcher among cache misses. Lower is better.

Observation #4: ***In cases where the prefetcher improves the performance, it is due to achieving high accuracy.*** We plot the four metrics for the evaluated prefetchers in Figure 15. Lateness and pollution are negative metrics (the lower the better), so we invert their bars so that higher is better for all metrics. We observe that the defining characteristic for the workloads where the prefetcher is helpful (Page Rank and Radiosity) is that the accuracy is high. For example, the Leap (LP) prefetcher attains 85% accuracy under Radiosity while only reaching 27% under BERT. Additionally, the Best-offset (BO) prefetcher achieves 48% accuracy under XZ; however, its limited coverage of 4% suggests that despite achieving relatively higher accuracy, the prefetcher is not actively fetching data to contribute to performance improvement.

We further analyze Page Rank to understand why prefetchers are able to reach relatively high accuracy even though the workload has the lowest locality (computed using the stack and block affinity metrics [32]). As Figure 16 shows, the Page Rank exhibits distinct phases in their workload. During the first phase, Page Rank loads graph information and exhibits high locality (Figure 16a). The best-offset prefetcher is also able to attain high coverage and accuracy (Figure 16b). However, in the second phase, Page Rank builds the graph, and the access pattern here has a very low locality. Consequently, the best-offset prefetcher becomes more inactive (low coverage) as its accuracy drops. During the last phase, Page Rank computes the score for each vertex. While its access locality is not high, the prefetcher performs well and most of the accesses hit in the cache. Note that while the pollution is bad, the cache miss rate is very low so its impact on performance

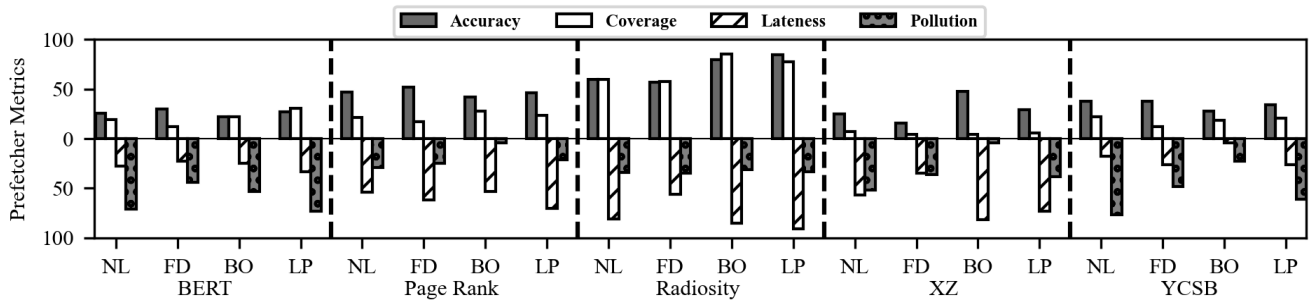

Figure 15: Accuracy, coverage, lateness, and pollution metrics for the prefetchers.

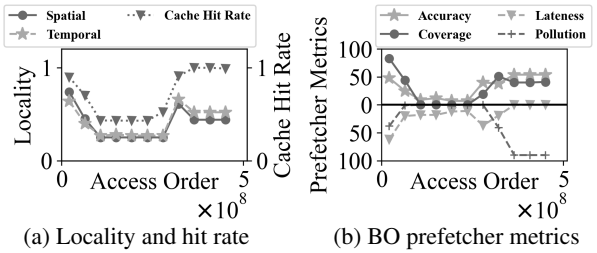

(a) Locality and hit rate (b) BO prefetcher metrics

Figure 16: Page Rank behavior over time.

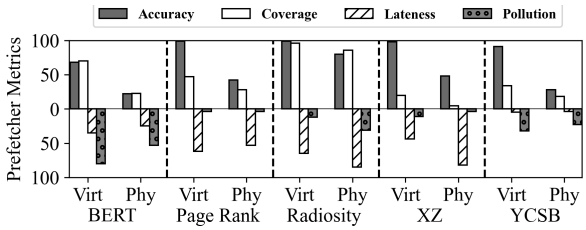

Figure 17: BO prefetcher metrics for virtual vs. physical.

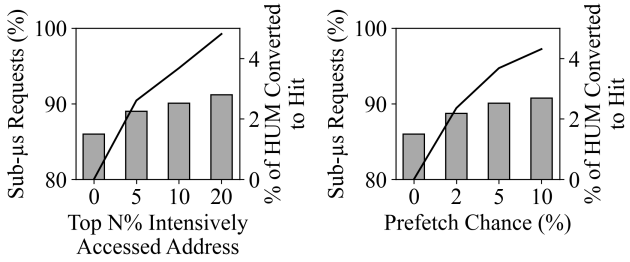

(a) Sensitivity to # of addresses. (b) Sensitivity to hint chance.

Figure 18: Improvement in performance with memory access pattern hints for BERT. Figure 18a is the sensitivity to the number of addresses for which hints are provided. Figure 18b shows the performance improvement as more hints are added. In both figures, the line represents the number of hit-under-misses without hints converted to cache hits with hints.

is negligible. This analysis indicates that while the prefetcher is beneficial for the first and last phases, the low locality in the second phase limits the performance.

Observation #5: ***Cache pollution is the main reason behind performance degradation when the accuracy is low.*** As shown in Figure 15, BERT and YCSB have low accuracies while their pollutions are high, leading to a result where enabling prefetchers degrades performance (Figure 13a). For XZ, even though the accuracy of the best-offset (BO) prefetcher is low, it is no worse than no prefetcher as it causes little pollution. We attribute this to BO's ability to disable prefetching based on its accuracy. For Page Rank and Radiosity, prefetchers exhibit low pollution although their lateness is high. Cache pollution degrades the performance of a CXL-flash, and prefetchers should be aware of the impact to avoid having detrimental effects on the device.

Observation #6: ***The virtual-to-physical address translation makes it difficult for the CXL-flash to prefetch data.*** To understand the effect of V2P address translation, we simulate the CXL-flash with the best-offset prefetcher using the virtual memory traces of the five application workloads, and Figure 17 compares the four prefetcher metrics between virtual and physical traces. We make two observations. First, aside from Radiosity, we observe a significant drop in accuracy from virtual to physical traces. The BO prefetcher under Page Rank is 99% accurate for the virtual memory trace, but with the physical trace, accuracy drops to 42%. Second, coverage also drops, indicating that the prefetcher becomes less active under physical memory accesses: for example, it drops from 76% to 26% under BERT. The drop in both accuracy and coverage for physical traces shows that the CXL-flash would perform better if it were addressed virtually.

Observation #7: ***If the kernel were to provide memory access pattern hints to the device, the CXL-flash performance improves by converting hit-under-misses into cache hits.*** We consider a hypothetically clairvoyant kernel that knows the physical memory access pattern. This is not too far-fetched as data-intensive applications often iterate multiple times and their behaviors can be profiled. More specifically, we assume that the kernel has information on the top intensively accessed physical frames, and can pass hints to the device prior to their actual accesses. To limit the overhead of kernel involvement, we model a probabilistic generation of access hints. Figure 18a shows the performance improvement for BERT when hints are generated at 10% for the top N% of intensively accessed addresses. We observe that with access hints to more addresses, the percentage of sub-microsecond latencies increases from 86% to 91% by converting hit-under-

misses (HUM) into cache hits. Figure 18b considers a variable hint generation chance, from 0% to 10% for the top 10% of intensively accessed addresses. Similarly, we see an overall improvement in performance, though it plateaus at 91%. Our experiments show that host-generated access pattern hints leveraging the host's knowledge of the workload behaviors can potentially improve the CXL-flash performance.

6 Related Work

The evaluated cache policies and prefetching algorithms are well-studied in prior proposals. However, most of them are for managing and optimizing the CPU cache [41, 55, 65], where the latency difference between a cache hit and a cache miss is much smaller than that in a CXL-flash. CFLRU [60] and Leap [53] share a similar design space to our device; however, the memory access intensity they face is not as extreme as what a CXL-flash needs to handle. Therefore, it is crucial to evaluate the effectiveness of these policies and algorithms under the design space of a CXL-flash.

Techniques to mitigate the performance degradation due to address translations and limitations of flash has been explored in prior works. Utilizing huge pages can reduce the number of address translations [54, 58]. FlashMap [40] and FlatFlash [23] combine address translation of the SSD with the page table to reduce overheads. eNVY [73] employs write buffering, page remapping, and a cleaning policy to enable direct memory addressability and sustain performance. Future research in CXL host systems should further explore the potential benefits of host-generated hints and insights from these prior works to reduce the overheads.

Memory disaggregation organizes memory resources across servers as a network-attached memory pool, enabling meeting the high memory requirements for data-intensive applications [37, 38, 52, 69]. While our work does not directly investigate memory disaggregated systems, using CXL-flash as disaggregated memory helps overcome the memory wall.

Utilization of non-DRAM to expand memory has been explored in prior works [28,40,63,74]. HAMS [75] aggregates persistent memory and ULL flash as a memory expansion by managing data paths among hosts and memory hardware in an OS-transparent manner. Suzuki et al. [67] present a lightweight DMA-based interface that bypasses the NVMe protocols to enable flash read access with DRAM-like performance. SSDAlloc [26] is a memory manager and a runtime library that allows applications to use flash as a memory device through the OS paging mechanism, which can cause overheads when accessing data in SSDs. FlatFlash [23] exposes a flat memory space using DRAM and flash memory by integrating the OS paging mechanism and the SSD's internal mapping table. While these prior works primarily focus on OS-level management and host-device interaction, our work builds on top of them by investigating the design decisions internal to a memory expansion device.

Memory expansion with CXL Type 3 devices is an active research area [36, 42, 50, 71]. Pond [50] utilizes CXL to improve DRAM memory pooling in cloud environments and proposes machine-learning models to manage local and pooled memory. While this work investigates how to use a CXL Type 3 device in a cloud setting, our work studies how to implement one using flash memory. DirectCXL [36] successfully connects host processors with external DRAM via CXL in real hardware and develops a software runtime to directly access the resources. Lastly, CXL-SSD [42] advocates combining CXL and SSD to expand host memory. While we share the same goal with this work, it mainly discusses the CXL interconnect and scalability potentials of CXL-SSDs.

ML-specific designs build systems that address the memory wall challenge [45, 48, 51]. MC-DLA [48] proposes an architecture that aggregates memory modules to expand the memory capacity for training ML models on accelerators. Behemoth [45] observes that many NLP models require large amounts of memory but not a lot of bandwidth, and proposes a flash-centric training framework that manages data movement between memory and SSDs to overcome the memory wall.

7 Conclusion

We explore the design space of a CXL-flash device and evaluate existing optimization techniques. Using physical memory traces, we find that 68–91% of memory access achieves a sub-microsecond latency for a CXL-flash device that can last at least 3.1 years. We discover that the address translation for virtual memory makes it particularly difficult for the CXL-flash's prefetcher to be effective and suggest passing kernel-level access pattern hints to further improve the performance.

While we attempt to generalize the results by testing the device with a variety of workloads and design parameters, it is important to acknowledge a few limitations. The current design of a CXL-flash as explored in this paper does not consider the flash's internal tasks such as garbage collection and wear leveling. In addition, the host system considered may not fully reflect the new system characteristics introduced by CXL. Therefore, we believe more work needs to be done in the CXL-flash research space, and our work can be a platform on which future research can build upon.

Abstract

Memory optimization kernel features, such as memory deduplication, are designed to improve the overall efficiency of systems like datacenter servers, and they have proven to be effective. However, when invoked, these kernel features notably disrupt the execution of applications, intensively consuming the server CPU's cycles and polluting its caches. To minimize such disruption, we propose STYX, a framework for offloading the intensive operations of these kernel features to SmartNIC (SNIC). STYX first RDMA-copies the server's memory regions, on which these kernel features intend to operate, to an SNIC's memory region, exploiting SNIC's RDMA capability. Subsequently, leveraging SNIC's (underutilized) compute capability, STYX makes the SNIC CPU perform the intensive operations of these kernel features. Lastly, STYX RDMA-copies their results back to a server's memory region, based on which it performs the remaining operations of the kernel features. To demonstrate the efficacy of STYX, we re-implement two memory optimization kernel features in Linux: (1) memory deduplication (`ksm`) and (2) compressed cache for swap pages (`zswap`), using the STYX framework. We then show that a system with STYX provides a 55–89% decrease in 99^{th}-percentile latency of co-running applications, compared to a system without STYX, while preserving the benefits of these kernel features.

1 Introduction

The modern OS offers various kernel features that can improve the overall utilization and/or performance of systems. Among them, memory optimization kernel features, such as memory deduplication, compressed cache for swap pages, and memory compaction to name a few, are devoted to utilizing the limited DRAM capacity of systems more efficiently. These kernel features are attractive to hyperscalers such as Google, Amazon, Meta, and Microsoft for two key reasons. First, DRAM technology scaling has notably slowed down, resulting in stagnant reduction in cost per GB of DRAM. Second, the DRAM capacity needed for datacenter servers has rapidly grown, not only for applications but also for software packages, profiling, logging, and other supporting functions required for efficient deployment of applications (*i.e.*, datacenter memory tax).

These kernel features have been extensively evaluated and enhanced [6, 19, 22, 27, 31, 40, 51]. They have proven to be effective, but they also incur notable deployment costs. Specifically, they are not frequently invoked, but they often perform memory- and/or CPU-intensive operations. They bring kilobytes to megabytes of usually cold data into the server CPU's caches and then make its cores intensively execute simple but repetitive operations on the data, often after disabling kernel preemption. As a result, they cause significant interference especially with co-running memory-intensive/latency-sensitive applications at the server CPU's cores and caches. This leads to a substantial increase in the high-percentile latency of the applications in datacenters (§3).

In this paper, we propose STYX, using SmarTNIC (SNIC) to efficiently manage the datacenter memorY taX (§4). Specifically, STYX makes use of two common Capabilities of SNIC: **(C1)** the RDMA capability to copy the server's memory regions, on which a kernel feature intends to intensively operate, to SNIC memory (① in Figure 1) and **(C2)** the compute capability to offload the intensive operations of kernel features from the expensive server CPU to the cheap SNIC CPU or accelerators (② in Figure 1). **(C1)** prevents the pollution

[§]Mansi and Sun have contributed equally as second authors.

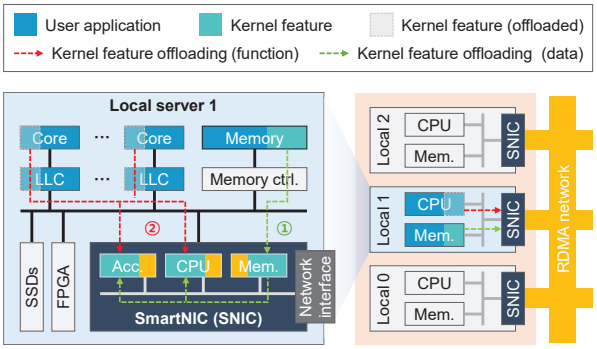

Figure 1: Overview of STYX framework.

of the server CPU's caches that stores application code and data, while **(C2)** frees the server CPU's cores from executing the intensive operations. As such, STYX offers a framework that allows us to deploy kernel features with significantly less disruption to the performance of co-running applications, without making the kernel features less effective.

We choose SNIC as our platform to offload intensive operations of memory optimization kernel features for two **R**easons. **(R1)** SNIC has already been deployed by hyperscalers (*e.g.*, Azure SNIC [15] and Amazon Nitro [4]) to minimize the datacenter tax [24] associated with executing network functions (*e.g.*, compression/decompression, encryption/decryption, and regular expression matching) at high rates. STYX reuses this existing capability without demanding novel or modified hardware. **(R2)** SNIC CPU's cores are not fully utilized as they are typically used to control accelerators in SNIC and orchestrate data transfers between the accelerators and the network controller. Note that STYX is built on a generic RDMA interface. As such, STYX also allows servers with standard RDMA NICs (RNICs) to seamlessly offload the intensive operations of kernel features to other servers with SNICs or RNICs.

To demonstrate the efficacy of STYX, we re-implement two memory optimization Linux kernel **F**eatures as examples: **(F1)** memory deduplication for virtual machines (VMs), also known as kernel same-page merging (`ksm` [14]) and **(F2)** compressed cache for swap pages (`zswap` [21]) (§5). Subsequently, we set up a server with an Intel Xeon CPU-based CPU and an NVIDIA BlueField-2 SNIC [20,37], and take `Redis` [41] driven by `YCSB` [11] as a representative memory-intensive/latency-sensitive application running on datacenter servers (§6). Lastly, we measure the 99^{th}-percentile (p99) response time (or latency) of `Redis` for various cases. (§7).

Specifically, we begin by evaluating the p99 latency values of `Redis` with systems deploying `ksm` (denoted as `sys-ksm`) and `zswap` (`sys-zswap`), and compare them with those of a system that deploys no memory optimization kernel feature (`sys-no-mo`). We show that `sys-ksm` and `sys-zswap` increase the p99 latency values by 4.8–9.7× and 8.1–11.0×, respectively, compared to `sys-no-mo`. Then, we evaluate the p99 latency values of `Redis` with systems deploying STYX-based `ksm` (`sys-styx-ksm`) and `zswap` (`sys-styx-zswap`), and demonstrate that they reduce the p99 latency values to 1.0–1.1× and 1.8–3.8×, respectively, compared to `sys-no-mo`, while preserving the benefits of `ksm` and `zswap`. Finally, we assess the impact of running the STYX-based kernel features on the performance of functions accelerated by SNIC. We choose regular expression matching (`rem`) as a representative function accelerated by a dedicated accelerator in the NVIDIA BlueField-2 SNIC. Even when offloading the intensive operations of `ksm` and `zswap` to the SNIC, STYX increases the p99 latency value of `rem` by only 1.3%.

2 Background

2.1 Memory Optimization Kernel Features

In this section, we provide an overview of two memory optimization kernel features in Linux: `ksm` and `zswap`. Other operating systems, such as Windows, also offer similar features like page combining [7,34] and memory compression [54]).

`ksm`. It is a memory deduplication feature in Linux. It is commonly used with kernel-based virtual machine (KVM) to quickly consolidate more VMs within a given physical memory capacity [35], by sharing pages with the same content among multiple VMs (*e.g.*, pages storing code for OS and common libraries). As it allows for more efficient storage of common data in cache or memory, it also notably improves performance for certain applications and operating systems [47]. It periodically and incrementally scans pages of two or more running processes to identify those with the same memory contents. Then, it merges those identical pages into a single physical copy, updates their page table entries with a copy-on-write (CoW) attribute, and reclaims the memory space previously used by the pages. Both the overhead and benefit of `ksm` are determined by the number of scanned pages per invocation of `ksm`, the frequency of scanning pages, and the maximum number of merged pages.

`zswap`. It serves as a compression backend for the Linux swap daemon (`kswapd`) which includes synchronous direct and asynchronous background paths. `kswapd` takes

the synchronous direct path when the memory allocator fails to allocate pages due to a lack of free memory space. This requires `kswapd` to immediately swap out the least recently used (LRU) pages to the backing swap device. `kswapd` takes the asynchronous background path when the amount of free memory space drops below the `page_low` watermark. This makes `kswapd` begin to swap out pages from the inactive page list, and continues until the amount of free memory space exceeds the `page_high` watermark.

When deployed, `zswap` intercepts the pages from both the paths above, compresses them, and places them in a dynamically allocated memory pool in DRAM (*i.e.*, `zpool`). Meanwhile, when the size of `zpool` reaches the `max_pool_percent` threshold, `zswap` wakes up and takes the LRU page from `zpool`, decompresses and relocates it to the backing swap device, and frees the compressed page from `zpool`. To serve a page fault, `zswap` first checks `zpool` to find whether the page is evicted to the backing swap device. If the page is found in `zpool`, it is simply decompressed and returned by `zswap`. Otherwise, the system follows the standard process for swapping in a page from the backing swap device.

Since `zswap` can notably reduce the need for accessing the slow backing swap device, it may improve the overall performance of the system; the page decompression on the synchronous direct path is part of the performance-critical path for handling page faults, but it is typically faster than retrieving pages from the backing swap device. As such, `zswap` has been evaluated by Google [27] and Meta [51] for potential deployment in production systems.

2.2 SNIC and RDMA

Recently, various SNICs have been developed to offload functions common in network applications such as security, compression, and network function virtualization as part of an effort to reduce the datacenter network processing tax [24]. Generally, an SNIC integrates a traditional network interface controller (NIC) with a CPU, ASIC- and/or FPGA-based accelerators, and memory and IO subsystems. For example, an NVIDIA BlueField-2 SNIC [37] consists of 8 ARM CPU cores with private L1 and shared L2 caches, a cache-coherent on-chip interconnect, DRAM and PCIe controllers, onboard DRAM as main memory, and ASIC-based accelerators for regular expression matching, encryption, and compression. AMD/Xilinx SN1000 [5] integrates an FPGA fabric with an SNIC similar to the NVIDIA BlueField-2 SNIC in a single chip. An SNIC is itself a complete system, recognized as an independent node.

RDMA is supported by most SNICs and standard NICs used in datacenters. As it allows a client to directly access the memory of servers at low latency and high bandwidth, it is now widely used by datacenters [16, 18, 28, 53, 56]. Additionally, an SNIC in a server can access the server's local memory through RDMA. RNIC supports two operating modes: two-sided RDMA and one-sided RDMA. The two-sided RDMA reduces packet processing overhead by delivering requests (or data) from a client directly to server's memory for application processing. One-sided RDMA allows the client to completely bypass the server's CPU and directly read from or write to the server's memory.

3 Impact of Running Kernel Features on Application Performance

A body of prior work has demonstrated that `ksm` and `zswap` have proven to be effective in improving the overall performance of systems [8, 19, 22, 27, 35, 47, 49]. Nonetheless, such benefits come with costs that have often discouraged system administrators from widely deploying them in datacenters. In this section, we analyze the costs associated with deploying `zswap` as an example.

Figure 2 shows a snapshot of (a) consumed CPU cycles, (b) last-level cache (LLC) miss rate, and (c) response latency of `Redis` that are captured when `zswap`-enabled `kswapd` is invoked. See Section 6 for the detailed evaluation setup and methodology. First, `zswap` increases the consumed CPU cycles by 26.4% during the captured time period (Figure 2(a)). Second, it increases the average LLC miss rate from 4.4% to 49.8% (Figure 2(b)). Lastly, it increases the mean, median, 3^{rd} quartile, and p99 latency values of `Redis` serving the same number of requests by 1.5×, 1.2×, 1.8×, and 2.1× respectively (Figure 2(c)).

Although we show the plots only for `zswap` in Figure 2, we observe that `ksm` also exhibits a similar impact on CPU cycle consumption, LLC miss rate and response latency of `Redis`. Subsequently, we discuss the primary sources of such increases in both `zswap` and `ksm` in detail.

`ksm`. It periodically scans pages and calculates a 32-bit checksum for each scanned page to more efficiently identify candidate pages for future merging. Among the candidate pages, `ksm` picks two pages and performs a byte-by-byte comparison to determine if the two pages can be merged. Both the checksum calculation and byte-by-byte comparisons of pages are CPU- and memory-intensive as they bring around 400MB of data to caches and CPU cores (often from DRAM) and do numerous

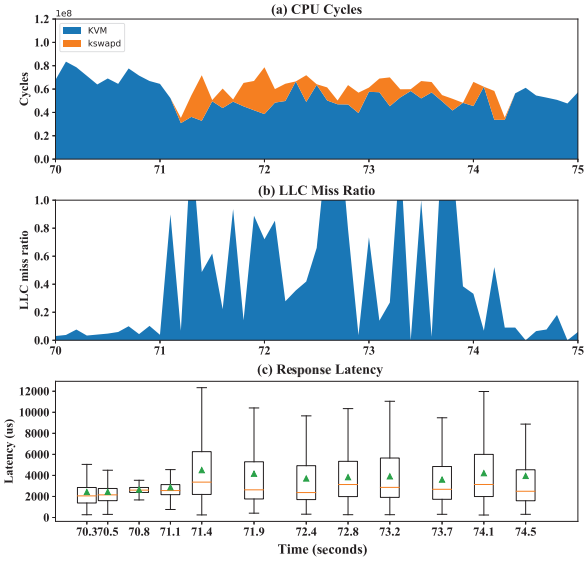

Figure 2: A snapshot of (a) consumed CPU cycles, (b) LLC miss ratio, and (c) response latency before and after invoking `kswapd` while running `Redis`. We gather the response latency values for every 1110 requests and plot them using a box, a vertical line, a triangle, and a horizontal line. The box, triangle, and horizontal line respectively represent the 1^{st} to 3^{rd} quartile range, mean, and median of the latency values for 1110 requests.

arithmetic and comparison operations for that amount of data per invocation of `ksm`.

`zswap`. When invoked, it performs compression and decompression, which are highly compute-intensive and thus significantly consume CPU cycles [23, 39]. For instance, in Figure 2, approximately 45,000 pages are compressed in only 5 seconds, consuming roughly 25–50% cycles of the server CPU's core while `zswap` is running. These pages represent 175MB (*i.e.*, 45,000 × 4KB) of *cold* data that is brought into the server CPU's LLC. Since they are unlikely to be used soon, they end up polluting the server CPU's LLC. Later, when compressed pages in `zpool` are evicted to the backing swap device (§2.1), the pages are decompressed and re-pollutes the server CPU's LLC with *cold* data again.

4 STYX Framework

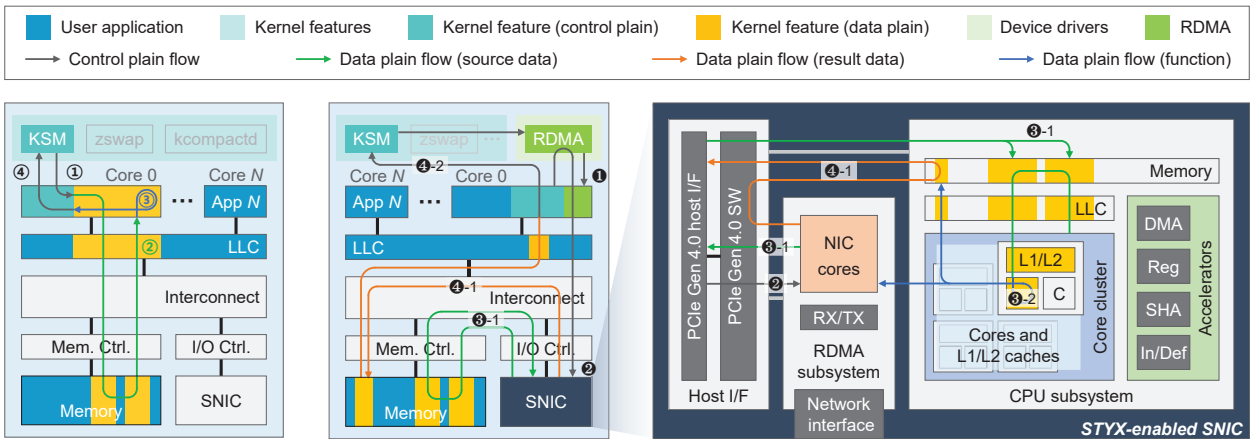
In Section 3, we demonstrated that widely used memory optimization kernel features are often CPU- and memory-intensive, and significantly interfere with co-running applications at the server CPU's cores and caches. To reap the benefits of deploying these kernel features while minimizing interference with the co-running applications, we propose STYX. In this section, we provide an overview of STYX and describe its workflow as a general framework. Subsequently, in Section 5, we delve into the usage of STYX for offloading CPU- and memory-intensive operations of `ksm` and `zswap` to SNIC.

4.1 Overview

We design STYX based on a key observation that memory optimization kernel features, similar to network applications, can be decomposed into control and data planes. We then assign the most CPU- and memory-intensive operations of the kernel features to the data plane, and have the SNIC's CPU handle the data plane. This facilitates STYX to significantly reduce the costs of deploying the kernel features without compromising their benefits.

Figure 3a depicts an abstracted workflow of conventional memory optimization kernel features. When invoked, a kernel feature running on the server's CPU ① determines one or more memory regions that it intends to operate on; ② copies the memory regions to the server CPU's caches; ③ operates on the memory regions (*e.g.*, comparing two pages using `memcmp` in the case of `ksm`); and ④ makes a decision for the next step (*e.g.*, whether merge two pages or not in the case of `ksm`) based on the result of ③. STYX considers ① and ④ as the control plane, while it assigns ② and ③ to the data plane.

In a conventional system, the server's CPU performs both control- and data-plane operations of a given kernel feature. As discussed in Section 3, the data-plane operations significantly pollute the server CPU's caches and intensively consume the server CPU's valuable cycles. In contrast, in an STYX-based system, the SNIC's CPU performs data-plane operations instead, while the server's CPU still performs the control-plane operations. Specifically, the control plane on the server's CPU first determines memory regions that the data plane on the SNIC's CPU will operate on, RDMA-copies the memory regions from the server's memory to the SNIC's memory, and then makes the data plane on the SNIC's CPU operate on the memory regions. After the data plane on the SNIC's CPU completes operations on the RDMA-copied memory regions, it RDMA-copies the results back to the server's designated memory region. Finally, as the conventional system does, the control plane on the server's CPU decides the next step based on the results.



(a) Conventional workflow

(b) Workflow of kernel feature offloading via STYX framework

Figure 3: Workflow of a memory optimization kernel feature in conventional and STYX-enabled systems. For brevity, only the cache and memory regions of the kernel feature's data plane are illustrated.

```
struct STYX_descriptor {
  func_type func;
  // memory regions RDMA-copied to SNIC
  u64* addrs; // starting addresses
  int* lens;  // lengths
  int  num;   // number
  // RDMA resources
  void* completion_queue;
  void* send_queue;
  void* recv_queue;
  ...
};
```

Listing 1: Data structure of `STYX_descriptor`.

4.2 Workflow

Figure 3b illustrates a high-level workflow of STYX framework, which is built on top of kernel-space RDMA verbs. It comprises four steps: ❶ setup, ❷ submission, ❸ remote execution, and ❹ completion.

❶ **Setup.** STYX first determines the functions that will be offloaded to SNIC. A function comprises data-plane operations within a specific kernel feature. For instance, `memcmp`, which performs a byte-by-byte comparison of two memory regions, can be such a function in `ksm`. Next, STYX establishes a communication interface between the server and the SNIC by setting up RDMA connections between them. Specifically, STYX allocates necessary RDMA resources, such as completion and work queues, in the kernel space on the server and the user space on the SNIC (❶ in Figure 3(b)). To avoid contention for the RDMA resources among functions, STYX sets up one RDMA connection for each function. Finally, for each function, STYX creates two descriptors, each called `STYX_descriptor`, on the server and the SNIC, respectively, and then associates the descriptors with the corresponding RDMA connection. `STYX_descriptor` is a data structure described in Listing 1, which stores the following information: a function identifier, pointers to the starting addresses of memory regions, the lengths and number of the memory regions, and pointers to the RDMA resources. It is designed to provide a uniform and generic interface for a server to provide necessary information for an SNIC that will execute a specific function on behalf of the server.

❷ **Submission.** Before a kernel feature executes a function, STYX on the server updates the descriptor associated with the function with the starting addresses and lengths of memory regions that it has determined to work on. Next, STYX uses two-sided RDMA to offload the function. Specifically, STYX on the server sends an RDMA `send` request based on the updated descriptor, making the SNIC RDMA-copy the memory regions from the server's memory to the SNIC's memory (❷ in Figure 3(b)). Lastly, STYX calls RDMA `recv`. This suspends the execution of the kernel feature until the SNIC sends the results of the function back to the server through RDMA `send`, and allows the kernel feature to yield the server CPU's core to other application processes.

Alternatively, STYX can employ one-sided RDMA. In this approach, STYX on the server posts the updated starting addresses and lengths to the server's designated memory region (*i.e.*, the descriptor on the server) registered to the SNIC. At the same time, STYX on the SNIC continuously polls the memory region using RDMA `read`. Once STYX on the SNIC obtains the updated addresses and

lengths, it proceeds with RDMA-copying the memory regions from the server's memory to the SNIC's memory using RDMA `read`. This one-side RDMA-based approach can allow STYX to free up the server's CPU for other application processes faster than the two-sided RMDA-based approach. However, it requires the SNIC's CPU to poll the registered memory region using RDMA `read` requests, resulting in consuming PCIe interconnect bandwidth and SNIC CPU's cycles.

❸ **Remote Execution.** After receiving an RDMA `send` request from the server, the SNIC starts to RDMA-copy the server's memory regions to the SNIC's memory region pointed by the RDMA `recv` request using a single scatter-gather transfer (❸-1 in Figure 3(b)). The completion of serving the RDMA `recv` request wakes up STYX on the SNIC to execute a function associated with the RDMA connection. Subsequently, STYX on the SNIC creates a worker thread to execute the function which operates on the RDMA-copied memory region (❸-2 in Figure 3(b)). Note that executing such a function may interfere with network applications co-running on the SNIC. Nonetheless, the SNIC CPU serves as a control plane for network applications executed by the SNIC accelerators (§1), and STYX utilizes unused or underutilized SNIC CPU cores. Therefore, STYX negligibly affects the performance of network applications running on the SNIC (§7.6).

❹ **Completion.** After completing the remote execution of the function, STYX on the SNIC posts an RDMA `send` request to send the results (*e.g.*, the checksum of a page in the case of `ksm`) to STYX on the server (❹-1 in Figure 3(b)). After STYX on the server receives the result through RDMA `recv` previously invoked at ❷, it makes the kernel feature resume the execution and read the results from the server memory (❹-2 in Figure 3(b)). At the same time, STYX on the SNIC invokes RDMA `recv`, which makes STYX on the SNIC sleep until it receives RDMA `send` from the server.

Similar to what is discussed in ❷, STYX on the SNIC can send the result to the server through one-sided RDMA `write` to a memory region registered on the server. However, this demands the server's CPU to keep polling the memory region until the completion signal is detected. This not only wastes the server CPU's cycles but also prevents the kernel feature from yielding the server CPU to application processes.

5 Offloading Kernel Features with STYX

In Section 4, we provided a high-level workflow of STYX as a general framework for offloading intensive operations (or functions) of memory optimization kernel features to SNIC. In this section, we will further elaborate on implementations of STYX-based `ksm` and `zswap`, as well as optimizations tailored for each kernel feature.

5.1 `ksm`

`ksm` is a memory-deduplication feature that merges pages with the same content. We identify the two most resource-intensive functions to offload to SNIC: (1) page comparison and (2) checksum calculation. The page comparison gives the relative address of the first byte that differs in two pages. This is used to determine whether the pages can be merged and the relative order of the two pages. The checksum calculation provides a word-size hash value calculated based on the page content and indicates whether a page has been changed between scan passes by the `ksm` daemon. Algorithm 1 describes one pass of STYX-based `ksm` where the page comparison and the checksum calculation are performed by `STYX_compare` and `STYX_checksum`, respectively.

Since we offload two functions to SNIC, STYX creates two RDMA connections and two descriptors during the setup phase (❶). `STYX_compare` requires two for the number of memory regions as it compares two pages (or memory regions). On the other hand, since

Algorithm 1: `ksm` with STYX offloading

```
1  Init stable_tree and unstable_tree
2  while pages for this pass > 0 do
3      cand_page = next page in the pass
4      for page ∈ stable_tree do
5          if STYX_compare(cand_page, page) then
6              merge(cand_page, page)
7              goto line 2
8      new_cksum = STYX_checksum(cand_page)
9      old_cksum = cand_page.cksum
10     cand_page.cksum = new_cksum
11     if new_cksum == old_cksum then
12         for page ∈ unstable_tree do
13             if STYX_compare(cand_page, page)
                 then
14                 merged_page = merge(cand_page,
                     page)
15                 cow_protect(merged_page)
16                 remove(page, unstable_tree)
17                 insert(merged_page, stable_tree)
18                 goto line 2
19         insert(cand_page, unstable_tree)
20 End of pass, sleep()
```

STYX_checksum calculates a checksum for a given page, it needs one for the number of memory regions. For the length of a memory region, both STYX_compare and STYX_checksum use the size of a page in byte. During the submission phase (❷), STYX updates the starting addresses of the memory regions in the descriptor for STYX_compare with the pointers to two chosen pages. For STYX_checksum, STYX takes the pointer to a selected page and updates the descriptor accordingly. Subsequently, STYX RDMA-copies these memory regions from the server memory to the SNIC memory. During the remote execution phase (❸), STYX on the SNIC performs a byte-by-byte comparison and an xxHash-based checksum calculation [10] on the RDMA-copied page(s). It then returns the relative address of the first byte that differs in the two pages (STYX_compare) and the word-size checksum (STYX_checksum), respectively, to STYX on the server. Receiving the results from STYX on the SNIC, STYX on the server decides whether it will merge the two pages or not, and updates the checksum value for the scanned page during the completion phase (❹).

5.2 zswap

zswap serves as a compression backend for kswapd, and it was incorporated into the Linux kernel starting from version 3.5. As described in Section 2.1, there are synchronous direct and asynchronous background paths.

Algorithm 2: kswapd with STYX offloading

```
1  while kswapd_enabled do
2      if free_page < page_low then
3          kswapd_running = true;
4          while kswapd_running do
5              page = page_to_swap_out()
6              if zpool > max_zpool_size then
7                  if STYX_decompression(LRU_page,
                     dst) fails then
8                      kernel_decompress(LRU_page,
                         dst);
9                  write_to_backing_swap_device(dst);
10                 free_zpool_space(LRU_page);
11             if STYX_compression(page, dst) fails
                 then
12                 kernel_compress(page, dst);
13             write_to_zpool(dst);
14             if free_page > page_high then
15                 kswapd_running = false;
16     else
17         kswapd_sleep();
```

STYX is capable of offloading functions from both paths to SNIC. Nonetheless, as an optimization, we choose to offload only the asynchronous background path which is taken when (1) the amount of free memory space falls below the page_low watermark, and (2) the size of zpool reaches the max_pool_percent threshold. Specifically, when (1) happens, STYX-based zswap makes SNIC compress pages and place the compressed pages in zpool until the amount of free memory space is above the page_high watermark. When (2) occurs, it makes SNIC decompress the LRU page from zpool and relocate it to the backing swap device. We propose this optimization because the latency involved in RDMA-copying pages to the SNIC memory over the PCIe interconnects (*i.e.*, $\sim 5\mu$s) may slow down the time-sensitive synchronous direct path, and degrade overall system performance. Algorithm 2 describes kswapd modified to support STYX-based zswap where the page compression and decompression are performed by STYX_compression and STYX_decompression, respectively.

Since we offload two functions to SNIC, the setup and submission phases for STYX-based zswap are exactly the same as STYX-based ksm except that zswap has only one memory region to RDMA-copy to the SNIC memory for both the functions. Finally, after the remote execution of STYX_compression and STYX_decompression, STYX on the SNIC will return the compressed and decompressed pages, respectively, to STYX on the server.

6 Methodology and Implementation

System Setup. We set up a server with an Intel Xeon Gold CPU and an NVIDIA BlueField-2 SNIC. The detailed hardware and software configurations of the server are listed in Table 1. Note that we lock the CPU frequency at 2.1 GHz and disable hyper-threading (HT) for more consistent performance over multiple measurement runs. VMs are pinned to specific CPU cores to reduce performance variations and interference caused by dynamic voltage/frequency scaling (DVFS) [12], HT [32], and VM scheduling.

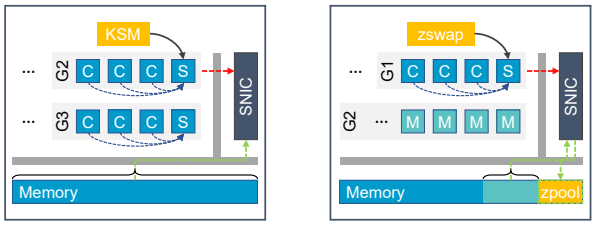
Workload. We run Redis [41] with Yahoo! Cloud Serving Benchmark (YCSB) [11] on the system. Redis is an in-memory data store and is used as a distributed, in-memory key–value database, cache, and message broker, with an optional durability feature. YCSB is a benchmarking framework to evaluate the performance of various in-memory key-value stores. It comes with four workloads: (a) update heavy, (b) read heavy, (c) read only, and (d) read latest that consist of (a) 50% read and 50% update, (b) 95% read and 5% update, (c) 100% read, and

Table 1: Hardware and Software configurations.

Intel Xeon 6138P Server
CPU: 16 Skylake cores @ 2.1GHz w/ HT disabled, 32KB L1, 1MB L2, and 1MB L3 caches per core **Memory:** 5-Ch. w/ 5 16GB DDR4-2666 DRAM modules **OS:** Ubuntu 18.04.6 LTS, Linux kernel 5.4
NVIDIA BlueFeild-2 SNIC
Network: ConnectX-6 Dx w/ two 25 Gbps Ethernet ports , RDMA over converged Ethernet V2 **CPU:** 8 ARM A72 cores @ 2.5GHz, 640 KB L1 per core, 4 MB L2 caches per 2 cores, and 6 MB L3 cache **Memory:** 1 Ch. w/ 16GB DDR4-1600 DRAM module **Accelerators**: regular expression matching, compression, and cryptography **OS**: Ubuntu 20.04.2 LTS, Linux kernel 5.4
Kernel Feature
ksm: `sleep_between_scan`=20ms, `free_mem_thres`=20 `pages_to_scan` ∈ [64, 1250] # adjusted by *ksmtuned* **zswap**: `compressor_type` = lzo, `max_pool_percent` = 20 `zpool_management` = zbud
Virtual Machine
Hypervisor: QEMU-KVM 2.11.1 **VM**: Ubuntu Cloud 18.0, 1 Core, 4GB memory

(d) 95% read and 5% insert, respectively.

Methodology. Figure 4 depicts the evaluation environments for `ksm` and `zswap`. `ksm` aims to reduce memory usage in virtualized environments where multiple VMs are running similar workloads. We set up 16 VMs and pin each VM to a physical core. Then, we organize the VMs into 4 groups, each comprising 3 VMs for `Redis` clients and 1 VM for a `Redis` server. To trigger `zswap`, we set up a background workload designed to allocate



(a) Setup for **`ksm`** (b) Setup for **`zswap`**

Figure 4: Experimental setup for evaluating STYX-based `ksm` and `zswap`. The blue-color boxes indicate the Redis server ('S') and client ('C'). The lighter-blue blocks ('M') represent the cores running a background workload.

and free memory space periodically. We need such a background workload because `Redis` is in-memory data store, and it should be configured not to incur any page faults. Otherwise, p99 latency is dominated by handling page faults. We use `cgroup` [1] to protect the pages used by `Redis` from being swapped out. In the experimental setup for `zswap`, `Redis` servers and clients run on the physical cores directly without VMs.

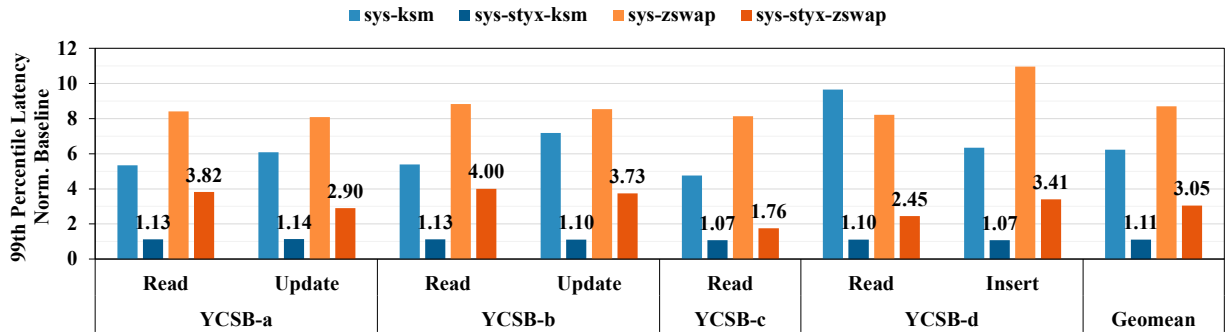
7 Evaluation

7.1 Latency

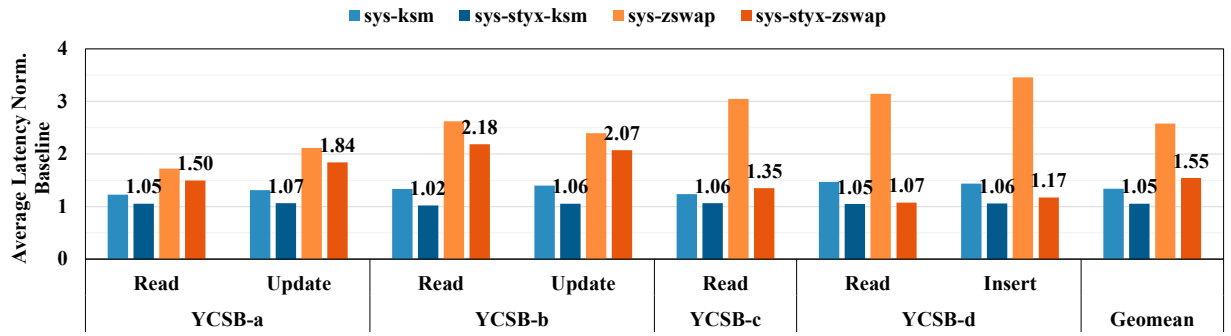
In this section, we choose p99 latency as a key performance metric for our evaluation because many important datacenter applications need to meet certain high-percentile latency requirements [36, 38]. Figure 5a shows the p99 latency values of `Redis` on systems that deploy `ksm` (`sys-ksm`), `zswap` (`sys-zswap`), STYX-based `ksm` (`sys-styx-ksm`), and STYX-based `zswap` (`sys-styx-zswap`), normalized to those of a system without deploying any memory optimization kernel feature (`sys-no-mo`). Overall, it demonstrates that STYX can significantly reduce the p99 latency increased by deploying `ksm` and `zswap`.

Specifically, on average (geometric mean), `sys-ksm` and `sys-zswap` give 6.24× and 8.70× higher p99 latency values than `sys-no-mo`, respectively. In contrast, `sys-styx-ksm` and `sys-styx-zswap` offer 1.11× and 3.05× higher p99 latency values than `sys-no-mo`, respectively. That is, `sys-styx-ksm` and `sys-styx-zswap` reduce the p99 latency increase by 5.62× and 2.85×, compared to `sys-ksm` and `sys-zswap`, respectively. Note that `sys-styx-ksm` offloads most of the intensive operations to SNIC, practically eliminating the p99 latency increase of `sys-styx-ksm`. On the other hand, `sys-styx-zswap` offloads only the intensive operations of the asynchronous background path to SNIC. That is, the intensive operations of the synchronous direct path still affect the p99 latency of `Redis`, contributing to more than 3× increase in p99 latency.

In addition, Figure 5b shows the average latency values of `Redis` on those systems. The average latency of `Redis` is also an important performance metric, as it is inversely proportional to the throughput. Note that `Redis` often throttles serving requests to prevent response latency from increasing too much when the system receives more requests than it can handle efficiently [3]. On average, `sys-ksm` and `sys-zswap` give 1.34× and 2.58× higher average latency than `sys-no-mo`, respectively. In contrast, `sys-styx-ksm` and `sys-styx-zswap`



(a) p99 latency



(b) Average latency

Figure 5: Latency values of `Redis` with `YCSB` workloads running on `sys-ksm`, `sys-styx-ksm`, `sys-zswap` and `sys-styx-zswap`, normalized to `sys-no-mo`.

offers only 1.05× and 1.55×, higher average latency than `sys-no-mo`, respectively. That is, `sys-styx-ksm` and `sys-styx-zswap` reduce the average latency increase by 22% and 40%, compared to `sys-ksm` and `sys-zswap`, respectively.

7.2 LLC Miss Rates

To analyze how STYX reduces the negative impact of deploying `ksm` and `zswap` on p99 latency of `Redis`, we measure the LLC miss rates of the server CPU every 1 second while evaluating `sys-no-mo`, `sys-styx-*` and `sys-*`. We report the p99 LLC miss rates from approximately 160 1s intervals instead of the average LLC miss rates, because intervals with high LLC miss rates are likely responsible for p99 latency values of `Redis`.

Table 2 summarizes the p99 LLC miss rates across all `YCSB` workloads at their highest throughput values that the systems can provide. This shows that the memory optimization kernel features can significantly increase the p99 LLC miss rates, bringing large amounts of cold data into the server CPU's caches when invoked. Specifically, `sys-ksm` and `sys-zswap` give 7.33× and 1.70× higher p99 LLC miss rates than `sys-no-mo`, respectively, in some intervals. In contrast, `sys-styx-ksm` and `sys-styx-zswap` offer 3.78× and 1.28× higher p99 LLC miss rates than `sys-no-mo`, respectively. That is, `sys-styx-ksm` and `sys-styx-zswap` reduce the p99 LLC miss rate increase by 48% and 25%, respectively. Such a benefit comes from the fact that `sys-styx-ksm` and `sys-styx-zswap` RDMA-copy the server's memory regions that `ksm` and `zswap` work on to the SNIC memory instead of the server CPU's caches.

Table 2: p99 LLC miss rates of three systems (`sys-no-mo`, `sys-*`, and `sys-styx-*`) for different `YCSB` workloads.

	a	b	c	d	GeoMean
`no-mo`	9.7%	7.1%	7.3%	8.0%	8.0%
`ksm`	60.4%	56.9%	59.8%	57.5%	58.6%
`styx-ksm`	40.4%	26.5%	27.2%	28.4%	30.2%
`no-mo`	18.5%	21.4%	22.2%	21.7%	20.9%
`zswap`	34.7%	41.3%	33.9%	32.6%	35.5%
`styx-zswap`	25.1%	27.8%	29.8%	24.7%	26.8%

Table 3: CPU utilization of two systems (sys-* and sys-styx-*) for different YCSB workloads.

	a	b	c	d	GeoMean
ksm	26.0%	26.0%	25.9%	25.9%	26.0%
styx-ksm	7.1%	7.3%	6.8%	6.7%	7.0%
zswap	23.5%	19.8%	20.5%	17.8%	20.3%
styx-zswap	13.0%	8.9%	11.8%	8.4%	10.4%

Note that the p99 LLC miss rate of sys-no-mo for ksm is much lower than that of zswap. This is because of the background workload designed to incur page faults for zswap. Besides, in the case of zswap, STYX offloads only intensive operations of the asynchronous background path to SNIC. That is, intensive operations of the synchronous direct path still pollute the server CPU caches when the background workload incurs page faults. Lastly, even in the case of ksm, STYX does not offload all the operations, either.

7.3 CPU Cycle Consumption

In addition to reducing cache pollution, STYX conserves the server CPU's cycles, as it offloads the CPU-intensive operations to the SNIC CPU. To assess the impact of running ksm and zswap on consuming the server CPU's cycles, we identify the number of 1-millisecond intervals that both a kernel feature and Redis co-run on a server CPU's core while measuring the number of server CPU's core cycles consumed by the kernel feature during these intervals. To get the average CPU utilization shown in Table 3, we sum up all the server CPU's core cycles consumed by the kernel feature and then divide it by the total number of the server CPU's core cycles during the intervals in which the kernel feature and Redis co-run.

Table 3 shows that STYX considerably reduces the consumption of the server CPU's core cycles. On average, sys-styx-ksm and sys-styx-zswap reduce the server CPU's core cycles consumed by ksm and zswap from 26% to 7% and from 20% to 10%, respectively. The server CPU's cycles saved by offloading intensive operations of ksm and zswap to SNIC can be used for Redis, which minimizes disruption of Redis operations during these co-running intervals.

7.4 Offloading Latency

Table 4 shows the breakdown of the latency values of ksm and zswap functions offloaded to the NVIDIA BlueField-2 SNIC. By analyzing the breakdown, we can identify the offloading steps that may provide further optimization opportunities. We do not include the latency breakdown of the setup step (❶), because it is called once and the latency cost is amortized over time. The submission step (❷) takes ∼0.5 microseconds, *e.g.*, only ∼2% of the total latency of offloading the functions to SNIC. This latency primarily comes from the time to send an RDMA send request to SNIC.

Table 4: The breakdown of the offloading latency values of each function and the percentage values of function execution time in total kernel feature execution time per invocation. f1 and f2 correspond to comparison and checksum of ksm, respectively. For f1, we measure the latency of comparing two pages with the same content, which gives the longest latency. f3 and f4 represent compression and decompression of zswap, respectively.

		f1	f2	f3	f4
styx-ksm/zswap	❷ (μs)	0.51	0.49	0.52	0.49
	❸ (μs)	14.61	12.93	20.26	16.97
	❹ (μs)	5.04	4.97	5.21	5.13
	% in Tot.	57.2	32.3	25.4	8.3
ksm/zswap	% in Tot.	36.9	19.5	12.3	6.1

The remote execution step (❸) takes a total of 13–20 microseconds depending on the offloaded functions. Specifically, it spends 5–7 microseconds for RDMA-copying memory regions from the server memory to the SNIC memory. It spends the remaining 8–15 microseconds for the SNIC CPU to execute the functions of ksm and zswap. As the RDMA-copy latency is responsible for a dominant fraction of the remote execution step, we may consider making SNIC's on-chip accelerators execute these functions to further reduce the remote execution latency. However, the accelerators in the NVIDIA BlueField-2 SNIC are connected to the on-chip PCIe interconnect. Thus, it still takes a notable amount of time to offload functions from the SNIC CPU to the accelerators (*e.g.*, ∼7 milliseconds for the compression accelerator), which involves another DMA transfer within SNIC.

The completion step (❹) consumes a notable amount of time spent by interrupt handling and process context switching between application and kernel feature processes. During this step, the SNIC CPU remains active after submitting the RDMA request until receiving an acknowledgment from the server CPU. This waiting time is included as part of the latency of the completion step.

7.5 Effectiveness of Kernel Features

It takes a longer time to offload functions of the kernel features to SNIC than to run them directly on the server CPU. This in turn increases the overall execution time

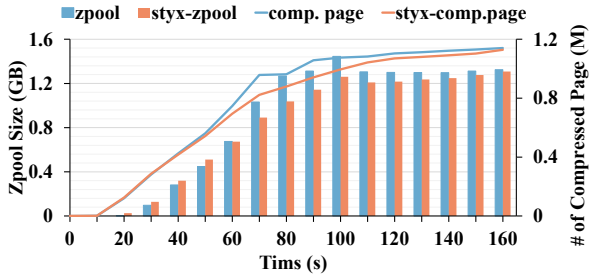


Figure 6: The number of the compressed pages (line) and the size of `zpool` (area) over time in `sys-zswap` and `sys-styx-zswap`.

of the kernel features and may affect the kernel feature's effectiveness. We take `zswap` as an example and plot: (1) the number of compressed pages and (2) the size of `zpool` over time in Figures 6. Although the compression operation performed by the SNIC in STYX does result in longer latency, the overall effectiveness and performance of `zswap` are not greatly affected. First, we observe that the size of `zpool` is not directly proportional to the number of compressed pages. This is because the compression ratio of pages varies across pages. Figure 6 shows that STYX-based `zswap` can provide a comparable compression rate close to what `zswap` can, based on the number of compressed pages. Figure 6 also shows that with STYX, the rate of growth of `zpool` is only 2% lower than that of the standard `zswap` implementation. This is explained by run-to-run performance variations.

Note that both `zswap` saves the disk I/O as it compresses the pages into swap memory and avoids the direct swap out. We monitor the disk I/O at the runtime of the workloads and see the overall disk I/O consumption is 39% lower when `zswap` is enabled. The disk I/O reduction is attributed to the swap-out compressing cache in `zswap`. Upon deploying STYX, the disk I/O throughput remains 35% lower than the `sys-no-mo` case where no `zswap` feature runs. We see that both `sys-zswap` and `sys-STYX-zswap` achieve comparable disk I/O saving. In summary, STYX-based `zswap` preserves the benefits of `zswap` while notably reducing the disruption of co-running applications caused by `zswap`.

7.6 SNIC Application Performance

Since SNIC has its own designated roles, we need to analyze the impact of running STYX on performance of applications that SNIC is designed to accelerate. Specifically, we choose regular expression matching (`rem`) as an application; since it has been extensively used for various network security applications and the NVIDIA BlueField-2 SNIC provides a dedicated accelerator. Table 1 gives an overview of the NVIDIA BlueField-2 SNIC. We take the `DPDK-Pktgen` tool [52] on a remote server to send network packets to the SNIC. We configure the SNIC and `DPDK-Pktgen` to exercise the maximum 25Gbps network bandwidth, and vary the size of packets to observe the utilization of the SNIC CPU's cores.

As the packet size increased from 128 bytes to 1024 bytes, the number of SNIC CPU's cores required to achieve the maximum `rem` throughput decreases from 5 to 1. Smaller packet sizes demand more packets per second to use the full network bandwidth, which in turn requires more cores. In our current implementation, STYX on the SNIC utilizes only ∼30% of a single core of the SNIC CPU, which is obtained after running the most CPU-intensive function, page compression in `zswap`. That is, the SNIC can handle STYX with little impact on the performance of `rem`. Our experiment shows that the SNIC running only `rem` gives a p99 latency of 13.83 microseconds, while the SNIC running both `rem` and STYX offers a p99 latency of 13.85 microseconds. It also confirms that the SNIC running both `rem` and STYX do not decrease the maximum throughput of `rem`.

8 Related Work

Exploring the improved compute efficiency of heterogeneous computing, many past proposals have focused on offloading CPU-intensive operations of user-space programs from the CPU to xPUs and FPGA. In contrast, relatively less attention has been given to offloading CPU- and memory-intensive operations of kernel-space programs from the CPU so far. Nevertheless, it has become increasingly important, especially for datacenter servers to cost-effectively reduce the high datacenter tax.

Some past proposals aim to make kernel features run more efficiently. One pioneering proposal is `Pageforge` [45], which implements a hardware mechanism in the memory controller to execute the page comparison operations of `ksm`. It also exploits the Error Correcting Code (ECC) engine in the memory controller to perform the checksum calculation operations of `ksm`. Although `Pageforge` is effective, it requires hardware changes in the memory controller. Lin *et al.* propose to accelerate checksum calculation using GPU [30]. `XLH` [35] enhances the page scan in `ksm`, utilizing hints from guest I/O in a VM environment. It allows `ksm` to identify mergeable pages earlier and merge more pages. Nonetheless, it does not reduce either the consumption

of the server CPU's cycles or the pollution of its caches. `ezswap` [25] estimates the compression ratios of pages in advance, compresses only highly-compressible pages, and store them in `zpool`. Classic `zswap` blindly chooses pages to swap out and compress based on the LRU policy. Song *et al.* propose an efficient way to enhance `zswap` by skipping the compression of incompressible pages [46]. These optimizations are orthogonal to our work and can be employed together with STYX.

Abeyrathne *et al.* [2] demonstrated the potential of offloading kernel functions to FPGA by utilizing the advanced features of the latest Xilinx FPGA with the provided kernel modules. STYX instead deals with the problems by elaborative and creative designs without any limitation on the FPGA model. Roulin *et al.* [42] examined the migration of the user-space network switch daemon to the kernel space. This setup aims to grant complete control of the routing ASIC to the Linux kernel, thereby reducing the overhead of kernel-space and user-space communication. However, this approach does not offer a general solution to the communication between the OS kernel and the offloading device, as it is specifically designed for network switch APIs.

There also have been many studies conducted on SNIC to explore its capacity in various ways. Offloading various functions, such as distributed services and intrusion detection, to SNICs is a promising approach to mitigate resource consumption on servers, enhance the performance of specialized operations, and improve overall energy efficiency [9, 13, 15, 17, 29, 48, 50]. Specifically, `LineFS` [26] offloads distributed file system. `FlexTOE` [44] offloads TCP to SmartNIC with flexibility and high performance. `Xenic` [43] uses the LiquidIO 3 SNIC [33] for fast distributed transactions. `Pigasus` [55] uses an FPGA-based SNIC to accelerate intrusion detection and prevention systems. STYX focuses on harnessing the capabilities of SNICs to effectively mitigate the datacenter memory tax.

9 Conclusion

In this paper, we first showed that memory optimization kernel features intensively consume the server CPU's cycles and pollute its caches when they are invoked. This in turn leads to a significant increase in the p99 latency of memory-intensive/latency-sensitive datacenter applications. Second, we proposed STYX as a solution to minimize the consumption of server CPU's cycles and the pollution of its cache caused by these kernel features. STYX accomplished these by leveraging the RDMA and compute capabilities of modern SNIC, and offloading the intensive operations of these kernel features to SNIC. Lastly, we demonstrated the effectiveness of STYX after re-implementing two memory optimization kernel features in Linux: `ksm` and `zswap` using the STYX framework and running memory-intensive/latency-sensitive applications. We showed that the systems with STYX-based `ksm` and `zswap` achieved 5.6× and 2.9× lower p99 latency values than the systems with classic `ksm` and `zswap`, while preserving the benefits of `ksm` and `zswap`.

Abstract

Automated management of a physical network's lifecycle is critical for large networks. At Google, we manage network design, construction, evolution, and management via multiple automated systems. In our experience, one of the primary challenges is to reliably and efficiently manage change in this domain – additions of new hardware and connectivity, planning and sequencing of topology mutations, introduction of new architectures, new software systems and fixes to old ones, etc.

We especially have learned the importance of supporting multiple kinds of change in parallel without conflicts or mistakes (which cause outages) while also maintaining parallelism between different teams and between different processes. We now know that this requires automated support.

This paper describes some of our network lifecycle goals, the automation we have developed to meet those goals, and the change-management challenges we encountered. We then discuss in detail our approaches to several specific kinds of change management: (1) managing conflicts between multiple operations on the same network; (2) managing conflicts between operations spanning the boundaries between networks; (3) managing representational changes in the models that drive our automated systems. These approaches combine both novel software systems and software-engineering practices.

1 Introduction

In large production networks, changes happen all the time. Lots of research and development has delivered a wide range of designs and products for managing changes to network data planes and control planes. Requirements for scalability, reliability, security, low cost, and rapid flexibility together have made it essential to automate many aspects of network management, but this work has mostly focused on managing networks *after* the physical components have been deployed. For example, Software Defined Networking (SDN) methods do not directly address designing the physical wiring of a network, or ensuring that the right switches and cables are ordered from vendors, or connected to effect a design, or how to sequence and schedule this physical work.

At Google, we have also found it necessary to automate many *abstract and physical aspects of a network's full lifecycle*, including network planning (what networks do we need to build and when, given capacity forecasts?), network design (what specific switches and links do we need?), materials ordering (what specific part numbers do we need to order and when, what cables need to be constructed?), network construction (where do data center operators need to place equipment and cables?), firmware installation, physical validation (are the links correctly connected and not suffering high error rates?), network repair processes (which links/switches can we safely drain before doing repairs?), etc. We must also provide our automated control planes with accurate, detailed "schematics" for the networks that they manage.

While initially we could perform *Network Lifecycle Management* (NLM) manually, in practice this was slow, error-prone, and inflexible. Those problems worsened with increasing scale, driving us to automate as much of this work as possible. For example, designing optimal inter-block cabling for a Jupiter fat-tree network is NP-complete, and a good approximation requires significant computation [31, 38]. Even at much smaller scales, processes like correctly rolling out router configuration changes are safest when they are carefully automated [23].

As we introduced systems to automate NLM, we discovered that we had not sufficiently understood or appreciated the difficulty of *change management* in this specific domain. Certainly, change management has always been a problem for network designers and operators, and much useful work has been done on ways to manage changes to device configurations (or SDN controller configurations) related to routing, access control lists, and other post-deployment issues.

However, several other aspects of change management began to delay our progress and undermine the value of our automation. These include managing conflicts between multiple operations on the same network; managing conflicts

between operations spanning the boundaries between networks; managing representational changes in the models that drive our automated systems; and introducing major changes in our software infrastructure.

In this paper, we focus on these change-management challenges, the solutions we developed for them, and some of the experience we gained. In particular, we address several distinct (but interacting) aspects of change management:

Managing conflicts between operations: deciding what order to do things in, and what process steps can be done in parallel without conflicts. The physical lifecycle of a network involves many steps with complex dependencies. In small networks, changes are *sometimes* sufficiently rare and rapid that they can be serialized without loss of efficiency. In a large, frequently-changing network, multiple changes, sometimes with extended execution time, *must* overlap, or else capacity delivery and upgrades becomes unacceptably sluggish (e.g., see §10.1). We must prevent operational conflicts that lead to outages, or even the risk of outages, because we want to do these operations on "live" networks.

Planners must also be able to analyze potential sequences of future changes to decide the best partial order, choose the least costly option, or detect if a sequence would lead to an infeasible or invalid state (we call this "what-if analysis"). Planners also sometimes need to *modify* the order of existing plans, as constraints or requirements change.

Therefore, a key contribution of this paper is the design of a plan-management service (§5.2), and the abstractions that allow us to explicitly represent how various future lifecycle states depend on each other or can be done in parallel.

Representational change: Automation depends on machine-readable data. Foundational to the work in this paper is the MALT network-model representation [27], which we use to represent the current, desired, and potential future states of network topologies at many levels of abstraction. Planning and design processes form a pipeline of successive refinements of these models, and the generation of derived data, such as instructions for creation and placement of cables, from these models. Likewise, operational data, such as device and SDN controller configurations, are primarily derived from these models.

A notable challenge in modeling is that our continued innovation in network designs and components requires us to rapidly evolve the MALT representation (e.g., Fig. 8). Previously, we found it hard to do this safely (without production outages) and without constantly and tediously updating lots of model-generating and model-consuming software; this seriously slowed our innovation.

We describe how we allow a wide variety of model-consuming systems, built and maintained by many different partner teams, to cope with evolution in our MALT representation and how we use it to encode specific designs, without requiring unsustainable engineering efforts on the part of those teams. (§7, §8)

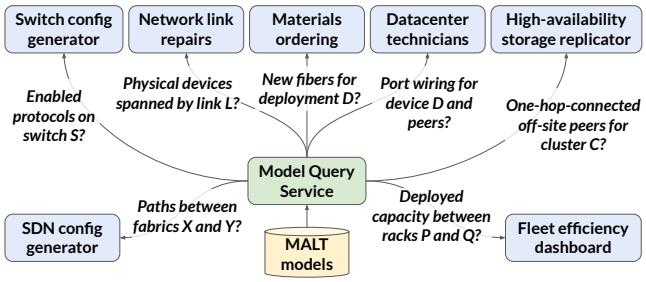

Figure 1: Some use cases for MALT models.

While this paper reports on our experience with large-scale datacenter network infrastructures, we are also applying the same tools and practices in several adjacent domains, such as the management of WAN systems, of machines, and of datacenter physical designs. Our approaches are useful at smaller scales, too.

Ethical concerns: The systems described in this paper do not handle or store any Personal Identifiable Information (PII), and do not raise any ethical issues.

2 Context

This paper focuses on our *Jupiter* datacenter network fabrics [30, 31], and our *B4* WAN fabrics [16, 18]. By "fabric" in this paper, we generally mean a Clos network consisting of many switches and links, with SDN controllers.[1]

We drive our network automation using machine-readable representations, primarily the MALT representation (*Multi-Abstraction Layer Topology*) representation, described in [27], and summarized below in §2.1. We organize these representations as *models* of the network fabric's topology and many other static details.

Our automation covers many aspects of a network's entire lifecycle, including (as depicted in Fig. 1 and Fig. 2):

- **Fabric planning**: Our infrastructure planning team decides when we need to build, expand, or decommission a fabric. They express their high-level goals (where should the fabric be built? Using what abstract architecture? Of what size?) via MALT *fabric intent* models. These models have relatively few details. Planners might explore several possible options for a fabric before committing to a specific choice.
- **Fabric design**: Before we can construct a network, we convert the fabric intent into *concrete* MALT models, via a fully-automated process somewhat like compilation of a program. The concrete models, after several levels of refinement, fully define the structure of the network, down to individual switches, fibers, racks, etc.

[1] We have other networks that use a more traditional design consisting of large non-SDN routers; our management processes for those networks are somewhat different.

- **Materials ordering**: When we commit to a decision to build or expand a fabric, we take the first (nearly) irreversible step of ordering materials (switches, fibers, etc.). Since these are expensive, after this point we generally avoid changing our intentions. The choice of exactly what materials to order is an automated process driven by MALT models and additional inputs.
- **Fabric deployment**: With the materials on hand, we can build the network (place racks, switches, and SDN controller machines, connect them with fibers, and test that it all works). This step is carried out by humans, using automatically-generated detailed human-readable plans based on the MALT models. We also install the necessary on-switch software using automated processes.
- **Controller and switch configuration**: Once the network is built, we automatically generate SDN controller and switch configurations from the MALT models, with additional configuration inputs.
- **Operations**: Our operators manage the run-time behavior of a network via various tools and services. For example, they might need to "drain" part of a fabric to carry out repairs or upgrades, and then "undrain" it later. The systems that carry out these operational changes are also driven, in part, by MALT models. We also have automated control planes (e.g., [22]) that depend on structural information expressed using MALT.
- **Health and repairs**: We have automated systems to decide whether the network is unhealthy, to diagnose the causes of problems, and to help us understand what systems would be affected by a faulty (or drained) component. These all use MALT as some of their input data.

It should be obvious that we rely on *accurate* and *up-to-date* MALT models for virtually all of our network management automation. The challenges discussed in this paper are all related to preserving that accuracy when our systems are constantly evolving.

2.1 Background on MALT

We briefly summarize the aspects of MALT [27] necessary to understand this paper.

MALT is an *entity-relationship model* representation, not a database. In an entity-relationship model, entities represent "things," which can be abstract (e.g., an entire fat-tree network) or quite detailed (e.g., a specific strand of fiber), or in-between (e.g., an IP adjacency aggregating multiple fibers). Entities have "kinds" (types), names, and attributes, Entities are connected via relationships, which have kinds, but neither names nor attributes.

A collection of entities and relationships forms a MALT *model*. We divide models into *shards*, with some shard-specific metadata. Model shards are typically (but not always) aligned with physical infrastructure boundaries at the city, region, or building scale. Some shards have millions of entities. Please refer to [27, Fig 3.] and [27, Appendix A] for example MALT models. Detailed, machine-readable versions of these examples are available for download [13].

We normally store shards in MALTShop, a purpose-built system that enables easy sharing of models between systems, which depends on naming, access control, and consistency. Shards in MALTShop have names (similar to UNIX pathnames) and access-control lists (ACLs). Every update to a shard creates a new, immutable version, with an immutable version number. MALTShop uses a copy-on-write mechanism to efficiently store many versions of a shard that is being incrementally updated.

MALTShop supports a generic query language, which walks an entity-relationship graph to extract a chosen subset model. It allows one query to span a set of multiple shards.

To manage evolution, each shard can assert compliance with one or more *profiles*. A profile is essentially a contract between a shard's producer and consumers that the shard conforms to a set of predicates. Profiles are versioned; when we need to change how we represent a network, we signal that by creating a new version of the corresponding profile.

Our planners, designers, and operators usually want to think in terms of the high-level abstract designs of these networks (e.g., a Jupiter network is a collection of blocks connected by spine blocks), rather than in terms of specific switches and fibers; the support for multiple abstraction layers in a single MALT model enables this separation of concerns.

2.2 Why automate?

Our work was motivated by our large, heterogeneous networks, but we believe this kind of automated approach would be valuable for a broad range of network operators (although we realize that the market for full-lifecycle automation software may be small).

Automation enables design flexibility and experimentation. The research community has generated a wonderful range of scalable network structures, including Fat-Trees [1], expander graphs [32], F10 [25], etc. These designs exploit path redundancy to support high bandwidth and availability at relatively low cost.

However, most non-hyperscaler enterprises appear not to be using modern multipath networks. In fact, the dominant provider of network hardware recommends a simple three-layer design with large "core" switches at the top, relatively large "aggregation" switches in the middle, and smaller "access" switches (e.g., top-of-rack or ToR switches) at the bottom [8] and other vendors recommend two layers [3].[2] Why do most enterprises avoid multipath networks? Our (admittedly anecdotal) understanding from several experts is that

[2]These are old citations; the age of these documents may reflect an inherent stasis.

most enterprises lack the design tools that they would need to construct and maintain fat-tree networks, let alone less-regular designs such as expander graphs. We speculate that the low adoption rate for research-generated network designs is at least partially due to a lack of tooling, especially to support safe and frequent changes. (There are, of course, other reasons.)

Risk management. Hyperscalers use multipath network topologies [2, 31, 34, 38] also because they support incremental expansion of, and upgrades to, live networks. The need for zero-downtime changes to the structure of these networks is driven by Service Level Objectives (SLOs) targeting 99.99% or better availability, which allows at most a minute of downtime per week. Some providers hope to achieve 99.999% availability, allowing just 5 minutes of downtime per year.

Most enterprise networks are more static than ours; every change creates the risk of a large-scale outage, so operators are extremely change-averse. Their use of non-multipath designs leads to less structural redundancy, which we and other hyperscalers exploit to allow frequent changes at relatively low risk. Our automated tooling both indirectly supports low-risk changes by enabling the use of fat-trees, and directly supports it by allowing us to validate all low-level changes against higher-level intent. Smaller enterprises would benefit from using such automation to mitigate change-management risks; e.g., assigning the same IP address to two different endpoints (a mistake we have made in manual workflows).

Addressable markets. Our work focuses on automated operations on large and frequently-changing networks. Many networks are too small or static to require such automation; how many enterprises actually have large networks? Data on this topic is difficult to find, often because it is only available via high-cost market-research reports. While the number of hyperscalers is small, when we include software-as-a-service and other forms of cloud, there are at least dozens of such providers [29]. The number of hyperscaler data centers is also growing consistently [9]. However, there are many other large non-hyperscaler data centers. There are also thousands of smaller "Points of Presence" (POPs); a typical pattern for both large and small enterprises is to build and maintain small fabrics in many POPs, motivating *frequent* use of design and turnup automation.

Takeaway: Many – perhaps most – network outages result from human error, often associated with physical-network changes [15, 21]; automation with a specific focus on change management can make these changes faster and more reliable. It also enables increased agility and innovation.

2.3 Related work

Prior work on network management has mostly focused on network device configuration management, such as configuration language design [7] and configuration generation for existing networks [5, 24, 34]. Although our networks' configurations are derived from network models, our focus here is on planning for topology designs, and for the physical construction, modification, and eventual decommissioning of networks, as well as for their day-to-day operation.

Most prior work (both academic and commercial) has also typically focused on managing the network as it is now, or on verifying near-term intent (i.e., to be implemented as soon as possible). This includes verification of data-plane [19, 20, 36] and control-plane [4] properties.

In contrast, this paper addresses the challenges of planning for future physical states of a network, especially on how to manage sequences of dependent changes in the face of confounding factors, and on how to validate both individual states and sequences of changes. We note that validated, accurate topology models can enable verification of control-plane and data-plane layers.

Some prior work (e.g., [32, 37]) discussed how topology design affects the complexity of lifecycle management, but did not address how to automate the management processes.

Network operators often expand network topologies to augment capacity [37]. Prior work [38] described how we expand live data center networks, through a layer of patch panels; it uses an integer linear programming algorithm to minimize the number of wires to move, while also maintaining sufficient bandwidth through multiple stages (so as to avoid packet loss). In this paper, we address how those multiple stages are planned and coordinated.

3 Change management challenges

We start by describing some of the many specific challenges in change management.

3.1 Orchestration of physical changes

In traditional, non-automated network management, changes to the physical infrastructure of the network (e.g., adding/moving/removing a switch or link) are typically treated as risky operations. Network operators often limit these to maintenance windows, during which some or all of the network becomes unavailable – and because these windows are disruptive, they can only be scheduled rarely, and then must be carried out as quickly as possible. This approach supports neither rapid evolution nor high availability.

More modern, scalable network designs such as Jellyfish [32] and other expander graphs, Facebook's Fabric [2], and Jupiter [31] use "multipath" designs that exploit path redundancy to support high bandwidth and availability at relatively low cost. Multipath topologies also support incremental expansion of, and other upgrades to, live networks, because their redundancy allows "draining" parts of the network during these operations.

For example, the Jupiter architecture consists of several types of blocks, each of which is a Clos fabric. Some of these blocks ("pods") provide connectivity to racks of machines via Top-of-Rack (ToR) switches; some ("fabric border routers", or FBRs) provide connectivity to WANs and other Jupiters;

some provide connectivity between other blocks in the same Jupiter.[3] This modular architecture allows us to build a large fabric (dozens of blocks) incrementally, rather than paying the capital costs and energy of building an entire fabric before we need all of it. Modularity also allows us to add blocks built from newer (faster/cheaper) switches and links to an existing fabric. In order to manage the evolving connectivity between blocks without having to completely rewire everything, we use a layer of patch panels [38], but even so, adding or removing a block requires significant human effort to reconfigure the patch panels.[4]

When we first started automating operations on Jupiter networks, we ran into the issue that each change to a fabric typically depends on the previous changes. However, our original topology-model representation only allowed us to represent one "intended" view of the network, so we had to serialize changes to a fabric: generate an intended model for one change, then carry out that change, and only then could we generate a model for the next change; the resulting delays become nearly intolerable. Our use of MALT solved that problem, because we could create multiple independent versions of a fabric's model in advance.

However, this still left us with the problem of managing the dependencies between a sequence of models – for example, ensuring that two different changes did not use the same switch port for conflicting purposes. Our solution to this kind of conflict avoidance serializes changes by means of a fabric-level lock, essentially a mutex.

Takeaway: To help us discover and avoid such conflicts as quickly as possible, we have now formalized the relationships between multiple plans for a given fabric using the concept of *PlanPoints*, described in §5, and managed by a service, *TopoPlan* (§5.2).

3.2 Representational change

Our network management systems are highly automated and thus heavily dependent on machine-readable data. This data is primarily represented in MALT, on which we focus in this paper, but we use several other standardized representations, such as OpenConfig [28] for telemetry. These representations must evolve over time, to support novel network designs, new hardware, new management concepts (e.g., failure-independent "zones" for high availability), etc.

For example, initially we did not model connectivity between machines and top-of-rack (ToR) switches, so we did not model machines. However, newer policies for machine-specific security and rate-limiting required authoritative intent for these connections, so we added machines to MALT models.

[3]The original Jupiter design incorporated "spine blocks" to form a folded Clos connecting the pods and FBRs. More recently, we connect those blocks directly without using spine blocks, but sometimes the pods themselves provide transit routing between other blocks [30].

[4]Our more recent deployments replace patch panels with optical circuit switches, which avoid much but not all of the human effort for reconfiguration [30].

Table 1: Acronyms and terms used in this paper.

Acronym/ term	Definition
DCNI	Data Center Network Interconnect
MALT	Multi-Abstraction-Layer Topology representation
MALTShop	A storage system for MALT
MSID	Model-Set ID
MBS	Model-building service
MDS	User-facing design service
MQS	Model-query service
NPI	New-product introduction
Block	Modular unit of fabric design
TopoPlan	Change-management service
UIM	Unified Intent Model
PP	Patch panel
PoR	Plan-of-Record

Consequently, a consumer querying a model for "all devices connected to ToR *T*" now receives not just the connected fabric switches, but also the connected machine entities. In practice, we've found that the complexity and level of detail in our models tends to increase over time.

While we attempt to make most representational changes backward-compatible, this is not always possible; sometimes our best guesses about what matters are wrong. We have learned that seemingly-innocuous changes lead to outages, because of the many clever ways in which programmers accidentally build fragile assumptions into their code.

Since our overall system-of-systems cannot have any significant (multi-minute) downtime, when we need to introduce a new MALT profile (see §2.1) to signal a representational change, we cannot insist that all producers and consumers cut over at the same instant. There are many such systems (especially model consumers) with their own release cycles and constraints on engineering resources. Beyond that, any such change is risky; we would not even want to switch to a new profile without carefully-monitored "canaried" rollouts.

Takeaway: For these velocity and safety reasons, we found it necessary to decouple profile feature *introduction* from model-reader *adoption* of such features. The previous paper on MALT [27] briefly discussed our approach to profile evolution. In §7 and §8.2 we expand that discussion, showing how we use a layer of abstraction to decouple many consumers from the details of profiles.

4 Model-generation systems overview

To help readers understand the implications of managing conflicts between, and changes to, our network plans, we first describe how we generate detailed network models. Appendices §A and §B describe model generation in more detail.

Fig. 2 summarizes the model-generation process, and Table 1 summarizes acronyms and terms used in this paper. First, a model writer (e.g., the network planner) initiates a model change by sending an RPC request ① to a "design service,"

MDS. MDS insulates humans and external systems from a need to understand the details of UIM or TopoPlan (§5.2).

MDS is responsible for (i) translating an imperative user-level request (e.g., "add a new block to a Jupiter fabric") into a sequence of declarative high-level intent changes, and (ii) managing request concurrency (for instance, we preclude certain types of requests from simultaneously modifying the same fabric, and thus sequence those requests with a lock). MDS also collects additional information (e.g., the available IP prefixes) necessary to create the UIM changes.

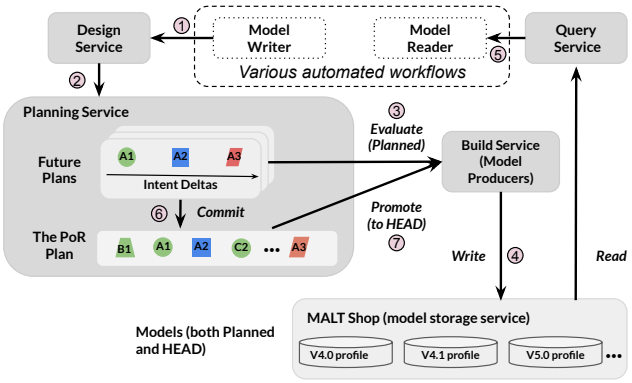

Figure 2: Model-generation systems.

We express model-generation intent in a *Unified Intent Model* (UIM), a form of MALT that abstractly represents the high-level graph of the global network at a given point in time. MDS represents intent changes as deltas to UIM.

This use of abstraction is an improvement on our prior system, in which all network changes consisted of precise orderings of low-level imperative mutations. Those were framed in terms of low-level details, such as the exact type and number of switches and their link-level connectivity; that approach bound decisions too early, making it hard to re-order a sequence of plans. Abstraction helps avoid this early binding.

Once MDS has mapped a request to a sequence of intent changes, it conveys ② this sequence to the TopoPlan plan management service (§5.2). TopoPlan supports parallelism between high-level requests by allowing interleaving of intent changes when they do not conflict. TopoPlan also supports "what-if" analysis, by maintaining multiple (sometimes thousands of) branches of possible future states.

Whenever we need to build concrete MALT models from a UIM plan (e.g., for physical installation), TopoPlan invokes ③ MBS, a "build service" that compiles the high-level intent to MALT models, which are stored ④ in MALTShop. Fig. 2 shows that we simultaneously generate semantically-equivalent concrete models in multiple profiles (see §2.1) – e.g., "V4.0," "V4.1," "V5.0" – to support profile evolution (see §7). For more details on MBS, and many more details on the model-generation process, including examples of UIM, see §A and subsequent appendices.

Models represent the intended network, so mismatches against actual state represent deployment errors (e.g., miscabling, etc.), and we correct reality to match the plans. We use various mechanisms to detect these mismatches, such as neighbor discovery via LLDP (IEEE 802.1AB [17]).

Model readers can query ⑤ these generated models via MQS, a semantic Query Service that also helps support evolution (see §8).

A single high-level operation may invoke these processes multiple times over the course of weeks or months. For instance, when we expand a live Jupiter fabric, we need to do this in several stages, to ensure the network always has sufficient residual capacity during each expansion step. This means we need to generate MALT models for each intermediate stage.

Network model mutations are not real-time. We have safety checkers to block planned changes if they would violate consistency checks, or capacity thresholds designed to leave room for switch or link failures. Systems with real-time goals, such as our SDN controller [11], maintain internal representations of network links, initialized from MALT models.

5 Physical-change plan management

To illustrate the problems of managing concurrent future changes, consider a simple example network with two switches A and B connected via four links (Fig. 3(a)). This network is currently carrying live traffic; hence we call the corresponding MALT representation of the network the "live" model. We would like to expand the network capacity by adding a third switch C (Fig. 3(b)). We call the MALT representation of this future network the "planned" model.

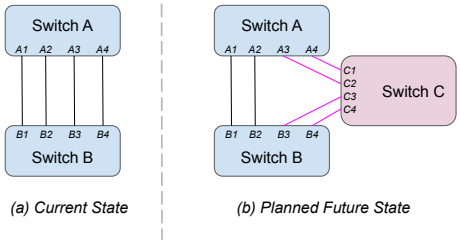

Figure 3: Models for current and planned network.

For several reasons, we want to generate a planned model well in advance. First, it allows us to accurately itemize the physical resources (switches, racks, fiber optic cabling, etc.) required to support switch C. Many of the resources have high costs and lead times: purchasing too much in advance wastes money, while purchasing too little or too late slows our ability to deliver network and compute capacity.

Second, modeling in advance allows us to simulate the future network, and validate it against reliability requirements. *E.g.*, if we must maintain $\geq 75\%$ of normal capacity during expansion, we must change the live network in stages, as shown in Fig. 4. We cannot directly switch between the initial and planned states, which would move two links from switch A (and B) simultaneously, causing 50% capacity loss.

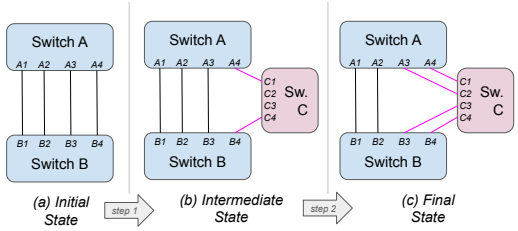

Figure 4: Two-stage migration from initial to final state.

We can also analyze or validate multiple options for a future plan, on metrics such as total cost of ownership (TCO).

5.1 Challenges with concurrent plans

Concurrent management of multiple plans creates several challenges: scaling issues, and (worse) the risks of incorrect planning decisions made because of stale models.

Scaling concurrent plans across a large and changing network: While one could use *ad hoc* methods to manage a set of concurrent plans, such as creating copies of future models in temporary storage, that quickly runs into scaling issues. Because our network is large and frequently changing, we have to manage a large set of concurrent plans. This creates two main problems: sequencing and validation.

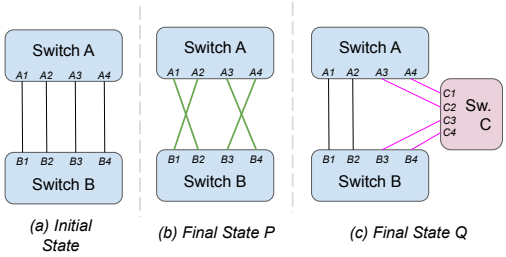

Figure 5: Two conflicting updates, *P* and *Q*.

For example, consider a planned change *P* that rewires the connectivity between switches A and B (Fig. 5(b)). This change conflicts with another planned change *Q* (Fig. 5(c)) to add switch C on ports (A3, A4, B3, B4), and thus we need to decide whether *P* or *Q* should come first.

However, different teams may be making the concurrent changes without coordinating, and the resultant sequence order can affect materials-ordering, instructions for technicians, etc. Worse, the live model is continually changing, and a fabric-level change that is applied to the "live" model (e.g., upgrading one or both switches) may invalidate the preconditions for *P* and *Q*, such as port reservations.

When each fabric has dozens of blocks and hundreds of switches, and must evolve rapidly to meet business needs (via expansions, upgrades, etc.), enforcing serialization on operations such as *P* and *Q* creates painful drag. While manual management of operational concurrency might be practical for just a few fabrics, an enterprise with dozens or hundreds of fabrics would find that unsustainable. Therefore, we need automation-friendly support: for tracking plans, and how they are ordered and sequenced; for rapid conflict-detection and plan-validation; and for speculative analysis of multiple future options (e.g., to cope with supply-chain issues).

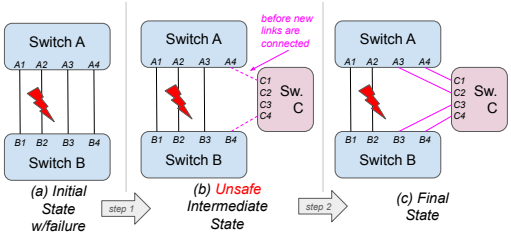

Figure 6: Stale models might lead to an unsafe state.

Stale models: The live network can change unexpectedly, rendering plans stale, along with any derived actions we might have taken. For instance, if a link is removed for repairs (Fig. 6(a)), the initial and final states are both "safe" because they meet our 75% capacity threshold. However, the transition to the intermediate state (Fig. 6(b)) creates an unsafe state (only 50% capacity) while we are changing links. Unless we update and revalidate the models for all intermediate states, we would not detect this risk.

Advance planning can also lead to confusion if, during the long period between plan creation and implementation, constraints change – e.g., supply-chain issues force the use of different hardware.

Thus, given hundreds of potentially-conflicting changes that need to be sequenced, and validated for safety or TCO, manual management of multiple models, or managing placeholder elements in a single "live" model, quickly becomes intractable.

5.2 Plan management service: TopoPlan

To address the many challenges of plan management, we developed TopoPlan, analogous to a software-development version control system (VCS). A network change, specified as patches to high-level intent, may be directly applied to the live (i.e., HEAD) intent. However, the TopoPlan service also allows network changes to be sequenced in branches.

As in a VCS, changes within a branch can be added, removed, reordered, or merged, while branches can be rebased or merged. Branches can represent highly speculative changes (e.g., hypothetical "what-if" scenarios), authoritative changes (e.g., scenarios which we have financially committed to), or changes that are somewhere in between.[5]

Concrete MALT models can be compiled for any change in any branch, allowing us to analyze the network-capacity and TCO implications of any hypothetical future network state. TopoPlan also allows us to detect *conflicts* over limited resources – e.g., two plans trying to use the same switch port for different purposes.

[5] In contrast to traditional VCSes, which are geared toward human users, are text-based, and have change-rate and branching limits, TopoPlan was built with automation in mind, with arbitrary branching, and focuses on sequencing changes to high-level intent, using Protobuf-based intent-patches with special merge semantics [14].

We show concrete examples in §10 of how using TopoPlan greatly improves our deployement and operational efficiency through project pipelining, stacking planned changes, and enabling accurate material orders for future projects.

Plans and PlanPoints: TopoPlan maintains multiple branches of possible future state. A single future change to the network is represented by a *PlanPoint*, which consists of (i) deltas to the UIM, and (ii) a best-estimate timestamp at which the changes will be realized. A series of PlanPoints is called a *Plan*, which groups together a set of network changes into a timeline. A Plan consists specifically of (i) a sequence of PlanPoints, and (ii) a baseline snapshot of MALT models to which the PlanPoint deltas are to be applied. MALT models can be compiled for every PlanPoint in the Plan simply by starting with the UIM of the baseline, and, for each PlanPoint, applying its UIM deltas and compiling concrete MALT models: we term this process *evaluating* a Plan. The compiling process internally invokes the model generation service, as discussed in §4, and attaches the generated concrete models to the PlanPoint.

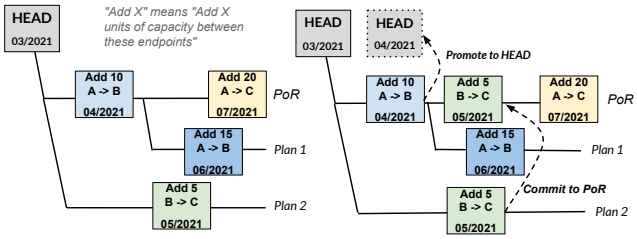

Figure 7: TopoPlan plans (left) and operations (right).

The *Plan-of-Record*, or PoR, is a canonical branch, which stores changes that we have committed to with a high degree of certainty (i.e., we have ordered materials that we really prefer not to waste). In the example of Fig. 7 (left), the PoR contains two PlanPoints that add capacity between B4 sites A -> B and A -> C. Plan 1 proposes increasing the capacity augment between A -> C from 10 to 15 units, while Plan 2 proposes an additional augment between B -> C. Note that, in this example, Plan 1 is "baselined" from a PlanPoint on the PoR, rather than from HEAD.

Committing and promoting plans: Changes on a non-PoR branch can be *committed* (Fig. 2 ⑥) to the PoR (Fig. 7 (right)) if the change does not conflict with other changes on the PoR, and when infrastructure planners sign off on the financial readiness of the change.

Only entire Plans can be committed to the PoR. When a Plan is committed, all its PlanPoints are validated against those on the PoR, and on success they are copied to the PoR. Conflicts are automatically detected by TopoPlan, but manually resolved by backing out, fixing a plan, and retrying. For example, in Fig. 7 (right), attempting the *commit* operation might reveal that we cannot add 5 B -> C units because we have already committed all free ports at C to the 20 A -> C units. We currently rely on human planners to make priority decisions outside TopoPlan, although automating some of these decisions is clearly worthy of future work.

Once the changes in a PlanPoint are ready to be realized in the physical network, the PlanPoint can be *promoted* (Fig. 2 ⑦) to HEAD (the intent representing the current desired state of the network). Promoting a PlanPoint applies its UIM change directly to HEAD, compiles HEAD to concrete MALT models, and removes the PlanPoint from the PoR.

Concrete MALT models can also be generated on demand for any PlanPoint on any branch (including PoR). These models can be used for what-if analyses, for example.

Changing plans: PlanPoints can be added, removed, edited, reordered by changing their timestamps, or merged by collapsing their UIM deltas. Plans can be created, deleted, or rebased by changing their baseline MALT snapshot. Both Plans and PlanPoints are versioned, and their version numbers are incremented on any of theses changes.

Every time HEAD is updated (100s of times per day), TopoPlan rebases the PoR to that new version of HEAD and does light-weight validation to ensure that no highly-certain PlanPoints are invalid. We also perform heavy-weight POR evaluation periodically, but not on every change to HEAD.

We also support backtracking and regeneration of a "known-good state." Thankfully we rarely use this; the complexity of backtracking is sometimes high, especially for plans near their deployment date, since dependencies can force us to unwind multiple changes. Undoing physical changes is expensive and risky, so we use multi-layered validations, as described later in this section, to avoid backtracking.

Lightweight operations: Network changes that are typically planned in advance are expensive capacity-related operations. Most network changes, however, are small-scale local updates (e.g., link repairs, ToR modifications); such changes are typically done immediately and are thus applied directly to HEAD. As a performance optimization, these direct-to-HEAD changes are typically not specified as PlanPoints (and thus skip the PoR), as they almost never affect future planned capacity changes.

Validations: Because compiling concrete MALT models could be slow and must be performed in sequence, we can perform a lighter-weight *UIM validation* operation on a Plan, which computes and validates the UIM for every PlanPoint without full MALT compilation. This runs intent-validation suites for each network and interconnection intent, first separately (to ensure certain properties and assumptions are met), and then globally (to ensure the UIM intents are consistent).

We also periodically run a detailed validation of the concrete models generated from the PoR PlanPoints. This validation is too expensive to run on every commit, so we made a tradeoff between speedy commits and full validation. Full validations still happen often enough to prevent costly mistakes. When our automated validations detect a conflict between plans (e.g., a missed dependency between PlanPoints

that would lead to double-allocation of a port), this usually requires human intervention, to modify one or more plans. Automated resolution is an intriguing research topic.

6 Model generation challenges

Our model-generation system faces several challenges:

Design complexity: Some aspects of our network designs are complex, requiring deep domain knowledge to convert abstract intent into concrete models. In a few cases, e.g., the *Data Center Network Interconnect* (DCNI) layer of connectivity between Jupiter aggregation blocks and spine-blocks, the design is complex enough to require algorithmic support, such as the ILP solver we use to "restripe" the DCNI on changes, while minimizing unnecessary changes to wiring [38].

Heterogeneity: We often add new technologies to our networks – we call these *new product introductions* (NPIs). NPIs sometimes involve novel concepts and so require representational change (see §7). We add NPIs without retiring old products during their useful lifetimes, so our networks are heterogeneous in many design details; our management systems must cope with that. Similarly, we need to be able to rapidly evolve our model-generation system without creating an un-maintainably complex code base.

These challenges, especially our need to support NPIs, pushed us to adopt a layered, modularized design for our model-generation system.

We compose our network designs from fundamental units ("blocks", e.g., server-aggregation blocks and spine-blocks in Jupiter, and B4 blocks [16, 18]). Each block could contain hundreds of chassis and tens of thousands of ports and internal links. A complete data center fabric is composed of up to hundreds of blocks, along with a DCNI. Our fleet has several dozen distinct block types, and each Jupiter or B4 network can have several different generations of blocks.

Our model-generation system uses a modular framework to generate product-specific block-level models, plus additional modules to compose these blocks into a consistent, complete network. For each block type, we have a topology "build unit": a software component that knows how to instantiate that block from high-level intent. These block-level build units are expressed as rules in a concise topology-description language. For many NPIs, we need only create a slightly-modified version of an existing build unit. Other build units, written in traditional programming languages, create inter-block (DCNI) links, assign IP addresses, or validate that the generated models are correct, etc.

When TopoPlan invokes MBS (Fig. 2), MBS creates a dataflow graph, in which the processing steps are the appropriate build units, the input is the intent in UIM, and the outputs are detailed MALT models. MBS constructs this dataflow graph dynamically, to account for changes in our overall network design (the details are beyond this paper's scope).

Scale: Our dataflow graphs are expensive to evaluate, requiring GiBs of I/O and many minutes of CPU time. Concrete MALT models are highly detailed, since they must represent the full underlying detail of our networks. A MALT model representing a single data center network can have millions of entities and relationships, and we have many data centers. Our WAN models have similar scale.

Therefore, MBS uses caching to avoid recomputing previously-generated models. Truly global changes to the Google network are rare and most changes are highly local, so we typically see cache hit rates above 99%, reducing the graph execution costs by two orders of magnitude.

7 Representation evolution

While MALT provides a common, flexible representation, we sometimes need to change its schema, or how we use it, to support NPIs or new management processes.

NPIs generally require changes to model generators, but not always to model readers. For example, a link-speed upgrade from 100G to 200G that otherwise involves no topological changes could be represented by changing the physical_capacity_bps attributes of some EK_PORT entities; this change might not require any updates to model readers.

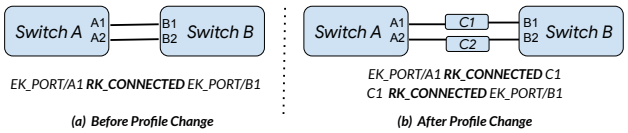

Figure 8: MALT representation of a simple network before and after a profile change.

However, many changes *do* require changes to readers. Fig. 8 illustrates this with a simplified example, where we add new devices (C1 and C2) between switches A and B. Suppose a model reader wants to query what peer switch port is connected to port A1 on switch A. With the old design (Fig. 8(a)), a query could just follow the RK_CONNECTED relationship from A1 to B1. With the new design (Fig. 8(b)), that query would only reach C1, probably not what the query-author intended; the model reader would have to be updated. Because model readers vastly outnumber model writers, such changes are disruptive. Further, a confused model reader (e.g., the configuration generator for our SDN controllers [11]) could cause outages. So, if we fail to realize that a reader needs an update, these changes are also risky.

We mitigate the risk by signalling change through the use of *profiles*. A profile [27] is effectively a versioned contract between model generators and readers, attached to each model. When a generator changes its output in a way that *might* confuse readers or require updates, we increment the profile version. Thus, a reader can detect during testing when it encounters a model with a profile it cannot understand.

MALT profiles by themselves do not avoid the need for updating model readers. Churn due to profile change was a major problem once MALT became widely adopted, which

led us to two requirements: (i) Model readers should have to change their code as little as possible (ideally, not at all) in response to profile changes, (ii) We must provide strong guarantees that migrating to a new profile will not result in regressions to model readers.

Key design choices. To avoid the need to update both model generators and all consumers at the same time, our generators produce multiple semantically-equivalent models, with different profiles, from the same intent (the example in Fig. 2 shows models in versions V4.0, V4.1, and V5.0). This allows some consumers to start testing against a new profile, while most consumers read from the most recent "released" profile (a few stragglers may use older profiles).

To simplify or avoid the code-update problem for most model consumers, we developed a semantic query engine, MQS (§8).

8 Model query service

MALT supports querying models via raw traversal-based queries [27]. However, profile changes could break raw MALT queries (see §7). Generating multiple profile versions mitigates this, but migrating to a new profile version is toilsome: (i) Raw MALT queries are structural rather than semantics-based; (ii) Client code does not always include regression tests for new profiles, and when it does, it is difficult to narrow errors to specific queries; (iii) Client code typically queries for specific data (e.g., ports within a rack), but raw queries return full MALT subgraphs (e.g., all the devices, trays, ports and their relationships), making it hard to predict whether a profile change will affect a given client.

This motivated us to develop MQS, an abstraction layer above MALT query, to minimize profile evolution toil. Stonebraker *et al.* discuss a somewhat different solution to the problem they call "database decay" [33].

8.1 Semantic queries

Instead of writing code that explicitly traverses the MALT graph, as was previously done, developers now write code in a new language that captures the semantics of their query (e.g., "give me all peer ports connected to this device") and hides the mechanics of the MALT graph traversal (e.g., "follow RK_CONNECTED relationships on this device's ports until I reach other ports"). The underlying implementation of these "semantic queries" might be different for each profile; this is hidden from the caller.

Semantic queries are recorded in a registry, allowing us to automatically test that they return the same (or at least, consistent) results across profiles and data sets. This testing framework automatically detects unexpected changes in query results for any potential profile or data change at change-review time, protecting model readers well before such changes can affect production.

8.2 Canned queries

MQS offers a *canned query* API. A canned query is a named function, with defined semantics that are profile-independent. Canned queries are *registered* with MQS. When called to execute a canned query, MQS translates it to an appropriate MALT query, executes it, and processes the returned subgraph to return a set of entities (see Fig. 9).

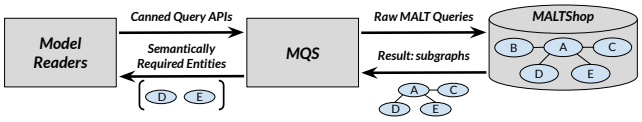

Figure 9: An MQS canned query converts a subgraph to just the entities that are semantically useful to the caller.

Several properties of MQS enable it to return consistent results across multiple profiles, without client code changes: (i) Canned queries can use different MALT queries for different profile versions. (ii) Canned query registration includes semantic tests, allowing centralized regression tests on upcoming "beta" profile versions. (iii) Canned queries return entities with attributes restricted to those that are relevant to clients. This, combined with returning entities rather than MALT subgraphs, greatly reduces the API surface of a model query, allowing easier testing and query evolution.

We run several kinds of centralized validations to ensure minimal profile evolution toil:

(a) **Profile version tests:** we test canned queries across multiple profile versions (including upcoming "beta" versions). Failing tests cause us to either fix the profile or to update the canned-query definition for the new version.

(b) **Data change tests:** When we backport bugfixes or introduce new kinds of products into our network, we introduce changes in multiple profile versions. Before committing these data changes to production models, we generate models in a test environment and compare canned query results between test and production environments.

(c) **Binary and configuration rollout tests:** Prior to releasing a new MQS binary or its associated configuration to production, we run canned queries against the canary and production versions; release automation proceeds only if the results are identical.

9 Cross-shard consistency

We do not try to represent all of Google's networks as one giant model. Not only would the scale create prohibitively expensive memory and communication costs, and complex coordination challenges, but also a single fault could put the entire infrastructure at risk. Instead, we shard the models at natural boundaries (e.g., one shard per datacenter fabric). Sharding allows us to limit the scope of most changes, which greatly simplifies conflict detection.

Many operations span shard boundaries (e.g., adding a WAN link to a datacenter). MALTShop allows queries to trans-

parently span multiple shards, but this raises a question: since we can have multiple future plans (hence, model versions) for each shard, and these plans can be mutated by independent processes, how do we query a *consistent* set of shard versions?

We currently lack a general solution to the shard-consistency problem[6], but we have a workable solution for all datacenter and B4 shards: we (conceptually) rebuild all shards from high-level intent on any intent change (and then use aggressive caching to avoid *actually* building more than necessary). Thus, each intent-change leads to a new *model set*, which is given a unique *model set ID* (MSID) via MALTShop's model-labeling feature. An MSID thus represents a consistent view across these model shards (but unfortunately, not across adjacent shards owned by other systems). MBS uses MSIDs to support consistent queries that cross shard boundaries.

10 Operational experiences

In this section, we dig into several operational experiences and lessons learned. We found the change-management features of TopoPlan to be especially useful in speeding up deployment activities by weeks or months.

10.1 Deadzone reduction

To illustrate one benefit of the PlanPoint abstraction (§5.2), we explain how this speeds up a capacity-delivery process.

We add capacity to Jupiter fabrics, in units of blocks, in a three-step process. **The early modeling** step creates a placeholder version of the block that will exist at a future time. This yields a concrete model from which we can create an order for materials, and it reserves resources, such as patch panel (PP) ports, for this expansion. Once materials are ready for deployment on the data center floor, the **turnup/prepare step** installs and qualifies the new block, but does not connect it to the DCNI. Finally, the **restripe step** gradually folds the new block into the fabric's topology.

However, the same Jupiter fabric may have multiple capacity changes in flight, and we are not always able to overlap the substeps of these augments. Consider the case of a PP expansion followed immediately by a block expansion. We cannot generate the block-to-PP physical striping for the new block until the new PPs and their port reservations are available in a model. Therefore, *if we had only one model*, the first two steps of the block expansion would be blocked until the PP expansion is completed. This results in a *deadzone*, a period when there is work that could be done in a fabric, and is technically unblocked (i.e., we have all the software infrastructure to do the work), but we cannot start because of model-change serialization.

The PlanPoint abstraction allows us to avoid this serialization and effectively pipeline execution. We can create a PlanPoint for the block's early model that uses the post-PP-expansion PlanPoint as its "previous model." The resulting PlanPoint captures a future state when the PP expansion has fully completed and the block's early has been built from it. We can then calculate specific fiber-bundle lengths from this PlanPoint, allowing us to order those bundles long before the PP expansion starts.

[6] We suspect it is similar to distributed-replica consistency, and something like vector clocks might work.

10.2 WAN change management

Our B4 WAN [16, 18] is mutated even more rapidly than a Jupiter fabric, due to its global scale. We change B4 multiple times per day: adding new "neighborhoods," expanding an existing neighborhood, augmenting link capacity between neighborhoods, migrating a neighborhood to a new technology (which entails moving some link endpoints), or removing a neighborhood.

As with Jupiter, we change a live neighborhood or adjacency in multiple steps, to preserve enough capacity to meet SLOs. Thus, we not only generate planned-state models for the end-state topology, but for all intermediate steps as well.

Sometimes projects may be executed independently (e.g., augmenting 2 disjoint edges), but in other cases they are interdependent: e.g., if neighborhood B is port-constrained, adding capacity between neighborhoods A <-> B might first require removing links between B <-> C. Due to real-world constraints, such as supply-chain disruptions, data-center construction delays, etc., the actual execution sequence of these projects rarely follows the global order by which they are initially committed to the plan-of-record (which happens well in advance).

We augmented TopoPlan to express and track such dependencies, adding a layer above TopoPlan to prevent unsupported execution sequences. This allows us to manage WAN projects extending years into the future. Because of the long lead times for materials (fiber bundles, optics, etc.), our ability to pipeline and avoid unnecessary and rigid serialization of plans can shorten deployment timelines by weeks or months.

10.3 Early materials procurement

Supply-chain problems often make procurement of materials (switches, transceivers, etc.) the longest step in a network change. So, we try to order materials as early as possible, ideally before we know exactly how a new network block will fit when we install it (given other in-progress changes with fuzzy completion schedules). In the past, we used heuristics based on prior projects (and some simple scaling rules) to do early orders; this was not always reliable.

Instead, now we speculatively generate a detailed model of the post-change network, and from that we compute and place a precise order. TopoPlan allows us to create these speculative models and manipulate them exactly as we manipulate "real" models, using unmodified software and workflows.

10.4 Software migration

Every software system sooner or later becomes obsolete. Our modeling infrastructure has gone through major software migrations several times, first transitioning consumers from an older representation to MALT, and then changing from a set of monolithic model generators to a modular, more evolvable framework. Managing these migrations without production outages required us to carefully introduce changes in phases. We describe our approach to migration in appendix §C.

11 Summary and future work

We have described how we plan and coordinate changes to large network infrastructures, with a specific emphasis on the need to support parallelism in the face of plan-changes caused by evolving real-world constraints. Since our network-management systems are heavily automated, our plan management must therefore also be automated to keep up with the pace of change, and to avoid mistakes.

We described the TopoPlan system for change management (§5.2), and the fundamental concepts (PlanPoints and branches) it relies on. We discussed how this approach has significantly increased the velocity with which we manage changes to both datacenter networks and WANs (§10.1, §10.2).

Automated network management also depends on explicit models of current and planned topologies, and innovation often requires representational change for our modeling language. We described how we support representational change without major software-engineering disruption, by means of explicit profiles (§7), and a profile-independent query layer that supports many (but not all) model consumers (§8).

Research challenges: While we have already greatly benefited from the work described in this paper, we see many challenges that demand future improvements in change management. In particular, supporting cross-shard consistency, at scale and without funneling all changes through a logically-centralized owner, remains unsolved (see §9). There might also be ways to expand the set of properties that can be validated automatically – not just simple resource conflicts, but also higher-level goals such as fault-resilience.

Acknowledgments

The systems described in this paper represent the design and engineering efforts of many current and former Googlers, in addition to the authors. We would especially like to thank Omid Alipourfard, Drago Goricanec, Xander Lin, Bret McKee, Joon Ong, Sujithra Periasamy, Mitchell Price, Fang Ruan, Michael Rubin, Shouqian Shi, Yiran Su, and Sting Zhou for their contributions.

We thank Vince Muir and Bryan Stiekes for their helpful advice. We also thank, for their feedback on this paper and earlier versions, Aditya Akella, Dennis Fetterly, several sets of anonymous reviewers, and our shepherd, Nik Sultana.

Appendices

Whenever it is necessary to build concrete MALT models from a UIM, we invoke MBS (§A), a "build service" that compiles the high-level intent from TopoPlan to generate MALT models, using product-specific model producers. Collectively, we refer to our module-generating software as Nimble (§B).

A Generic build service: MBS

Model production is the result of the execution of a dataflow graph of *build units* (§B.1). Build units are product-specific, but the orchestration of their execution to construct MALT models is generic. MBS is an execution engine that, given a set of named inputs, (i) constructs the dataflow graph of build units, (ii) executes that graph to produce MALT models, and (iii) transactionally stores the generated models in MALTShop. A set of output models in one transaction is given a *Model Set ID* (MSID), so that model readers can see a consistent snapshot of models.

The main input to MBS is a global UIM representing specifications for the entire Google network at a given point in time; this concisely represents the desired high-level state (e.g., the number of network fabrics in a location, their topology type, interconnect capacity between sites, etc.). MBS is also stateful; build units record their low-level decisions as an input to future model builds, to reduce network churn.

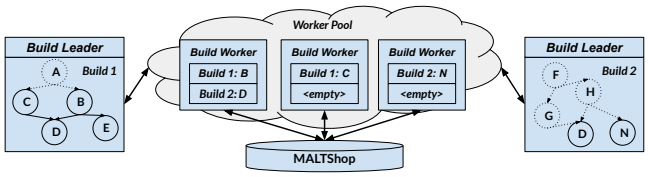

Figure 10: An illustration of our distributed build system showing two independent builds in progress.

Two-phase build. MBS is a distributed dataflow graph evaluator. A graph node can represent either a datum or a rule: data nodes are almost always MALT model fragments, while rule nodes execute build units. Rule nodes are connected to data nodes via either input edges, which specify the input models for a build unit, or output edges, which specify a build unit's output models.

Because the dataflow graph used to generate a set of concrete MALT models is highly data-dependent (e.g., a new MALT model output will be added if we're modeling a new data center location), we dynamically construct this dataflow graph in MBS, by executing a much smaller, static dataflow graph. Special build units in the static graph read the intent model and compute the full, dynamic graph, which MBS then executes to produce concrete models.

Graph execution (static or dynamic) is orchestrated by a leader and worker distributed system (Fig. 10). To execute a graph, MBS assigns it to one leader, which parses and validates the graph, then executes rules in parallel, using a pool of workers, as the rule inputs become available.

Build performance optimization. The resulting full-size dataflow graph, with 100s of thousands of rule nodes, is slow and expensive to evaluate, requiring GiBs of I/O and many minutes of CPU time. Therefore, MBS uses extensive caching to avoid recomputing previously-generated models. Caching is based on hashes of input data nodes and rule specifications, allowing MBS to skip rule evaluation if the corresponding hashes identify a cached output model.

Why we built a distinct system: While Google and others have created extensive distributed dataflow graph execution engines [6, 10] and tooling to efficiently manage and build binaries from source code [12, 26], we created MBS as a distinct system for several reasons:

(a) **Dynamic graphs:** Existing systems expect the execution graph to be provided as an input, rather than itself being dynamically generated based on the input intent models.

(b) **Stateful execution:** Updates to a fabric's concrete model should implement the new planned intent while making as few changes as possible to the existing network (to limit the costs of physical changes). Existing build systems [12] did not easily allow execution i of model generation to consume the output of execution $i-1$.

We suspect the combination of (a) and (b) is novel in the context of build systems.

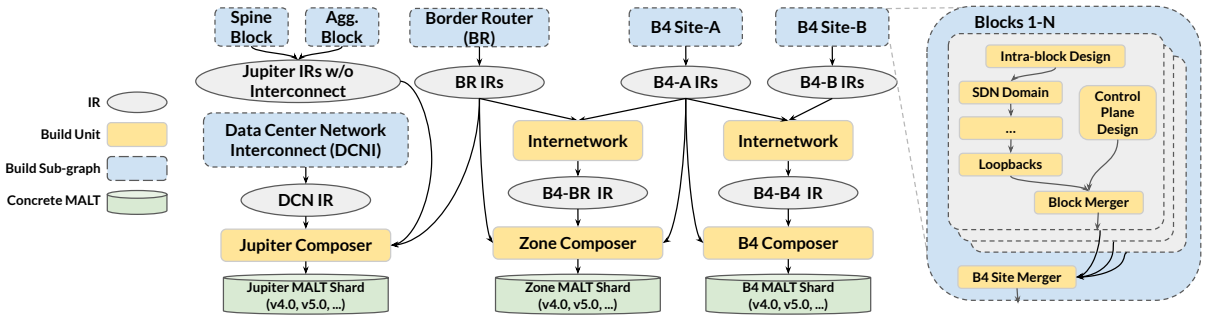

Figure 11: Simplified build graph for producing Jupiter and B4 models, with some areas abstracted for clarity. An expanded view of the B4 subgraph is shown on the right as an example (with some IRs omitted).

B Model generation: Nimble

We developed an ecosystem of re-usable *build unit* software modules, collectively called Nimble, each responsible for constructing a specific part of a model. We organize the build units into a dataflow graph that makes their dependencies explicit. Compared with a monolithic generator, using modular build units respects the knowledge domains involved in designing different aspects of a network (e.g., topology design, IP assignment, port allocation, link striping, etc.).

Modularity also provides natural boundaries to confine problem complexity. For instance, we divide topology design into deterministic descriptor-driven build units and dynamic solver-driven build units. This makes the generation of large-scale topologies with specific properties more tractable than directly solving a monolithic topology optimization problem. Modules without dependencies (or satisfied dependencies) can be executed in parallel, which helps scaling. Finally, modularity supports heterogeneity, since we can add or change just the necessary build units, and reuse others.

Each product's model-producers typically define dozens of build-unit types, to collectively perform the full spectrum of model generation tasks for each fabric and interconnect in the network, including topology generation, IP address allocation, SDN controller domain assignment, etc. We roughly categorize build units into four classes: (i) intra-block topology generators (§B.1.1), (ii) inter-block capacity generators (§B.1.2), (iii) model fragment composers (§B.1.3), and (iv) model validators (§B.1.4). While the first two categories both generate topologies, their designs are drastically different. The model fragment composers and validators are at the end of the design pipeline, and are necessary to support model sharding and ensure correctness.

Fig. 11 depicts a simplified example build graph involving the model producers for both B4 and Jupiter networks. Build units shown in the figure are abstracted, simplified representations of those we use in production.

B.1 Build unit overview

A build run creates two categories of model data: (i) the final concrete MALT model(s) adhering to a specific profile, and (ii) Intermediate Results (IRs): internal data, also represented in MALT, that facilitate communication between build units, but are not exposed for external consumption.

Some IRs are ephemeral, since they are consumed by downstream build units in the same build run. Some IRs are memoized results, required for the future build runs (e.g., the set of allocated ports). Memoization avoids the need to always build all output from scratch. Some IRs are part of the inputs to the composers (see §B.1.3), which process and stitch these together to generate the concrete, versioned model-shard outputs. Each build unit may take as input the model intent, previous IRs, and previous concrete models, and outputs IRs or concrete models.

We compose our network fabrics from fundamental units called "blocks" (e.g., server-aggregation blocks and spine-blocks in Jupiter, and B4 blocks [16, 18]). Each block could contain hundreds of chassis and tens of thousands of ports and internal links. A complete data center fabric is composed of up to hundreds of blocks, along with a "Data Center Network Interconnect" (DCNI). Our fleet can have several dozen distinct block types, as their technology evolves.

Each block type has a fixed, deterministic internal topology, but the DCNI or WAN interconnect depends on their dynamic properties (e.g., block type, uplink capacity, port availability, etc.). We generate each intra-block topology from a declarative topology description (§B.1.1) but we generate the DCNI and WAN interconnects via solvers that optimize link striping and port allocations (§B.1.2).

B.1.1 Intra-block topology generator

The intra-block topology generator is effectively a compiler that parses a *topology descriptor* that declaratively describes the desired block topology, and emits a corresponding MALT fragment of the detailed design. These descriptors are parameterized templates for each topology type. This process is deterministic, and does not require a complex solver, given the regular design of block internals.

The descriptor language expresses intent for a given block type as a hierarchy of modules, with specific entity-kinds (e.g., packet switches or ports) as leaf nodes. Descriptors can

specify entity attributes, which can be parameterized (e.g., the index of a module within its parent), and naming schemes. Interconnection patterns between entities, such as ports, are selected via *mappers* such as *fullmesh* or *biject*, within a scope called a *group*. When invoking the compiler, a build unit can pass certain parameters (abstracted from the model intent) to the descriptor; e.g., to control the number of racks within the B4 block. This allows one descriptor to support a variety of topologies for the same block-type generation. (§B.2 provides more details on the descriptor-based approach.)

While the build-graph structure is flexible, for simplicity, the typical pattern in most model producers' pipelines is for the first build unit to invoke the compiler to construct the backbone IR for a block, while subsequent build units build on this IR with additional entities and relationships (e.g., allocating management IPs, SDN control domains, etc.).

B.1.2 Inter-block capacity design

The internal topology of a block is typically static throughout its lifecycle. Inter-block connectivity, however, is frequently updated as we add or decommission blocks, add capacity between blocks, or fix incorrectly-wired fibers. Updates to the topology must meet capacity and availability requirements, and also minimize change to deployed reality (i.e., not move fibers unnecessarily). We have several solver-based build units for inter-block connectivity that tackle different classes of problems. *E.g.*, the *Internetwork* build unit in Fig. 11 uses a generic interconnect design and management solver for block-level striping, port-allocation, interface IP addressing, etc. This is used to generate WAN connections between B4 sites, and to the *Border Routers* of the data center fabrics.

These build units try to maximize the path diversity between pairs of sites or blocks, which improves tolerance of physical faults (e.g., link-, chassis-, block-level failures), while adhering to physical deployment constraints (e.g., minimizing the number of wasted ports).

For pairs of B4 sites, for example, each site may span several Points of Presence (PoPs), each containing multiple blocks; the interconnect solver minimizes the maximum imbalance in block-to-block, PoP-to-PoP, and block-to-PoP allocations of links across block-pair. We formulate this as a mixed integer programming optimization problem.

The design problem for the data center network interconnect (DCNI) has a large optimization space. We discuss that solver in appendix §B.3.

B.1.3 IR composers

At the end of each model generation run, a set of *composers* is responsible for stitching together the IRs produced by the upstream built units to create the concrete model shards. The MALT models are sharded for a variety of reasons, such as domain isolation and scalability, as discussed in [27]. We have a dedicated composer for each model shard.

Within each shard, the composer processes and merges IRs, based on their tagged profiles, to generate profile-compliant models for all supported profile versions. We define our pipeline such that any profile-agnostic processing (e.g., resource allocation, etc.) is done as early as possible, while profile-dependent modeling is typically branched further downstream, at or near the composers; this helps ensure data consistency across profiles.

B.1.4 Validators

During each model generation run, we also validate attributes, and design rules in several categories: (i) *Intent validation* ensures that the UIM is internally consistent and its changes are legitimate; e.g., the UIM satisfies the properties required by model producers. (ii) *Property validation* focuses on validating network-specific invariants we expect in each model (e.g., ports do not conflict, IP addresses are not duplicated), and (iii) *intent-to-model validation*, which is designed to harden the intent-to-model translation that typically requires dynamic solvers (e.g., whether the striping between a B4 neighborhood and Jupiter delivers the intended capacity, while satisfying diversity and balance requirements). Finally, (iv) *model-change scope validation* ensures the scope of model changes matches the corresponding change in the intent. [7]

During the course of development, all these validation suites have caught some exceptions, especially for NPIs, which if left undetected would have caused network outages or costly deployment errors.

B.2 Details: intra-block topology generator

This section provides additional details on how we support a high-level approach to block-level design. The intra-block topology generator includes (i) topology descriptors that fully declare the topology and (ii) a compiler that parses the descriptors and translates them into MALT models. These descriptors deterministically declare the intended topology.

We explain several key aspects of topology descriptors using an example snippet (Fig. 12) of the descriptor of a B4 Stargate block [16]. We simplified the descriptor for clarity.

Hierarchy: A network is a hierarchy of *modules* with a single tree root and multiple branches. The root module of a block is usually an EK_NETWORK, and its name is globally unique.

Modules: A module, the basic building block in descriptors, defines one MALT entity kind and the topology within the entity. As our networks are heterogeneous, multiple modules (with distinct names) may refer to the same entity kind. For instance, we have two module definitions for EK_PHYSICAL_CHASSIS in Fig. 12. A descriptor can have multiple instances for the same module.

[7] MBS also performs more basic validations such as MALT lint checks and profile schema checks.

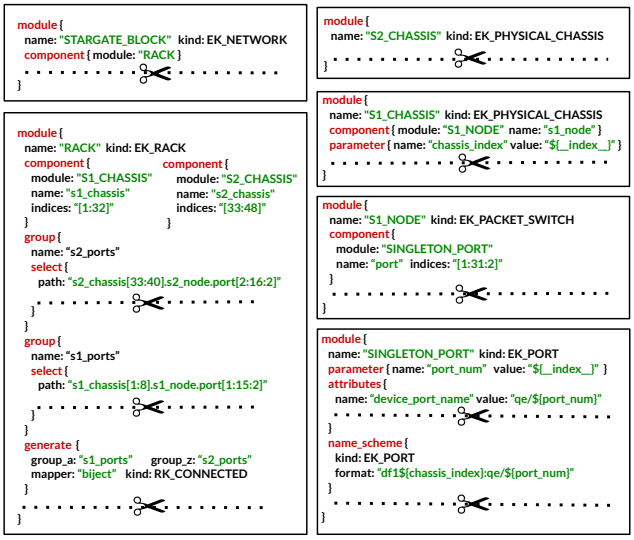

Figure 12: A snippet of a topology descriptor for a Stargate Block.

Components: The topology within a module is defined by recursively including other modules as its *components*. The number of components (of the same entity kind) included in the parent module is concisely expressed using indices. For instance, in the module "S1_NODE", the singleton port component is defined with indices [1:31:2], indicating that there are 16 entities in this module, with indices from $\{1, 3, ..., 31\}$. The default relationship between a module and its components is that the module entity RK_CONTAINS all its components. Other relationship types can be specified to override that default, at the component type granularity.

Attributes: Entities in MALT models can have attributes, such as taxonomy (e.g., chassis type) and state (e.g., link is in turnup). Attributes specified in topology descriptors are self-contained: i.e., they are either static values, or they are deterministically computable using the *parameters* defined within the upstream hierarchy (branch) of the entity.

Parameterization: The descriptor is not another topology programming language – we omitted constructs such as conditionals. However, allowing basic parameterization of modules offers useful flexibility and concision. The most common use of parameters is to pass information top-down. For instance, the chassis_index parameter of the "S1_CHASSIS" module is subsequently used by the singleton port contained by the chassis. If a module is componentized with indices, we have multiple instances of this module; the "${__index__}" provides each instance's index. Parameters defined in a module are recursively visible to all components and sub-components in the module.

Relationships: To create relationships between components or create intra-block links between ports, the descriptor introduces the *Group* operation to *Select* a set of components within a module hierarchy, and then applies a *Generate* operation to generate relationships or links between the components of the two groups. A *mapper* is used to decide how the components in *group_a* are mapped to those of *group_z*. Two common mappers are *biject* (pairwise, requiring the two groups to have the same number of items) and *fullmesh*. In Fig. 12, the "RACK" module uses group and generate to define how S1 ports and S2 ports are connected.

Naming schemes: Each MALT entity has a unique ID, combining its name and entity kind. A topology descriptor specifies a naming scheme by either constructing it ad-hoc (potentially using parameters) or simply referring to a preconstructed regular expression (in most cases).

Given a descriptor, the topology compiler is responsible for parsing the descriptor and generating the corresponding MALT model fragment. Internally, the compiler parses modules top-down, builds multiple branches based on the component indices while enforcing parameter scopes within each branch, and finally constructs entity names, attributes and relationships. The compiler also allows customized mappers in the Generate operations to compensate for topology irregularities. Because the compiler does not make any topology-specific assumptions, it is generic and reusable across all descriptors.

For most model producers, their first build unit instructs the topology compiler to construct the backbone IR for a network. Subsequent build units decorate the IR with additional entities and relationships (e.g., allocating management IPs and SDN control domains). Fig. 11 depicts these data flows. When invoking the compiler, a build unit can pass certain parameters (abstracted from the model intent) to the descriptor; for instance, to control the number of racks within the B4 block. This enables us to support a variety of topologies for the same network generation while reusing the same descriptor.

B.3 Details: inter-block topology generator

This section expands on the discussion in §B.1.1, describing how we generate models for the Data Center Network Interconnect (DCNI) in a Jupiter network.

DCNI overview. A Jupiter network uses a layer of Patch Panels (PPs) between server blocks and spine blocks. Each block (server or spine) directly connects to the front side of PPs, and the block-to-block connectivity is (indirectly) established by cross-connecting the back side of PPs. Having a PP layer removes a lot of complexity that would be introduced by directly connecting server and spine blocks, e.g., reduced fiber length and human labor. This is discussed in detail in [38].

We use the term DCNI (Data Center Network Interconnect) to describe the two collections of "physical" links, i.e., block-to-PP links and PP cross-links. The challenge for inter-block design is to produce an optimal DCNI. We call the resulting block-to-block paths "logical" links.

Block-to-PP generation. The Jupiter model producer has a dedicated DCNI build unit. This build unit first performs the block-to-PP link generation to construct the physical topology, and then generates PP cross-links to produce the desired

logical block-to-block topology. For a given block, its block-to-PP fibers fan out equally across every patch panel using a predetermined pattern (i.e., agnostic to intent). Once the block is deployed, such fibers never change.

The block-to-PP links are dynamically allocated in three steps: (i) A *block-to-PP spec generator* translates the UIM into an IR specifying the number of PP ports needed for each block; (ii) A *patch panel port allocator* takes that IR as input, and dynamically assigns available ports to block-to-PP fibers in an on-demand manner. It must read the previous models in order to honor deployed reality; (iii) A *bad port swapper* reads bad-port UIM, and uses reserved ports to replace those bad ports. An external device-repair workflow automatically creates bad-port UIM to record faulty ports. Since block-to-PP link restripe does not affect traffic (because these new links have not been used to carry traffic), this restripe is accomplished in one shot, i.e., without phasing.

PP cross-link generation. Given the physical topology, obtaining the desired logical topology is a complex problem. Thus, the DCNI build unit invokes a dedicated external solver, which translates PP cross-link generation into an ILP (Integer Linear Programming) problem, as described in [38].

Although the ILP solver is able to compute the desired final state, it does not naturally support the crucial requirement that the DCNI must carry live traffic during restripe. This requirement is addressed by having multiple incremental restripe stages, where each stage only alters a small portion of topology, to ensure that the network has sufficient residual capacity in all stages. We use an automated *expansion planner* to decide the number of required stages. Given a restripe request, the expansion planner iteratively searches for the smallest number of stages C (starting from 1) that satisfies the residual capacity requirement. For each evaluated value of C, the DCNI build unit invokes MDS to generate a series of C hypothetical models that resemble each intermediate stage. The residual bandwidth is then calculated, from these models, by counting the number of added/removed links. We provide additional details for the restripe process in §B.4.

Another goal of the DCNI build unit is to ensure topology stability. By its nature, the logical topology solver is not deterministic. Invoking the solver in different model generation runs could cause the DCNI to change arbitrarily, even without any intent change, forcing us to do useless re-wiring. Thus, we use a persistent memoization layer, allowing the solver to store its calculated topology solutions persistently. This both prevents redundant calculation, and ensures that the DCNI build unit generates deterministic output.

B.4 Case study: Jupiter restripe

When we add blocks or spine blocks to a Jupiter network, we must perform a "restripe" operation, to redistribute uplinks from aggregation blocks to spine blocks. When we do a restripe that could affect in-service links, we must do it incrementally, to avoid distrupting too much capacity at once.

In this section, we use the restripe process to illustrate details about the DCNI build unit.

There are three major catogeories of Jupiter data center restripes. (i) Front-only restripe: the restripe only adds/removes the block-to-PP links that do not have fiber jumpers on the back side, so it touches only the front side of patch panels. These added/removed links do not carry live traffic, so incremental restripe is not required. (ii) Back-only restripe: the restripe only alters the PP cross-links, so the scope of change is limited to the fiber jumpers on the back side. Incremental restripe is required since it changes the logical block-to-block links. (iii) Combined restripe: the restripe alters both block-to-PP and PP cross-links at the same time. It is the most labor-intensive process compared with the other categories, and it is also required to be an incremental restripe.

We observed that for most common restripe use cases, the model update process could be divided into one front-only restripe and multiple stages of back-only restripe. As an example, when a new block is added to a Jupiter fabric, we first add the block-to-PP links (front-only restripe), and then we use multiple incremental stages to update PP cross-links (back-only restripes). Such granularization helps reduce the sequence requirement in the workflow, and allows better parallelism among different workflows that are expanding different parts of a Jupiter fabric.

Intermediate restripe stages. Similar to most model changes, the DCNI design is also driven by intent changes. Fig. 13 shows an example of high-level Jupiter data center intent (on the left side), which is part of the global UIM. The fields that are related to DCNI are highlighted in blue (e.g., the number of PP chassis). The DCNI build unit is responsible for translating the Jupiter intent into DCNIShape, a protocol buffer defined as the input to the topology solver interfaced with the *PP-Cross-Link Gen* build unit, a subcomponent of the logical DCNI build unit.

The PP cross-link restripe process consists of small stages to gradually transform the current topology to the desired one given by the solver. We use a single PP rack as the smallest granularity of restriping stages, because it provides natural grouping of the logical block-to-block links. Thus the whole restripe process boils down to rewiring patch panels in multiple incremental stages.

Conceptually, the model for each stage could be summarized as a 4-tuple: $(\mathsf{T}_o, \mathsf{PP}_o, \mathsf{T}_n, \mathsf{PP}_n)$, where T_o and T_n denote the two sets of all physical block-to-block links in the old and new topologies; PP_o and PP_n form a partition of all PP indices, where PP_n represents PPs that are restriped to have links from T_n, and PP_o represents the rest of patch panels that still have links from T_o. Fig. 14 shows a 3-stage restripe with three PPs:

(a) Before restripe. There is no old topology. The "new" physical topology T_0 connects server block 1 and spine block 1 via PP 1, 2, and 3. Thus the tuple is

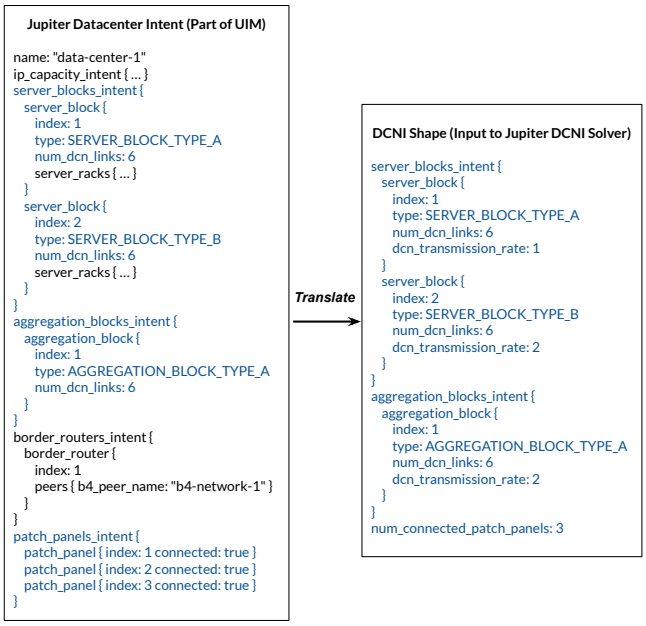

Figure 13: An example of DCNI intent translated from UIM.

$(\{\},\{\},\mathsf{T}_0,\{1,2,3\})$.

(b) Stage #1. The new topology physical T_1 connects server block 1, 2, and spine block 1. Only patch panel 1 has been updated. Thus the tuple is $(\mathsf{T}_0,\{2,3\},\mathsf{T}_1,\{1\})$.

(c) Stage #2. The new topology T1 remains the same. PP 2 is further folded into the logical topology. Thus, the tuple could be summarized as $(\mathsf{T}_0,\{3\},\mathsf{T}_1,\{1,2\})$.

(d) Stage #3. The new topology T1 remains the same. All PPs are updated into the logical topology. There is no more "old" topology as restripe is completed. Thus, the is tuple $(\{\},\{\},\mathsf{T}_1,\{1,2,3\})$.

This tuple is stored in an IR called MaskedDcnTopology IR. The PP-Cross-Link Gen build unit will read the previous MaskedDcnTopology IR and Jupiter intent to update the tuple, and then translate the tuple to an intermediate topology.

C Live migration to new infrastructure

Our legacy modeling infrastructure[8] had numerous problems, including scaling issues, and weak support for schema evolution and parallel operations. For production safety, we could not simply stop using the old systems and immediately migrate its many users to our new model-generation infrastructure (Nimble) until we were confident that the old and new systems were functionally equivalent. Even small discrepancies can cause serious outages. However, we could not just stop using the old systems while we tested the new ones, as that would have blocked all network operations for weeks or months.

[8]The legacy infrastructure was similar to a relational database schema.

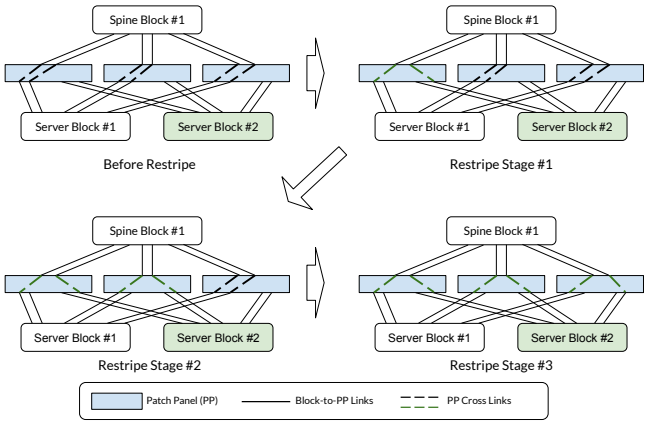

Figure 14: An example of 3-stage restripe with three PPs.

We conducted a live migration from the old systems in four phases:

Phase I: Exporter. We wrote an *exporter* pipeline that converted legacy models to equivalent MALT models. This allowed most model consumers to migrate to MALT. At this point, the legacy models were still treated as authoritative.

Phase II: Validation. To avoid production outages, we had to ensure that models produced by Nimble were functionally equivalent to the exporter-generated models. We built a pipeline that reverse-engineered UIM and relevant state from the exporter's output, yielding intent that we could feed to Nimble. We could then check that Nimble and the exporter generated identical MALT models from semantically-equivalent intent.

Phase III: Read migration. After the model equivalence checks passed consistently for several weeks, we atomically flipped the MALTShop paths where the exporter and Nimble wrote their models, automatically causing readers to consume Nimble-generated models. We staged this changeover on a per-model-shard basis, enabling read migration for some shards while we were still fixing differences for other shards.

Phase IV: Write migration. We then migrated all model writers (e.g., capacity-delivery and data center expansion workflows) to use MDS. After this, we deprecated the legacy model-design tools.

Phased migration turned out to be invaluable. Together with our high-level design principles for reliable systems [35], we managed to finish the fleet-wide migration of our critical modeling infrastructure without any production incidents.

AAsclepius: Monitoring, Diagnosing, and Detouring at the Internet Peering Edge

Abstract

[1] Network faults occur frequently in the Internet. From the perspective of cloud service providers, network faults can be classified into three categories: cloud faults, client faults, and middle faults. This paper mainly focuses on middle faults. To minimize the harm of middle faults, we build a fully automatic system in Huawei Cloud, namely AAsclepius, which consists of a monitoring subsystem, a diagnosing subsystem, and a detouring subsystem. Through the collaboration of the three subsystems, AAsclepius monitors network faults, diagnoses network faults, and detours the traffic to circumvent middle faults at the Internet peering edge. The key innovation of AAsclepius is to identify the fault direction with a novel technique, namely PathDebugging. AAsclepius has been running for two years stable, protecting Huawei Cloud from major accidents in 2021 and 2022. Our evaluation on three major points of presence in December 2021 shows that AAsclepius can efficiently and safely detour the traffic to circumvent outbound faults within a few minutes.

1 Introduction

Network faults, including congestion, link failures, BGP misconfigurations, *etc.*, occur frequently in the Internet [1–8]. Obviously, network faults could degrade the network performance, and even lead to outages [9, 10], threatening the connectivity of the Internet. As a cloud service provider (CSP) which serves users at the Internet peering edge, the quality of service (QoS) for users is significantly harmed by the frequent network faults.

As pointed by BlameIt [11], from the perspective of CSPs, network faults can be classified into three categories based on where they occur (see Figure 1): 1) *cloud faults* which occur in the *cloud network* (cloud AS [2]); 2) *client faults* which occur in the *client network* (client AS); 3) *middle faults* which occur in the *middle network* (all AS'es between the cloud AS and the client AS). First, the cloud network is fully controlled by CSPs. We have already deployed a battle-tested system in Huawei Cloud to heal cloud faults, and this paper does not focus on cloud faults. Second, the client network is neither controlled by nor directly connected to CSPs. Therefore, when client faults occur, what we can do is to request the corresponding Internet service providers (ISPs) [11] for fault healing. Third, the middle network is not controlled by but directly connected to CSPs. Same as other CSPs, Huawei Cloud is connected to the middle network through dozens of points of presence[3] (PoPs). All PoPs and datacenters in Huawei Cloud are interconnected by a private backbone. Leveraging the private backbone, the traffic between clients and Huawei Cloud can go through different PoPs. This implies that we can choose different middle paths (paths in the middle network) by choosing different PoPs, so as to handle middle faults. In

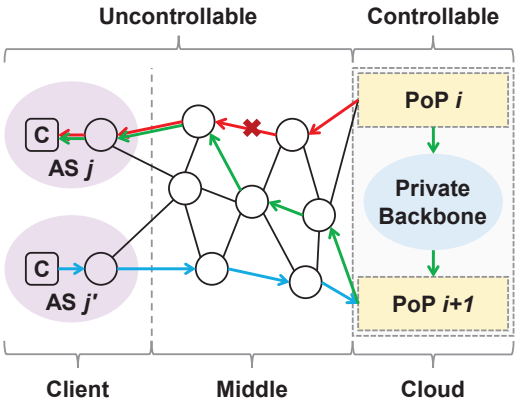

Figure 1: Three categories of network faults. "C" refers to a client in the client AS, and "×" refers to a middle fault. When a middle fault occurs in the red path, we can detour the traffic to egress at PoP_{i+1}, so as to route the traffic along the green path to circumvent the fault.

[1] Co-primary authors: Kaicheng Yang and Yuanpeng Li. Corresponding author: Tong Yang (yangtongemail@gmail.com).

[2] AS refers to autonomous system, which is a very large network or group of networks with a single routing policy.

[3] Point of presence is the point where Huawei Cloud accesses the Internet, see more details in Section 2.1.

summary, this paper focuses on middle faults, and identifies client faults as well.

The design goal of this paper is to design a fully automatic system to minimize the harm of middle faults. The system should have three main functions: fault monitoring, fault diagnosis, and traffic detouring. First, the system should persistently monitor the middle and client networks in a lightweight manner to detect and report faults. Second, the system should accurately diagnose the reported faults at fine granularity. Third, for a middle fault, the system should efficiently and safely detour the traffic to a healthy path, and detour the traffic back immediately when the fault disappears.

Towards the design goal, the most important and challenging issue is to identify the fault direction, since no existing works handle this problem. Suppose we find a middle fault between a PoP_i and a client AS_j. If a fault occurs in the path from PoP_i to AS_j, we define the direction of this fault as outbound direction, and similarly we define inbound direction. In this case, fortunately, we have many PoPs, and thus outbound faults can be quickly circumvented: detouring the traffic through another PoP_{i+1} to the client (see Figure 1). This action is quick because it only needs to update the routing table of PoP_i. If a fault occurs in the inbound direction from AS_j to PoP_i, unfortunately available solutions to change the traffic path need to change the routing tables of all routers in the middle network, which is obviously slow. The above observations pose great importance on *identifying the fault direction.* Further, it is challenging to identify the fault direction. On the one hand, the middle network where faults occur is completely out of our control. On the other hand, our monitoring results do not include direction information.

Researchers and engineers have proposed various solutions for network faults at Internet scale [1, 11–24]. Among them, BlameIt [11], Edge Fabric [12], Espresso [13], Entact [14], and CPR [15] are most related to our application scenarios. However, as shown in Table 1, these works only have two of the three main functions, and none of them identifies the fault direction. BlameIt monitors and diagnoses network faults in the cloud environment. However, it does not support traffic detouring and fault direction identification. Edge Fabric, Espresso, Entact, and CPR support traffic detouring, but they do not diagnose network faults. In summary, all existing works do not meet our design goal.

Aiming at the design goal, we design a system, namely **AAsclepius** (**A**uto**Asclepius**). AAsclepius consists of three subsystems: a monitoring subsystem, a diagnosing subsystem, and a detouring subsystem. Each subsystem is responsible for implementing a main function. Below we only show how the diagnosing subsystem addresses the above challenge of identifying fault direction.

Diagnosing subsystem: AAsclepius uses a decision tree with intuitive design to achieve the **accuracy** and **fine granularity** of diagnosis. Our experienced experts have spent a long time configuring the thresholds (§ 5) used in the decision tree. These thresholds have proven to work excellently after two years of validation. Our key innovation is to propose a technique, namely *PathDebugging*, to address the most important and challenging issue, *i.e.*, identifying the fault direction. For a middle fault between a PoP_i and a client AS_j, the idea of PathDebugging is to replace the path from AS_j to PoP_i with a zero-fault path. In spite of the simple idea, the implementation procedure is rather complicated, and the details are provided in Section 5.3.

To date, AAsclepius has been running for two years, keeping Huawei Cloud free of major accidents. In December 2021, we conducted an evaluation on three major PoPs. The results show that for all outbound faults, AAsclepius can efficiently and safely detour the traffic to circumvent them within a few minutes.

2 Settings

2.1 Cloud Infrastructure

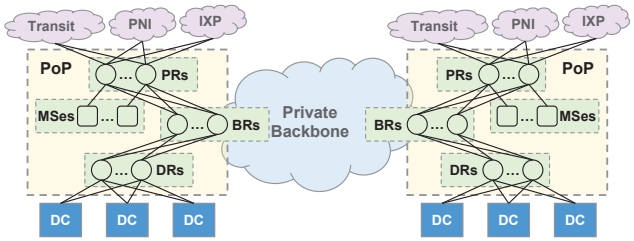

Figure 2: A PoP houses multiple peering routers (PRs) to access the Internet, backbone routers (BRs) to access the private backbone, and datacenter routers (DRs) to access datacenters. Each peering router is connected to a monitoring server (MS) cluster (currently we only deploy one server per PR) used for monitoring QoS (§ 4.2).

In order to serve approximately one billion geo-distributed users, Huawei has deployed a cloud consisting of dozens of PoPs and datacenters globally, as well as a private backbone that interconnects all PoPs and datacenters. To access the Internet, as shown in Figure 2, each PoP houses multiple peering routers (PRs) as edge routers, exchanging BGP routes and traffic with transit providers, private network interconnects (PNIs), and Internet exchange points (IXPs) outside the PoP. The interconnectivity between all PoPs and datacenters provided by the private backbone greatly improves the flexibility of traffic detouring. Traffic from any datacenter is first routed to the backbone routers (BRs) via datacenter routers (DRs). Through the private backbone, the traffic can then be routed to egress at any PoP. Similarly, the inbound traffic can also ingress at any PoP. Such flexibility of traffic detouring is the basis of AAsclepius (§ 6).

To serve users, each PoP announces a distinct set of IP prefixes as its *dominating prefixes*. Obviously, the PoP at which the inbound traffic will be routed to ingress is only determined

Desired functions	AAsclepius	BlameIt [11]	EdgeFabric [12]	Espresso [13]	Entact [14]	CPR [15]
Fault monitoring	✓	✓	✓	✓	✓	✓
Fault diagnosis	✓	✓	×	×	×	×
Direction identification	✓	×	×	×	×	×
Traffic detouring	✓	×	✓	✓	✓	✓

Table 1: Comparison with prior solutions.

by its IP destination address. Unfortunately, if a PoP fails to announce its dominating prefixes, the inbound traffic with IP destination address in those prefixes will not be routed to Huawei Cloud. To achieve fault resilience, each PoP additionally announces the dominating prefixes of the other PoPs with multiple duplicate AS'es prepended to their `AS_path`[4] (*e.g.*, 12345, 12345, 12345). In this configuration, the traffic is normally routed as before. If a PoP fails to announce its dominating prefixes, after BGP converges, the traffic that originally ingresses at that PoP will be routed to ingress at another PoP. Therefore, the availability of Huawei Cloud service is guaranteed as long as one PoP remains operational.

We have built a traffic monitoring system in Huawei Cloud, passively counting the sizes of flows entering or exiting Huawei Cloud at <Source IP, Destination IP> granularity for billing using programmable switches. This system not only helps AAsclepius with fault monitoring as it can determine the AS'es and IP /24 prefixes which contain clients of Huawei Cloud, but also helps AAsclepius with traffic detouring as it can provide visibility to the traffic volume between any PoP and AS. While it is cost-efficient to passively monitor stateless traffic volume, it is too expensive to maintain per-flow state for a large cloud to monitor network faults, and therefore AAsclepius still uses *active probing*.

2.2 Domestic Network Infrastructure

China's network is mainly controlled by three top-tier transit-providers. To serve geo-distributed users, each top-tier transit provider builds its own large-scale backbone network with sufficient intra-bandwidth interconnecting with all its client networks. By comparison, the inter-bandwidth across different transit providers is usually limited. Such infrastructure guarantees that from a PoP's perspective, the IPs in the same AS share similar middle paths. It also motivates AAsclepius' design (further shown in § 6): for traffic suffering from network faults, AAsclepius detours it across different PoPs within the same transit-provider for better performance, instead of detouring it across different transit-providers in the same PoP.

3 AAsclepius Overview

Currently, because most traffic of Huawei Cloud exits from PoPs deployed in our country, we have deployed AAsclepius on a large scale in our domestic infrastructure. As mentioned above, AAsclepius has three subsystems: a monitoring subsystem, a diagnosing subsystem, and a detouring subsystem.

[4]The BGP AS path attribute sequentially lists the AS numbers comprising the path to the destination.

Below we briefly present the modules and workflow of these subsystems (see Figure 3). Because most of Huawei Cloud traffic is still IPv4 traffic, AAsclepius targets at only IPv4 traffic currently. The terminologies frequently used in this paper are shown in Table 2.

Table 2: Terminologies frequently used in this paper.

Terminology	Meaning
Active IP address	An IP address which will respond to ICMP probes. (§ 4.1)
IP*	A representative IP address in a prefix for probing. (§ 4.1)
Victim-AS	An AS which is identified as suffering from faults. (§ 4.3)
Fake fault	A network anomaly that causes a healthy-AS to be identified as a victim-AS. (§ 5.1)
Backup PoP	PoP_{i+1} is the backup PoP of PoP_i. (§ 5.3)
Victim traffic	The traffic that is suffering from faults. (§ 6)

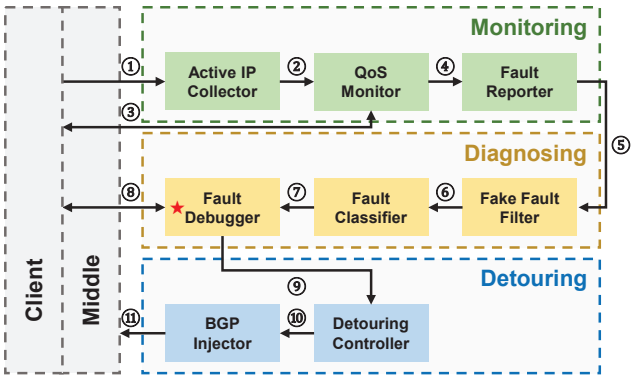

Figure 3: The workflow of AAsclepius.

Monitoring subsystem (Figure 3 top). This subsystem consists of three modules: an *active IP collector*, a *QoS monitor*, and a *fault reporter*. The QoS monitor and the fault reporter are deployed on a per-PoP basis.

① The active IP collector monitors all IP /24 prefixes in the AS'es which contain clients of Huawei Cloud, and collects all active IP addresses.

② The active IP collector selects representative IP addresses for each IP /24 prefix and informs the QoS monitor.

③ The QoS monitor in each PoP receives representative IP addresses, and runs QoS agents to send ICMP probes to representative IP addresses in order to measure their packet loss rates.

④ The QoS monitor aggregates packet loss rates at AS-granularity, and passes them to the fault reporter.

⑤ The fault reporter in each PoP receives the aggregated packet loss data from the QoS monitor in the same PoP, then identifies and reports victim-AS'es to the diagnosing subsystem.

Diagnosing subsystem (Figure 3 middle). This subsystem consists of three modules: a *fake fault filter*, a *fault classifier*, and a *fault debugger*. The fake fault filter is deployed on a per-PoP basis.

⑥ The fake fault filter receives reported victim-AS'es from the fault reporter in the same PoP, identifies and filters fake faults, and outputs the other faults to the fault classifier.

⑦ The fault classifier receives the faults from the fake fault filter in many PoPs, classifies the faults into three categories, and passes middle faults to the fault debugger.

⑧ The fault debugger receives middle faults from the fault classifier, and runs debugging agents to monitor a second path for each middle fault.

⑨ The fault debugger then compares the monitored packet loss rates of QoS agents and debugging agents to identify the direction for each middle fault.

Detouring subsystem (Figure 3 bottom). The detouring subsystem consists of two modules: a *detouring controller* and a *BGP injector*. The BGP injector is deployed on a per-PoP basis.

⑩ The detouring controller receives middle faults from the fault debugger, generates detouring strategy for each middle fault, and outputs the strategy to the BGP injector.

⑪ The BGP injector receives detouring strategy from the detouring controller, generates corresponding BGP routes, and announces them to PRs or DRs to detour the victim traffic.

4 Monitoring Network Faults

The monitoring subsystem consists of the active IP collector (§ 4.1), the QoS monitor (§ 4.2), and the fault reporter (§ 4.3). Each module will be introduced in one subsection.

4.1 Collector: Selecting Representative IPs

The first module in the monitoring subsystem is the active IP collector (collector for short). The collector, deployed in a VM in Huawei Cloud, is used to collect and select active IP addresses. It proceeds in two steps. 1) For only IP /24 prefixes in the AS'es which contain clients of Huawei Cloud, we decide to actively send ICMP probes to IP addresses in them, and regard the monitored performance as the QoS for users in this prefix. To guarantee the accuracy of active monitoring, we need to select active IP addresses as targets for probing. Therefore, the **first step** is to collect active IP addresses from the AS'es which contain clients of Huawei Cloud. 2) Considering that the active IP addresses in each IP /24 prefix share similar middle paths and client paths[5], it is of no value to monitor all of them. To achieve lightweight monitoring, we need to further reduce the overhead by selecting representative IP addresses (IP*s for short) in each prefix for probing. Therefore, the **second step** is to select IP*s in each IP /24 prefix, and then passes them to the second module, *i.e.*, the QoS monitor. Below, we describe the two steps of the collector in detail.

The first step of the collector proceeds as follows. The collector maintains *health points* as the indicator of activeness for each IP address, and only scans IP /24 prefixes in the AS'es which contain clients of Huawei Cloud by sending ICMP probes to each IP address in them periodically. In each round of scanning, if an IP address responds to the ICMP probes, its health points will increase; otherwise, its health points will decrease. The health points will decay over time, so as to indicate recent health status. After each round of scanning, the collector selects the IP addresses whose health points exceed a predefined threshold as active IP addresses.

The second step of the collector proceeds as follows. After each round of scanning, for each IP prefix, the collector sorts the active IP addresses in it based on the health points from the highest to the lowest. The IP addresses that usually belong to gateways (*e.g.*, .1, .254) will be given bonus health points before sorting. Then, for each IP /24 prefix, the collector selects the top-k active IP addresses in it as IP*s, and passes them to the QoS monitor. By default, we set k to 5. For those prefixes that contain clients of Huawei Cloud, we set a larger k to better reflect the QoS. Note that the information of the AS'es and IP /24 prefixes containing clients of Huawei Cloud is provided by the traffic monitoring system built in Huawei Cloud (§ 2.1).

4.2 Monitor: Monitoring QoS

The second module in the monitoring subsystem is the QoS monitor (monitor for short). The monitor is used to monitor the QoS for users in different AS'es. It is deployed based on the following considerations. 1) As Huawei Cloud can serve users from any PoP, we need to monitor the QoS by monitoring the performance of IP*s from every PoP. 2) To avoid the disturbance of cloud faults and traffic detouring (§ 6), we should start monitoring as close to the PR as possible. 3) Considering that the cloud traffic can egress at any PR, we should monitor all PRs to achieve full coverage of monitoring, *i.e.*, send probes to each IP* through all PRs. Therefore, AAsclepius deploys the monitor on a per-PoP basis as follows. As shown in Figure 2, for each PR, AAsclepius deploys a server directly connected to it, namely *monitoring server*. On each monitoring server, the monitor runs a QoS agent to send ICMP probes, which will egress at the PR connected to the monitoring server, so as to achieve full coverage. This deployment can easily scale out from a monitoring server to a cluster consisting of multiple monitoring servers, so as to improve the capability of the monitor.

The monitor proceeds in two steps. First, the monitor monitors the performance of each IP* received from the active IP collector. Specifically, **every minute**, the monitor executes a round of monitoring: for each IP*, each QoS agent sends ICMP probes to it, and computes its average packet loss rate

[5] Client paths refer to the paths in the client AS.

among all QoS agents, so as to achieve full coverage. We call this process **QoS monitoring**.

Second, the monitor aggregates the performance of IP*s at AS-granularity, and then passes the aggregated performance data to the third module, *i.e.*, the fault reporter. Specifically, after each round of monitoring, for each AS, the monitor computes the average packet loss rate of all IP*s in it as its packet loss rate. The reason behind is as follows. It is expected that we can monitor the QoS in every IP /24 prefix to achieve fault monitoring at prefix-granularity, but not all IP /24 prefixes contain active IP address. The network infrastructure in our country can ensure that the IP*s in the same AS share similar middle paths, and thus share similar middle faults (discussed in Section 2.2). Therefore, monitoring the QoS at AS-granularity will not degrade the sensitivity to middle faults. In our deployment, we find the above attribute also applies to the network of every ISP in every province. Therefore, we call the network of every ISP in every province a *pseudo AS*, and aggregate the performance of IP*s at pseudo-AS-granularity to ease maintenance. *In the rest of this paper, we always use AS to refer to pseudo AS.*

4.3 Reporter: Reporting Victim-AS'es

The third module in the monitoring subsystem is the fault reporter (reporter for short). The reporter, deployed on a per-PoP basis, is used to identify victim-AS'es and filter victim-AS'es suffering from transient faults. The reporter proceeds in two steps.

In the **first step**, the reporter receives the aggregated performance data from the QoS monitor deployed in the same PoP, and identifies whether an AS is suffering from faults based on three observations. The first observation is that the packet loss rate of each AS remains relatively stable when no fault occurs; once a fault occurs, the packet loss rates of the AS'es suffering from the fault suddenly increase. Therefore, for each AS, we decide to monitor the variation of its packet loss rate, and use a *fault threshold* to identify whether it is suffering from faults. The second observation is that different AS'es have different patterns of packet loss rates, because different AS'es point to different middle paths and client paths, and are maintained by different ISPs. Therefore, we should use an AS-specific fault threshold rather than a unified one. The third observation is that the condition of the Internet varies over time, and therefore the fault threshold should dynamically evolve as time goes by.

Based on the above considerations, the first step proceeds as follows. The reporter considers that each AS is in *healthy-state*, *i.e.*, not *victim-state* (suffering from faults), at the beginning. Here, we use "victim" instead of "faulty" to avoid confusion, as a client AS suffering from faults may have no faults occurring in its own network (the faults can occur in the middle path between the AS and the PoP to affect the traffic). The reporter maintains packet loss rates for each AS in recent W minutes. For AS_j, the reporter computes the average ($l_{avg}(j,t)$) and standard deviation ($\sigma(j,t)$) of packet loss rates, to characterize its current pattern, where t (Minute) is the current time. Let $\mathcal{T}_v(j,t)$ be the fault threshold used to identify whether AS_j is suffering from faults at time t. We set

$$\mathcal{T}_v(j,t) = l_{avg}(j,t-1) + \max(\tau\sigma(j,t-1), \delta)$$

where δ is a constant (by default 3%) to filter minor faults. For AS_j, every minute, the reporter receives its current packet loss rate $l_{cur}(j,t)$ from the QoS monitor, and then compares $l_{cur}(j,t)$ with $\mathcal{T}_v(j,t)$. If $l_{cur}(j,t)$ exceeds $\mathcal{T}_v(j,t)$, the reporter identifies that AS_j is suffering from faults, and transits AS_j to victim-state. We call an AS in victim-state as a *victim-AS*, and a time period in which an AS is continuously in victim-state a *victim-period*. For a victim-AS, to avoid the disturbance of high packet loss rate caused by faults, its fault threshold will stop to update when it transits to victim-state from healthy-state. When the packet loss rate of a victim-AS stays below its fault threshold for W minutes, we consider that all its packet loss rates in the sliding window are not affected by faults. In this case, the victim-AS will transit back to healthy-state and restart to update its fault threshold. In our deployment, we set the window size W to 60 and τ to 3. Here, we provide some insights into their settings. We set window size W to 60 (1 hour) because it can stably present the recent condition of Internet. As shown in Figure 10, the average packet loss rate varies smoothly per hour (with less than 0.1% variation). We set τ to 3 because *3σ-rule* is widely used in outlier detection. When there is no fault, the loss rate of each IP* can be regarded as independent and identically distributed. Therefore, the average loss rate of IP*s ($l_{avg}(j,t)$) follows normal distribution according to central limit theorem, and applies to 3σ-rule.

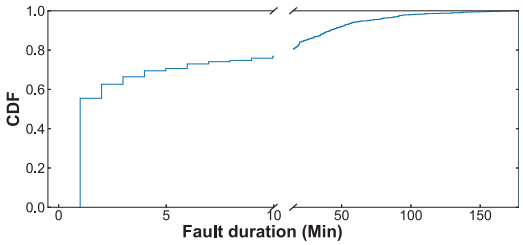

Figure 4: CDF of fault duration of victim-AS'es.

In the **second step**, based on another observation, the reporter filters victim-AS'es suffering from transient faults, and reports the remaining victim-AS'es to the diagnosing subsystem. The observation is that transient faults disappear quickly, and thus have limited harm to our cloud service. Therefore, we would like to ignore transient faults. Based on the above consideration, the second step proceeds as follows. Suppose the current time is t. The reporter only reports the victim-AS'es that satisfy the following two requirements to the diagnosing subsystem: 1) the victim-AS is identified as suffering from faults at time t; 2) the victim-AS has ever been identified as suffering from faults for at least M minutes continuously in the current victim-period. In our deployment, we set M to

3. We select M based on an analysis of the distribution of the fault duration[6] of victim-AS'es in three major PoPs in December 2021. As shown in Figure 4, the fault duration of almost 2/3 of victim-AS'es is below 3 minutes. Therefore, setting M to 3 can efficiently filter transient faults without compromising much timeliness.

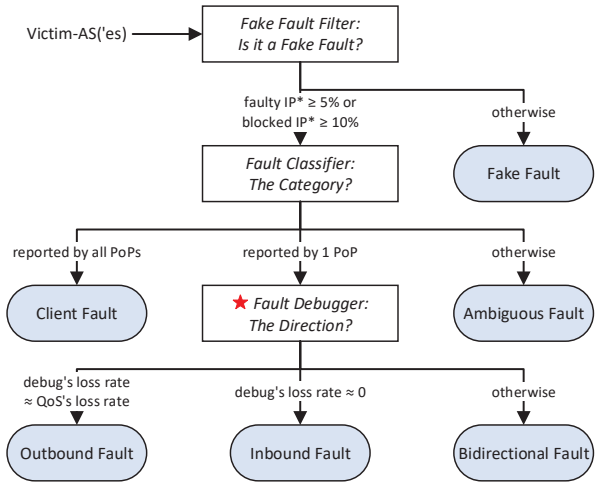

Figure 5: Decision tree.

5 Diagnosing Network Faults

In this section, we show how to use a decision tree in the diagnosing subsystem to achieve accurate and fine-grained diagnosis. As shown in Figure 5, there are three critical decision nodes in the decision tree: the fake fault filter (§ 5.1), the fault classifier (§ 5.2), and the fault debugger (§ 5.3). The design of the structure of the decision tree is quite intuitive. With the reported victim-AS'es, first, the fake fault filter first filters those fake faults that lead to misreported victim-AS'es. Second, the fault classifier pick out the middle faults that AAsclepius may circumvent from the true faults. Third, the fault debugger classifies the middle faults into inbound/outbound/bidirectional faults to guide the subsequent traffic detouring. Each decision node will be introduced in one subsection.

5.1 Fake-filter: Filtering Fake Faults

Motivation: The fault reporter in the monitoring subsystem reports a victim-AS when the average packet loss rate of all IP*s in the AS increase. However, the increase of average packet loss rate does not mean that a real fault occurs. For example, when a router that hosts an IP* is updating its operating system, it may not be able to respond to ICMP probes. Thus the packet loss rate of this IP* will suddenly increase to 100%, which also leads to the increase of average packet loss rate. If a victim-AS is actually healthy, we say it is suffering from **fake faults**. Therefore, it is desired for each PoP to filter all victim-AS'es with fake faults.

[6]The fault duration of a victim-AS refers to the interval between the first time and the last time it is identified as suffering from faults in the same victim-period.

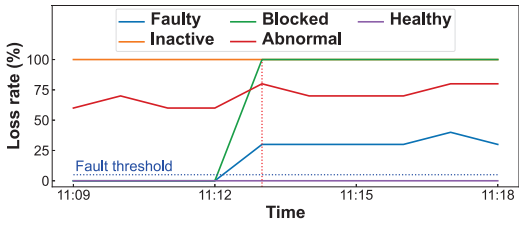

Figure 6: IP* Classification.

Workflow: To prevent fake faults from interfering with our diagnosis, AAsclepius deploys the first module in this subsystem: a fake fault filter for each PoP (*Fake-filter* for short). In each PoP, Fake-filter performs analysis for each IP* to identify whether a reported victim-AS is caused by a fake fault, and we will only diagnose real faults in next two modules. The input of Fake-filter includes: a victim-AS$_j$ with its IP*s, and the historical loss rate of each IP*. Then we analyze why the average packet loss rate increases a lot. Fake-filter divides the IP*s into 5 categories according to their loss rate (see Figure 6), but only use three categories (faulty IP*s, blocked IP*s, and healthy IP*s) to identify fake faults. The 5 categories of IP*s are detailed below.

- Symbols: Suppose at time t_{fault}, victim-AS$_j$ transits to victim-state, lasts for $M = 3$ minutes, and then is reported to Fake-filter. Note that the setting of M is discussed in Section 4.3. Let $T_{pre}[3Min]$ be the 3 minutes before t_{fault}, and let $T_{post}[3min]$ be the 3 minutes after t_{fault}.
- **Faulty IP*s:** We call an IP* a faulty IP* if it satisfies the three conditions: 1) its average loss rate in $T_{pre}[3Min]$ is lower than fault threshold $\mathcal{T}_v(j,t_{fault})$; 2) its average loss rate in $T_{post}[3Min]$ is in $[\mathcal{T}_v(j,t_{fault}),100\%)$; 3) its highest loss rate in $T_{post}[3min]$ is lower than 100%. We consider that faulty IP*s are affected by the fault occurring at t_{fault}.
- **Blocked IP*s:** We call an IP* a blocked IP* if it satisfies the three conditions: 1) its average loss rate in $T_{pre}[3Min]$ is lower than $\mathcal{T}_v(j,t_{fault})$; 2) its average loss rate in $T_{post}[3Min]$ is higher than $\mathcal{T}_v(j,t_{fault})$; 3) its highest loss rate in $T_{post}[3Min]$ reaches 100%. These IP*s are often blocked in two cases. First, they are added into a blocklist by some network devices (IP blocking). Second, with a small probability, they suffer from serious faults.
- **Healthy IP*s:** We call an IP* a healthy IP* if its average loss rates in both $T_{pre}[3Min]$ and $T_{post}[3Min]$ are lower than $\mathcal{T}_v(j,t_{fault})$. We consider that healthy IP*s are not affected by the fault occurring at t_{fault}.
- **Inactive IP*s:** We call an IP* an inactive IP* if its average loss rate in $T_{pre}[3Min]$ is 100%. Inactive IP*s previously responded to ICMP probes, but stop responses before $T_{pre}[3Min]$.
- **Abnormal IP*s:** We call an IP* an abnormal IP* if its average loss rate in $T_{pre}[3Min]$ is in $[\mathcal{T}_v(j,t_{fault}),100\%)$. We suspect that abnormal IP*s have suffered from other network anomalies or network faults occurring before $T_{pre}[3Min]$.

Identifying fake faults: After classifying faults into the above five categories, we analyze whether it is a fake fault. Obviously, the last two categories cannot be used for identification. We define two metrics using the first three categories. We define *faulty IP* ratio* as $\frac{\#\text{ faulty IP*s}}{\#\text{ total}}$, and define *blocked IP* ratio* as $\frac{\#\text{ blocked IP*s}}{\#\text{ total}}$, where # total = # faulty IP*s + # blocked IP*s + # healthy IP*s. We set two thresholds for the two metrics respectively. According to long time maintenance, we find when If the faulty IP* ratio is no less than 5%, or the blocked IP* ratio is no less than 10%, Fake-filter reports the fault as real; otherwise, Fake-filter reports the fault as fake.

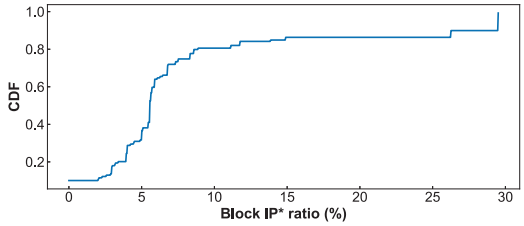

Figure 7: CDF of block IP* ratio of victim-AS'es without faulty IP*s.

While the threshold for faulty IP* ratio is mainly set according to long-time operational experience, we provide some insights in the setting of the threshold for block IP* ratio. When real faults occur, an affected IP* will be either faulty IP* or block IP*. When there is no real fault, the faulty IP* ratio keeps close to 0, but the blocked IP* ratio often reaches a little larger than 0 (*e.g.*, 5%) due to IP blocking. Therefore, we should set a larger threshold for blocked IP* ratio to filter the fake faults caused by IP blocking. We analyze the distribution of the block IP* ratio of all reported victim-AS'es without faulty IP*s in May 10th, 2023. These reported faults are of high probability to be fake faults as no faulty IP* is reported, and a fault with a larger block IP* ratio should have a larger probability of being real fault. As shown in Figure 7, about 80% reported victim-AS'es have less than 10% block IP* ratio. Therefore, setting the threshold for blocked IP* ratio to 10% may efficiently filter most fake faults while not missing serious faults.

5.2 Classifier: Identifying Fault Category

Overview: To identify fault category, AAsclepius deploys the second module in this subsystem: the fault classifier (classifier for short). Recalling in the previous module, Fake-filter in each PoP filters fake faults, and reports the other faults to the classifier. The input is the received faults from many PoPs in every minute: <PoP$_1$,victim-AS list$_1$> ... <PoP$_n$,victim-AS list$_n$>. For each victim-AS, the classifier outputs its fault category: client fault, middle fault, or *ambiguous fault*. For each middle fault, the classifier will report the corresponding PoP and victim-AS to the third module, *i.e.*, the fault debugger.

Workflow: Our observation is the same as the prior work [11]: most of the time the victim-AS is caused by either client faults or middle faults. We use the number of PoPs that report each victim-AS to identify fault category, and there are three cases.

- Case 1: If a victim-AS is reported from only one PoP, the classifier identifies the fault as a middle fault.
- Case 2: If a victim-AS is reported from all PoPs, the classifier identifies the fault as a client fault.
- Case 3: Otherwise, it is too difficult to identify, and we have to concede, and the classifier identifies the fault as an ambiguous fault.

The reason of the above classification is as follows. Considering a client in an AS, for different PoPs, the middle paths are different, while the client paths are usually similar. Therefore, 1) that a victim-AS is reported from 1 PoP is incurred by middle faults with high probability; 2) that a victim-AS is reported from all PoPs is incurred by client faults with high probability; 3) that a victim-AS is reported from multiple but not all PoPs, and the above probabilities of middle faults and client faults both decrease a lot. Our maintenance results (see Figure 8) show that the probability of case 3 is around 7%, and thus currently we just ignore case 3.

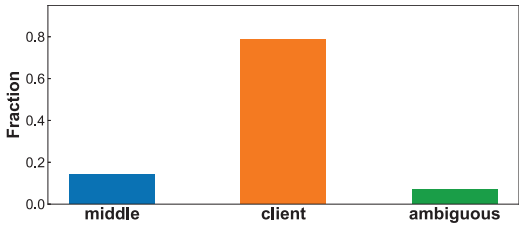

Figure 8: Fraction of each category of faults.

Operational experience: In our daily maintenance, we find a situation that will degrade the accuracy of our diagnosis: although multiple PoPs report the same victim-AS, the time they first report is not always the same, but sometimes with a one-minute or two-minute difference. A potential reason behind is as follows. In the early stage of a network fault, there may be only a small amount of congested links. Due to the randomness of the routing inside the victim-AS, the ICMP probes may go through paths with slight difference, and thus the results measured at different PoP points may be slightly different. For example, suggest that ICMP probes sent from both PoP$_i$ and PoP$_{i+1}$ reach a router using equal cost multi-path strategy (ECMP) in a client AS, and there are two equal-cost paths towards the destination. One of the path first becomes congested due to the randomness of hash functions, while the other one remains uncongested. Suggest that the ICMP probes from PoP$_i$ are forwarded to the congested link, and those from PoP$_{i+1}$ are forwarded to the uncongested link, then only PoP$_i$ reports this AS as a victim-AS. As the congestion further evolves (which may take one or two minutes), both PoP$_i$ and PoP$_{i+1}$ report this AS as a victim-AS. In this case, if the classifier diagnoses a victim-AS once it is reported, the victim-AS may be misdiagnosed because there could be some PoPs that have not reported this victim-AS in

time. To address this issue, for each reported victim-AS, we decide to delay the diagnosis for two minutes. Specifically, only when a victim-AS is continuously reported from a PoP for three minutes, the classifier starts to diagnose it. The classifier diagnoses the victim-AS based on the number of PoPs that report it in the past three minutes, instead of the number in the current minute.

5.3 Debugger: Identifying Fault Direction

Overview: Recalling that the previous module reports a PoP and a victim-AS to this module. Suggest PoP_i is reported to find that victim-AS is suffering from middle faults. This module, namely fault debugger (debugger for short), is used to further identify and output the direction of the middle fault. There are three faults with different directions: outbound faults, inbound faults, and bidirectional faults. We propose a novel technique, namely *PathDebugging*, to perform the debugging process. This technique is the key novelty of AAsclepius.

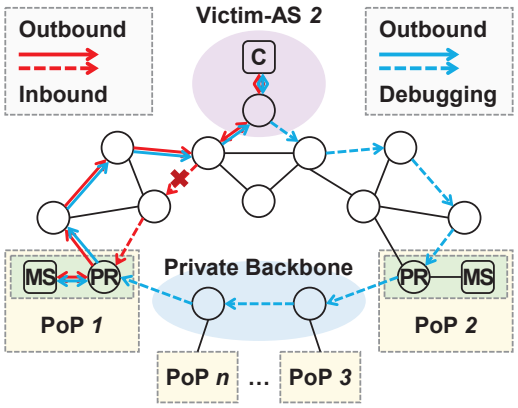

Figure 9: PathDebugging. "**MS**" refers to the monitor server in the PoP, "**C**" refers to a client in the victim-AS_2, and "×" refers to a middle fault.

Statement of fault direction: As shown in Figure 9, there are four paths between the monitor server (MS) and the client (C): two outbound paths (solid lines with arrows), one inbound path (dash red lines with arrows), and one debugging path (dash blue lines with arrows including the part across the private backbone). In this Figure, the reported PoP and victim-AS from the previous module are PoP_1 and AS_2. This means that we only know there is a fault between PoP_1 and AS_2, but do not know the fault direction. Outbound faults, inbound faults, and bidirectional faults point to different directions. For different fault directions, we will use different detouring strategies in the detouring subsystem (§ 6).

Rationale: To identify whether the fault is in the outbound path or the inbound path, the idea of our key technique PathDebugging is to replace inbound path with a zero-fault path, which is named the **debugging path**. After replacement, we monitor the packet loss rate of the ICMP probes between the reported PoP and victim-AS: 1) if the loss rate does not change, it means it is an outbound fault; 2) if the loss rate decreases to near 0, it is an inbound fault; 3) if the loss rate decreases but not reach 0, it is a bidirectional fault. Next we show how to set a debugging path and route the ICMP reply packets along the debugging path.

Workflow: Recall that each PoP has multiple PRs (peering routers), each PR is connected to a monitoring server, and each monitoring server runs a QoS agent. We deploy another agent named *debugging agent* in each monitoring server. These two agents are very similar except that they use different source IP addresses. By leveraging the debugging agent and BGP prefix announcement, next we show how to set the debugging path and let the ICMP reply packets follow the debugging path.

Phase 1: announcing BGP prefixes. We have deployed many PoPs: PoP_1, PoP_2, ..., PoP_n. We associate every two adjacent PoPs for debugging and detouring. We call PoP_{i+1} the *backup* of PoP_i. For PoP_i, we assign a unique IP /24 prefix to the debugging agents in it, and the prefix is announced by all PRs in the backup PoP_{i+1}. For example in Figure 9, the PRs in PoP_2 announce the unique prefix of the debugging agent in PoP_1.

Phase 2: activating the debugging path. This phase aims to let the ICMP reply packets follow the debugging path, and observe the packet loss rate. Take Figure 9 as an example. The debugging agent in PoP_1 chooses a source IP address from its unique IP /24 prefix Pre_1, and then sends ICMP packets along the outbound path (the solid line) to the client. The ICMP reply packets will follow the debugging path (the dash blue line crossing the private backbone), because the PRs in PoP_2 announce the unique prefix Pre_1. Note that there is no fault in the debugging path for the following two reasons. First, as the middle fault is identified when only PoP_1 reports the fault, there must be no fault in the path from the victim-AS to PoP_2. Second, the private backbone is adequately provisioned, and thus can be considered as faultless. To save monitoring overhead, the debugging path is inactive by default, and will be activated when the module Fake-filter starts to report a victim-AS and a PoP.

Phase 3: identifying fault direction. Let l_{QoS} be the average packet loss that is monitored by QoS agents. Let l_{debug} be the average packet loss rate that is monitored by debugging agents. The fault debugger then identifies the fault direction according to the following formula.

$$Direction = \begin{cases} Inbound & \texttt{Cond}_1 \\ Outbound & \neg\texttt{Cond}_1 \wedge \texttt{Cond}_2 \\ Bidirectional & \neg\texttt{Cond}_1 \wedge \neg\texttt{Cond}_2 \end{cases}$$

$$\texttt{Cond}_1 = \left[l_{debug} \leqslant 3\%\right]$$
$$\texttt{Cond}_2 = \left[|l_{QoS} - l_{debug}| \leqslant 3\%\right]$$

The rationale behind the formula is as follows. 1) If it is an inbound fault, there should be no fault in outbound path and

debugging path, and therefore l_{debug} should be small, which corresponds to $\texttt{Cond}_1 = \left[l_{debug} \leqslant 3\%\right]$. Here, 3% equals to the constant δ (Section 4.3) that we use to filter minor faults. 2) If it is an outbound fault, both debugging agent and QoS agent should detect the fault, and therefore they must not meet $\texttt{Cond}_1$. Further, considering there is no fault in inbound path and debugging path, the difference between l_{debug} and l_{QoS} should also be small, which corresponds to $\texttt{Cond}_2 = \left[|l_{QoS} - l_{debug}| \leqslant 3\%\right]$. 3) If it is an bidirectional fault, as discussed in 1) and 2), it should not meet $\texttt{Cond}_1$ and $\texttt{Cond}_2$.

6 Detouring Victim Traffic

The detouring subsystem consists of a detouring controller and a BGP injector deployed on a per-PoP basis. We describe how the detouring controller and the BGP injector cooperate to detour traffic suffering from faults (so called victim traffic), circumventing outbound faults (§ 6.1) and inbound faults (§ 6.2), respectively. For bidirectional faults, we can split them into outbound faults and inbound faults, and then circumvent them separately. Therefore, we will not discuss how to circumvent bidirectional faults.

6.1 Circumventing Outbound Faults

Rationale: For every outbound fault associated with one victim-AS$_j$ and one reported PoP$_i$, the traffic from PoP$_i$ to victim-AS$_j$ is the victim traffic. To circumvent the outbound fault, considering its backup PoP$_{i+1}$ not reporting victim-AS$_j$, we decide to detour the victim traffic to egress at PoP$_{i+1}$. As the cloud network is fully under control, to achieve this, we can inject BGP routes to DRs in PoP$_i$. Because traffic detouring will inevitably degrade the latency when there is no fault, we need to detour the victim traffic back as soon as possible after the fault disappears. As AAsclepius deploys the QoS monitor on monitoring servers directly connected to PRs, the traffic detouring at DRs will not interfere with QoS monitoring. Therefore, the monitoring subsystem can continuously identify whether victim-AS$_j$ is suffering from faults after detouring, and thus we can detour the victim traffic back when we have high confidence that the fault has already disappeared.

Workflow: The workflow of detouring victim traffic proceeds as follows. First, to ensure safety, before detouring the victim traffic, the detouring controller checks whether the PRs in PoP$_{i+1}$ and the private backbone will exceed 80% load rate after this detouring. Here, AAsclepius can easily determine the load rate of the PRs and private backbone after traffic detouring because the traffic monitoring system built in Huawei Cloud (§ 2.1) shares its visibility to traffic volume between any PoP and any AS to AAsclepius. Second, if the checking result is safe, the detouring controller then collects all IP prefixes of victim-AS$_j$ from PRs in PoP$_{i+1}$ rather than PoP$_i$, so as to guarantee that the PRs in PoP$_{i+1}$ can route the detoured traffic to the destination IP address. Third, the detouring controller passes the collected IP prefixes of victim-AS$_j$ and the IP addresses of PRs in PoP$_{i+1}$ to the BGP injector in PoP$_i$. In PoP$_i$, the BGP injector maintains a BGP connection with each DR. Fourth, the BGP injector generates corresponding BGP routes for the received IP prefixes of victim-AS$_j$. For these routes, the `local_pref`[7] is set to a very large value (*e.g.*, 1000), and the `next_hop`[8] is set to the received IP addresses of PRs in in PoP$_{i+1}$. Fifth, in PoP$_i$, the BGP injector announces the generated BGP routes to all DRs. By setting `local_pref` to a large value, the generated routes can override the original routes, and then the victim traffic will be detoured to egress at PoP$_{i+1}$. Once victim-AS$_j$ has been identified as not suffering from faults continuously for **10 minutes** by the fault reporter in PoP$_i$ (§ 4.3), the detouring controller will then inform the BGP injector in PoP$_i$ to withdraw the corresponding routes, so as to detour the victim traffic back.

6.2 Circumventing Inbound Faults

Rationale: For every inbound fault associated with one victim-AS$_j$ and PoP$_i$, the traffic from victim-AS$_j$ to PoP$_i$ is the victim traffic. Similarly, we decide to detour the victim traffic to ingress at PoP$_{i+1}$. However, the PoP at which the victim traffic ingresses is directly selected by ISPs, not the CSP. To address this issue, we can change the BGP announcement of PoP$_i$, and leverage BGP to detour the victim traffic. In order for the QoS monitor to continuously monitor existing faults to provide guidance on when to detour the victim traffic back, the change of the BGP announcement should not involve the prefixes assigned to the QoS monitor.

Workflow: The workflow of detouring victim traffic proceeds as follows. First, the detouring controller performs the safety checking similar to that in circumventing outbound faults. Second, In PoP$_i$, the detouring controller informs the BGP injector to announce the dominating prefixes of PoP$_i$ to all PRs. Note that the BGP injector needs to prepend multiple duplicate AS'es to the `AS_path` of these prefixes. In this way, after BGP converges, the victim traffic will be routed to ingress at PoP$_{i+1}$. Note that the dominating prefixes of PoP$_i$ are also announced by the other PoPs with multiple duplicate AS'es prepended to their `AS_path` (§ 2.1). We should ensure that PoP$_{i+1}$ prepends relatively less duplicate AS'es to the `AS_path` of these prefixes.

Discussion: A major risk of changing the BGP announcement at PRs is that it detours not only the victim traffic, but also all the other inbound traffic of PoP$_i$ (we call them innocent traffic). The latency of innocent traffic will inevitably degrade. Currently, considering the inevitable side effects, we currently disable AAsclepius to execute automatic detouring for inbound faults. AAsclepius only notifies the network operators of inbound faults, and provides an API for traffic detouring.

[7] The BGP local preference attribute is the second BGP attribute that can be used to choose the exit path for an AS.

[8] The BGP next hop attribute is the next hop IP address that is used to reach a certain destination.

6.3 Discussion

We first discuss the benefits of identifying fault direction, which is the key novelty of AAsclepius. Then, we discuss the potential downsides in the additional path asymmetry introduced by AAsclepius.

Benefits of identifying fault direction: Identifying fault direction can help minimize impacted traffic during traffic detouring. Because the start point of outbound path (cloud → client) is under control, to circumvent outbound faults, we can accurately determine outbound traffic requiring traffic detouring. Because the start point of inbound path (client → cloud) is beyond control, to circumvent inbound faults, we must change BGP announcement, and all inbound traffic is impacted. Therefore, with fault direction, we can reroute traffic accordingly to minimize impacted traffic.

Negligible downsides in introducing path asymmetry: According to RFC 3349 [25], the additional path asymmetry introduced by AAsclepius during detouring victim traffic may degrade performance of TCP traffic. Nevertheless, path asymmetry is a common phenomenon in the Internet (87% path-tuples show path asymmetry [26]). AAsclepius has been running for years, without customers complaining about performance degradation. Further, some prior works (Meta Edge-Fabric [12]/ Microsoft CASCARA [27]) also introduce additional path asymmetry as they switch transit-providers for better performance or cost-effectiveness. Therefore, we conclude that the additional path asymmetry should have negligible impact on traffic performance.

7 Evaluation

We first present the deployment status of AAsclepius (§ 7.1). Then, we present the performance of monitoring subsystem, diagnosing subsystem, and detouring subsystem (§ 7.2-7.4). In addition, we select several typical faults as case studies to illustrate the workflow of AAsclepius (see Appendix A).

7.1 Deployment Status

We have fully deployed AAsclepius on a large scale in our country. In August 2020, we start to run AAsclepius for just some provinces. After a month of testing, we start to run AAsclepius for the whole country. So far, AAsclepius has been running stable for two years. AAsclepius has diagnosed thousands of faults and circumvented more than two hundred middle faults. In 2021 and 2022, AAsclepius protects Huawei Cloud from major accidents. Our SRE team identifies network faults that cause more than five VIP customers to experience more than 5% packet loss rate for 10 minutes as major accidents. Major accidents typically last several hours, involving tens of AS'es, with (i) construction-related optical cable cuts, (ii) router failures, and (iii) traffic congestion being main root causes. For example, in August 2022, an outbound fault (may lead to major accident) affecting three provinces began at 20:57, resulting in a packet loss rate of up to 40%. AAsclepius executes traffic detouring at 21:04 (within 8 minutes) to circumvent the middle fault, and the fault finally ended at 22:30.

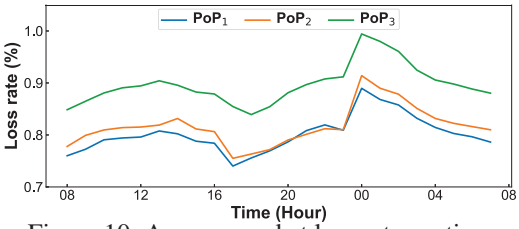

Figure 10: Average packet loss rate vs. time.

7.2 Performance of Monitoring Subsystem

We present the performance of the monitoring subsystem in three major PoPs in December 2021. First, we present the trend of packet loss rate and the distribution of victim-AS'es in different hours. Then, we present the distribution of fault duration of victim-AS'es. The following figures present data aggregated over 31 days in December.

Average packet loss rate vs. time (Figure 10): For the three major PoPs, we calculate the average packet loss rate of all IP*s in different hours. First, we find that the trend of the packet loss rate in each PoP is similar. This is possibly because the middle network in our country is adequately provisioned and well engineered, and thus the packet losses are mainly contributed by the client network. Because each IP* shares similar client paths in different PoPs, its packet loss rates in different PoPs are also similar, and thus the average packet loss rate in each PoP shares similar trends. Second, we find that the packet loss rate sharply increases to the peak at 0:00/24:00. It is possibly because ISPs in our country usually update routes and maintain network devices at this time, which is usually accompanied by network faults such as BGP misconfigurations, leading to the increase of average packet loss rate. Third, we find that the average packet loss rate in PoP_1 is slightly higher than that in PoP_2 and PoP_3. We suggest this is because that the middle network PoP_1 connected to usually has a relatively higher load.

Distribution of victim-AS'es vs. time (Figure 11): For each PoP, we count the distribution of victim-AS'es occurring in different hours. First, similar to the packet loss rate, we find that the distribution of the occurrence of victim-AS'es in each PoP is similar. Second, we also find that victim-AS'es are more likely to occur at 0:00/24:00. Third, we find that the distribution of the occurrence of victim-AS'es is positively correlated with the trend of packet loss rate. We suggest this is because a higher packet loss rate implies poorer network quality, which means more faults and thus more victim-AS'es.

Fault duration of victim-AS'es (Figure 12): Similar to Figure 4, we further present the distribution of fault duration of victim-AS'es in each PoP. We also find that the distribution is quite similar in each PoP. Considering that each PoP shares similar network quality, we can set unified parameters for each PoP to ease maintenance.

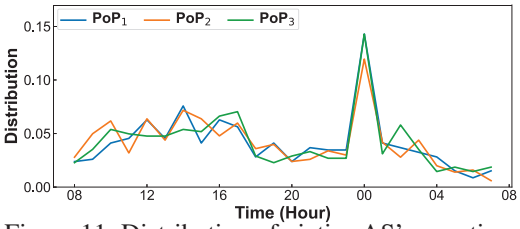

Figure 11: Distribution of victim-AS'es vs. time.

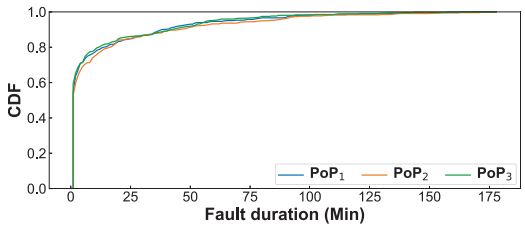

Figure 12: CDF of fault duration of victim-AS'es.

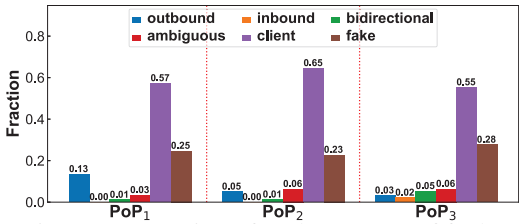

Figure 13: Fraction of each category of faults.

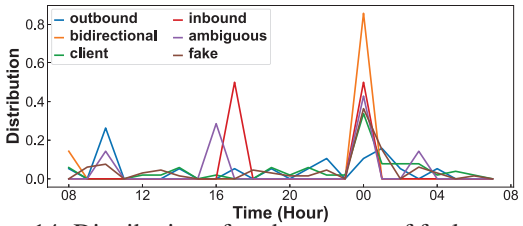

Figure 14: Distribution of each category of faults vs. time.

7.3 Performance of Diagnosing Subsystem

We present the performance of the diagnosing subsystem in three major PoPs in December 2021. First, we present the fraction of each category of faults. Then, we present the distribution of each category of faults in different hours. The following figures present data aggregated over 31 days in December.

Fraction of each category of faults (Figure 13): We count the fraction of each category of faults in each PoP. We find that the fractions in each PoP are similar: more than 50% of the faults are client faults, about 25% are fake faults, less than 15% are middle faults. It is possibly because the middle network in our country is well engineered and adequately provisioned, so that middle faults occur less frequently. We find that the fraction of outbound faults is far larger than that of inbound faults. The results show that outbound faults, inbound faults, and bidirectional faults account for 7%, 1%, and 2%, respectfully. We suspect this is because there is much more user download traffic than user upload traffic in the middle and client network, and thus the outbound paths are more likely to be congested.

Distribution of each category of faults vs. time (Figure 14): We count the distribution of each category of faults occurring in different hours. Similar to the distribution of victim-AS'es occurring in different hours (see Figure 11), we find that faults are more likely to occur at 0:00/24:00.

Potential misclassifications: Misclassifications are unavoidable. When there is a false positive (a non-middle fault is classified as a middle fault), AAsclepius may execute useless traffic detouring and increase the latency. When there is a false negative (a middle fault is classified as a non-middle fault), AAsclepius may not reduce the packet loss rate of victim traffic and receive complaints from customers. Because most network faults occur beyond our control, we can hardly obtain ground truth and misclassification rate. Nevertheless, AAsclepius can reduce packet loss rate in most traffic detouring (see Figure 16) and has protected cloud from major accidents for years, indicating an extremely low misclassification rate.

7.4 Performance of Detouring Subsystem

We present the performance of the detouring subsystem in three major PoPs in December 2021. We first present the response time of AAsclepius to middle faults. We then present the effect of traffic detouring on the packet loss rate and latency of victim traffic. The results show that the detouring subsystem is fast and effective. Note that we currently disable AAsclepius to execute automatic detouring for inbound faults, and thus all traffic detouring in this section is for outbound faults.

Evaluation criteria: In order to evaluate the detouring subsystem, we deploy *VM agents* in VMs in Huawei Cloud to perform *VM monitoring*. Similar to QoS agents, VM agents also send ICMP probes to each IP*. Because the probes sent from VMs are routed the same as the cloud traffic, we regard the performance of VM monitoring as the QoS, and use it to evaluate the effect of traffic detouring.

Response time to middle faults (Figure 15): We define the response time to a middle fault as the interval between the time its associated victim-AS transits from healthy-state to victim-state and the time the detouring subsystem reports the traffic detouring is executed. We find that the response time to all middle faults is within 8 minutes. Typically, the monitoring subsystem takes 3∼5 minutes to identify and report a victim-AS; the diagnosing subsystem takes 3∼4 minutes to identify its category and direction; the detouring subsystem takes less than 30 seconds to execute the traffic detouring.

Packet loss rate optimization (Figure 16): For each middle fault, we compare the average packet loss rate of its associated victim-AS in VM monitoring within 5 minutes before and after the corresponding traffic detouring is executed. We find that each traffic detouring reduces the packet loss rate by 7.0% on average. There are only less than 10% traffic detouring degrading the packet loss rate by less than 0.5%.

This is possibly because that the middle faults have already disappeared when the traffic detouring is executed.

Latency variation (Figure 17): For each middle fault, we compare the average latency of its associated victim-AS in VM monitoring within 5 minutes before and after the corresponding traffic detouring is executed. We find that each traffic detouring slightly degrades the latency by 1.9ms on average. This is reasonable because traffic detouring usually degrades the latency when no fault occurs, and the degradation has already been weakened by the middle faults.

8 Related Work

Fault monitoring and diagnosis at Internet scale: Based on the measurement methods, existing fault monitoring and diagnosis solutions can be mainly classified into three categories: 1) active solutions which send probes to the Internet [14, 28–30]; 2) passive solutions which monitor ongoing connections [12, 13, 15, 17, 31, 32]; 3) hybrid solutions which combine active and passive solutions [1, 11, 16, 18, 19, 33]. Among these solutions, BlameIt [11] (hybrid), Entact [14] (active), Edge fabric [12] (passive), Espresso [13] (passive), and CPR [15] (passive) are most related to our application scenarios. BlameIt uses its passive measurement data to monitor faults and identify the fault category in the first phase, and further triggers impact-prioritized probes to localize the faulty AS for middle faults with the largest impacts in the second phase. However, BlameIt does not identify the fault direction, and is therefore distinguished from AAsclepius. The other solutions above do not diagnose faults but support traffic engineering, and we will cover them in the next paragraph.

Traffic engineering: There are substantial traffic engineering solutions, most of which are dedicated to optimizing CDN performance. A related kind of solutions select egress path and ingress point that a client should be directed to as a function of path performance [12–16, 34, 35]. Among them, Entact [14] measures path performance by sending probes to different IP /24 prefixes through alternate paths. Edge Fabric [12] and Espresso [13] passively measure path performance in different IP /24 prefixes by directing a small amount of flows to alternate paths and tracking their performance. Similar to AAsclepius, Espresso leverages Google's private backbone, B4 [36], and thus can route traffic to egress at distant PoPs. Through deployment in the kernel, CPR [15] even provides path failover at connection granularity. However, all the listed traffic engineering solutions optimize their traffic performance by selecting alternate outbound paths based on end-to-end measurement, and thus can only handle outbound faults. In contrast, AAsclepius detours traffic based on the category and the direction of the faults, and thus can handle both inbound and outbound faults. Therefore, these solutions are distinguished from AAsclepius. AAsclepius is also complementary to these solutions, as it can provide fine-grained fault category and fault direction information, which is useful for CDN performance optimization. Other solutions include IP anycast [37], co-located DNS and proxy servers [38], end-user mapping with EDNS [39], *etc.* [40].

Solutions in datacenters: Network faults in datacenters have been studied over decades, and researchers have provided various solutions [41–63]. These systems work excellently in data centers, but have not been extended to Internet scale.

9 Conclusion

Network fault is a widespread phenomenon in the Internet, which could harm the QoS of Huawei Cloud. Existing works do not identify fault direction. In this paper, we propose a fully automatic system, namely AAsclepius, to monitor and diagnose network faults, and detour victim traffic to circumvent middle faults. The key novelty of AAsclepius, PathDebugging, achieves identifying the directions of middle faults. AAsclepius has proven itself to be mature and reliable in two years of production deployment, and we consider extending AAsclepius to IPv6 network. Although the core methodology applied to IPv4 network can still be applied to IPv6 network, the main difficulty in the extension is how to efficiently find active IP addresses of high quality for QoS monitoring in the IPv6 address space which is much more larger than IPv4, and we are seeking for the solution.

A Real-world Case Studies

To better illustrate the workflow of AAsclepius, we present several typical faults as case studies.

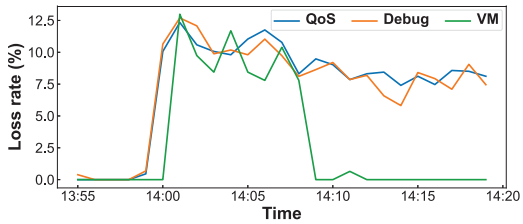

Figure 18: A typical outbound fault.

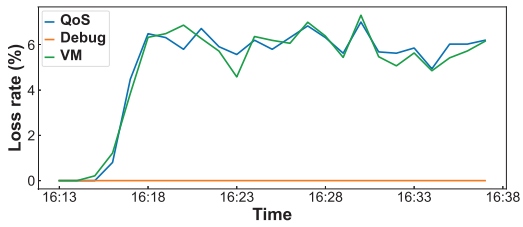

Figure 19: A typical inbound fault.

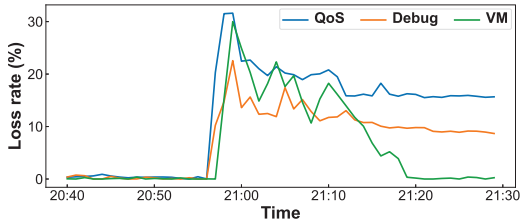

Figure 20: A typical bidirectional fault.

A typical outbound fault: Figure 18 plots the packet loss rates of QoS monitoring, debug monitoring[9], and VM monitoring during a typical outbound fault. The monitoring subsystem identifies a victim-AS at 14:00 at the first time, and reports the fault at 14:03. The diagnosing subsystem then identifies its fault category as a middle fault. The loss rate of debug monitoring keeps about 10%, which is similar to that of QoS monitoring. Therefore, the diagnosing subsystem identifies the middle fault as an outbound fault. The detouring subsystem detours the victim traffic at 14:08, and we can see the loss rate of VM monitoring suddenly decreases to almost 0%. In summary, the packet loss rate of VM monitoring decreases from up to 12.5% to almost 0% within 8 minutes. The outbound fault ends at 15:07, and the diagnosing subsystem detours the traffic back at 15:17, which is not plotted here.

A typical inbound fault: Figure 19 plots the packet loss rates of QoS monitoring, debug monitoring, and VM monitoring during a typical inbound fault. The monitoring subsystem identifies a victim-AS at 16:17 at the first time, and reports the fault at 16:20. The diagnosing subsystem then identifies its fault category as a middle fault. The packet loss rate of debug monitoring keeps less than 1%. Therefore, the diagnosing subsystem identifies the middle fault as an inbound fault. As we disable the automatic detouring for inbound faults, this fault is not circumvented, and the packet loss rate of VM monitoring keeps similar to QoS monitoring.

A typical bidirectional fault: Figure 20 plots the packet loss rates of QoS monitoring, debug monitoring, and VM monitoring during a typical bidirectional fault. This fault is a large-scale fault involving tens of victim-AS'es, and we just present one of them. The monitoring subsystem identifies the victim-AS at 20:57 at the first time, and reports the fault at 21:00. The diagnosing subsystem then identifies its fault category as a middle fault. The packet loss rate of the debug monitoring keeps around 15%, which is about 10% lower than that of the QoS monitoring. Therefore, the diagnosing subsystem identifies the middle fault as a bidirectional fault. The detouring subsystem detours the outbound traffic at 21:09, and the packet loss rate of VM monitoring decreases from about 20% to 10%. Due to the large scale of this fault, network operators manually detour the inbound traffic at 21:11, and the packet loss rate of VM monitoring decreases to less than 1% at 21:20. In summary, the packet loss rate of VM monitoring decreases from 30% to less than 1% within 20 minutes.

[9] We call the monitoring process performed by debugging agent in PathDebugging as debug monitoring for short.

Deploying User-space TCP at Cloud Scale with LUNA

Alibaba Group

Abstract

The TCP remains the workhorse protocol for many modern large-scale data centers. However, the increasingly demanding performance expectations—led by advancements in both hardware (e.g., 100Gbps linkspeed network) and software (e.g., Intel DPDK support)—make the kernel-based TCP stack no longer a favorable option. Over the past decade, multiple parties have proposed various user-stack TCP stacks offering *things-as-usual* TCP support with significant performance improvement. Unfortunately, we find these proposals may not function well in the field, especially when subjected to large-scale deployments.

In this paper, we present LUNA, a user-space TCP stack widely deployed at Alibaba Cloud. We elaborate on the design tradeoffs, emphasizing three unique features in thread, memory, and traffic models. Further, we share our lessons and experiences learned from the field deployment. Extensive microbenchmark evaluations and performance statistics collected from the production systems indicate that LUNA outperforms kernel and other user-space solutions with up to 3.5× in throughput, and reduce up to 53% latency.

1 Introduction

At Alibaba Cloud, we follow a "compute-storage disaggregation" philosophy to enable the frontend computing servers (a.k.a Elastic Computing Service) and backend storage services (e.g., Elastic Block Storage, EBS) to evolve and scale separately. Initially, we adopted kernel TCP to connect computing servers to the storage servers for high compatibility and out-of-the-box usability.

However, advancement in hardware, including ultra-low latency (ULL) NVMe SSDs and high linkspeed networks (e.g., 100Gbps to 200Gbps), have significantly raised users' expectations for cloud storage systems. Kernel TCP is no longer a suitable option to deliver satisfactory performance, as it cannot fully leverage these benefits, and can lead to high tail latency and low single-core throughput. Moreover, kernel TCP can impose the well-known "data center tax" (e.g., consuming 70% of its CPU cycles in the kernel) [6, 20, 22].

Back in 2017, we started to notice such mismatches between the inefficient kernel TCP stack and the growing capabilities of new devices. We then began to look for an alternative solution to connect the frontend servers to backend storage systems. We explored the possibilities of replacing TCP with other protocols, such as Remote Direct Memory Access (RDMA), or leveraging hardware offloading (e.g., TCP Offload Engines). In fact, we have successfully deployed RDMA within our backend storage systems and achieved the expected performance gains [14]. Moreover, we have also designed a UDP-based protocol and leveraged Data Processing Units (DPUs) to accelerate one of our services, EBS [29].

Yet, interconnecting frontend and backend for all services is a different story. First, it requires inter-DC support to let storage services to be accessed from geo-distributed availability zones—not well supported by RDMA back then. Moreover, the interconnection network needs to provide compatibility and legacy support for various services, thereby prohibiting a complete overhaul with both the protocol altered and specialized hardware installed.

It is user-space TCP to the rescue. We noticed that a series of work, from both academia and industry, had demonstrated great performance potentials (e.g., saturating 40Gbps with IX [7]) by moving the TCP from the kernel to the user space [7, 9, 20, 21, 32]. More importantly, user-space TCP solutions provide a familiar programming model to the upper-level applications and offer legacy support by nature.

Unfortunately, we are unable to shoehorn existing user-space TCP solutions onto our production systems. First, these stacks normally use separate threads for application logic and the TCP processing (e.g., IX [7] and mTCP [20]), thereby incurring high communication overhead and impacting our Service Level Objectives (SLOs). Second, these solutions usually follow a copy-based memory model (e.g., mTCP and VPP [9]), aggravating memory bandwidth bottlenecks. Third, existing solutions require exclusively ownership of the NICs, thus preventing legacy support for kernel traffic.

In this paper, we present LUNA, a user-space TCP stack in Alibaba Cloud. We have successfully deployed LUNA in the field for more than 5 years and enable it to be the de-facto transport layer for all new servers in Alibaba Cloud since its release. Similar to previous practices (e.g., mTCP [20] and IX [7]), LUNA runs in a LibOS mode, operates in a shared-nothing architecture between threads and leverages DPDK user-space driver support.

[*] Equal contribution
[†] Corresponding author

Compared to previous practices, there are also three unique features in thread, memory and traffic models help LUNA successfully serve as an alternative to the kernel TCP. First, LUNA uses the run-to-completion (r2c) thread model. In each thread, LUNA packs both the application logic and TCP stack together, and process them with an event loop in each thread. Under this design, LUNA can significantly reducing the context switch overhead. Second, LUNA supports full data-path zero copy for both send and receive buffers based on a user-space slab subsystem. The zero-copy buffer effectively reduces the overhead from data movement. Third, LUNA can collaborate with kernel TCP stack to provide legacy support. We orchestrate the two types of traffic in the same NIC by utilizing Flow Bifurcation and SR-IOV to reserve certain ranges for user-space traffic.

We extensively evaluate LUNA against kernel TCP and two other user-space TCP implementations (mTCP [20] and VPP [9]) in a series of microbenchmarks. Results show that LUNA can outperform kernel and other user-space TCP stacks with up to 3.5× in throughput and reduce latency by up to 53%. Also, we compare performance between LUNA and kernel in the field across three representative scenarios. The field statistics show that LUNA could reduce latency by up to 50% and/or improve throughput by up to 50%.

The rest of the paper is organized as follows. We introduce the network architecture and the corresponding requirements at Alibaba Cloud (§2). We discuss the motivations behind LUNA in §3. We present the LUNA overview (§4) and three features in thread (§5), memory (§6) and traffic model (§7) designs. We further conduct series of evaluations on both microbenchmarks and field deployment (§8). We end this paper with several lessons we learned from deployment (§9) and a short conclusion(§10).

2 Background

2.1 Alibaba Cloud Storage Network Architecture

Alibaba Cloud offers various storage services, such as Elastic Block Storage (EBS), Object Storage Service (OSS), and Cloud Tablestore Service (OTS). In Figure 1, we illustrate the typical three layers of a service, including the interface, the function, and the persistence. In a nutshell, the interface layer comprises a set of servers to relay users' requests from the Internet (e.g., OSS and OTS) or the virtual stack within computing instances (e.g., vhost for EBS) to the function layer. The users' requests are further parsed and processed by the function layer (e.g., the BlockServers of EBS) before finally being sent to the persistence layer (i.e., Chunkstore Server, the storage engine of our distributed file system Pangu) for storage or retrieval. We use Pangu [25], an HDFS-like distributed file system developed by Alibaba Cloud, as the persistence layer.

Our cloud architecture adheres to a "compute-to-storage disaggregation" philosophy. This allows the computing

servers—hosting the interface layer and virtual machine instances subscribed by the users—and backend storage systems (i.e., the function and persistence layers) to scale and evolve at different paces. In this case, we can divide our networks into two scopes, the frontend network and the backend network (see Figure 1). In the frontend network, we primarily use TCP. The backend network normally follows a two-layer Clos topology of Point of Delivery (PoD) and utilizes TCP or RDMA [14]. We focus on the frontend network in this paper.

2.2 Requirements for Our Networks

Following hardware evolution. With an ever-increasing user base, we are always in the process of expanding our fleet to accommodate more users and offering better performance. To achieve such goals, cloud vendors like us usually seek help from hardware advancement. For example, there are two aspects of recent development that fundamentally change the landscape of our data center networks. First, the network linkspeed has jumped from 10Gbps to 50Gbps and, more recently, 200Gbps. Moreover, high-throughput and low-latency storage devices become readily accessible. For example, off-the-shelf products, such as Intel P5800 [19] and Samsung Z-NAND SSD [36], can achieve up to 6GB/s throughput with around 10 microseconds latency. The combination of the two provides opportunities but also drastically raises the users' expectations of the cloud storage services.

Inter-DC access. A major difference between frontend and backend network is that the former needs to support computing servers accessing the storage servers from different clusters, data centers or even geographically far-apart availability zones. On the contrary, supporting the latter is relatively straightforward—normally a two-layer Clos of PoD.

Legacy support. Over the years, the sizes and types of our

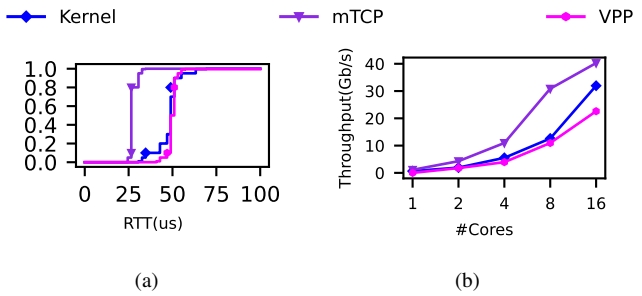

Figure 2: Different network stacks' performance in an offline RPC microbenchmark. a) RPC latency CDF with a single core; b) Maximal throughput and multi-core scalability.

storage services have been rapidly growing. Consequently, many outdated servers, while functioning, do not offer certain functionalities (e.g., DPDK-ready NICs), thereby may still require classic kernel traffic support.

3 Motivation & Related Work

In this section, we revisit the motivations behind LUNA. Although LUNA was initiated back in 2017, we believe the many observations and related work that inspired LUNA remain valid today and may even be strengthened over time.

3.1 Revisiting Kernel TCP

The kernel TCP was (in 2017) and may still remain to be a popular choice for large-scale clusters for its ease of usage and compatibility. However, it has become evident that the kernel TCP can no longer meet the performance demands of data centers (e.g., charging expensive data center tax due to kernel interruptions and memory copies) [6, 22, 33]. Here, we examines the kernel TCP performance via a microbenchmark.

We set up *knb* (Kuafu Network Benchmark)—an internal network stack benchmark that emulates the RPC services in the datacenters—to evaluate the kernel TCP latency and throughput. In this test, the client node sends a RPC request with 4KB messages to the server, measures the latency when receiving the RPC response with the same message size from the server, and then sends out the next request. (See § 8 for *knb* detailed usage.)

From Figure 2, we can see that the kernel TCP performance is far from our SLOs. Specifically, Figure 2(a) indicates the median basic RPC latency of kernel TCP has already reached 50μs. In stark contrast, our high-performance class EBS requires end-to-end response latency to be 100μs [3]. Figure 2(b) further shows that the kernel network stack on a single core could only provide a maximum of 600Mbps throughput. Moreover, Figure 2(b) also reveals that the performance issue of the kernel TCP cannot be resolved by allocating more cores. A possible reason is that the kernel overhead—such as inter-core competition—increases with the scaling of CPU cores.

3.2 Beyond Kernel TCP

Since the kernel TCP can be inefficient for the modern data center networks, it becomes urgent to explore possible alternatives. In general, there are three types of solutions: 1) developing new protocols, 2) moving TCP stack to user space, and 3) hardware offloading.

First, researchers have been proposing new transport layer protocols to replace TCP [4, 13, 16, 30]. pFabric [4] assigns priorities to packets based on the flow size, and tends to discard lower-priority packets in the switch when the buffer is full, thereby achieving both high throughput and low flow completion time. pHost [13], Homa [30] and NDP [16] leverage receiver-driven traffic control where the sender's sending rate is limited by the tokens sent from the receiver side. As each receiver has a global view of the incoming traffic, the receiver-driven protocols can achieve high bandwidth and low latency, and avoid the in-cast issue. For instance, Homa achieves less than 15μs for short messages on a 10 Gbps network running at 80% load. Moreover, these new protocols can eliminate the head-of-line blocking issue in TCP due to its byte-streaming nature.

Moreover, there are multiple work explore building a user-space TCP stack, such as mTCP [20], IX [7], ZygOS [35], TAS [23] and F-Stack [1]. These proposals usually leverage the user-space NIC drivers such as DPDK [2] to directly access packets from the NIC queues, and optimize the performance with techniques such as polling, batching [7, 20], cache planning [23], lock-free [7], and zero-copy buffers [7, 24]. The user-space network stacks minimize the overhead from the kernel, and demonstrate significant performance gain under the hardware advancement. For example, IX could achieve one-way latency of 5.7μs and fully utilize the 40Gbps bandwidth with 8 cores.

Third, there are several attempts aim to resolve the network performance issues with hardware assistance. For example, offloading TCP processing entirely [8, 37, 38] or partially [31] to specific devices can significantly improve packet processing performance and reduce the CPU overhead. RDMA [15] offloads traffic control and data movement to hardware, thus bypassing the CPU and achieving microsecond-level latency.

3.3 Our Choice

Among the available options, we chose to build a user-space TCP stack (i.e., LUNA) based on two aspects of reasons.

Inter-DC access and legacy support. Recall that, unlike the backend network, the frontend network needs to provide inter-DC access support (e.g., connecting computing servers from geo-distributed availability zones to storage servers). Therefore, we did not choose RDMA because it did not support inter-DC communication back then. Further, designing and deploying a new transport protocol (with hardware offloading) may also be rather challenging due to the required support for legacy software/hardware (e.g., sharing the NICs with kernel TCP traffic).

Table 1: Characteristics of existing user-space TCP

	kernel collaboration	zero-copy	high throughput	low latency
mTCP				
VPP			✓	
IX		✓	✓	✓
LUNA	✓	✓	✓	✓

Engineering effort. Note that enabling inter-DC access over RDMA or providing legacy support with the new protocol is still achievable but can be time-consuming. For example, the intra-region RDMA solution was not proposed until 2021 and a recent paper further discusses their strenuous effort on realizing wide-area RDMA accessing at Azure Cloud [5]. Back in 2017, we did have a rather tight timetable. Therefore, we chose user-space TCP stack solution to avoid designing/debugging the protocol and/or hacking support for legacy hardware. In fact, it only takes us 9 months to build LUNA from scratch to deployment. Later on, we have gradually added various optimizations and patches over the next five years (§ 9).

3.4 Why Not Just Use Existing Solutions?

Once we decided to use a user-space TCP stack for the frontend network, the next question is—"should we employ existing user-space TCP solutions or should we build our own?" Owning to the following reasons or concerns, we chose to develop a new user-space TCP stack, called LUNA.

High packet processing overhead. The microsecond-scale Service Level Objectives (SLOs) place significant pressures on packet processing speed within the network stack. Several existing user-space TCP solutions (e.g., mTCP and IX) delegate TCP protocol processing and application logic to separate threads for better portability. Meanwhile, others (e.g., VPP and TAS [23]) assign network and application processing to different cores for better scaling. Such partitioning could slow the processing speed due to context switch overhead or inter-core communication. For example, in Figure 2(a), we further profile the mTCP and VPP with the microbenchmark in §3.1. The results indicate that VPP suffers high latency, mainly introduced by the CPU cycles waste, and inter-core communication overheard.

Expensive memory copying. Data movement contributes a large proportion of datacenter tax. In a typical cloud storage service test on the 50Gbps network, memory copy can consume up to 12.5% CPU cycles, severely impacting the end-to-end latency (see §8). When the bandwidth grows to 100Gbps or more, the memory copy will take more than 40% CPU cycles, and further incur the memory bandwidth bottleneck problem. However, for user-space network stacks with a traditional IO path like mTCP [20] and VPP, there are two copy operations on the both receive and send paths (i.e., from user to TCP receive/send buffer and between TCP buffer to the packet). Figure 2(b) shows that, mTCP could not fully utilize the 50Gbps network bandwidth even with 16 cores. Our further analysis concludes that the memory copying does consequence with excessive overhead. One reason that most user-space TCP solutions do not support zero-copy buffer is that the traditional BSD-like socket interface would introduce inevitable memory copy between the application and TCP buffer for isolation.

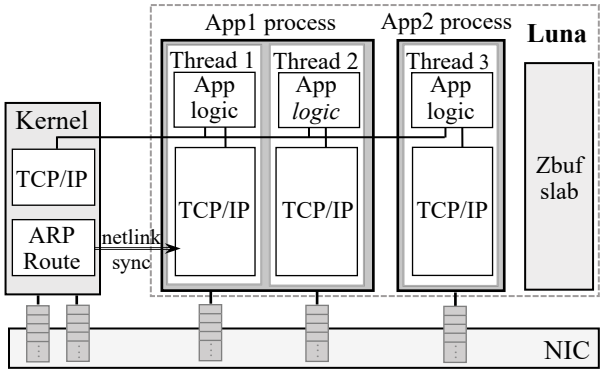

Figure 3: LUNA architecture

Supporting kernel traffic. Our storage services are deployed across multiple clusters consisting of several generations of machines. For many servers, their hardware are not capable of running user-space networks (e.g., lack of hugepages support). Moreover, many applications (such as monitoring agents) still rely on the kernel TCP. However, many user-space TCP stacks [1, 7, 20, 23] demand to exclusively own the entire NIC, thus could not collaborate with applications relies on kernel network stack on the same machine.

Implementation quality. Many existing user-space TCP works are research-oriented and thus can have various compatibility or performance issues. For instance, VPP is not well-compatible with Mellanox NICs when applying flow director filters. IX requires a particular Linux kernel version to run as it relying on the Dune kernel module, and also only provides drivers to the Intel NICs of outdated versions. Hacking into these problems will take an unexpected amount of engineering effort with rather limited community support. Hence, building a new user-space TCP from scratch can be actually more time-saving.

4 LUNA

4.1 Overview

LUNA is a high-performance user-space TCP/IP network stack that powers the frontend network in nearly all Alibaba Cloud Storage Services. Figure 3 shows that LUNA supports both kernel and user-space IO paths. LUNA leverages NIC multi-queues to separate user-space traffic from the kernel's. The u/ser-space IO path bypasses the kernel by leveraging the DPDK's user-space driver [2] to poll packets from the NIC

queues, processes them with a customized TCP/IP network stack, and interacts with applications mainly through an RPC library. The user-space IO path follows a run-to-completion mode, which runs iterations to complete both packet processing and application logic in a single thread on each core, and shares nothing between cores. LUNA separates kernel traffic and user-space traffic with NIC's hardware support. In this case, the kernel traffic for traditional applications remains unaffected. LUNA leaves the control plane (i.e., ARP table and route table management) to the kernel, and uses the *netlink* interface to access the route information.

4.2 Similar Design Choices

LUNA shares several similarities with existing work in the data path and the architecture. Here, we will discuss our rationales behind these design choices.

LibOS mode. LUNA operates in a LibOS mode, similar to the mTCP [20] and F-stack [1]. In this setup, the application and LUNA run in the same process and share the memory address space. Alternatively, one can run the network stack in the separate process, and communicate via shared memory. In this case, if there is only one network process in every server to serve different application processes, it is called the *Microkernel* mode (e.g., Google Snap [27]). Another solution is to have one network stack process for each application process, known as the *Sidecar* mode.

Although microkernel-based solutions at the industry level were not widely popular back in 2017, we later—after the launch of LUNA—have observed several instances adopting this approach. One notable example is Snap [27]—a user-space network stack deployed in Google's datacenter. One prerequisite for Snap is to closely follow the weekly release cycle of the network stack in Google Cloud. As a result, to avoid service interferences, the support transparent/live upgrade becomes indispensable. For microkernel-based solutions, enabling transparent/live upgrade is rather straightforward as the network stack is an independent process. Further, to achieve high efficiency, Snap also adopts Google's Pony Express transport protocol and one-side operation.

LUNA does not adopt the Microkernel or Sidecar mode due to performance concerns because both modes require frequent inter-process communication, incurring high runtime overhead. Note that LUNA still uses TCP for the transportation layer (see§3) and thus can not fundamentally modify the protocol like Pony Express or adopt one-side operation for high performance. We are aware that LibOS mode lacks live/transparent upgrade support as the network stacks with LibOS mode have to be compiled with the application code together. From our perspective, this disadvantage is acceptable as the TCP protocol is rather mature (i.e., not requiring frequent changes) and our storage services have periodical upgrading schedules. Hence, LUNA can just follow storage service upgrading roadmaps.

User-space NIC driver. Like most kernel-bypass network systems [1, 7, 10, 20, 21, 23, 32, 35], we build LUNA with DPDK [2] for its rich development kits and active community support. LUNA leverages DPDK's PMDs (Poll Mode Drivers) to directly access packets from the NIC queues. We also utilize DPDK's hugepage management, and data structures like hash map and *mbuf*. Further, as there are several generations of NICs in our cloud, the user-space driver provides a convenient way to communicate with them in a uniform interface.

Share-nothing architecture. To exploit the parallel processing capability of multi-core systems, like many previous designs [7, 20], LUNA runs the threads in a share-nothing mode. Each core processes its own traffic divided by the NIC's multi-queue technique, and finishes related application-layer processing on the same core. LUNA does not use a dispatcher mode (like TAS [23]) or load balancing (like task-stealing in Shenango [32]) due to cache efficiency and synchronization overhead (e.g., from lock and atomic operations) concerns. Note that there is already a service-level load balancing inside applications. The share-nothing architecture improves multi-core scalability, as the system can simply allocate more cores to applications to improve performance. Moreover, run-to-completion LibOS avoids the potential CPU cycles waste in dispateched mode as the user-space network stack has to keep polling the NIC queues.

TCP stack. As discussed in § 3, LUNA uses TCP as the transport layer protocol. LUNA implements TCP according to RFCs [28, 34], and supports congestion control, flow control, RTT estimation, and SACK. LUNA is compatible with other standard TCP stacks like Linux kernel network stack.

4.3 Unique Features

To better serve our systems in the field, LUNA also includes unique features from the following aspects:

Thread model. LUNA uses a run-to-completion thread model to run network and application-layer processing in the same thread. We use this design to improve the performance, and avoid risks in scheduling (e.g., thread-hang) with the characteristics of our storage service workloads (§ 5).

Memory model. LUNA supports a full data-path zero-copy buffer on receive and send end, aiming to minimize the data movement overhead. LUNA realizes its full-stack zero-copy with the aid of a user-space slab subsystem. This subsystem introduces little overhead and maintains the traditional programming model.

Traffic model. LUNA collaborates with kernel network stack, to offer the legacy applications with kernel TCP support, and to leverage kernel TCP for the control plane (e.g., ARP). LUNA uses the Flow Bifurcation and SR-IOV support to reserve a certain port range for user-space traffic, so that there is no interference with kernel traffic. The kernel network stack directly processes the control plane messages such as ARP requests and responses, and manages the control plane

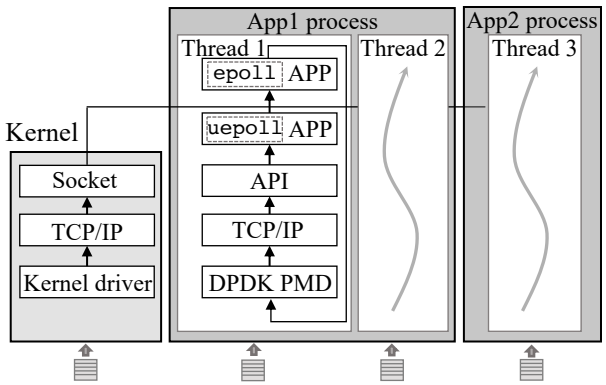

Figure 4: LUNA thread model

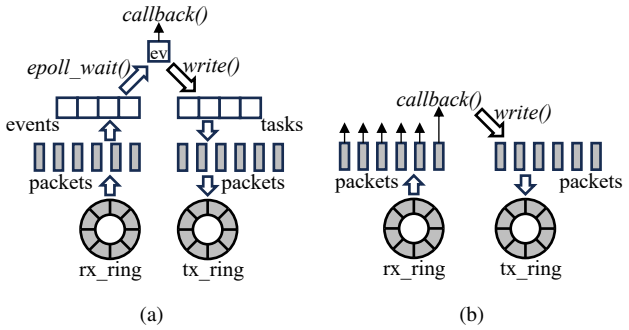

Figure 5: run-to-completion thread model in LUNA. a) batch-r2c mode; b) inline-r2c mode.

states. LUNA can obtain control plane information via *netlink* interface.

5 Thread Model

Figure 4 shows that LUNA uses a run-to-completion (r2c) thread model that encapsulates application logic and network stack processing in a single thread. During runtime, LUNA employs an event loop for each thread. Between threads, LUNA keeps a share-nothing isolation. Moreover, LUNA supports applications to use both kernel network stack and user-space IO path (§ 7), and the two types of traffic could be processed in the same thread.

5.1 Run-to-complete model

We assign varying numbers of cores to LUNA based on the service type. For instance, in a block server (i.e., the functional layer of EBS), LUNA can utilize 8 cores, while a computing server (from ECS) typically employs only 4 cores. Each core initiates one thread and shares nothing with the other. Moreover, each thread uses an event loop to manage data processing.

LUNA offers two distinct r2c modes——*inline-r2c* and *batch-r2c*——each tailored for different scenarios. In both r2c modes, LUNA starts the loop after receiving a fixed number of packets (called a batch) from the corresponding NIC Rx queue. Then, LUNA processes the packets based on the type of r2c mode.

For batch-r2c, Figure 5(a) shows that LUNA processes the received packets one at the time through the TCP/IP stack, and then adds a read event to the event queue for every packet with TCP payload. These read events would be immediately processed by application after the LUNA has processed all the received packets in this round. Then, the RPC framework invokes the callback functions registered to each event, generates the response messages, and sends the messages to the send buffer. After all the events are processed, LUNA adds the protocol headers for the messages in the send buffer, forwards them to the NIC, and starts the next round.

For inline-r2c, Figure 5(b) demonstrates that LUNA also processes the packets one by one. However, LUNA avoids adding event to the event queue, and instead immediately invokes the registered callback function, generates the response along with the protocol headers for the packets, and send them out. In short, inline-r2c will process every packet to completion.

Obviously, inline-r2c eliminates the overhead from event enqueue and dequeue, and improves the cache locality, thereby providing better performance. However, inline-r2c also requires a new programming model and forces the upper-layer application to use a zero-copy raw-packet-like read-/write interface. Moreover, inline-r2c is only available in LibOS model as the application-layer code has to co-locate with the network stack. In contrast, batch-r2c works in a more traditional epoll-like or libev-like programming model, and is compatible with a traditional BSD-Socket-like interface. In practice, we deploy inline-r2c on performance-oriented services like EBS, and use batch-r2c for services such as object store due to compatibility concerns.

The r2c design can significantly reduce the overhead and improve performance. First, there is no context switch between application and stack processing. Second, as the network stacks receive a fixed-sized batch of packets from NIC in each iteration, it allows the upper-layer application to handle them in a timely fashion (i.e., no need for buffering packets). Hence, CPU could get most data from the L1 and L2 cache directly, especially in inline-r2c. Moreover, as there are few buffered packets, the DDIO will not fill up the Last Level Cache (LLC), and further improves the cache hit rate [11].

5.2 Discussion

The risks of r2c model. R2c model could significantly improve performance. However, it is not favored by many user-space TCP stacks. A primary reason is that r2c model may be stuck at application level, causing severe tail latency and packet drop in NIC queues. LUNA adopts the r2c design because the logics in our storage services (i.e., applications) is rather simple and stable. Moreover, another safeguard is that our applications also adopt flow control and can avoid burst traffic by limiting the number of concurrent connections and in-flight requests. Hence, with relatively simple logic at

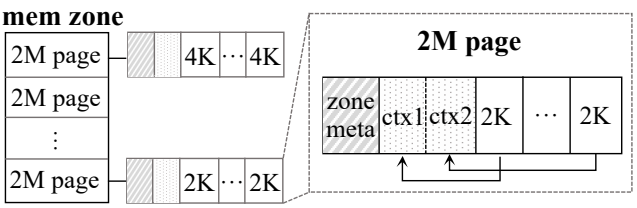

Figure 6: The structure of *Zbuf*.

the application level and flows throttled, it is unlikely for the requests to be stuck in the application level and cause packet drop. Note that it is still possible for a thread in LUNA to get stuck by various exceptions (e.g., application bugs, burst incast load, etc.), resulting in dropping packets and TCP/RPC timeouts.

Unsuitable scenarios for r2c model. The LUNA's r2c design is not always suitable for all scenarios. In OSS service, we discover that dedicating multiple cores to polling for run-to-completion is not reliable because there are other services on the same machine that should be guaranteed with a large number of cores. Therefore, LUNA dedicates only one core for NIC IO and protocol processing, and places application logic to other threads on the other cores. The application thread will block the event-poll when there is no more events to avoid wasting CPU cycles on unnecessary polling.

6 Memory Model

LUNA achieves full-stack zero-copy to mitigate the overhead associated with frequent data movement. A straightforward approach to realize end-to-end (i.e., from NIC to TCP, and application) zero-copy is to only transfer the memory addresses of the read/write buffers. This is challenging for user-space TCP due to three factors. First, the lifecycle (and status) of a buffer is different from the application to the network. The application typically frees or reuses the buffer after dispatching it to the network stack, whereas the network stack must retain the buffer until it receives "acks". Second, the NIC requires the physical memory address while applications use the virtual address. Third, the traditional BSD-socket APIs and socket-oriented programming models are designed with copy semantics for the isolation between the user space and kernel space. To overcome these challenges, in LUNA, we build a user-space slab system, called *Zbuf*, to provide cross-layer memory lifecycle management and address translation.

6.1 *Zbuf*

User-space slab subsystem. *Zbuf* works as a user-space slab subsystem that pre-allocates memory chunks for users. Figure 6 shows the structure of *Zbuf*. We can see that *Zbuf* reserves several hugepages allocated from the DPDK's memory address space and divides them into multiple 2MB *memory zone*s. The header of each *memory zone* records the meta information such as the physical address. *memory zone* is further split into *obj*s, which could be directly allocated by the

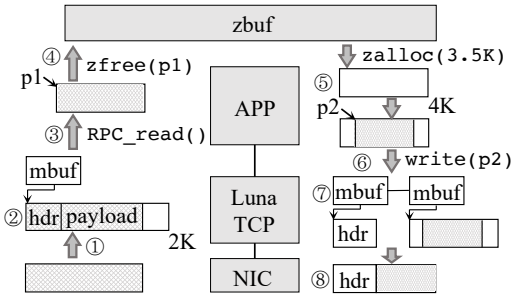

Figure 7: The LUNA receive and send path with zero-copy.

users (i.e., applications). The metadata of *obj*s (denoted as ctx in Figure 6) is co-located with *obj*s in the same *memory zone*, right after zone metadata. All *obj*s within the same *memory zone* share the same size but the sizes can be different from one *memory zone* to another (e.g., 2KB vs. 4KB in Figure 6).

***Obj* lifecycle management.** *Zbuf* uses a reference counter to manage the lifecycle of each *obj*. The counter is set to 1 after initialization. Afterward, the counter increases by 1 whenever the corresponding *obj* is replicated and decreases by 1 each time the *obj* is freed. The *obj* will be put back to the free-list of the *memory zone* once the count reaches 0.

Metadata and physical address translation. Translating the virtual address to the physical address and parsing the metadata are straightforward in *Zbuf*. For example, consider a user allocating a 4KB *obj*. The user then generates a 2KB string *str* within the *obj*, and the virtual address of *str* is *addr*. When the user sends *str* to the network stack, it would increase the reference count of the corresponding *obj*. *Zbuf* first compares *addr* with the address range of contiguous *memory zone*. By getting the offset of *addr* to the start of *memory zone* area and dividing the offset with 2MB, *Zbuf* could get the index of the *memory zone* which *obj* belongs to. As the *memory zone* metadata records the start address of contiguous *obj* and the size of each *obj*, the user could directly get the index of the *obj* containing the *str*, and get the *obj* meta data from the *obj* meta array. Therefore, the users could directly make replicas or free the objects inside the *obj*s, but do not need to manage the *obj*. Since the metadata of *memory zone* records the physical address of itself, the physical address of *str* could be calculated by adding the offset of *str* to the *memory zone*. When the *str* is going to be sent to the NIC, LUNA can calculate the physical address following the same procedures above.

6.2 Full-stack Zero-copy

With the support of *Zbuf*, LUNA provides full-stack zero-copy on data receiving and sending. Moreover, upper-layer applications could still use the traditional programming model except for a few minor changes. Now, we use Figure 7 to illustrate the procedures on both ends.

On the receiving end, LUNA registers *obj* addresses to NIC receive queue, so that the NIC will deliver the received

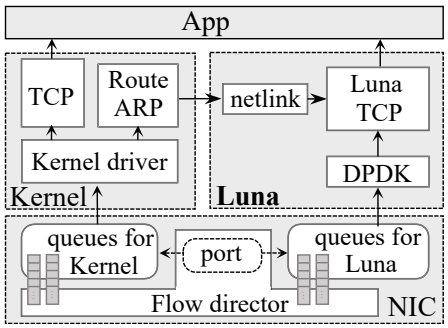

Figure 8: LUNA traffic model

packet data to the *obj* through DMA (①). The network stack processes the packet with network protocols (②) and delivers the pointer to the readable payload (marked as $p1$ in figure 7) to the upper-layer application with an RPC interface (③). The application could directly free the payload after finishing the message processing (④). *Zbuf* will locate the related *obj* and free it by decreasing the reference count.

On the send data path, application first allocates a writable buffer from the *Zbuf*, or reuses the memory space of the received data, and then directly writes data to the buffer (⑤). The content (marked as $p2$ in figure 7) is directly sent to LUNA's TCP send queue, and the send API automatically increases the reference count of the related *obj* (⑥), to avoid the *obj* to be freed by the application after sending. LUNA allocates a new segment to generate the packet header (⑦), and sends out the header and content as a whole packet together through the DPDK interface (⑧). Moreover, if the application wants to multicast the data (typical in cloud storage service), it just needs to send out the same data segment multiple times, and *Zbuf* will accordingly increase the reference count of the *obj*. And the *obj* stored in the LUNA's send buffer will be freed after receiving the acknowledge packet.

6.3 Discussion

Alternative solutions. There are also other design choices to achieve end-to-end zero copy. One is to pass the pointers of the read/write buffers between the application and network stack. However, adopting this practice requires the application to fundamentally alter the programming model and manage the buffer at application layer. For cloud services, it can be rather difficult as there are multiple applications developed by various developer teams. Another approach is to leverage *mmap* to avoid copying large size messages [24], which could maintain the programming model and standard BSD-socket API format. However, the *mmap* call can introduce considerable overhead of additional system calls [24].

7 Traffic Model

7.1 Traffic Split

LUNA uses Flow Bifurcation mechanism [18] (supported by NIC's flow-director) and SR-IOV functionalities to separate kernel network traffic from the user-space network traffic, thereby offering legacy support. LUNA establishes the hardware filtering by setting the mask to the destination port of TCP packets on each machine. LUNA routes the incoming TCP packets with certain destination ports to the specific virtual functions, which are then processed in user space. The TCP packets that do not align with the port filters and the not-TCP packets would still be accepted and processed by the kernel network stack.

LUNA uses different flow-director filter rules for clients and servers. On the client side, LUNA reserves the port from 61440 to 65535 for the user-space traffic, and allocates contiguous sub-ranges of the port number to different LUNA applications. The sub-range within an application are further divided into ranges for different Rx queues which are processed by the corresponding LUNA threads.

For instance, LUNA could reserve TCP port numbers between 61440 to 63487 to APP_A, and write the flow-direct filter rules to direct dest port between 61440 to 62463 to $Thread_1$ in APP_A. Then LUNA can direct TCP ports between 62464 to 63487 to $Thread_2$ in APP_A. On the server side, LUNA first uses flow-director rules to direct TCP packets with the same destination port as the application-listening port to the corresponding application. Moreover, the RPC layer over LUNA will establish full-mash connection for all thread peers between each client node and server node. Hence, LUNA on the server side can simply hash all connections to different server threads according to the source TCP port for load-balance scheduling. For example, the TCP destination port of 1234 is directed to APP_A, and uses the lowest 2 bits of the TCP source port to hash the packets to the 4 threads of APP_A. Each client thread initializes connections with typical host ports to establish a connection with every server thread, and selects a connection for each RPC request for load balancing.

Further, although LUNA is compatible with standard TCP stacks in the design and implementation, LUNA avoids directly communicating with the kernel network stack. In other words, LUNA only supports kernel-to-kernel and LUNA-to-LUNA traffic, and does not permit kernel-to-LUNA connection (or reverse). The reason for this choice is that LUNA implements a tailored TCP for the datacenter environment to optimize the performance (§ 9), and there are different versions of LUNA running in different datacenter applications. If we use LUNA to directly communicate with kernel network stack, we have to verify and evaluate the communication among all versions of kernels and the LUNA. Therefore, this introduces extra verification costs every time updating the kernel or modifying the kernel network configuration.

7.2 Thread Model Support

When the applications need to communicate with different clusters through both kernel and user-space IO paths, LUNA will process them in the same thread, so that the applications don't need to manage the requests separately. In every

iteration, after finishing the user-space run-to-completion processing, LUNA will get a batch of events from kernel's *epoll* framework by calling *epoll_wait()*, and handle the events by calling the callback function registered by the application. LUNA calls *epoll_wait()* with non-blocking, and limits the batch size of kernel events to prevent user-space IO path from starving.

7.3 Control Plane

As LUNA only processes the TCP packets, the control plane packets (e.g. ARP and ICMP requests) are sent to the kernel network stack, and the kernel also manages the control plane states (e.g. ARP table and route table).

LUNA gets the control plane information with *netlink*, a rather infrequent behavior. LUNA initializes a netlink socket which dumps the ARP table and route table in the kernel, and wait event through linux *epoll*. When there are any variations in these two tables, the kernel will send messages to the netlink socket and raise epoll events. Then this would invoke LUNA to receive the update message and update the control plane information managed in user space.

Delegating the control plane to the kernel brings two benefits. First, LUNA could focus on the transport layer and leverage the well-developed kernel control plane implementation. This also enables the LUNA to evolve independently without worrying about keeping up with changes in the control plane. Second, this allows LUNA to fast recover from the system failures, as the just-restarted LUNA could simply regain the control plane information stored in the kernel.

7.4 Discussion

Alternative solutions. There are several approaches to collocating user-space traffic within kernel network stack. The first one is to separate different NICs (or different ports of the same NIC) for user-space traffic and kernel network traffic. Unfortunately, this can severely waste bandwidth. Another approach is to receive all the packets using the user-space TCP and then re-dispatch certain filtered packets back to the kernel via KNI (Kernel NIC Interface). This solution can also impact the performance and crash the whole network service when the failure occurs in user-space network stack.

Complex filtering rules. LUNA splits the traffic according to the TCP ports to collaborate with the legacy applications and employs share-nothing design between cores for high performance. However, the traffic splitting is limited by the NIC hardware capabilities. The commodity NICs (e.g., Intel and Mellanox NIC cards) provide limited flow director support, i.e., setting masks to certain fields of the packet headers (e.g., IP address and TCP/UDP port number).

In LUNA design, one application keeps the same listening port for all server threads to cater the existing programming models. And the LUNA RPC framework establishes full-mash connection channels between every thread of each peer node for load balancing. Therefore, LUNA has to write multiple flow director filter rules to the NIC to spray the traffic to different Rx queues, and the number of rules increases dramatically when the number of LUNA threads is not a power of 2. For instance, when a machine running 12 LUNA threads communicate with a peer node running 6 LUNA threads, this will lead to 160 traffic filter rules on both nodes, imposing significant overhead onto the packet receiving, and resulting in packet drops.

One simple approach to solve this problem is to assign different listening ports for each LUNA thread. However, this also requires modification of the application logic. A more practical way is to reserve range of the port numbers with flow-director, and perform build-in hash-based RSS to establish the connections to different LUNA queues. Yet, this feature is not supported by the commodity NICs when the LUNA was developed. Once the flow bifurcation rule is deployed, we have to provide legacy support for previous versions for compatibility. As a result, LUNA still requires complex filtering rules at the moment.

8 Evaluation

8.1 Microbenchmark Evaluation

8.1.1 Experiment Setup

We first evaluate with microbenchmarks in the emulated client-server environment to compare LUNA against other candidates including kernel TCP, mTCP and VPP. Both client and server machine are equipped with an Intel(R) Xeon(R) CPU E5-2682 v4 @ 2.50GHz CPU with 128GB DRAM each. We connect the client with server through a Mellanox ConnectX-4 Lx NIC with 2× 25Gbps network port, and utilize both the port for a total 50Gbps bandwidth.

For the kernel network stack, we use Linux 4.19, and bind all traffic to the certain CPU cores to optimize the performance. We download the latest versions of mTCP and VPP, and modify them to fit our environment. For VPP, we use half of the cores for the VPP threads processing network packets, and use the rest cores for application logics. As for the common hardware offloading, we enable both *tso* and *lro* for Linux kernel, and enable *tso* for LUNA. For mTCP, *tso* is not supported, and *lro* is not supported by default. For VPP, we failed to enable *lro* and *tso* on our cx4 NIC with default driver after a series of attempts. And the MTU is 1,500 bytes for all the systems.

We use *knb*, a datacenter network microbenchmark, to evaluate the performance of LUNA and the rest. *knb* emulates the RPC workloads in the datacenter, and evaluates the network stack performance at both client and server side. *knb* runs a configured number of threads at client and server, and builds long-lived TCP connection between every client and server thread, similar to most data center RPC frameworks. Then, the *knb* client will send requests with configurable message size to the server. Afterwards, the server send back the response with the same message size on each request, and the

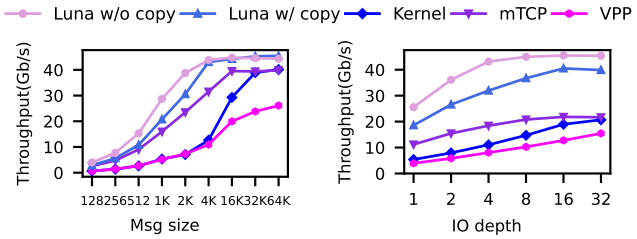

Figure 9: Different message sizes (*iodepth* =1, #core=8)

Figure 10: Different *iodepth* (msg_size=4KB, #core=4)

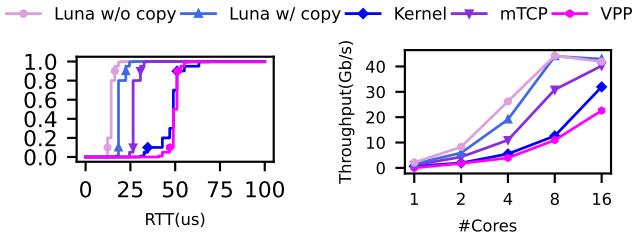

Figure 11: Response latency CDF (msg_size=4KB, *iodepth* =1)

Figure 12: Multi-core scalability (msg_size=4KB, *iodepth* =1)

client will send another request when it receive a response. The number of in-flight requests on each connection could be controlled with the variable *iodepth*.

8.1.2 Experiment Results

Throughput We first evaluate the throughput under different message sizes. Here, we set LUNA with both the copy mode (backed by batch-r2c) and the zero-copy mode (backed by inline-r2c). In this experiment, we allocate 8 cores for each candidate, and limit iodepth to 1 (i.e., only one request on each connection, and do not send next request until receiving the response). The Figure 9 shows the result. LUNA with zero-copy can fully utilize the bandwidth when the message size grows to 4K, a typical size in our storage services. The throughput of LUNA is 3.5× of kernel, and outperform mTCP and VPP by 50%. The mTCP and VPP do not fully utilize the bandwidth in these experiments. For mTCP, its performance is limited by the heavy overhead from copy and context switch. As for VPP, when the packet size is small, it shows a similar performance with kernel network stack, mainly as a result of wasted CPU cycles on idle polling. When packet size grows larger, VPP shows a even worse performance than Linux kernel (possibly due to *lro* and *tso* are not enabled in VPP).

We also evaluate the throughput under different setups of iodepth as RPCs in datacenters are always concurrent on the same connection. In this experiment, we dedicate 4 cores for each candidate (commonly seen in servers of the interface layer), and set the message size to be 4KB. Figure 10 shows that the throughput grows with the increasing of iodepth. Moreover, the zero-copy version of LUNA can saturate the bandwidth with an iodepth of 16. LUNA provides 2× throughput than mTCP and kernel network stack.

Latency We then evaluate the latency of the network stacks, and show the results in Figure 11. In this experiment, we allocate one core for VPP network worker thread and one core for *knb* application thread. Then, we use a single core when test other network stacks. We set the iodepth as 1 (i.e., no backlog blocking latency) and set the message size to be 4KB. The result shows that, LUNA with zero-copy reduces the 99^{th} percentile latency by 25% than LUNA with copy, and reduce 70% latency than the kernel network stack.

Multi-core scalability. In Figure 12, we evaluate the multi-core scalability of the tested network stacks. In this experiment, we limit the iodepth to be 1, and set the message size to be 4KB. We can see that LUNA shows a near linear multi-core scalability, and full-utilize the bandwidth with 8 cores with zero-copy. mTCP shows relatively good multi-core scalability as it also uses the share-nothing architecture. Yet, it still could not fully saturate the bandwidth due to the performance limitation. The kernel network stack and VPP show a similar multi-core scalability because there are extra inter-core communication overhead and contention over locks between different cores.

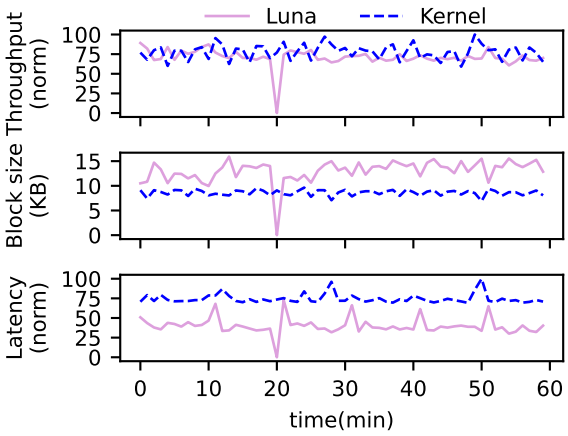

Figure 13: Performance of distributed-storage service for a public cloud OLTP service, collecting tracing data within 1 hour.

8.2 LUNA Performance in the Field

In this section, we will introduce the performance of LUNA with the datacenter storage services in the wild, and make comparison with the traditional kernel network stack. Since LUNA has been deployed in Alibaba Cloud storage service for more than 5 years, most servers that require high-performance are running on LUNA instead of kernel network stack. Therefor, we only show the performance comparisons in the services that still have legacy nodes running the kernel network stack.

EBS for OLTP. OLTP (On-Line Transaction Processing) ser-

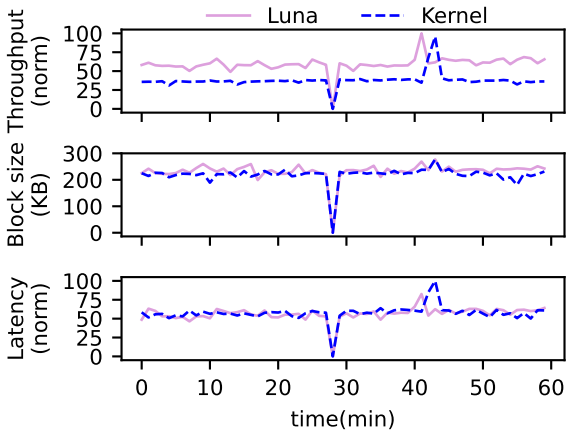

Figure 14: Performance data of distributed-storage service for a public cloud video transcoding service, collecting tracing data within 1 hour.

vice generate typical latency-sensitive workloads for the cloud storage system. Under such workloads, the IO throughput of the storage are usually not very high, but have rather demanding requirements on latency. Here, we show the LUNA deployment in a storage cluster serving a public cloud OLTP service. In these clusters, there are several generations of machines. The LUNA is only deployed to the server nodes that meet the hardware requirements, and still use the kernel network stack in the other legacy server nodes. Note that this cluster uses different network stack IO path only in the frontend network communicating with the block servers, but uses the same version of the backend network and the chunk servers.

In figure 13, we demonstrate the performance of the distributed-storage IO which is captured by the hypervisor-level monitoring during 1 hour. We can see that LUNA outperforms the kernel network stack with both 50% lower end-to-end average latency with similar end-to-end throughput. This gain mainly benefits from the thread model design and zero-copy support therefor reduces the processing and queueing delay. Note that the workload over LUNA has larger IO block sizes as they are from different customers, thereby higher pressure on the delay.

EBS for video transcoding. Here, we show LUNA performance on another EBS cluster which serves a public cloud video transcoding service. In this scenario, the datacenter application requires both high throughput and low latency. This cluster also uses both LUNA and kernel network stacks to communicate with blockserver agents (BAs) in the frontend network. Similarly, the backend network shares the same backend network and chunk server (CS) architecture. all the server nodes share the same workloads. We also collect and compare the user-layer performance data at the hypervisor. Figure 14 indicates that, when the service node with LUNA and kernel network stack have the similar user-level IO latency, LUNA provide about 50% higher IO throughput than the kernel network stack.

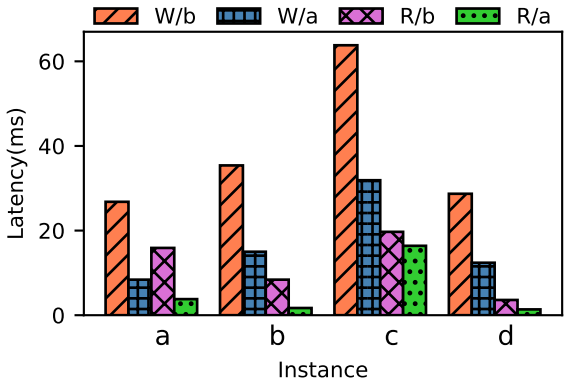

Figure 15: OTS response latency comparison before and after an architecture upgrade, collected from several typical instances.

TABLE STORE. LUNA is deployed in TABLE STORE, a NoSQL database service of Alibaba Cloud. TABLE STORE provides storage and real-time access to massive structured data. Here, we collect and compare the performance data between two generations of the TABLE STORE architecture, named V1.0 and V2.0. The workload remains unchanged after the architecture upgrade. The architecture evolution mainly includes using LUNA user-space network to replace the Linux kernel at both the frontend network and the backend network, and using the user-space file system to replace the Linux ext4. In our offline estimation, LUNA contributes 30%-50% to the total performance gain. Figure 15 shows that, TABLE STORE service instances upgraded to V2.0 reduce the end-to-end latency by 50% to 68%.

9 Lessons From Deployment

Portability. We believe there are four levels of portability.

- Kernel-based applications do not need any code changes to use the new stack (e.g., LOS [17]).
- The application needs to replace the APIs while keeping the same API formats and semantics.
- The API formats are different but the programming model and the API logic stay the same (e.g., change malloc/free to create/destroy).
- Redesign the entire programming model and the API logic.

Our lesson is that, to achieve extremely high performance, refactoring legacy application (i.e., programed with the kernel network stack) is inevitable. However, as a fundamental component of datacenter software codebase, the network stack is often widely used and serves various kinds of applications. Hence, changing the programming model is unacceptable. In this case, we would recommend a user-space network stack to obtain portability between 2) and 3).

In Alibaba Cloud storage, the applications attach to the network through an RPC framework which is also supported

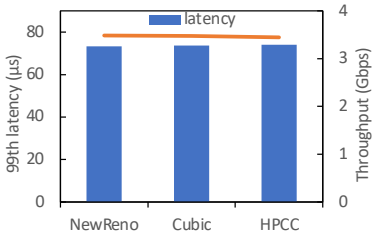

Figure 16: Performance microbenchmark of different congestion control algorithms tested in Alibaba Cloud cloud storage network.

by the network group, and programed in a *libevent-like* model, so adapting to the batch-r2c and inline-r2c does not require any change to the programming model. However, in order to achieve zero-copy at both receive and send side, LUNA provides io-vector-oriented receive/send APIs which directly describe the addresses and lengths of the readable/writable buffers of each RPC call. Therefore, the applications with zero-copy have to change the receive/send API formats. Nonetheless, the data buffers can be allocated or freed as if they are allocated from the heap through the *Zbuf* APIs with the same formats.

TCP tailoring. With a relatively simple environment as the datacenter network, we can tailor the implementation of TCP to achieve better performance. For example, LUNA implements a straightforward yet high-performance TCP fast path for the packets arriving in order. Note that out-of-order packets are not common in the datacenter. In our practice, we found that simply using NewReno [12] could deliver satisfying congestion controlling in many services and does not rely on any novel hardware features (Figure 16). Additionally, we also use HPCC [26] for the communication between VMs in the computing cluster to improve tail latency.

Fast recovery from the failures. For high availability, the network stack should fast recover from the failures such as switch flips and black holes. In our services, applications use LUNA via an RPC framework, which detects connection failure and tries to reconnect the peer node through different network links, e.g., another NIC port, or ToR switch. Further, LUNA also improves the failure recovery procedures based on the characteristics of the datacenter environment. For example, the network distance of every two nodes in our cluster is no more than 4 switch hops. As a result, LUNA could set a tighter timeout threshold, e.g. 4 milliseconds. Currently, the longest recover time for LUNA is guaranteed to be less than 2 seconds.

Alibaba Cloud storage network evolution. The evolution of LUNA is driven by service. Back in 2017, Alibaba Cloud planned to launch a high-performance ESSD service—the first elastic block storage service achieving both 1M IOPS and 100μs latency—around early 2018. With the release date within a year ahead, we therefore chose user-space TCP stack solution to avoid designing/debugging the protocol and hacking support for legacy hardware. It only takes us 9 months to build LUNA from scratch to deployment.

In the initial release, LUNA still uses socket-like APIs and requires data copy from the application to the network stack on the send path. Later, to support the bare-metal servers, LUNA needs to run on a Data Processing Unit (DPU) which has rather limited resources. Therefore, we designed a new RPC framework which removes the RPC serialization stage, supports the inline-r2c thread model (§ 5) and the zero-copy IO on both ends (§ 6). Note that this also requires the EBS to change the programming model to use io-vector-oriented APIs with *Zbuf* for zero-copy, and co-design with LUNA's flow control to adopt the inlined-r2c thread model.

The upper bound of LUNA. In this paper, we discussed that LUNA can efficiently utilize 50Gpbs NICs. However, for even higher bandwidth (e.g., 200 to 400Gbps), the LUNA's run-to-completion with a shallow buffer may lead to NIC queue overflow and packets dropping. Moreover, when the message size is 4KB, LUNA needs at least 8 cores to saturate the 100Gbps network bandwidth. Therefore, for adopting a high linkspeed network, we believe leveraging hardware acceleration becomes necessary. Additionally, while TCP can use multi-path transmission with Multipath TCP, the head-of-line blocking problem in TCP and its limitations in failure-recovery have still led us to design a new protocol specifically for high-performance cloud storage. Our recent effort, called Solar [29], which involves using a new transport layer protocol co-designed with the DPU exemplifies this point.

10 Conclusion

In this paper, we describe LUNA, a user-space TCP stack at Alibaba Cloud storage network. We discuss our efforts in building LUNA with a focus on the thread, memory and traffic model. Apart from introducing LUNA, we have also covered various design tradeoffs and lessons from the last five years of development. We hope the experiences shared in this paper shall benefit practitioners from both academia and industry.

Acknowledgments

The authors thank our shepherd Yizhou Shan and the anonymous reviewers for their feedback. We also thank the EBS, Pangu, AIS Fushionnet, OSS and OTS teams for their tremendous help on the LUNA project. This research was partly supported by Alibaba Innovation Research, Alibaba Research Fellow and NSFC(62102424) program.

Abstract

Due to the need to perform expensive background compaction operations, the CPU is often a performance bottleneck of persistent key-value stores. In the case of replicated storage systems, which contain multiple identical copies of the data, we make the observation that CPU can be traded off for spare network bandwidth. Compactions can be executed only once, on one of the nodes, and the already-compacted data can be shipped to the other nodes' disks, saving them significant CPU time. In order to further drive down total CPU consumption, the file replication protocol can leverage NVMe-oF, a networked storage protocol that can offload the network and storage datapaths entirely to the NIC, requiring zero involvement from the target node's CPU. However, since NVMe-oF is a one-sided protocol, if used naively, it can easily cause data corruption or data loss at the target nodes.

We design RubbleDB, the first key-value store that takes advantage of NVMe-oF for efficient replication. RubbleDB introduces several novel design mechanisms that address the challenges of using NVMe-oF for replicated data, including pre-allocation of static files, a novel file metadata mapping mechanism, and a new method that enforces the order of applying version edits across replicas. These ideas can be applied to other settings beyond key-value stores, such as distributed file and backup systems. We implement RubbleDB on top of RocksDB and show it provides consistent CPU savings and increases throughput by up to 1.9× and reduces tail latency by up to 93.4% for write-heavy workloads, compared to replicated key-value stores, such as ZippyDB, which conduct compactions on all replica nodes.

1 Introduction

To provide high availability, disk-based key value stores are often replicated on multiple machines [2, 21, 22, 25, 35, 43]. A standard architecture for replicating key-value stores is that each machine runs a local key-value instance, and a replication layer controls which replica gets shipped to each instance.

However, key-value stores spend a significant portion of their computing resources on background compaction operations, which rebalance and garbage-collect the data on disk. For example, in the case of log-structured merge trees (LSM trees), the standard disk-based key-value store design [2, 4, 8, 22, 41], previous work has shown that compaction can consume up to 45% of CPU in production workloads, and by avoiding compaction, key-value stores can increase their throughput by up to 2× [12]. We have reproduced these experiments and find that with RocksDB, compaction consumes up to 72% of the total CPU cycles.

This leads to the simple observation that, in the case of replicated key-value stores, where each node sees identical commands, the compaction operations conducted on each machine that stores the replica of the data represent *redundant effort*. Therefore, we can design an architecture, where a *primary* node conducts compaction operations locally, and then ships the already-compacted files to the *secondary* nodes that store the data copies, thereby significantly reducing their CPU consumption.

However, such an approach has two important drawbacks. First, it increases the amount of network traffic because not only do the regular operations need to be replicated, but also the compacted files. Fortunately, network traffic in modern datacenters is often underutilized; for example, cluster traces from Alibaba [1] and Snowflake [47] show that 50-–75% of network capacity consistently remain idle. Therefore, reducing CPU consumption at the expense of additional network traffic is often a desirable trade-off. Second, shipping the files from the primary to the secondary nodes still requires some processing from both: at the extreme, if both ends use TCP, then shipping the files will incur the cost of processing the TCP packets on both ends, as well as the cost of traversing the storage stack on the secondary nodes.

To address the second problem, we turn to NVMe-oF, a networked storage protocol that minimizes CPU costs at secondary nodes. NVMe-oF extends the NVMe protocol to allow one server to access a disk of a remote server directly, with minimal involvement of the remote server's CPU. Even better, most commodity datacenter NICs support offloading the entire NVMe processing at the remote server, by allow-

ing the remote NIC to talk directly to the NVMe storage device. Therefore, if we use NIC-offloaded NVMe-oF, the secondary's host CPU will not be involved at all in processing the incoming replicated files, thereby completely eliminating all of its CPU costs due to compaction.

However, using NVMe-oF to replicate files across storage nodes creates two challenges. First, since the remote node's local file system (e.g., ext4) is not involved in writing the files, it is not aware of the updated file and its location, has no way to read it, and may even accidentally overwrite it. Second, the key-value application running on the remote node must also be synchronized with the incoming files. Its application-level in-memory data structures must be updated to find and read data from new files that were updated on its local storage device, and it must not read data from stale files that were deleted in the compaction process.

In this work, we introduce RubbleDB, the first distributed storage system that leverages offloaded NVMe-oF for efficient replication. The key contributions underlying RubbleDB's design are mechanisms that provide both *file system synchronization* and *application synchronization* at the remote node, so it can safely and correctly read data that was written to it via NVMe-oF.

In order to simplify file system synchronization, we make the observation that modern SSD-based datacenter storage systems [4, 8, 9, 16, 35] write data in large immutable (and often fixed-sized) chunks, and do not allow in-place updates. Therefore, RubbleDB pre-allocates all on-disk data on all nodes as fixed-sized fixed-location files. RubbleDB maintains a *file map* that stores the mappings between the file names and the pre-allocated file locations, and indicates whether a file contains live or stale data. When a new file is replicated, it is sent to a pre-allocated location that does not contain a live file. When a file is deleted in the compaction process, it is simply marked as stale in the map, and is not actually deleted.

For application-level synchronization, RubbleDB needs to keep the secondaries' in-memory data structures synchronized, so when they read data from disk, they read the most up-to-date object versions. To do so, RubbleDB ensures that changes made to the in-memory data structures in the secondary nodes will be consistent with the compactions executed by the primary node. It also carefully synchronizes the deletion of objects flushed from disk or memory, in order to avoid accidentally deleting objects that were processed out-of-order in the secondary nodes.

Our evaluation demonstrates that RubbleDB consistently leads to significant CPU and I/O bandwidth savings compared to a baseline, which represents the architecture of systems such as Meta's ZippyDB [17, 43] or CockroachDB [42], which run compaction on all nodes in a replication group. These savings enable RubbleDB to consistently achieve the same or higher throughput than the baseline across the entire YCSB suite [20], as well as on five traces from Twitter's key-value cache clusters [49]. In particular, RubbleDB provides a speedup up to 1.9× and a tail latency improvement of up to 93.4%. We also show that RubbleDB consistently provides higher performance in different scenarios, including different replication factors, different numbers of RocksDB instances per physical server, and different types of storage devices.

While in this paper we focus on the particular use case of a replicated key-value store, we believe our design ideas are applicable to other common storage applications with primary-backup replication, such as replicated file systems [16, 26, 34, 48] and disaster recovery and backup services [38].

2 Background and Motivation

This section lays out the background and motivation for the paper. §2.1 provides background information on the most common data structure for disk-based key value stores, the log structure merge tree (LSM tree), and demonstrates that background compaction operations in LSM trees consume significant CPU. §2.2 provides a primer on the NVMe-oF protocol and then shows the performance benefit of using NVMe-oF for storage replication with a microbenchmark.

2.1 The High Cost of Compactions

LSM trees. LSM trees [37] are a popular data structure for disk-based key-value stores, which powers many modern key-value stores, such as RocksDB [8], LevelDB [4] and WiredTiger [9]. Since small random writes significantly hurt SSD (and HDD) performance, the main design goal behind LSM trees is that data written to disk is always written in large contiguous chunks and is never updated in-place.

As a representative system for LSM trees, we provide a primer on how RocksDB, a popular key-value store works. In RocksDB, to avoid small random writes to disk, all incoming data writes are batched in memory, in a data structured called the MemTable. Each entry in the MemTable has a sequence number that enables key versioning. MemTables can be *active*, which means that they are mutable and can be updated with new incoming updates, and *immutable*, which means they are waiting to be flushed and cannot be updated further. Eventually, the immutable MemTables get flushed to disk and written using a format called sorted string table (SST) files, which are composed of sorted key-value pairs. SST files are composed of blocks, each of which can be a data block or a metadata block. The metadata blocks include index blocks whose entries point to the keys at the start of each data block.

SST files are organized hierarchically into levels (L0, L1, ..., LN), where the "upper levels" (e.g., L0 is "higher" than L1 in the hierarchy) store the more recently updated versions of each key-value pair. Data from the MemTable is flushed into L0, which stores files with overlapping key ranges, while the files in lower levels (L1,...,LN) have non-overlapping key ranges.

A key feature of LSM tree-backed stores is *background compaction*, which periodically scans multiple SST files from two adjacent levels, combines them into a single file, and

flushes the new file into the lower level. In this process, deleted and overwritten keys are discarded, freeing up space for new data. Compactions are necessary not only for freeing up space on disk, but also for reducing the number of I/Os required on average to read data from the LSM tree [37].

To reconstruct the LSM tree after a failure, RocksDB persists a log containing changes to the tree, e.g., deletion or generation of SST files. RocksDB records such changes using *version edits*, where a version represents the current set of SST files in the tree. For example, a version edit may record the removal of stale SST files and the generation of new merged files. Although compaction jobs run in parallel, they produce version edits in a serializable order because RocksDB protects the tree status with a mutex.

CPU consumption of compactions. Compactions are expensive and can affect the performance of the key-value store. A compaction job requires reading the data of all the files involved in the compaction (often involving tens of MB of data or more), sorting them, and writing them back to disk.

As an example, we measure the CPU time consumed by compactions by running a microbenchmark (described in §5.2) on a replicated 3-node key-value store, where each node conducts compaction locally, under a data ingestion microbenchmark (YCSB load [20]). In this workload, 72% of CPU time was dedicated solely for compaction jobs! Due to their high cost of compactions, there is a large body of work on reducing their resource consumption in single-node LSM trees [12, 13, 29, 32, 39], e.g., by delaying them, synchronizing them with incoming requests, or optimizing the LSM tree data structures and parameters to reduce their cost.

Saving compaction CPU and I/O bandwidth in replicated key-value stores. Our focus is orthogonal to these single-store optimizations: we make the observation that in settings where the same data is replicated on a set of R key-value stores, we do not have to run R identical compaction jobs across all nodes, which are essentially performing the same exact computation. Therefore, compaction can occur only once (on the *primary* node), and the already-compacted SST files can be shipped to the *secondary* nodes, which hold the backup copy of the data.

Such an approach has the potential to significantly reduce CPU consumption on the secondary nodes, since they no longer need to issue read and write I/O and sort the compacted data, the latter of which typically consumes the most CPU during compaction jobs [12, 13, 29]. In addition, this would eliminate the compaction read I/O of secondary nodes, since they would not need to read the files that need to be merged by the compaction job, but it would not eliminate the secondary's write I/O, since the new file would still have to be written back to the disk. Finally, it would also reduce the memory pressure on the secondary nodes due to compaction.

However, executing compactions only on primary nodes has a price. The primary cost of this approach is increased network bandwidth and NIC resource consumption, since now not only the "regular" incoming read/write requests need to be replicated, but also the post-compaction SST files. Fortunately, in many datacenters the network is often underutilized: for example, in traces from Alibaba [1] and Snowflake [47], 50–75% of the network capacity is idle. In addition, the primary node would consume some additional CPU in shipping the files to the secondary nodes' disks.

Therefore, since this approach involves a trade-off primarily between minimizing CPU consumption on the secondary nodes and increasing total network bandwidth, we seek to ship the SST files with a protocol that will minimize CPU usage on the secondary nodes. To this end, we turn to NVMe-oF, a state-of-the-art networked storage protocol supported by Linux and modern NICs, which can be run without the involvement of the secondary nodes' CPU.

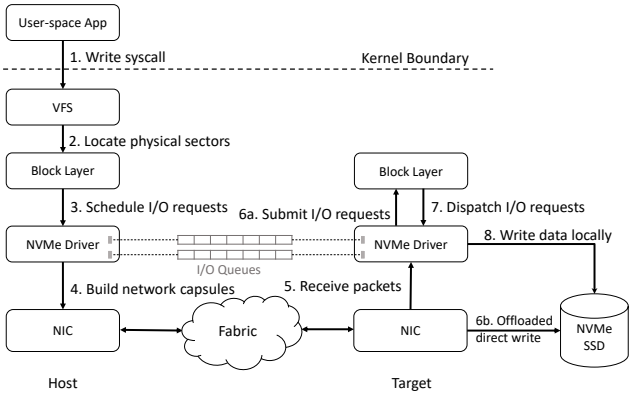

Figure 1: NVMe-oF overview.

2.2 Motivation for Using NVMe-oF

NVMe-oF primer. NVMe-oF is an extension of the NVMe protocol for networked storage. NVMe-oF allows an application to directly access a storage device that is connected to a remote server, using the NVMe protocol. Figure 1 depicts the flow of an NVMe-oF request. The *host* (left side of the diagram) is the server that initiates the request, and the *target* is the remote server and the SSD connected to it. The NVMe-oF request is initiated by an application on the host, which issues a system call, and subsequently traverses the entire OS storage stack, treating it as a regular local NVMe request, until it reaches the NVMe driver.

Take a write request as an example (Figure 1): the userspace application issues a WRITE() system call on the file located on an NVMe-oF mounted disk (step 1), then just like a normal local I/O, it goes through the Linux Virtual File System (VFS) to find the inode, which maps the physical sectors on the disk and is then submitted to the block layer (step 2) where it gets batched by the I/O scheduler, and is dispatched to the host-side NVMe driver (step 3).

The *host* and *target* drivers maintain multiple I/O queues for exchanging the NVMe-oF capsule, which is a data structure that contains essential information needed for an NVMe

	gRPC + WRITE()	NVMe/TCP	NVMe/RDMA
Throughput	1028 MB/s	2986 MB/s	3748 MB/s
CPU	155%	135%	50%

Table 1: Comparison of throughput and CPU consumption of 1 MB writes with different protocols. NVMe-oF (via TCP or RDMA) is much more efficient than replicating through userspace.

communication between the host and the target. The NVMe driver handles this request by constructing a corresponding NVMe-oF command within a capsule, mapping data and metadata from the memory, and submitting it to one I/O queue. The capsule is then forwarded to the relevant network stack (step 4) depending on the fabric type (TCP, RDMA, etc.) and is then forwarded to the target. For NVMe/TCP, the capsule is embedded in TCP packets and contains both data and metadata, while for NVMe/RDMA, the target and the host exchange the capsule using two-sided RDMA operations. With NVMe/RDMA, the capsule records the memory address of the data buffer in the host and the target consequently reads that portion of memory using a one-sided RDMA read.

On the target (step 5), after the driver extracts the NVMe-oF command and user data from the network packet, it generates the block layer request and submits it to the block layer for I/O scheduling (step 6a). The target's NVMe driver, at last, receives the I/O request from the block layer (step 7) and writes the user's data to the local NVMe SSD through the PCIe bus (step 8).

In the past few years, major NIC model lines (e.g., NVIDIA ConnectX, Broadcom Stingray, Intel IPU) have supported completely offloading the NVMe-oF target datapath to the NIC, and allowing the NIC to directly write the data to the NVMe device. This offers an alternate datapath that bypasses the target's CPU completely (step 6b). When the NIC attached to the target receives an NVMe capsule from the *host*, it executes the NVMe request and directly writes data on the NVMe SSD via DMA.

Potential benefit of NVMe-oF for replication. Popular distributed storage systems (e.g., CockroachDB [42] and Ceph [48]) often use an RPC (e.g., gRPC [3]) to send data from the primary to the secondary node, which in turn is written locally to the SSD (e.g., with a WRITE() system call).

We compare the throughput and CPU usage of this userspace-based baseline with two NVMe-oF protocols (NVMe/RDMA, which stands for NVMe-oF over RDMA and NVMe/TCP, which stands for NVMe-oF over TCP), in a microbenchmark that writes 1 MB data chunks over the network in a closed loop, with two servers using the same experimental setup on CloudLab [40] described in §5.1. In the experiment, each server contains one primary node that is writing to a secondary node on the second server, with a total of 256 available cores. The aggregate results are shown in Table 1. The result shows that the throughput of gRPC with WRITE() is only 34% of the throughput NVMe/TCP while the CPU usage is 20% higher. In addition to the more complex logic in the RPC framework, the userspace stack requires extra user-kernel boundary crossings and context switches when the data buffer is delivered to the userspace application from the TCP/IP stack in the kernel and then written to the local file which incurs a kernel trap. NVMe/TCP, on the other hand, processes the data write completely in the NVMe driver in the kernel, therefore saving a substantial amount of CPU cycles in each write request, thereby increasing the throughput. In addition, NVMe/RDMA outperforms NVMe/TCP due to the elimination of unnecessary copying and CPU bypassing.

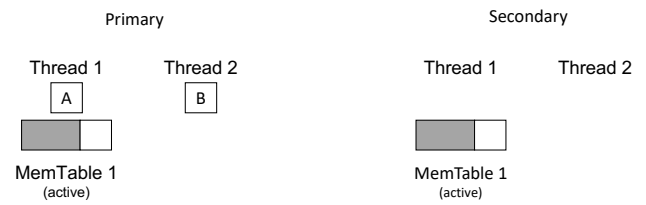
3 Challenges

Substituting a userspace replication protocol with NVMe-oF introduces challenges at two different layers: at the file system level and the application level.

File system inconsistency. NVMe-oF introduces inconsistency at the file system level. A naive way to ship files through NVMeoF is to simply allocate a new file on the remote disk and write to it. However, in such a scheme, the secondary node will not even see the new SST files in its file system. This is because the SST files are created in the primary's file system, and NVMe-oF only forwards NVMe commands, which get executed below the file system layer in the secondary node's storage stack (see Figure 1). So, the primary and secondary nodes may see different files systems on the same NVMe disk. Even worse, the data sent by the host could accidentally overwrite data in physical blocks at the secondary that it is not supposed to access, since the local file system of the target may have changed its file-to-block mapping.

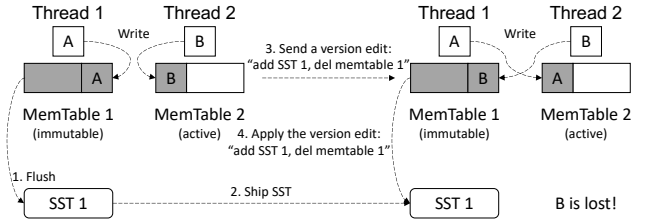
Application inconsistency. Even if the target's file system is synchronized with the host's view, NVMe-oF introduces inconsistency at the application level. Since the persistent key-value store maintains in-memory data structures (e.g., to buffer writes), these data structures may not be synchronized between the primary and the secondary, leading to data loss. In particular, in RocksDB, there will be discrepancies between the primary and secondary node within their MemTables, which store the values of recently-written data in memory.

Figure 2 shows an example where discrepancies in the primary and secondary's MemTables cause data loss in the secondary. Consider the case where there is one active MemTable (MemTable 1), which is nearly full and only has capacity for one more object (Figure 2a). Now consider that two objects (A and B) arrive concurrently. Both primary and secondary use two threads to process incoming requests, and in this case RocksDB does not provide any guarantee on the order that the writes will be processed. In the primary, object A is written before B, and is therefore written to MemTable 1, which is sealed and marked inactive, while object B is written to the newly active MemTable 2. Next, the primary forwards objects A and B to the secondary, but the secondary applies them in the opposite order due to non-deterministic thread scheduling: B is written to MemTable 1, and A is written to MemTable 2. Consequently, the secondary's MemTable 1 stores different



(a) Initial state, single active MemTable.

(b) The secondary executes concurrent requests at a different order.



(c) The secondary removes MemTable 1, losing object B.

Figure 2: An example of inconsistency across node MemTables.

data than the primary's MemTable 1 (Figure 2b).

Now, the primary flushes MemTable 1 to disk, causing it to delete the objects stored in MemTable 1 from memory. If it then ships the new SST file to the secondary, and instructs it to also delete it to delete MemTable 1 as well, this will result in the loss of B at the secondary, because B will not be stored neither in its MemTables, nor on its disk (Figure 2c). In this case, the reason for the data loss is due to the fact that thread scheduling across the nodes in a non-deterministic fashion, so operations are applied in a different order, causing discrepancies.

Making matters worse, even if we had a way to force secondary nodes to process requests in the same order as the primary, the content of the MemTables would still diverge. This is because RocksDB's MemTables store their data using randomized skip lists, which will cause MemTables in different nodes to contain a different number of entries and become full at different times.

4 Design and Implementation

We present the design and implementation of RubbleDB, and explain the key mechanisms that allow RubbleDB to address the inconsistencies introduced by replication via NVMe-oF.

RubbleDB is a replicated key-value store, composed of a set of RocksDB instances, with a replication layer on top. RubbleDB uses chain replication [45] to provide strong consistency and fast recovery. The client only communicates with the replicator layer, which is in charge of dispatching requests to the proper primary node (in case of write) or tail node (in case of a read) and of handling failure recovery. Figure 3

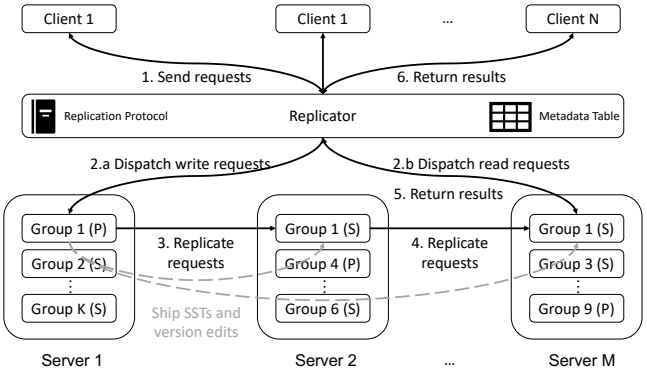


Figure 3: RubbleDB overview.

depicts the overall architecture of RubbleDB. There are N clients and K replication groups, and in between sits the replicator layer. Replication groups contain R RocksDB instances or *nodes*, one of which is the primary, and the others are secondaries. Only the primary performs flush or compaction jobs. Therefore, in addition to replicating client write requests, the primary node also ships compacted SST files via NVMe-oF, assuming sufficient network bandwidth is available. If the network becomes congested, RubbleDB can fall back to local compaction on all replicas. Specifically, RubbleDB compares the latencies of shipping SST files and local compaction. If the former is consistently greater over a time period, RubbleDB falls back to regular compaction. Different replication groups store disjoint key spaces. By default, the R replicas are stored on R different random servers. In the future, we plan to support other more sophisticated data placement policies [18, 19]. We intentionally keep each replication group small (by default 10 GB), so the recovery load can be spread across multiple nodes in the cluster when a server or disk fails. It is worth noting that we assume no dishonest or malicious node (e.g., we assume all nodes operate under a single organization in a single data center). Next, we discuss the design details of the two main key components of RubbleDB: the replicator layer and replication groups.

4.1 Replicator Layer

To provide a clean key-value interface from users and hide the complexity of dealing with the replication protocol, RubbleDB uses a replicator layer as a proxy layer between users and replication groups. Users simply send regular RocksDB requests to and receive results from the replicator layer, which transparently handles the replication protocol. The replicator thus has two roles: 1) routing requests to a replica of the group that contains the requested key-value pairs and 2) detecting and recovering from any failed replicas.

Different replication groups contain separate key spaces. To route requests, the replicator maintains a metadata table that records the key space and network addresses for each replica group. Once it receives a request, the replicator first looks up the group number in the metadata table. Next, according to the replication protocol, it forwards the request to a specific

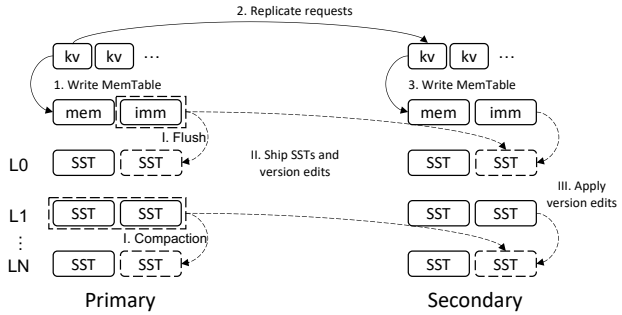

Figure 4: Replication process.

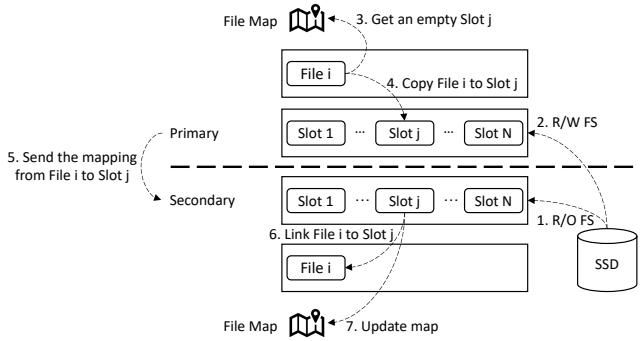

Figure 5: Primary ships SST files to pre-allocated slots.

replica within that group. The replicator also sends heart beat messages to every replica periodically to confirm its health. If it does not receive any replies from a replica after a time threshold, the replica is assumed to have failed, and the replicator starts the recovery process.

In Figure 3 foreground data flows are represented by a solid arrow, while background flows are dashed. The figure only shows the background requests belonging to replication group 1, which is replicated across servers 1, 2 and M. Clients first send requests to the replicator (step 1), who after consulting the metadata table forwards the requests to replication group 1 (step 2). Following the chain replication protocol [45], write requests (e.g., put and update) go to the head (step 2.a), while reads (e.g., get and scan) go to the tail (step 2.b). In the case of writes, the primary (head) replicates the write request to the next secondary in the chain (step 3), which applies the write and then replicates it to the next node in the chain (step 4). When the tail node completes a request (read or write), it will reply to the replicator (step 5), which finally returns the results to the client (step 6).

It is important to note that the replicator is only a logically centralized component that orchestrates traffic and recovery. To prevent the replicator from being a performance bottleneck or a single point of failure, it can be implemented as a distributed fault-tolerant cluster [17, 42]. We leave this direction, as well as other aspects of the replicator's design, such as dynamic load balancing and dynamic key-space partitioning, for future work.

4.2 Replication Groups

Each node within a replication group is a small RocksDB instance, composed of a primary node (head of the chain) and a chain of secondary nodes, which store the backup copies of the data. Figure 4 presents how a primary interacts with one of its secondary nodes. Solid and dashed arrows represent foreground and background operations, respectively. Write requests are executed from the head replica (the primary) to the tail (steps 1-3). Read requests are omitted in Figure 4 because they are only sent to the tail secondary node.

Steps I-III show how RubbleDB avoids background compaction jobs in secondaries. In step I, flush and compaction jobs happen normally in the primary (triggered by filled MemTables or upper-layer SST files). These jobs change the primary's LSM tree in three ways: 1) deletion of the data being compacted (both in-memory immutable MemTables and on-disk SSTs, depicted with dashed rectangles in Figure 4), 2) creation of compacted SSTs (dashed rounded rectangles), and 3) modification of the LSM tree version (information recording current SST files in the tree). RubbleDB ensures that the same changes also occur in the secondaries by shipping both compacted SSTs and version edits over the network (step II). Shipping the compacted SST file addresses 2), so the secondary only needs to delete the original obsolete SST files according to the version edits and update its own LSM tree version (step III).

However, it is not trivial to guarantee the correctness of steps II and III due to the challenges described in §3. In §4.2.1 we discuss how RubbleDB solves the challenge of file system inconsistency, while in §4.2.2 we describe how RubbleDB addresses application inconsistency.

4.2.1 File Pre-allocation

As the primary and secondary nodes mount their own local file systems (e.g., ext4) on top of the same storage device, each local file system will not be aware of changes made by the other file system, e.g., file creation. To ensure that shipped SST files are visible to secondary nodes, RubbleDB uses *file pre-allocation*. Before running, secondary nodes allocate many pre-allocated file slots, which we call a *file pool* on their local storage devices, after which, the primary mounts these devices. So both sides will be aware of the file pool in their local file systems. During runtime, the primary ships an SST file to a secondary by writing the content to a fixed-sized slot in the pool with direct I/O (to make sure the file gets written to disk and bypasses the primary's local buffer cache). Thus, only the data blocks of the slot file are updated and the inode remains unchanged. The secondary can also read the content with direct I/O after the file is written.

Note that this means that secondary and primary nodes cannot rely on the buffer cache to cache hot data blocks from disk. Fortunately, RocksDB (and most other key-value stores) implements its own userspace-based cache, the block cache, which can replace the operating system's buffer cache.

There are four practical issues with this pre-allocation

scheme: 1) determiming the size of slot files, 2) managing slot files in the pool, 3) avoiding dynamic file remapping by the local file systems, and 4) ensuring that RocksDB will correctly point to the pre-allocated files even when it changes file names. We discuss each issue below.

File size. To guarantee that the primary can find a slot to ship SST, secondaries need to allocate a sufficient number of file slots for every possible file size. Fortunately, key-value stores like RocksDB typically store data in more or less fixed-sized (or size-capped) files. Moreover, the number of SST files in each layer of an LSM tree is also limited by compaction. For example, by default in RocksDB, the size of an SST file is 64 MB and the maximum number of SST files is 4448. In this case, a secondary would need to create 4448 64 MB file slots. In our implementation we use a fixed-size file that is slightly larger (17 MB) than the target file size of RubbleDB's RocksDB instances (16 MB), since files may occasionally exceed the target size. When files are smaller than the fixed size of the slot, the remainder of the slot is zero-padded.

Slot management. The primary acquires slots in the pool before shipping SST files to secondaries. Similarly, when deleting an SST file post compaction, the corresponding slot is released. We design a *file map* to track the mapping between slots and SST files and to indicate whether a slot contains a live SST file. Both the primary and secondary nodes have a copy of the map. It is necessary for secondaries to own a map copy because once the primary fails, one of them will be chosen as the new primary.

In a flush or compaction job, the primary first acquires empty slots in its file map and then executes the compaction. After shipping the compacted files to the secondary nodes, it sends the map updates to all secondaries with the version edits, so the same updates are applied in all the secondary nodes. After receiving the updates, the secondary marks the slots of the old files, whose space can be overwritten, as released, and it updates the primary's file map to notify it about the slot release. The reason slots are released by secondary nodes is to avoid the case where the primary node releases a slot, and then acquires it again before the secondary node was notified of the slot release, which would be viewed by the secondary as an illegal operation, where a new file overwrites an already-acquired slot.

File remapping. The pre-allocated file slots' mappings from file offset to physical block address may change over time. Various reasons can cause remapping, including dynamic volume management, file system extent adjustment, etc.. To minimize interference from the file system and volume management, RubbleDB uses a dedicated and static disk partition for the file pool in each secondary node. The partition is mounted as read-only in the secondary, since the secondary never writes to its SSD drive, and read-write in the primary node. In case of a crash, where a secondary needs to become a primary, it remounts with read-write mode.

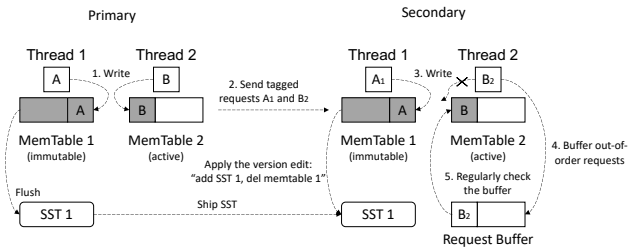

Figure 6: Partially-ordered writes using MemTable ID.

Renaming RocksDB names each SST file with a unique integer, e.g., `002023.sst`. This leads to another issue of pre-allocating slot files: their fixed file names. Because the secondary mounts the partition as read-only, it cannot rename the slot files to the RocksDB format. To address this issue, RubbleDB creates a symbolic link from a file with the RocksDB-defined name to the slot file, so the RocksDB instance on secondary can correctly access its read-only file pool.

Multiple groups. If there are multiple replication groups, primary nodes from different groups will acquire slots concurrently. To avoid contention, RubbleDB creates a dedicated SST pool (and map) for each group. Recall that since each pool sits on a different disk partition, there are no concurrent writers to a file in RubbleDB.

Figure 5 summarizes the file replication workflow. Before the replication group is formed, a disk partition is created for the file pool on each secondary. The primary and secondary mount the partition as read-only (step 1) and read-write (step 2), respectively. Suppose that the primary node generates SST file i in a flush job, it first queries the file map for an empty slot j to ship the SST file (step 3). Next, the content of SST file i is written in slot j with direct I/O (Step 4). The data of slot j will be transferred to the secondary node's SSD via NVMe-oF. At the end of the flush job, the primary sends the mapping between file i and slot j to the secondary (step 5), so the secondary knows how to create the correct symbolic link (step 6) and update its file map copy (step 7).

4.2.2 LSM Tree Synchronization

Flush and compaction jobs are essentially performing merge sort and do not change the actual state of RocksDB from the client's perspective[1]. These merge sorts contain inputs: MemTables and SST files to be merged in the case of flush and compaction, respectively, while the output is always SST files that will be written to disk. This property implies that the inputs and output of a flush or compaction job must contain the same set of live key-value pairs. Primary nodes naturally satisfy this requirement since they execute compaction locally. However, secondary nodes sometimes have mismatched sets of inputs and output live key-value pairs when applying version edits. Recall from the example in Figure 2, in the secondary node, the input to the flush job (MemTable 1) has

[1]Although stale data will be discarded during compaction jobs, it is already ignored by RocksDB since read requests fetch the most recent data.

different live objects from the output (SST 1). Consequently, the secondary node loses B while redundantly storing two copies of A.

To guarantee the data consistency of secondary nodes, they need to ensure that the inputs and outputs of every version edit contain the same set of live objects before applying it. However, comparing all objects across multiple MemTables or SST files is very costly. Instead, RubbleDB forces a partial order of requests and total order of version edits. These two ordering techniques synchronize the secondary nodes' LSM trees with the primary's. We describe them below.

Partially-ordered writes. Figure 6 describes how RubbleDB addresses the MemTable discrepancy issue discussed in the example in Figure 2 by ordering write requests with MemTable ID. In the primary, after an object is inserted to the active MemTable, each write request is returned with the ID of that MemTable (step 1). The primary tags each write request with this MemTable ID and forwards it to the secondary (step 2, the subscripts are the IDs). With the IDs, the secondary now knows to which MemTable the primary wrote each request. The secondary follows the same order as the primary, by maintaining a request buffer to cache out-of-order requests. For example, even if the secondary scheduled thread 2 before thread 1, it will fail to write B_2 to MemTable 1 as its tag (2) does not match with the MemTable ID (1) (step 3). So, thread 2 will store the request B_2 in the request buffer (step 4). When thread 1 executes, A_1 it will be written to MemTable 1. Therefore, MemTables 1 on both the primary and secondary nodes will have the same set of objects, which will not cause data loss like in Figure 2c. Last, every time RocksDB switches to a new MemTable, each thread in a secondary checks the buffer to execute any request that can be applied correctly to the MemTables, i.e. its tag is equal to the ID of the active MemTable (step 5).

This scheme represents a partial order because secondary nodes only sort write requests belonging to different MemTables. Write requests that have the same MemTable ID as the primary's MemTable have identical tags and can execute in any order. This does not affect the correctness when all updates in a MemTable have unique keys because MemTables (skip lists in RocksDB by default) and flush or compaction jobs (merge sorts) will sort them anyway. However, in the case where there are updates for the same key, as both MemTables and flush or compaction only select the most recent update, the secondary has to maintain the same order among those different updates. RubbleDB achieves such an order by further splitting the key space among threads. For example, all updates of key A will be handled by primary's thread 1 in Figure 6. Then, RubbleDB relies on in-order request delivery (e.g., streaming RPC) to ensure those updates arrives at a single thread of the secondary in the same order.

Totally-ordered version edits. Partially ordering writes only guarantees that the secondary nodes eventually have the same live objects in their MemTables as the primary node. However, due to request buffering, updates applied on the secondary nodes may lag the primary, so the same MemTable ID in a secondary node may have fewer entries than the one in the primary. Such lag introduces challenges when applying version edits in secondaries. Back to Figure 6, suppose that at time t, the version edit `(add SST 1, del MemTable 1)` arrives at the secondary but the request A_1 has not been executed. Applying the version edit at time t may allow the client to read A_1, even if it has not been written. This breaks the consistency guarantee of chain replication, which requires that a client can only read a value after it has received an acknowledgment that the value has been written successfully.

To avoid the scenario above, we have to ensure that the sets of live objects in the inputs and outputs of each version edit in the secondary are the same. We exploit the fact that in RocksDB flush or compaction jobs generate version edits in a serializable order (the current version is protected by a mutex) even though they run in parallel. So, the primary node tags version edits with sequence numbers to indicate their order, and the secondary nodes maintain a counter and a buffer for version edits. The counter is incremented every time the secondary applies a version edit. The secondary checks two conditions before applying an edit: 1) whether the sequence number is equal to the counter and 2) whether its inputs are ready. The latter is checked for flush jobs only, since the inputs of a compaction are always ready if it passes step 1) (i.e. the previous flush or compaction job has finished). A MemTable is ready only when it becomes immutable (full). If either of the two conditions fails, the version edit is cached in the buffer, which is regularly checked by all threads.

With these two ordering techniques, RubbleDB synchronizes the LSM tree state in a replication group and addresses the challenge of application inconsistency.

4.3 Implementation Details

We implement RubbleDB using RocksDB 6.14.0 and gRPC 1.34.0, comprising a total of about 900 and 4000 lines of Java and C++ code, respectively. Each replica in RubbleDB is a RocksDB instance, and different parts of the system communicate with each other using streaming gRPC calls. To simulate concurrent clients, we modify YCSB to issue requests as batches to our replicator in an open loop. We open-source all the code on GitHub[2].

5 Evaluation

We seek to answer four evaluation questions:

Q1: How does RubbleDB's SST file replication affect the CPU, network, and disk I/O usage of RubbleDB? (§5.2)

Q2: How does the replication mechanism of RubbleDB affect its performance under different workloads? (§5.3)

Q3: Does the utility of NVMe-oF change as a function of the available storage resources? (§5.3)

Q4: How fast can RubbleDB recover from failures? (§5.4)

5.1 Experimental Setup

Setup. We conduct all experiments on CloudLab [24, 40]. Unless otherwise specified, replication groups run on multiple r6525 servers and clients run on one c6420 machine with the replicator. Each r6525 server has two 32-core AMD 7543 CPUs at 2.8 GHz, 256 GB DDR4 memory, a 1.6 TB Dell Enterprise SSD, and a dual-port Mellanox ConnectX-6 100 Gb NIC. By default, RubbleDB uses the Mellanox NIC's NVMe-oF offload feature. A c6420 server has two 16-core Intel Xeon Gold 6142 CPUs at 2.6 GHz and 384 GB DDR4 Memory. The OS is Ubuntu 20.04 LTS with a Linux version of 5.4.0. We configure NVMe-oF target offloading following NVIDIA's official guide [7].

RocksDB configuration. We intentionally keep each key-value instance small, so that if an instance fails there will be a relatively small amount of data to re-replicate. Therefore, we use 16 MB SST files and MemTables and an L0 of size 64 MB, so the LSM tree will contain 64 GB data at most. Direct I/O is enabled with a 2 GB block cache. We run DB instances on each server within a cgroup with 4 physical cores. The number of background threads is therefore set to 4 (number of cores). All other parameters remain default.

	Baseline		RubbleDB	
	Read	Write	Read	Write
R = 2	163.7	185.6	94.6	206.6
R = 3	241.4	274.4	97.8	309.9
R = 4	343.3	387.5	101.7	410.7

R = 2	34.5	0	34.5	105.7
R = 3	57.2	0	57.3	211.1
R = 4	80.0	0	80.1	314.7

Table 5: The total network traffic (GB) via gRPC and NVMe-oF on one node, with co-location factor of 1 and different replication factors.

Benchmark. We evaluate RubbleDB on all YCSB [20] workloads and five Twitter production traces [49]. Table 2 summarizes the workloads' read-write ratio. Four clients concurrently access all replication groups.

Baseline. For an apples-to-apples comparison, the baseline is a replicated RocksDB system, which is configured identically to RubbleDB, except that it does not replicate SST files, and does not include the various mechanisms RubbleDB uses to support NVMe-oF replication (e.g., buffering at the secondary nodes, processing version edits in-order). The baseline here would represent the standard approach of replicated key-value stores, such as ZippyDB [17,43] and CockroachDB [42], where each node compacts its data independently.

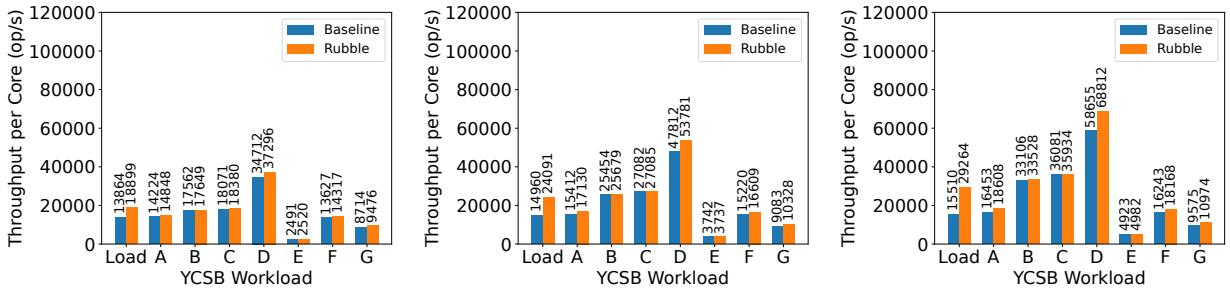
Evaluation metrics and terms. We use two primary evaluation metrics: throughput per core, which represents CPU efficiency, and tail latency. We use two knobs replication factor (R) and co-location factor (C) to indicate the numbers of replication groups (K), servers (M), and replicas in our experiments. We define $C = \frac{K}{M}$ and fix $M = R$, so, $K = C \times R$. For example, a replication factor of 3 and co-location factor of 2 means that on 3 servers ($M = 3$) exist 6 RocksDB instances ($K = 2 \times 3$) (2 primaries and 4 secondaries).

5.2 Performance Breakdown (Q1)

We run the YCSB load workload with a co-location factor of 1 and replication factors of 2, 3, and 4 in this section to collect CPU, disk, and network statistics.

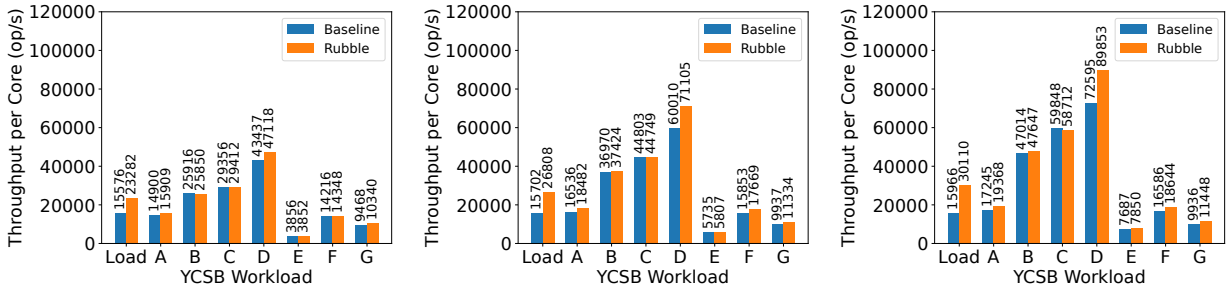
CPU savings. Table 3 presents the amount of CPU time the baseline and RubbleDB spend performing compaction and handling incoming requests. Handling requests includes both reading and writing data from RocksDB, as well as handling the incoming RPCs (i.e. via gRPC), buffering data on the secondary nodes, and applying version edits.

As expected, the secondary nodes on RubbleDB consume no CPU cycles executing compactions, while in the baseline system, each secondary node consumes roughly the same



(a) Replication Factor = 2 **(b)** Replication Factor = 3 **(c)** Replication Factor = 4

Figure 7: YCSB throughput as a function of replication factor with a co-location factor of 1.



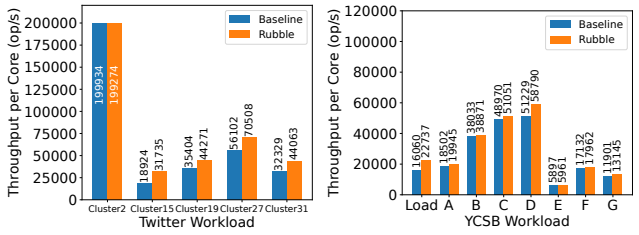
(a) Replication factor = 2. **(b)** Replication factor = 3. **(c)** Replication factor = 4.

Figure 8: YCSB throughput as a function of replication factor with a co-location factor of 2.

amount of CPU cycles as the primary (there are $R-1$ secondary nodes per primary). Under R=2, 3, and 4, the primary node of RubbleDB consumes 0.8%, 4.2%, and 7.8% more compaction CPU than the primary node of the baseline, respectively. This is because the primary has to send compacted SST files and version edits to each secondary node. The overhead increases with the number of secondary nodes.

In terms of handling regular requests, the primary node of RubbleDB consumes slightly more CPU (up to 7.7%) than the baseline's primary node, because it tags every write request with a MemTable ID. The secondary nodes of RubbleDB consume up to 18.8% more CPU than the baseline's, because of the need to buffer incoming requests and version edits. All in all, due to the reduction in the compaction load of the secondary nodes, RubbleDB spends 34.4%, 44.3%, and 50.5% less time processing the same workload than the baseline with R=2, 3, and 4, respectively.

I/O savings. Table 4 reports the amount of data read and written by one node. Since we run the YCSB load workload and disable the write-ahead log, the I/O is caused by compaction. In RubbleDB, only the primary performs compaction, which reads the inputs files and ships compacted SST files to every secondary. Therefore, RubbleDB's read I/O keeps nearly constant, 98.0 GB on average, while its write I/O grows with the replication factor proportionally, averagely $R \times 103.1$ GB. Both the read and write I/O in the baseline, however, increases with the replication factor because all nodes perform compaction. So, RubbleDB saves more read I/O with a higher replication factor, up to 44.2%



(a) **(b)**

Figure 9: Throughput on (a) Twitter cluster traces with a replication factor of 3 and co-location factor of 1, and (b) YCSB using Optane SSD with a replication factor of 2 and co-location factor of 2.

when $R = 4$. There is a modest increase (12.9% at most) in write I/O due to the padding of SST files in RubbleDB, which increases the amount of data that is written for each SST file. We leave reducing the overhead of padding to future work.

Network overhead. Table 5 presents both the gRPC and NVMe-oF traffic. The former consists of forwarding key-value requests and version edits, while the latter includes shipping SST files. The network overhead in RubbleDB includes: (a) sending version edits by gRPC and (b) shipping SST files via NVMe-oF. We approximate (b) by calculating the total volume of shipped SST files. From Table 5, (a) is negligible, and (b) is close to the compaction write I/O.

5.3 End-to-end Performance (Q2, Q3)

Throughput with YCSB. Figures 7 and 8 compare the throughput per core of RubbleDB with the baseline under the load and YCSB workloads, with a co-location factor of 1 and 2, respectively. RubbleDB consistently provides the

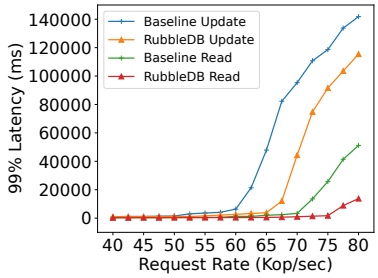


Figure 10: 99% Latency of YCSB A with replication factor of 3 and co-location factor of 1.

same or higher throughput per core compared to the baseline, and has a higher relative speedup for workloads with a high percentage of writes.

As the replication factor increases, RubbleDB provides higher relative gains. For example, under the load workload with a co-location factor of 2, a replication factor of 4 (Figure 7c) yields a speedup of 1.9×, while the speedup of $R = 2$ is 1.5×. The reason is that with higher replication factors, the baseline spends more secondary cores cycles per replication group executing compactions, while RubbleDB experiences a very marginal increase in the primary's CPU consumption (due to the need of shipping SST files to additional secondary nodes). Therefore, with a higher replication factor, RubbleDB has the ability to marshal more available CPU cycles belonging to the freed up secondary node cores, in order to process more incoming requests. In addition, RubbleDB achieves higher absolute throughput and speedup with a co-location factor of 2. The reason is that with more co-located replication groups, RubbleDB is better able to utilize the CPU, since there are more available pending tasks to execute at any given time.

Throughput with Twitter traces. We measure RubbleDB's throughput on five Twitter traces[3] with different read-write ratios, including cluster 2, 15, 19, 27, and 31 [49]. As Figure 9a shows, for write-heavy traces, RubbleDB provides a speedup of 1.7× and 1.4× in clusters 15 and 31, respectively. For cluster 19 and 27, which are ready-dominant, RubbleDB still achieves a 1.3× speedup. These results are largely consistent with the YCSB results.

Tail latency. RubbleDB provides better tail latency than the baseline when there are many compactions. Prior work has shown that compaction jobs interfere with request processing, leading to high tail latencies [12, 13]. Since RubbleDB significantly reduces the overall compaction load, as a result, it decreases the chance that compactions interfere with regular requests.

Figure 10 shows the 99th percentile latency under the YCSB A workload with 3 replicas and a co-location factor of 1, RubbleDB reduces 99th percentile latency of updates and reads by 11.5%-92.1% and 18.4%-93.4%, respectively.

[3]We sample 30GB records from the traces as we have 3 replication groups

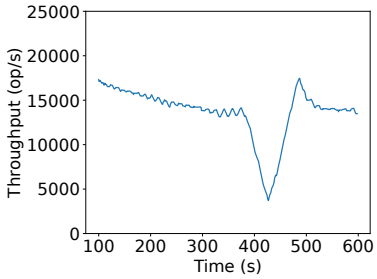

Figure 11: Throughput when a node fails under YCSB load.

The absolute latency is high because our system uses a batch size of 1,000 in evaluation, which means each replica returns a reply after processing all 1,000 requests in a batch. Since write requests go though all replicas sequentially, the update latency will be 3× higher than read latency. We also observe one data point (updates at 40 Kop/sec) showing 14.2% tail latency degradation. This is because out-of-order writes will be cached in the request buffer. Such queuing overhead only appears under light compaction pressure.

Object size. By default, YCSB uses 1 KB objects. When we run YCSB with smaller objects, which are typical in many datacenter settings [11, 17, 49] RubbleDB consistently provides even higher speedups, because a larger fraction of CPU time is spent on compacting data. For example, under YCSB load with a replication factor of 3 and co-location factor of 1, RubbleDB exhibits a 1.6× speedup with 100 B objects compared to a 1.5× speedup with 1 KB objects.

Different storage devices. We try to understand whether a different type of storage device affects RubbleDB's performance. To this end, we run RubbleDB and the baseline on two d750 servers from CloudLab, each of which use Intel Optane SSD P5800X, an SSD with single-digit µs average latencies.We run the experiment with a replication factor of 2 and co-location factor of 2. We are only able to run this experiment with two servers, because of the low availability of Optane SSD on CloudLab.

The results are presented in Figure 9b. Interestingly, the usage of low-latency storage does not materially affect RubbleDB's speedup. While the absolute throughput numbers for read-heavy workloads are higher (for an apples-to-apples comparison compare this experiment with Figure 8a), in the load workload the results are nearly identical. The reason is that while Optane SSD has much better latency than the enterprise SSD we use in the other experiments, its bandwidth is relatively similar, and in the case of LSM trees, write throughput will be determined by disk I/O bandwidth rather than I/O latency, since disk writes are sequential and large. We conclude that RubbleDB provides speedups on very different types of storage devices.

5.4 Recovery Performance (Q4)

To test RubbleDB's recovery from failure, we run a 3-node setup with a single replication group, and kill one of the tail

secondary nodes. We follow the recovery algorithm in [45], which designates the "middle" secondary node as the new tail. We plot the throughput over time in Figure 11. As the figure shows, due to the nature of chain replication RubbleDB is still able to service requests throughout the period when the node is down. In total, it takes about a minute and a half for the cluster to get back to its full throughput capacity.

6 Related Work

We split the related work into two categories: (a) replicated key-value stores, (b) systems that share data with different protocols, e.g., NVMe-oF and RDMA.

Replicated key-value stores. The typical design of replicated key-value stores and databases, such as ZippyDB [17,22, 43], CockroachDB [42], MongoDB [6] and Cassandra [31], is to implement a replication layer on top of multiple single-instance key-value stores, such as RocksDB [8], LevelDB [4] and WiredTiger [9]. In all these systems, all nodes that store up backup copies of data perform their own compactions, leading to high CPU and disk read I/O consumption.

There are several prior systems that do some form of compaction offloading. Ahmad et al. [10] propose offloading large compactions in HBase to a remote compaction server in order to reduce load on the primary nodes serving incoming requests. Hailstorm [14], separates the storage and compute layers, and offloads compaction to nodes that have a low load in a peer-to-peer fashion. Both of these systems allow shifting the computational load of compactions from an overloaded node to an underloaded one, but unlike RubbleDB do not reduce the total compaction load on the cluster by running compaction only once for replicated data.

Closer to RubbleDB, Tebis [46] is a replicated key-value store that reduces CPU consumption by avoiding compacting data multiple times for each replicated chunk of data. However, Tebis has several major design differences from RubbleDB and therefore faces different challenges. First, Tebis' design is based on a key-value architecture that separates keys from values [33]. Therefore, secondaries need to rewrite all the pointers in the indices. Due to the choice of key-value separation, Tebis cannot be applied to standard key-value stores that do not separate keys from values, such as RocksDB, LevelDB or WiredTiger. In addition, while key-value separation provides significant gains with large objects, it can degrade performance for small object workloads, which are common in datacenters [11, 17, 49]. Second, in Tebis, only the primary processes requests, whereas secondary nodes merely store replicated SST files. So, Tebis does not encounter the application inconsistency issue in RubbleDB. Third, instead of NVMe-oF, Tebis uses RDMA with local writes to ship SSTs, which cannot leverage the offloading feature of the NIC. Also, Tebis does not need to deal with inconsistencies caused by the file system.

Storage systems that use NVMe-oF. Several systems use NVMe-oF to access data from remote blocks [5, 15, 27], but only allow each application instance to exclusively access their SSDs. Therefore, these systems do not allow a primary node to replicate to a secondary node's disk directly over NVMe-oF. In other words, unlike RubbleDB, in order to replicate data, these systems require the primary to go through the entire application software stack of the secondary nodes.

Storage systems that use RDMA. Similar to NVMe-oF, the RDMA protocol allows one host to access the other hosts' memory without the CPU involvement of the target. There are a large number of in-memory systems that exploit RDMA for faster operations [23,28,35,44]. While both one-sided RDMA and NVMe-oF may introduce synchronization challenges at the target, the challenges are different, since NVMe-oF operates directly on block storage, potentially introducing corruptions to the local file system at the target.

Shared file systems. Shared file systems [26, 36, 48] provide users across different servers with a consistent view of a file system. However, providing a consistent file system abstraction across multiple nodes can come at a significant performance and scalability cost [30]. Since replicated key-value stores do not require a full synchronized file system interface across nodes, running them over a distributed file system would incur unnecessary overhead.

7 Conclusions

This work explores how to utilize NVMe-oF, a CPU-efficient networked storage protocol, for a common storage use case, replication. The main challenge in using NVMe-oF for replication is that data might need to be read by the target node in parallel to the replication process, introducing inconsistency both at the file system and application level. We demonstrate how such inconsistencies can be addressed in the context of a replicated LSM tree-based key-value storage system, RubbleDB, using two primary mechanisms: file pre-allocation and application data structure synchronization. We believe our ideas can be applied in other common storage settings, such as distributed file systems (e.g., HDFS [16], Ceph [48]) and for storage or application backup. In addition, with the trend of NIC accelerators becoming more powerful in contrast with the plateauing of CPU performance, we anticipate using NVMe-oF for common storage operations will become even more attractive in the future.

8 Acknowledgments

We thank our shepherd, Philippe Bonnet, and our anonymous reviewers for their valuable feedback and suggestions. We also thank Muli Ben-Yehuda, Jianan Luo and Michael J. Freedman for their helpful feedback during the project. This work was supported by NSF award CNS #2106530 and ARO award W911NF-21-1-0078 and was conducted on CloudLab.

Distributed Transactions at Scale in Amazon DynamoDB

Amazon Web Services

Abstract

NoSQL cloud database services are popular for their simple key-value operations, high availability, high scalability, and predictable performance. These characteristics are generally considered to be at odds with support for transactions that permit atomic and serializable updates to partitioned data. This paper explains how transactions were added to Amazon DynamoDB using a timestamp ordering protocol while exploiting the semantics of a key-value store to achieve low latency for both transactional and non-transactional operations. The results of experiments against a production implementation demonstrate that distributed transactions with full ACID properties can be supported without compromising on performance, availability, or scale.

1 Introduction

Application developers have come to rely on database transactions for dealing with failures and concurrency in a distributed system. ACID (atomicity, consistency, isolation, and durability) properties simplify the development process. Transaction atomicity ensures that sequences of operations can be executed without worrying about failures leaving a partial result. Transaction isolation ensures that the developer can write their code without worrying about interference from concurrently executing application instances that read and write shared data.

Despite their utility, NoSQL databases have not generally supported transactions. NoSQL databases such as key-value stores emerged as an alternative to relational databases with a strong emphasis on scalability and performance, especially for customers moving their core data into the cloud. Core features of relational databases, including SQL queries and transactions, were sacrificed to provide automatic partitioning for unlimited scalability, replication for fault-tolerance, and low latency access for predictable performance.

Amazon DynamoDB [9] (not to be confused with Dynamo [8]) powers applications for hundreds of thousands of customers and multiple high-traffic Amazon systems including Alexa, the Amazon.com sites, and all Amazon fulfillment centers. In 2022, over the course of Prime Day, Amazon systems made trillions of calls to the DynamoDB API, and DynamoDB maintained high availability while delivering single-digit millisecond responses and peaking at 105.2 million requests per second. When customers of DynamoDB requested ACID transactions, the challenge was how to integrate transactional operations without sacrificing the defining characteristics of this critical infrastructure service: high scalability, high availability, and predictable performance at scale.

In designing the transaction protocol for DynamoDB, we chose to build transactions differently from other systems and cloud services. The DynamoDB transaction design has the following unique combination of capabilities:

Transactions are submitted as single request. Transactions have commonly been introduced into the database application programming interface (API) with two operations that begin and end a transaction (such as BEGIN and COMMIT in PostgreSQL). These operations serve to delimit the sequence of database operations that are performed within the transaction. The downside of such an abstraction is that there might be a long time between when an application starts a transaction and when it completes its work by committing the transaction. In a multi-tenant service, long-running transactions are undesirable as they tie up system resources on servers that manage data for multiple applications. Instead, DynamoDB transactions comprise a set of operations that are submitted as a single request and either succeed or fail without blocking. Like other DynamoDB operations, transactions provide predictable performance at scale, which is an architectural tenet for DynamoDB.

Transactions rely on a transaction coordinator while non-transaction operations bypass the two-phase coor-

dination. Requiring individual *Gets* and *Puts* to use the full transaction coordination and commit protocol would have had too great of a performance impact on these frequent operations. Thus, all non-transaction operations in DynamoDB are executed directly on the storage servers for the data being accessed, while still being serialized with respect to multi-item transactions.

Transactions update items in place. Increasingly, multi-version concurrency control (MVCC) is employed in database services so that read-only transactions can access old versions of the data while transactions that write data produce new versions. DynamoDB does not support multiple versions of the same item, and adding multi-version concurrency control would have entailed major changes to the storage servers, required version retention policies, and introduced additional storage costs that would need to be passed on to our customers. The implication of a single-version store for transaction processing is that read-only and read-write transactions might conflict.

Transactions do not acquire locks. While two-phase locking is used traditionally to prevent concurrent transactions from reading and writing the same data items, it has drawbacks. Locking restricts concurrency and can lead to deadlocks. Moreover, it requires a recovery mechanism to release locks when an application fails after acquiring locks as part of a transaction but before that transaction commits. To simplify the design and take advantage of low-contention workloads, DynamoDB uses an optimistic concurrency control scheme that avoids locking altogether.

Transactions are serially ordered using timestamps. Techniques for ordering transactions based on timestamps [4] were devised decades ago. The basic idea is that each transaction is assigned a timestamp that defines its position in the serial order. As long as transactions appear to execute at their assigned time, serializability is achieved. A key innovation in the DynamoDB transaction design is extending timestamp ordering to accommodate and exploit the semantics of a key-value store.

This paper presents the DynamoDB transaction API. It also gives examples of how transactions may be used in practice. Furthermore, it illustrates the path of a transaction through the service, describes optimizations to timestamp ordering for workloads with a mix of transactions and singleton operations on a key-value store and, it reports the results of experiments run on a production system, demonstrating predictable performance and scalability.

Operation	Description
`PutItem`	Inserts a new item or replaces an old item with a new item.
`UpdateItem`	Updates an existing item or adds a new item to the table if it doesn't already exist.
`DeleteItem`	Deletes an item from the table
`GetItem`	Reads the item with a given key

Table 1: DynamoDB CRUD APIs for items

2 DynamoDB Application Programming Interface

2.1 Key-value store

DynamoDB [9] is a fully managed NoSQL database service that provides fast and predictable performance at any scale. DynamoDB was motivated by the lessons learned from Dynamo [8] and shares most of the name but little of its architecture. Customers create tables that can grow to virtually any size. A DynamoDB table is a collection of items, and each item is a collection of attributes. Each item is uniquely identified by a primary key. DynamoDB provides a simple interface to store or retrieve items from a table or an index.

2.2 Read and write operations

Table 1 contains the primary operations available to clients for reading and writing items in DynamoDB tables. Since DynamoDB is a key-value store, the most common operations used by applications are for reading an item (`GetItem`), inserting (`PutItem`), updating (`UpdateItem`), and deleting (`DeleteItem`) an item with a given key. These last three operations are collectively called *writes*. A write operation can optionally specify a condition that must be satisfied to be successful.

2.3 Transactional operations

As shown in Table 2, DynamoDB provides two operations for performing transactions: `TransactGetItems` for read transactions and `TransactWriteItems` for write transactions. These operations are submitted as a single request and either succeed or fail immediately without blocking. `TransactGetItems` and `TransactWriteItems` are executed in a serializable order with respect to other DynamoDB operations.

`TransactGetItems` retrieves the latest versions of items from one or more tables. Since it conceptually reads all of the items at a single point in time, the returned values are from a consistent snapshot. DynamoDB rejects the `TransactGetItems` request if a conflicting

```
//Check if customer exists
Check checkItem = new Check()
        .withTableName("Customers")
        .withKey("CustomerUniqueId")
        .withConditionExpression("attribute_exists(CustomerId)");

//Update status of the item in Products
Update updateItem = new Update()
        .withTableName("Products")
        .withKey("BookUniqueId")
        .withConditionExpression("expected_status" = "IN_STOCK")
        .withUpdateExpression("SET ProductStatus = SOLD");

//Insert the order item in the orders table
Put putItem = new Put()
        .withTableName("Orders")
        .withItem("{"OrderId": "OrderUniqueId", "ProductId" :"BookUniqueId", "CustomerId"
:"CustomerUniqueId", "OrderStatus":"CONFIRMED","OrderCost": 100}")
        .withConditionExpression("attribute_not_exists(OrderId)")

TransactWriteItemsRequest twiReq = new TransactWriteItemsRequest()
            .withTransactItems([checkItem,putItem, updateItem]);

//Single transaction call to DynamoDB
DynamoDBclient.transactWriteItems(twiReq);
```

Listing 1: DynamoDB Write Transaction Example

Operation	Description
`TransactGetItems`	Reads a set of items from a consistent snapshot and returns their values
`TransactWriteItems`	Performs a set of writes that include PutItem, UpdateItem, and DeleteItem operations and optionally a set of conditions
`CheckItem`	Checks that the latest value of an item matches the condition

Table 2: DynamoDB Transaction APIs

operation is in the process of modifying any item being read.

`TransactWriteItems` is a synchronous and idempotent write operation that allows multiple items to be created, deleted, or updated atomically in one or more tables. `TransactWriteItems` uses a client request token to guarantee idempotency. The transaction may optionally include one or more preconditions on current values of the items. DynamoDB rejects the `TransactWriteItems` request if any of the preconditions are not met.

To motivate the need for multi-table write transactions with preconditions, consider an online marketplace application. The application stores data in three DynamoDB tables - `Customers`, `Products`, and `Orders`. Upon registration, every customer receives a unique identifier that is used as a key in the `Customers` table which stores customer information such as customer id, customer billing and shipping address. The `Products` table contains information about the products, such as their price and availability; each product is uniquely identified by its product identifier. Orders are stored in the `Orders` table where each order has a unique identifier. A successful order requires the customer account to be verified, the product to be available and marked as sold, and the order itself to be created. These operations should be performed atomically as a single transaction. Listing 1 gives an example of a transaction that purchases a book. This transaction verifies that the customer account exists without updating any attributes in the `Customers` table using `CheckItem`, verifies the book is in stock, and marks the product as sold in the `Products` table using `UpdateItem`, and creates an entry in the `Orders` table using `PutItem`.

3 Transaction execution

3.1 Transaction routing

All operations sent to DynamoDB reach a fleet of front-end hosts called request routers. Request routers authenticate each request and route the request to the appropriate storage nodes based on the key being accessed. The mapping of key-range to storage nodes is maintained in a

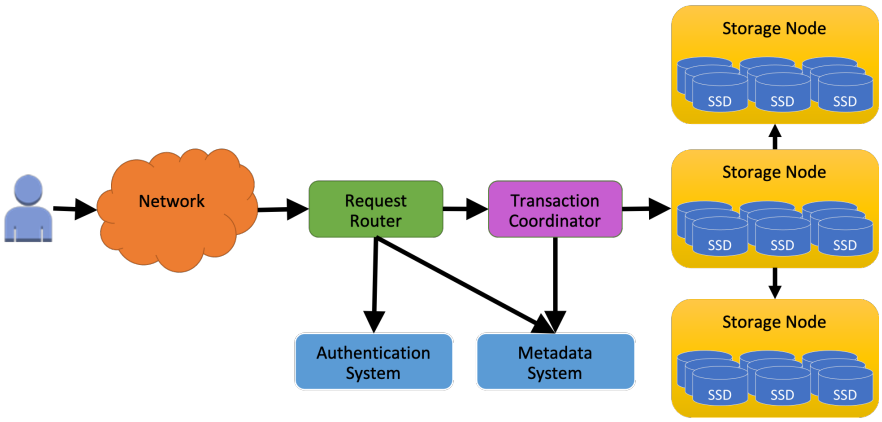

Figure 1: DynamoDB Transactions high-level architecture

metadata subsystem.

Similar to non-transactional requests, each transaction operation initially is received by a request router. The request routers performs the needed authentication and authorization of the request and forwards it to a fleet of transaction coordinators. Any transaction coordinator in the fleet can take responsibility for any transaction. The transaction coordinator breaks the transaction into item-level operations and runs a distributed protocol in which the storage nodes for these items participate. Figure 1 illustrates the high-level diagram of the components involved in the execution of a transaction.

3.2 Timestamp ordering

Timestamp ordering [4, 13] is used to define the logical execution order of transactions. Upon receiving a transaction request, the transaction coordinator assigns a timestamp to the transaction using the value of its current clock. To handle the overall transactions load, there are a large number of transaction coordinators operating in parallel, and different transaction coordinators assign timestamps to different transactions. As long as transactions appear to execute at their assigned time, serializability is achieved.

Once a timestamp has been assigned and preconditions checked, the storage nodes participating in the transaction can perform their portions of the transaction without coordination. Each storage node independently is responsible for ensuring that requests involving its items are executed in the proper order and for rejecting conflicting transactions that cannot be ordered properly.

Although serializability holds even if the transaction coordinators do not have synchronized clocks, more accurate clocks result in more successful transactions and a serialization order that complies with real time. The clocks in the coordinator fleet are sourced from the AWS time-sync service [1], thus keeping them closely in sync (within a few microseconds). However, even with perfectly synchronized clocks, transactions can arrive at storage nodes out-of-order due to message delays in the network, failures and recovery of transaction coordinators, and other system issues. Storage nodes deal with transactions that arrive in any order using stored timestamps.

3.3 Write transaction protocol

A two-phase protocol ensures that all of the writes within a transaction are performed atomically and in the proper order. To achieve atomicity, the transaction coordinator prepares all items in the first phase. In the second phase, if all the storage nodes accept the transaction, then the transaction coordinator commits the transaction and instructs the storage nodes to perform their writes. If any of the storage node cannot accept the transaction, then the transaction coordinator will cancel the transaction. Listing 2 shows the pseudo code for the `TransactWriteItem` protocol.

To implement timestamp ordering for write transactions, DynamoDB records the timestamp of the write operation with every item. All write operations including singleton writes and writes within `TransactWriteItems` update the item timestamp.

Storage nodes also persist per-transaction metadata for each in-flight transaction, including the transaction's identifier and timestamp. This metadata is attached to items that are part of the transaction and remain with the items during partition-related changes, such as split. This ensures that such changes do not interfere with transactions and can happen in parallel. This information about a transaction is updated and checked during the two-phase protocol and can be discarded once the transaction has completed.

In the prepare phase of the protocol, the transaction coordinator sends a message to the primary storage nodes for the items being written. This prepare message in-

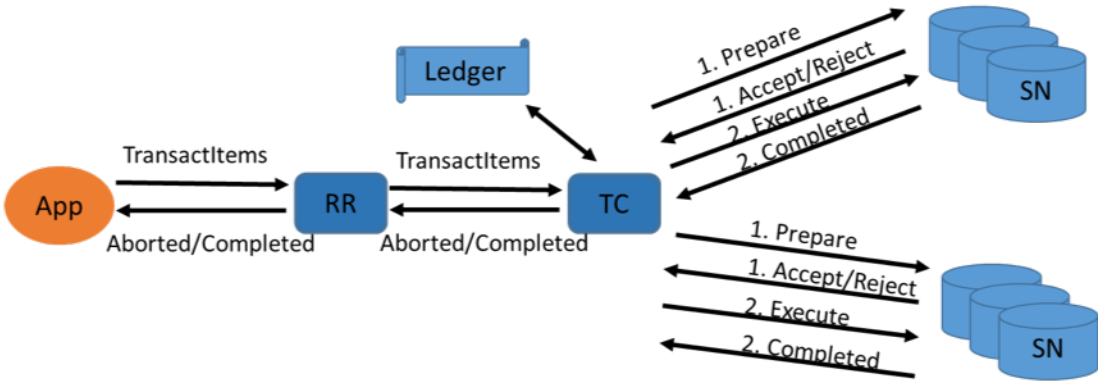

Figure 2: Two-phase protocol

```
TransactWriteItem(TransactWriteItems input):
  #Prepare all items
  TransactionState = PREPARING
  for operation in input:
       sendPrepareAsyncToSN(operation)

  waitForAllPreparesToComplete()

  #Evaluate whether to commit or cancel the
  transaction
  if all prepares succeeded:
     TransactionState = COMMITTING
     for operation in input:
        sendCommitAsyncToSN(operation)
     waitForAllCommitsToComplete()
     TransactionState = COMPLETED
     return SUCCESS
  else:
     TransactionState = CANCELLING
     for operation in input:
        sendCancellationAsyncToSN(operation)
     waitForAllCancellationsToComplete()
     TransactionState = COMPLETED
     return ReasonForCancellation
```

Listing 2: `TransactWriteItem` protocol

cludes the transaction timestamp, transaction ID, and the operation that the transaction intends to perform on the item. The storage node accepts the transaction if all of the following criteria are true for every local item that is part of the transaction:

- All preconditions on the item are met.
- Writing the item would not violate of any of the system restrictions such as exceeding the maximum item size.
- The transaction's timestamp is greater than the item's timestamp indicating when it was last written.
- The set of previously accepted transactions that are attempting to write the same item is empty.

Listing 3 shows the pseudo code for prepare phase of the `TransactWriteItem` protocol. Note that these last two conditions are correct but over restrictive and can be relaxed as discussed in the next section.

If the transaction is accepted by all the participating storage nodes, then the transaction coordinator will commit the transaction. If the transaction is not accepted by any of the participating storage nodes, then the transaction coordinator will cancel the transaction. After the decision has been made to commit the transaction, each participant storage node performs the desired writes on its local items and records the timestamp of the transaction as the items' last write timestamp. Items for which a precondition was checked but that are not being written also have their timestamps updated. Listing 4 shows the pseudo code for commit/cancel phase of the `TransactWriteItem` protocol.

After all participant storage nodes have executed the commit or cancellation, the transaction coordinator responds to the request router with a "completed" message and whether the transaction successfully committed. The request router forwards this response to the customer.

Items that have been deleted require special handling since, once they are deleted, there is no longer a last write timestamp. Instead of maintaining tombstones for deleted items, which would incur both a high storage cost and garbage collection cost if items are frequently created and deleted, DynamoDB stores a partition-level max delete timestamp. When an item is deleted, if the deleting transaction's timestamp is greater than the current max delete timestamp, then the max delete timestamp is set to the transaction's timestamp. When a storage node receives a prepare message for a write to a non-existent item, it compares the new transaction's timestamp against the maximum delete timestamp to decide whether to accept or re-

```
def processPrepare(PrepareInput input):
  item = readItem(input)

  if item != NONE:
    if evaluateConditionsOnItem(item, input.conditions)
      AND evaluateSystemRestrictions(item, input)
      AND item.timestamp < input.timestamp
      AND item.ongoingTransactions == NONE:
        item.ongoingTransaction = input.transactionId
        return SUCCESS
    else:
        return FAILED
  else: #item does not exist
    item = new Item(input.item)
    if evaluateConditionsOnItem(input.conditions)
      AND evaluateSystemRestrictions(input)
      AND partition.maxDeleteTimestamp < input.timestamp:
        item.ongoingTransaction = input.transactionId
        return SUCCESS
  return FAILED
```

Listing 3: `TransactWriteItem` protocol - Prepare phase

ject the transaction. Storing the max delete timestamp at a partition level provides a correct and efficient solution. In the current approach, transactions may be cancelled in instances where they would not have been cancelled if tombstones were maintained for deleted items. Though in practice, an insignificant percentage of transactions are cancelled due to the transaction's timestamp being lower than the partition's maximum delete timestamp.

3.4 Read transaction protocol

Read transactions are also performed using a two-phase protocol, though in a different manner from write transactions and from other systems. The standard timestamp ordering scheme maintains a read timestamp on each item. Updating this timestamp for operations in a read transaction would have turned every read into a more costly write operation on persistent, replicated data. To avoid this latency and cost, DynamoDB devised a two-phase writeless protocol for executing read transactions.

In the first phase of the protocol, the transaction coordinator reads all the items that are in the transaction's read-set. If any of these items are currently being written by another transaction, then the read transaction is rejected; otherwise, the read transaction moves to the second phase. In its response to the transaction coordinator, the storage node not only returns the item's value but also its current committed log sequence number (LSN). The current committed LSN of the item is the sequence number of the last write that the storage node performed and acknowledged to the client. The LSN increases monotonically.

In the second phase, the items are read again. If there have been no changes to the items between the two phases, namely the LSNs have not changed, then the read transaction returns successfully with all of the item values that were fetched. In the case where an item has been updated between the two rounds of the protocol, the read transaction is rejected.

In both failure and success cases, the storage node returns the LSN. By doing so, the transaction coordinator is able to redrive another round of reads for all items without having to restart the entire transaction. In the event that the item is being prepared by a write transaction, the storage node simply rejects the read.

3.5 Recovery and fault tolerance

Since DynamoDB automatically recovers from storage node failures, such failures are of no concern to the transaction protocol. If a storage node that is the primary for an item fails, then leadership will fail over to another storage node that is part of that item's replication group. The metadata about transactions that had been accepted by the previous primary node is persistently stored and replicated within the group, and so is immediately available to the new primary. Transaction coordinators when continuing the transaction protocol are not even aware that they may be communicating with a different set of participating storage nodes.

Transaction coordinator failures are of greater concern. Transaction coordinators can fail because of hardware or software issues. To ensure atomicity of transactions and that transactions complete in the face of failures, coordinators maintain a persistent record of each transaction and its outcome in a ledger. A recovery manager peri-

```
def processCommit(CommitInput input):
  item = readItem(input)

  if item == NONE
    OR item.ongoingTransaction != input.transactionId:
    return COMMIT_FAILED

  applyChangeForCommit(item, input.writeOperation)
  item.ongoingTransaction = NONE
  item.timestamp = input.timestamp
  return SUCCESS

def processCancel(CancellationInput input):
   item = readItem(input)

   if item == NONE
    OR item.ongoingTransaction != input.transactionId:
      return CANCELLATION_FAILED

   item.ongoingTransaction = NONE

   #item was only created as part of this transaction
   if item was created during prepare:
       deleteItem(item)

   return SUCCESS
```

Listing 4: `TransactWriteItem` protocol - Commit/Cancel phase

odically scans the ledger looking for transactions that have not yet been completed (and for which a reasonable amount of time has passed since the transaction was received). Such *stalled* transactions are assigned to a new transaction coordinator who resumes executing the transaction protocol. In the case where a transaction coordinator is incorrectly determined to have failed and its transaction reassigned, it is okay for multiple coordinators to be finishing the same transaction at the same time since duplicate attempts to write an item are ignored by its storage node.

When the transaction has been fully processed, a *completed* record is written to the ledger indicating that no further work is required. Information about a transaction can be purged from the ledger when it has been completed, though retaining these records turns out to be useful for monitoring and debugging.

The transaction ledger is a DynamoDB table with transaction identifiers as the key. Multiple recovery managers regularly scan the ledger in parallel for stalled transactions that must be resumed. Each recovery manager starts its scan of the table from a random key and scans up to thousands of transactions.

Storage nodes also invoke recovery when local items have stalled transactions. If a storage node receives a write or read for an item that is already being written by another transaction, then it checks to see if the pending transaction on the item may have stalled. If the accepted transaction has a timestamp that is older than some threshold, the storage node sends a message with the key for the item and the pending transaction id. The recovery manager receiving this message checks the ledger for the state of the transaction and, if the transaction has not been completed, resumes its execution.

4 Adapting timestamp ordering for key-value operations

The classic timestamp ordering concurrency control scheme [4, 13] can be extended with novel optimizations when applied to a key-value store where reads and writes of individual items are mixed with multi-item transactions. Individual key `get` and whole item `put` operations can be added to an ordered execution history, while allowing for increased concurrency and the ability to execute operations out of order. We have implemented some of these techniques in DynamoDB and others we plan to integrate as we hear more feedback from our customers. This section describes our innovations on timestamp ordering along with the benefits.

Reads to individual items can always be performed successfully even if there is a prepared transaction that is attempting to write that item. A `get` operation that is not part of a transaction is routed directly to a storage node that is responsible for the key of the item being read, bypassing transaction coordinators. The contacted storage

node immediately returns the latest stored value regardless of whether a prepared transaction may later overwrite the item. Implicitly, this `get` operation is assigned a read timestamp that is later than the write timestamp on the stored item and before the commit timestamp of the prepared transaction. In other words, the read is serialized between the last completed write and the pending transaction.

Writes to individual items can be performed immediately and serialized before any prepared transactions in many cases. Non-transactional `put` requests are also directly routed to the storage nodes for the item being written. The primary storage node assigns a write timestamp that is earlier than the timestamps of any transactions in the prepared state. Note that a prepared transaction has not yet performed its intended write to the item, and thus it is okay for a received put to jump ahead of such a transaction in the serialization order. The same holds for individual modify and delete operations that are received directly by storage nodes. The outcome of such operations will likely be overwritten by a prepared transaction if and when it commits. There is one case where a single-item write cannot jump ahead of a previously prepared transaction, namely when a condition on the item had been checked during the process of preparing the transaction and the newly received write operation may violate that condition. For example, suppose that a write transaction is attempting to withdraw 100 dollars from a bank account and it includes a pre-condition to ensure that the current balance contains sufficient funds. If this transaction is in the prepared state, and its condition has been verified, then the system cannot allow another withdrawal that reduces the balance below 100 dollars to jump ahead of the prepared transaction. Nor can the system permit the item to be deleted. In general, it is challenging for storage nodes to determine whether a previously checked arbitrary condition might be violated by a newly received write. However, doing so for common conditions, like numerical bounds checking, could substantially reduce rejected write operations in contentious workloads.

Writes to individual items can be performed immediately or delayed and serialized after any prepared transactions in other cases. Even if a newly arriving single item write operation violates a checked condition for a prepared transaction, the storage node need not reject the write. The storage node can buffer the write operation until the transaction completes. Note that an already prepared transaction is expected to commit or cancel quickly. Waiting for the transaction is not likely to add significant delay to new write operations and the added delay is typically less than rejecting the write and requiring the client to resubmit it. Once the transaction is completed, a queued write operation can be assigned a later timestamp and serialized after the transaction. As a further optimization, if the storage node receives a put or delete operation that has no precondition, then this operation can be assigned a write timestamp that is later than that of any previously prepared transactions and can be performed immediately. If and when a prepared transaction with an earlier timestamp commits, its writes will be ignored.

Write transactions can be accepted even with an old timestamp. If a write operation that is part of a transaction arrives at a storage node that has already performed a write (either an individual put or transactional put operation) with a later write timestamp, this transaction can still be accepted and enter the prepared state. If this transaction is committed, its write operation is ignored with the observation that, even if performed earlier, it would have been completely overwritten by the later put operation. This argument does not hold if the last write was a modify operation that partially updated the item's contents. The benefit of accepting a transaction with an old timestamp, although it has no effect on some items being written, is that the transaction may contain write operations on other items that are allowed to complete.

Multiple transactions that write the same item may be prepared at the same time. A storage node that has already prepared a transaction can accept a second transaction that is attempting to write the same item. That is, for any given item, a series of transactions that are writing the item may enter the prepared state before any of those transactions commit and perform their writes. If the transactions contain `put` operations that fully overwrite the item's contents (or `delete` operations), then the transactions can actually commit in any order as long as the `put` (or `delete`) of the transaction with the latest timestamp is the last one to be performed. Transactions with modify operations that perform partial updates must execute in their assigned timestamp order since the final value of the item depends on the sequence of execution.

Read transactions can be executed in a single round rather than using a two-phase protocol. A transaction that reads multiple items could complete in a single phase as follows. Suppose that storage nodes supported a variant of the GetItem operation, called *GetItemWithTimestamp*, that takes a read timestamp as a parameter in addition to a primary key. This *GetItemWithTimestamp* operation returns the latest value of the item if its last write timestamp is earlier than the given read timestamp and if any prepared transactions have later timestamps, and otherwise rejects the request. When presented with a new read transaction, the transaction coordinator assigns a timestamp for the transaction and calls *GetItemWithTimestamp* in parallel for each item that is being read. The coordinator buffers the item values that are fetched. If none of the storage nodes reject the `get` call for having an old timestamp, then the coordinator returns the set of

buffered values as the response to the read transaction call; otherwise, it returns an exception. This approach is optimistic in that a concurrent write to any one of the items being read could cause the transaction to be rejected. While conceptually simple, there is a subtle potential problem with this approach, namely the storage node could later accept a write with a timestamp that is earlier than that of the previously executed read transaction. That could cause a subsequent read-only transaction to not be serializable with respect to a previously executed transaction. This is a well-known issue with timestamp ordering and is avoided by having storage nodes maintain a timestamp recording when each item was last read in addition to the last write timestamp. Storage nodes would then require future write transactions to have timestamps that are later than both the previous read and write timestamps on all items being written.

Transactions that write multiple items in a single partition can be executed in a single round rather than using a two-phase protocol. If all of the items that are being written in a transaction happen to reside in the same partition, and hence are stored on the same storage nodes, then the transaction does not require separate prepare and commit rounds. Since there is only one primary storage node participating in the transaction, it can perform all of the pre-condition checks that are required to accept the transaction and then immediately perform the write operations. The contacted storage node informs the transaction coordinator whether the transaction completed successfully.

5 Experiments

This section presents our findings about the performance of transaction requests along various dimensions, such as request rate, transaction size, and contentious workloads.

5.1 Comparison of latencies for varying throughput of transactions

We conducted an experiment that scaled up the transaction request rate while maintaining the same number of operations per transaction to demonstrate that scale has a minimal effect on the latency of transactions in DynamoDB. There were three workloads in this experiment: one with fifty percent writes and fifty percent reads, one with one hundred percent reads, and one with one hundred percent writes. A uniform key distribution and an item size of 900 bytes were used in these tests. Workloads were scaled from 100 thousand to 1 million operations per second. Note that 1 million operations per second are not same as 1 million transactions per second, as each transaction consists of 3-operations. Figure 3 and Figure 4 shows the 50th and 99th percentile performance of

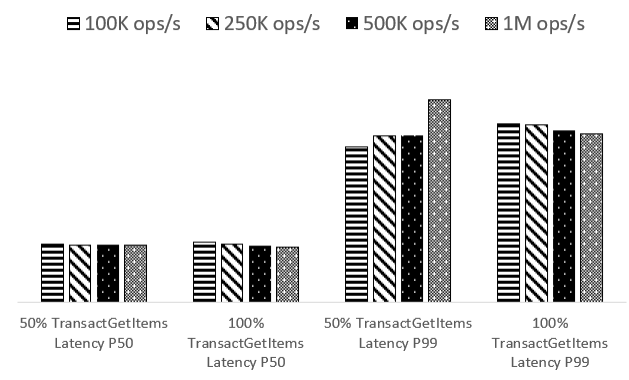

Figure 3: Comparison of `TransactGetItems` latencies for varying throughput

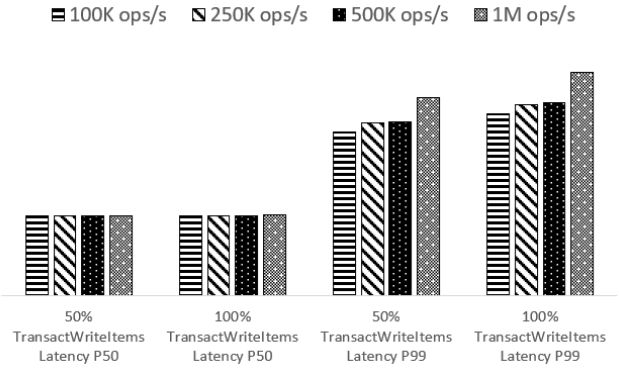

Figure 4: Comparison of `TransactWriteItems` latencies for varying throughput

`TransactGetItems` and `TransactWriteItems` operations for each workload. With the increase in throughput, both `TransactGetItems` and `TransactWriteItems` exhibit negligible variances at P50. The latency increases slightly at P99 as the request rate increases; this is due to increased java garbage collection on the transaction coordinators when the load is heavier.

5.2 Comparison of latencies for varying number of operations per transaction

We conducted an experiment to evaluate the impact of transaction size on performance by varying the number of read and write operations per transaction while maintaining a constant total number of operations. The same uniform key distribution and items of 900 bytes were used as the previous test. Workloads ranged from accessing 3 to 100 items per transaction at a constant rate of 1 million items per second.

Figure 5 and Figure 6 show the performance of the read and write transactions for the various workloads at

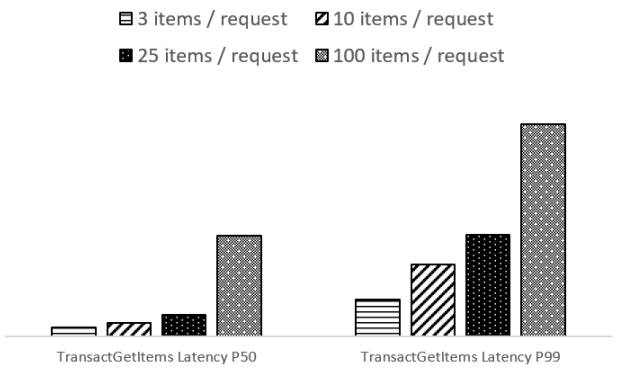

Figure 5: Comparison of latencies for varying number of operations per `TransactGetItems` request

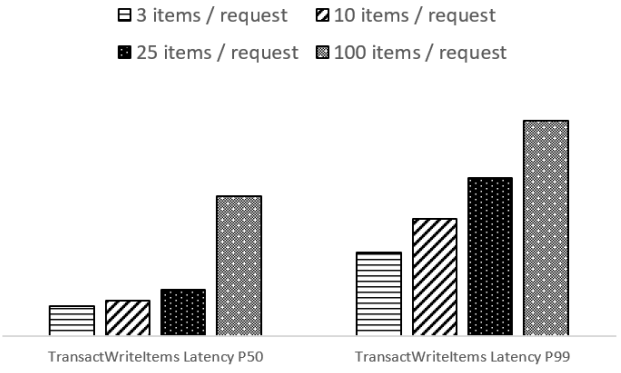

Figure 6: Comparison of latencies for varying number of operations per `TransactWriteItems` request

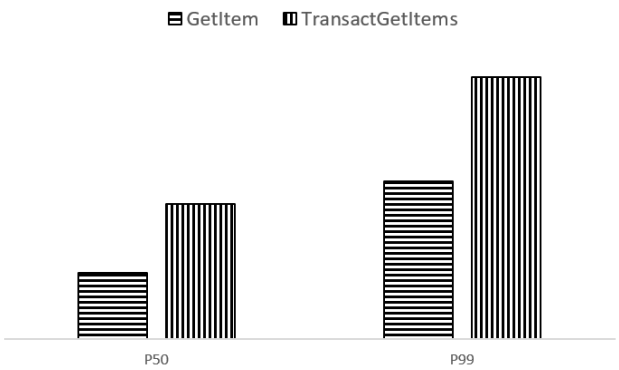

Figure 7: Comparison of latencies for `GetItem` vs single operation `TransactGetItems` request

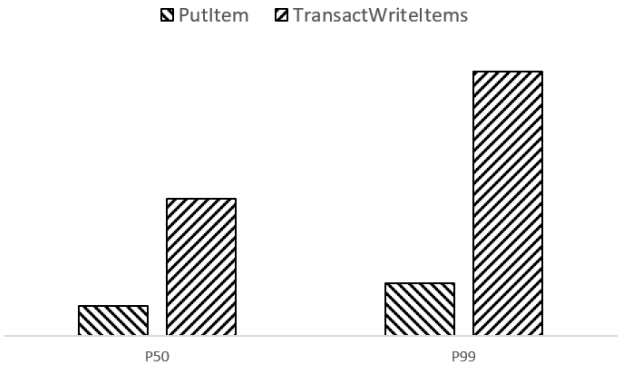

Figure 8: Comparison of latencies for `PutItem` vs single operation `TransactWriteItems` request

the 50th and 99th percentiles. As the number of operations in each transaction increases, so does the latency. Although reads and writes to items within a transaction are processed in parallel, the latency of the transaction request is determined by its slowest operation. Transactions that involve a greater number of operations are more likely to experience a slow read or write. Additionally, the latency of `TransactWriteItems` is determined by the time it takes to persist the request to the ledger. Larger requests take longer to write to the ledger. Also, large transactions result in a larger message payload for the request, which takes longer to travel over the network between the request router and transaction coordinator.

5.3 Comparison of latencies for transactions vs non-transactions

To examine the performance of transactions vs non-transactional requests to DynamoDB, we conducted an experiment comparing the performance of single operation transactional reads and writes against non-transactional singleton reads and writes. For this experiment, we ran tests that submitted 100 thousand requests per second for each of the following DynamoDB APIs; `TransactWriteItems` (transactional write), `TransactGetItems` (transactional read), `PutItem` (singleton non-transactional write), and strongly consistent `GetItem` (singleton non-transactional read). Each request accessed a 900 byte item using the same uniform key distribution that was used in the previous experiment.

Figure 7 shows the performance of single operation transactional vs non-transactional reads at the 50th and 99th percentile. Latency for read transactions is slightly less than 2x the latency for non-transactional reads, on account of the two consistent reads that are required as part of the `TransactGetItems` protocol.

Figure 8 shows the performance of single operation transactional vs non-transactional writes at the 50th and 99th percentiles. Latency for write transactions is about 4x the latency of non-transactional writes. This is as a result of the two-phase write protocol being executed

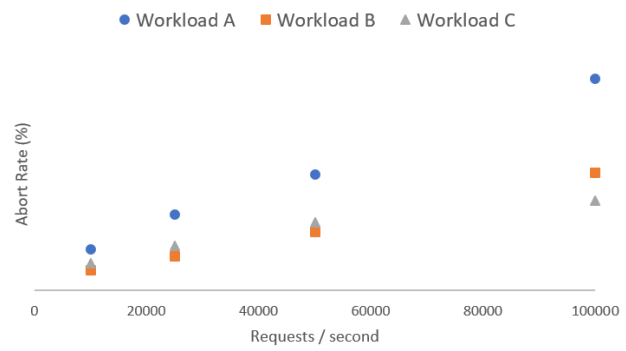

Figure 9: Cancellation rates for workloads with *contention index = 0.001*

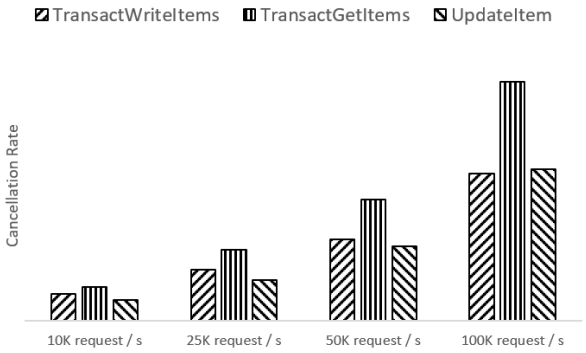

Figure 11: Cancellation rates for workload C with *contention index = 0.001*. Note: each request type represents an equal portion of total traffic

on each `TransactWriteItems` request, with additional overhead being added for writing and checkpointing the transaction state to the Transaction Ledger.

5.4 Comparison of cancellation rate for varied contentious workloads

To examine the performance of transactions on contentious workloads, we ran an experiment with a fixed pool of *hot* items while scaling up throughput. Contention arises when multiple transactions are concurrently trying to access the same items(which are referred to as *hot* items). In this context, a *contention index* [16] refers to the fraction of *hot* items that are accessed by a given transaction. For these experiments, throughput was scaled from 10 thousand to 100 thousand transactions per second with a fixed contention index of 0.001, which indicates that each transaction accesses one of one thousand *hot* items [16]. The experiments ran with three different workloads: workload A consists of write transactions only, workload B consists of 50% write transactions + 50% read transactions, and workload C consists of transactions + non-transactions operations (25% write transactions, 25% read transactions, 25% non-transaction writes, 25% non-transaction consistent reads). Each transaction accesses 10 items with one of the items being from the *hot* item pool and the remaining 9 items being from a much larger set of keys. For non-transaction reads and writes, each item is chosen from the *hot* item pool. For each test, we measured the cancellation rate, which is the percentage of requests that were rejected because of a conflict with another transaction on a given item.

Figure 9 reports the cancellation rates for the workloads with *contention index = 0.001*. For all workloads, the cancellation rate increases with the transaction request rate. As each item can only be acted upon by a single transaction at a time, the level of contention and the cancellation rate rise when more transactions include operations on the pool of *hot* items. Workload A, write transactions only, had the highest rate of cancellations for all transaction requests rates. Comparatively, workload B, with 50% write transactions and 50% read transactions, had about half the cancellation rate as workload A at all levels of throughput. The cancellation rates are lower for workload B as read transactions cannot be the source of conflict.

A `TransactGetItems` operation will be cancelled (rejected) if any item being read has a write transaction in progress or if the item has changed between the two phases, but will not trigger a cancellation of any other operation. Moreover, figure 10 highlights that read and write transactions were cancelled at similar rates for workload B at all throughput levels with both types of transactions only getting cancelled if there was an ongoing write transaction on the targeted item.

Workload C had the lowest cancellation rates at all throughput levels, as a result of having fewer sources of conflict than the other workloads. Figure 11 provides a

breakdown of cancellation rates by operation type for workload C. `GetItem` (non-transaction reads) had no cancellations at all throughput levels as they are serializable with transactions and do not get rejected; if a `GetItem` request is received while a write transaction is in progress on a given item, the `GetItem` will read the current item value without conflict. Both `UpdateItem` (non-transaction writes) and `TransactWriteItems` (write transactions) have comparable cancellation rates as these requests will only be cancelled because of a conflict if there is an ongoing `TransactWriteItems` operation on the targeted items. Finally, `TransactGetItems` (read transactions) had the highest cancellation rate of any operation during this test since read transactions execute optimistically and conflict with any concurrent write.

6 Related work

A growing number of NoSQL databases have added support for transactions in recent years. Each of these systems choose different tradeoffs, resulting in a variety of isolation levels, expressiveness, and relationships with non-transactional writes [3, 5, 12, 14–17].

Many of the systems use a two-phase commit protocol that is similar to DynamoDB's protocol. G-store [7] and L-store [11] are two examples of systems that propose an alternative to two-phase commit protocols. They avoid the two-phase commit protocol by co-locating all the keys of the transaction on the node that processes the transaction and executing the transaction on that single node.

Some systems use locks [2, 16] for concurrency control, while others use timestamps. Different systems use various sources of time, including precise clocks [5], local nodes' clocks, and hybrid logical clocks [10]. Granola [6] is an example of system that uses both locks and timestamps for concurrency control; a transaction is executed either in locking mode or timestamp mode.

7 Conclusion

Adding transactions to DynamoDB without impacting the scale, availability, durability and predictability that customers have come to expect was a daunting task. Instead of the limited form of transactions provided in previous systems, customers asked for full ACID transactions updating multiple items from different partitions of the same table or across different tables. Working backwards from customer scenarios informed us that long running transactions were not required and that the workloads were not highly contentious. We designed transactions as single-shot operations with optimistic concurrency control using timestamp ordering to ensure that transactions are both serializable and scalable. This work shows that transactions implemented in a replicated and partitioned NoSQL database can be achieved with high scalability, high availability, and predictable performance.

8 Acknowledgements

DynamoDB transactions have been greatly influenced by the invaluable feedback of our customers, driving us to innovate on their behalf. We are fortunate to be accompanied by an exceptional team throughout this journey. We express our appreciation to Shawn Bice, Andrew Certain, Raju Gulabani, Amit Gupta, Rishabh Jain, Vaibhav Jain, Nate Riley, Tony Petrossian, Amit Purohit, Julien Ridoux, Rashmi Krishnaiah Setty, Stefano Stefani, Benjamin Wood, Ming-Chuan Wu, and the entire DynamoDB team for their contributions that have been instrumental to the success of this project. We are grateful to the anonymous reviewers and our shepherd, Leonid Ryzhyk, for their invaluable contributions in refining this paper. Special thanks to Chris Andreson, Darcy Jayne, and Murat Demirbas for going the extra mile to provide valuable assistance.

Prefix Siphoning: Exploiting LSM-Tree Range Filters For Information Disclosure

Abstract

Key-value stores typically leave access control to the systems for which they act as storage engines. Unfortunately, attackers may circumvent such read access controls via *timing attacks* on the key-value store, which use differences in query response times to glean information about stored data.

To date, key-value store timing attacks have aimed to disclose stored values and have exploited external mechanisms that can be disabled for protection. In this paper, we point out that *key* disclosure is also a security threat—and demonstrate key disclosure timing attacks that exploit mechanisms of the key-value store itself.

We target LSM-tree based key-value stores utilizing *range filters*, which have been recently proposed to optimize LSM-tree range queries. We analyze the impact of the range filters SuRF and prefix Bloom filter on LSM-trees through a security lens, and show that they enable a key disclosure timing attack, which we call *prefix siphoning*. Prefix siphoning successfully leverages benign queries for non-present keys to identify prefixes of actual keys—and in some cases, full keys—in scenarios where brute force searching for keys (via exhaustive enumeration or random guesses) is infeasible.

1 Introduction

Key-value stores serve as the storage engines of many cloud and enterprise systems, from object caches [44,46,47] through stream processing [6,14,54] to database systems [2,29,31,41]. Performance of these modern data intensive systems often depends on their key-value storage engine's performance [51]. Consequently, research on key-value stores overwhelmingly focuses on *efficiency*: from I/O efficiency of writes [20,21], point queries [18,19], and range queries [45,65] to memory efficiency [24,43], energy efficiency [5], multi-core scalability [37,58], and reducing I/O write amplification [51].

But systems also depend on their key-value storage engine for the *security* of stored data. This dependency is not obvious, because key-value stores typically provide only a dictionary abstraction without access control mechanisms [16,30,38,40], leaving access control to the system. Systems enforce access control by mediating user accesses to the key-value store, often based on access control lists (ACLs) stored as value metadata in the key-value store. While this approach blocks users from directly making unauthorized queries, users may still be able to indirectly glean information about restricted data if the key-value store is vulnerable to *timing attacks* [11].

A timing attack exploits differences in query response times to glean information about stored data. A system using a key-value store that is vulnerable to timing attacks can itself become vulnerable to such attacks, because the system's query response time depends on the storage engine's response time, making differences in key-value query response times manifest as differences in the system's response times.

To date, key-value store timing attacks [55,56] have aimed to disclose stored values. We point out, however, that *key* disclosure is also a security threat. In some systems, keys can *explicitly* contain secret data. For example, database systems that use key-value storage engines (e.g., CockroachDB, YugabyteDB, or MyRocks) encode rows (or subsets of rows) onto keys [7,26,28,32]. This makes key disclosure equivalent to database data disclosure. Keys may also be *implicitly* secret, with users expecting them to be hard to obtain. For instance, in object storage systems, such as Amazon S3, identifying valid keys may create an insecure direct object reference vulnerability [48], which enables attackers to probe access to the objects associated with the disclosed keys.

Unfortunately, resilience to timing attacks is not a goal in existing key-value efficiency work—in fact, such resiliency can be at odds with improved performance. In this paper, we demonstrate this trade-off: we analyze key-value store performance mechanisms through a security lens and show that they enable a key disclosure timing attack.

We focus on write-optimized key-value stores based on log-structured merge (LSM) trees [49], which are in widespread use [12,13,15,18,20,22,30,37,42,51,57,60]. In these designs, data in secondary storage consists of multiple immutable files called *SSTables*. LSM-trees can efficiently sustain write-intensive workloads, but queries may require multiple I/Os to search the many SSTables [49,57]. LSM-trees minimize unnecessary I/Os by issuing the I/O only if the queried key is likely to be in the SSTable. Likelihood is determined by querying an in-memory *filter* [10], which space-efficiently *approximately* represents the SSTable's contents. Specifically, filter queries can make "one-sided" errors: if the queried key is present in the SSTable, then the filter always returns true; but for a small fraction of non-present keys, the filter might return a false positive response.

Standard filters can answer point (single-key) queries [8,10,33], but do not support range queries of the form "does the

*Both authors contributed equally to this research.

SSTable contain a key in range $[X,Y]$." Consequently, LSM-tree range queries must search the many SSTables, performing multiple superfluous I/Os [65]. To address this problem, recent work has proposed *range filters*, which are filters that support range queries in addition to point queries. Range filters such as SuRF [65] and RocksDB's prefix Bloom filter (PBF) [25] compactly store some or all prefixes of each of the SSTable's keys, and leverage this information to answer range and point queries.

From a security perspective, however, we show that *certain range filters enable a key disclosure timing attack on LSM-trees*. We describe an attack framework, called *prefix siphoning*, which exploits general range filter characteristics present in both SuRF and PBF. Prefix siphoning successfully leverages benign point queries for non-present keys to identify prefixes of actual keys—and in some cases, full keys—in scenarios where brute force searching for keys (via exhaustive enumeration or random guesses) is infeasible.

Prefix siphoning targets systems with the common design paradigm of storing a key's ACLs as part of its value [1, 4], which means that to check access permissions, the system's query handling always tries to read the queried key's value from the key-value store. Prefix siphoning exploits this property to determine if a random key is one on which the LSM-tree's filter returns a false positive. This is possible because whether the filter returns true or false can be determined by the attacker observing the query's response time, as the filter's response decides whether the LSM-tree performs I/Os. For range filters meeting our characterization, finding a false-positive key implies that the false-positive key shares a prefix with some stored key. Prefix siphoning then performs further point queries—tweaking the queried key—to maximize the length of the disclosed prefix. Prefix siphoning can sometimes subsequently perform a limited enumeration search to fully identify the stored key. Our prefix siphoning implementation performs multiple such steps concurrently, ultimately extracting multiple keys or prefixes.

We evaluate prefix siphoning against SuRF and PBF analytically as well as empirically and demonstrate its feasibility in practice. For example, we successfully use prefix siphoning to extract 64-bit stored keys from a RocksDB [30] datastore employing SuRF in minutes, whereas brute force search of this key space is infeasible. Our analysis and evaluation also quantify the cost of prefix siphoning, showing that it effectively reduces the key search space size by multiple orders of magnitude. For instance, SuRF prefix siphoning requires ≈ 10 M queries to disclose a key from a 50 M 64-bit key dataset—implying a $40992\times$ reduction of the key search space size.

Our results draw attention to the security vs. performance trade-offs in key-value store design, and encourage practitioners and researchers to evaluate the security impact of their work. We hope that our characterization of vulnerable range filters will spur research on more secure filters.

2 Background

This section provides background on key-values stores (§ 2.1), LSM-trees (§ 2.2), and filters (§ 2.3).

2.1 Key-value stores

A key-value store exposes a dictionary-like abstraction with the following operations.

- *put*(k,v). A *put* stores a mapping from key k to value v. If key is already present in the store, its value is updated.
- *get*(k). The *get()* (or point query) returns the value associated with the requested key.
- *range_query*(k_1,k_2). A range query returns all key-value pairs falling within the given range.

Due to their simple and general abstraction as well as high performance, key-value stores serve as the storage engines for many, more complex systems. Examples of such systems include database systems (e.g., Cassandra [42], MongoDB [2], and MySQL [3]) and storage systems (e.g., CEPH [1]).

2.2 LSM-based data stores

The log-structured merge (LSM) tree [49] is a popular choice as the core storage structure for write-optimized key-value stores, which must sustain write-intensive workloads. An LSM-tree consists of levels, each of which contains multiple immutable static sorted table (SSTable) files storing key/value pairs. Two SSTs at the same level never overlap in the key range they store, but SSTables at different levels may overlap.

A *put* request inserts the key-value pair into an in-memory buffer called the Memtable, which is the LSM-tree's only mutable storage object. Once the Memtable fills up, its data is flushed to secondary storage as an SSTable file. The LSM-tree periodically performs *compaction*, where it unifies SSTs between levels to eliminate duplicate (stale) key-value pairs.

A *get* query searches for the target key in a top-down manner: first in the Memtable and subsequently in the relevant SSTable (if it exists) in each level. Searching an SSTable requires I/Os to read it from secondary storage. Once the key is found, its value is returned and the query completes.

However, this design penalizes queries, which may require multiple I/Os to search many SSTables [49, 57]. In particular, a *get()* for a *non-present* key (not associated with any value) searches every level before failing. This not only increases the query response time, but may "thrash" the page cache by reading in many SSTables which will not be accessed later.

LSM-trees minimize unnecessary I/Os by issuing the I/O only if the queried key is likely to be in the SSTable. Likelihood is determined by querying an in-memory filter (described in § 2.3), which space-efficiently *approximately* represents the SSTable's contents. The LSM-tree only reads an SSTable from secondary storage if its filter returns true for

the queried key. As a result, most non-present key queries can respond without performing I/Os.

Likewise, a range filter (§ 2.3.1) can answer both point and range queries with one-sided errors. Using a range filters instead of a standard filter enables an LSM-tree to avoid superfluous I/Os also for range queries, which can improve range query throughput by orders of magnitude [45].

2.3 Filters

A *filter* [10] is a data structure used to approximately represent a set D a of keys. A filter can be *immutable* or *dynamic*. An immutable filter is provided D upon its creation and can subsequently only be queried. A dynamic filter learns D dynamically, via *insert* operations.

Responses for filter queries allow "one-sided" errors: if $k \in D$, then a query for k returns true; but for a fraction of keys $k \notin D$, a query for k might answer true instead of false. We say k is a *positive/negative key* if a filter a query for k answers true or false, respectively. A positive key k is a *false positive* if $k \notin D$. We also say that the filter *passes* positive keys and *rejects* negative keys.

Filters are compared by their space efficiency and false-positive rates. Space efficiency is measured in bits per key. The *false-positive rate* (FPR) of a filter is the probability over keys not in D of being a false positive. I.e., $FPR = FP/(FP+NK)$, where FP is the number of false-positive keys and NK is the number of negative keys. Filters typically have configurable FPRs, with lower FPRs requiring more bits per key for increased accuracy [8, 10, 33].

Bloom filters A Bloom filter [10] is a widely-used dynamic filter (e.g., the default filter of RocksDB). It consists of an m-bit array and j hash functions $H_1, \ldots, H_j$. The parameters m and j determine the filter's FPR and space. Insertion of key k sets the bits indexes $H_1(k), \ldots, H_j(k)$. A query for k returns true if and only if all bit indexes $H_1(k), \ldots, H_j(k)$ are set.

2.3.1 Range filters

A *range filter* is a filter that also supports range queries with one-sided error: a query for $[a,b]$ returns true if there exists $k \in D \cap [a,b]$, but might also return true if $D \cap [a,b]$ is empty.

3 Motivation: avoiding key disclosure

We observe that keys stored in a key-value storage engine can contain sensitive data. It is therefore desirable that users are not able to efficiently discover stored keys that they are not authorized to access. Of course, users can always guess such keys and check if their queries return an authorization error, but such brute force searches are infeasible on large key spaces. The goal is for brute force search to be the only attack option, i.e., to block more efficient key extraction attacks.

Explicitly secret keys Some systems encode secret data in stored keys, which makes key disclosure equivalent to disclosure of the encoded data. For example, database systems such as CockroachDB, YugabyteDB, and MyRocks store table rows as values in a key-value storage engine, with the associated key consisting of the table's id and the row's primary key (one of the cell values). The motivation for this technique is that it enables the database system to perform efficient primary key lookups using key-value store range queries [7, 26, 28, 32].

Implicitly secret keys In many cases, keys are tacitly assumed to be secret or, at least, hard to guess. One example of implicitly secret keys are *object identifiers*. Many web applications and object storage systems maintain object id-to-value mappings in a key-value store. Key disclosure thus allows attackers to probe access to the associated objects, resulting in an insecure direct object reference vulnerability [48]. While objects typically have ACLs, users often neglect to configure these ACLs. This is not a hypothetical concern: for instance, there are numerous scanning tools for "open" (unprotected) Amazon S3 objects [9, 23, 50, 53, 61, 62], and open S3 objects have led to exfiltration of employee information, personal identification information, and other sensitive data [27].

4 Threat model

We consider a *high-level system*, such as a database system or object store, that utilizes a key-value storage engine to respond to user queries. Key ACLs are stored as part of the value associated with the key. As the high-level system performs key-value queries to satisfy a user's query, it checks the ACL of each key it accesses by inspecting the key's value. If the user is not authorized to read a key, the system returns a failure response to the user.

The attacker's goal is to identify keys stored in the system's key-value storage engine. The attacker cannot compromise the system (e.g., to run attack code) and cannot eavesdrop on requests performed by other users and/or on their responses. The attacker can only interact with the system by making requests via its interfaces, such as a representational state transfer (REST) API [34, Chapter 5].

We assume that the attacker can craft their requests in a way that causes the high-level system to make key-value store point queries for arbitrary keys (i.e., chosen by the attacker) while processing the request. For simplicity, we refer to this process as the attacker "querying the key-value store."

We make no assumption about the attacker's physical location with respect to the attacked system. We only assume that the attacker can observe microsecond-level timing differences in the response times of queries for different keys. Prior work has shown that this assumption is true for attacks over both local and wide area networks. For instance, Crosby et al. were able to measure a difference of 20 μs over the circa 2009 Internet (and 100 ns over a local area network) [17]. This ability

can be improved in specific cases. When attacking a system hosted in the public cloud, for example, the attacker can turn themselves into a local-area attacker by placing themselves in the datacenter hosting the target. Moreover, systems that process different requests concurrently (e.g., HTTP/2 servers) are vulnerable to concurrency-based timing attacks [36], which can observe timing differences of 100 ns over the Internet.

5 Prefix siphoning

Prefix siphoning is a general template for conducting timing attacks, extracting partial or full keys, on systems that use an LSM-tree based storage engine with a certain type of *vulnerable* range filter (for both point and range queries). The class of vulnerable range filters contains the filters SuRF [65] and RocksDB's prefix Bloom filter (PBF) [25].

Prefix siphoning exploits range filters that respond to point queries based on key prefix information, which exists to support range queries—i.e., filters where range query support affects the point query implementation. Accordingly, prefix siphoning is based *only on point queries* and does not perform range queries. Henceforth, therefore, the term "query" always refers to a *get()* point query. We leave exploring attacks against range queries to future work.

In the following, we describe the attack's high-level ideas (§ 5.1), characterize the class of vulnerable filters (§ 5.2), and present the attack template (§ 5.3). We describe instantiations of the attack against SuRF and PBF in §§ 6–7.

Notation We treat keys as sequences of symbols over an alphabet Σ (e.g., bytes). When x denotes a key or a set, then $|x|$ refers to the number of symbols or elements, respectively, that x contains.

5.1 High-level ideas

Prefix siphoning exploits an *inherent* trait of filter use in LSM-trees: that whether a key "passes" the filter determines if the LSM-tree searches the SSTable for the key to satisfy a query. This means that for SSTable files that do not reside in the OS page cache, the filter's output for a key significantly affects the LSM-tree's query response time. If the filter returns false for the key, the response is satisfied with only main memory access; otherwise, the LSM-tree needs to perform I/Os to read SSTables from secondary storage. Even for fast storage such as NVMe devices, the difference in query response times between these two cases is enough to affect the system's overall response time in an attacker-measurable way.

This basic filter trait suffices to mount an "approximate membership test" timing attack. The attack simply queries for the target key k and measures the response time. If the response time is fast (i.e., k is rejected by the filters), then k is definitely not stored in the LSM-tree. Otherwise (i.e., k passes some filter), then k is likely in the LSM-tree. The key k might also be a filter false positive and not exist in the LSM-tree, which occurs with a probability bounded by the filter's FPR.

Prefix siphoning starts by randomly generating keys until it finds a key that "passes" the membership test above. For random keys, passing the test overwhelmingly means that the key is a filter false positive. Crucially, it takes just hundreds of attempts to find a false-positive key, because filters are typically configured for FPRs of a few percents for space efficiency reasons [65].

Our main observation is that in vulnerable range filters, a false-positive key likely shares a prefix with some stored key k, whereas negative keys (rejected by the filter) do not (at least with high probability). The crux of a prefix siphoning attack is an algorithm exploiting this trait to *identify* the shared prefix k' through $O(|k|)$ further queries for modified keys iteratively derived from the initial false-positive key.

The revealed prefix of k can already contain sensitive information. But if the system's query responses distinguish between failures due to target key non-presence and lack of authorization, prefix siphoning can fully extract k by performing brute force search of the unknown suffix, thereby *extending* the revealed prefix to k.

Of course, a system whose responses distinguish between non-present and unauthorized keys is also vulnerable to "brute force" key guessing or enumeration attacks based using the above "membership test" primitive. But such attacks are infeasible for many key spaces (e.g., 64-bit or string keys). The point of prefix siphoning is to narrow down the search space by exploiting vulnerable range filters. Moreover, prefix siphoning extracts key prefixes even if the target system's responses do not reveal whether a key is non-present or unauthorized, whereas the "membership test" primitive cannot.

5.2 Vulnerable range filter characterization

We denote an instance of the filter by F and the set of keys it represents by D. A range filter is *vulnerable to prefix siphoning* if it has the following characteristics, denoted C1–C2. They say that a false-positive key κ likely shares a prefix with some key from D and that an attacker can efficiently identify this prefix by making queries for keys derived from κ.

C1 If κ is a false-positive key for F, then with high probability, κ shares a prefix with some $k \in D$.

C2 There exist the following probabilistic algorithms, which work by querying the system:

1. *FindFPK()*: Using an expected constant number of queries, outputs a random false-positive key κ.
2. *IdPrefix(κ):* Given a false-positive κ, uses $O(|\kappa|)$ queries to identify the shared prefix k' that κ shares with some key $k \in D$, if such a prefix exists; otherwise, the output is unspecified.

The *FindFPK* and *IdPrefix* algorithms are specific to the

range filter design, and need to be developed by the attacker.[1] We refer to designing such algorithms for a range filter as *instantiating* the attack against that filter.

C2 implies existence of a timing attack, and is therefore formally sufficient to characterize the vulnerability. In practice, however, our attack instantiations rely on fundamental properties of filter use in LSM-trees. To highlight this aspect of the attacks, we explicitly capture these properties in C3.

C3 1. A *get*(k) query's response time is measurably lower if k misses in every filter than if k hits in some filter.

2. The filter's FPR is small but non-negligible (e.g., 1% or 0.1%).

C3(1) implies that it is possible to distinguish negative from positive keys using query response times. It is trivially true because LSM-trees employ filters to speed up queries for which SSTable searching is superfluous, such as filter misses. Our attacks in this paper exploit microsecond-level time differences between queries satisfied completely from main memory and those that require I/O to secondary storage. (There remain time differences between queries that read an in-memory SSTable residing in the OS page cache and those that do not, due to a filter miss. We leave exploiting such smaller time differences to future work.)

C3(2) implies that generating keys uniformly at random will generate a false-positive key with hundreds to thousands of attempts, on average. It holds because in practice, filters are typically configured with small but non-negligible FPRs (e.g., 0.5%–5%), as negligibly small FPRs blow up the filter's memory consumption [65].[2]

5.3 Prefix siphoning template

Prefix siphoning consists of two phases. First, a preliminary phase learns to distinguish queries of negative and positive keys (§ 5.3.1). The second phase consists of multiple rounds, each of which extracts a key or key prefix (§ 5.3.2). Rounds are run concurrently (see § 9).

5.3.1 Learning to distinguish positive from negative keys

The attack starts with a preliminary phase that builds a distribution of query response times, which is used by the second phase to distinguish positive from negative keys.

The distribution is built by measuring response times of multiple *get()* requests for random keys. With large key spaces, such random keys are mostly negative keys, but a small (though non-negligible) fraction will be positive (due to C3). Such positive keys are overwhelmingly likely to be false positives, but that does not matter for this step, which is only concerned with distinguishing negative from positive keys, regardless of whether the positive output is correct.

The expected distribution observed is a bimodal distribution, with peaks corresponding to the average response time of negative and positive keys. From this distribution, the attacker can derive a cutoff value that likely distinguishes negative (fast) from a positive (slow) queries.

5.3.2 Extracting keys

This phase consists of multiple rounds, each of which extracts a key. Each round consists of three steps: ① finding a false-positive key κ, ② identifying the prefix that κ shares with some stored key k, and, when possible, ③ extending the prefix to extract k. Rounds are run concurrently (§ 9).

Step ① and ② simply invoke the attacker's *FindFPK* and *IdPrefix* algorithms, respectively. These steps are actually the "meat" of the attack, and we later describe their instantiations for SuRF (§ 6) and RocksDB's prefix Bloom filter (§ 7).

Whether step ③ is possible depends on the properties of the attacked system (and this is why it is not part of the vulnerable range filter characterization). If the system's query responses distinguish between failures due to target key absence and lack of authorization, then the attacker can extend the revealed prefix k' with some symbol sequence α and query for the key $k'\alpha$. The response will indicate lack of authorization if and only if $k'\alpha$ is a valid key. The attacker can thus iterate over all possible suffixes until k is found. Because k is not known to the attacker, they must first try all possible single symbol extensions, then all two symbol extensions, and so on. This process requires $O(|\Sigma|^{|k|-|k'|})$ queries, which can be several orders of magnitude less than a full-key brute force search. Crucially, step ③ only attempts to extend "long" prefixes, for which extension is feasible. Other prefixes are discarded.

Rationale for step decomposition For fixed-length keys, it might seem that the *IdPrefix* algorithm (step ②) for identifying the prefix is superfluous. After all, given that κ shares a prefix with some stored key k, the attacker can enumerate all possible suffixes from the end to the beginning, until identifying k. For example, suppose keys are 14-character strings and the attacker has found a false-positive key `manchestercars` because it shares the prefix `manchesterc` with the stored key `manchestercity`. Without knowing (or caring about) the shared prefix, the attacker can start querying for `manchestercara`, `manchestercarb`, ..., `manchestercaaa`, `manchestercaab`, and so on—all of which fail due to key absence—until reaching `manchestercity`, which will fail due to lack of authorization. As before, this process requires $O(|\Sigma|^{|k|-|k'|})$ queries and so it theoretically achieves the same results directly, without requiring an *IdPrefix* algorithm.

Why, then, is existence of an *IdPrefix* algorithm defined as one of the characteristics of a vulnerable filter? The answer is that without knowledge of the prefix, the attacker cannot efficiently schedule their work in step ③. They cannot distinguish a small suffix space (as in the example above) from

[1] Existence of *FindFPK* and *IdPrefix* is required in addition to C1 because a filter satisfying only C1 may not allow an attacker to extract the prefixes.

[2] Prefix siphoning can still be performed for exponentially low false positive rates, but its cost (in terms of number of queries needed) increases proportionally to the decrease in the false positive rate.

a huge space—e.g., if the false-positive key only shared the prefix `m` with `manchestercity`.

The *IdPrefix* algorithm protects us from the above pitfall. By identifying the shared prefix, it enables the attacker to decide whether to try and extend the prefix to a full key. Moreover, when multiple rounds execute concurrently, the attacker can collect many prefixes and then prioritize extending the longest ones.

6 SuRF prefix siphoning

Here, we instantiate a prefix siphoning attack against LSM-trees employing the SuRF [65] range filter. § 6.1 summarizes SuRF and § 6.2 shows that it is vulnerable to prefix siphoning.

6.1 SuRF primer

The succinct range filter (SuRF) [65] is the first proposed general range filter. Like the LSM-tree SSTables it approximates, SuRF is an immutable structure. SuRF can speed up LSM-tree range queries by 5×, but it imposes a modest cost on point queries due to having higher FPRs than a Bloom filter [65].

At a high level, SuRF is a pruned trie. A *trie* is a tree data structure that stores keys sorted according to the lexicographic order of Σ. Each edge is labeled with a symbol and each node corresponds to the concatenation of all edge labels on the path to that node. Each leaf thus corresponds to a key and each internal node to a key prefix (Figure 1(a)). An internal node can also correspond to a key (if the key set is not prefix-free), which is indicated by one of its fields. For space-efficiency, SuRF uses a succinct trie representation.

SuRF further saves space by *pruning* the trie. The basic SuRF variant (SuRF-Base) stores the minimum length key prefixes that uniquely identify each key, i.e., shared key prefixes plus the symbol following the shared prefix of each key (Figure 1(b)). SuRF's pruning results in a space-efficient but only approximate representation of the key set.

Both point and range queries are satisfied from the pruned trie structure. A *get*(k) returns true (possibly erroneously) if and only if the path induced by k terminates at a node associated with a key. For example, in Figure 1(b), `BLOOD` is a false positive. Range queries rely on the trie's ordered structure. For example, to check if the SuRF contains a key $k \in [a,b]$, the query finds the node corresponding to the smallest key $\geq a$. If it corresponds to a key $> b$, the query returns false; otherwise, it returns (possibly erroneously) true.

SuRF variants to reduce FPR SuRF-Base's FPR is data-dependent, i.e., depends on the key set. Compare, for example, two sets of 26 keys: $A = \{x\alpha \,|\, x \in A, \ldots, Z\}$ and $B = \{\alpha x \,|\, x \in A, \ldots, Z\}$, where α is some long string. For A, SuRF's FPR is nearly 100%, as any key except $A, \ldots, Z$ is a false positive. But for B, the FPR is extremely small, as only keys that begin with α pass the filter.

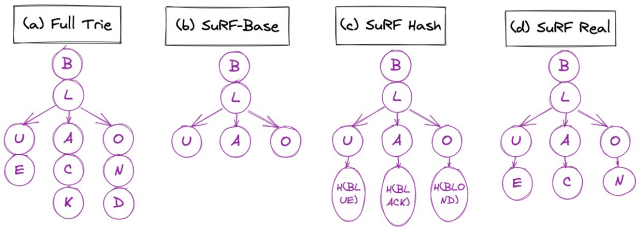

Figure 1: Trie and SuRF variants over the key set `BLUE`, `BLACK`, and `BLOND`. (Figure adapted from [65].)

To improve the FPR, SuRF offers variants that augment SuRF-Base's pruned structure with a few bits per leaf of information about the leaf's suffix. These bits reduce the FPR by allowing queries to reject keys that share a prefix with the stored key but have a different suffix, in exchange for increasing per-key memory consumption.

SuRF-Hash (Figure 1(c)) hashes the leaf's key and stores n bits from the hash value, where n is configurable. *SuRF-Real* (Figure 1(d)) stores the first m bits of the key's suffix, where m is configurable.

6.2 Vulnerability of SuRF

Every SuRF variant has the characteristics defined in § 5.2. C3(1) holds trivially. C3(2) holds empirically: SuRF-Base has an FPR of 4% for random 64-bit keys and SuRF-Hash reduce this FPRs to ≈ 0.1% [65]. C1 holds because in every SuRF variant, *every* false-positive key κ shares a prefix with some stored k—C1 holds with probability 1.

To show that C2 holds, we describe how to efficiently find a false-positive key (§ 6.2.1) and how to identify the prefix that it shares with a stored key (§ 6.2.2). We assume the ability to check if a key is a filter positive or negative key based on measuring query response times. The implementation of this check is described in § 9.

6.2.1 Finding a false-positive key (FindFPK)

For SuRF, our *FindFPK* algorithm simply generates queries for uniformly random keys until it detects a positive response, based on the cutoff determined in the attack's preliminary learning phase (§ 5.3.1). Due to C3, this step is expected to terminate with a few hundreds to thousands of attempts.

We refer to the random positive key found as a false-positive key, because that is the overwhelmingly likely event. However, the attack still works if, unbeknownst to the attacker, the found key is actually a true positive key.

6.2.2 Identifying a shared prefix (IdPrefix)

For a false-positive key κ, let $k = k(\kappa)$ be the stored key whose shared prefix k' with κ is the longest among all stored keys. We write $\kappa = k'\alpha$ and $k = k'\beta$. Our algorithm will output k'.

SuRF-Base/Real To find k', we exploit SuRF's structure, namely that any key starting with a proper prefix of k' is a

negative key. Let $\kappa = \kappa_1 \dots \kappa_n$. We repeatedly remove the last symbol from the key, iteratively checking if the keys $\kappa_1 \dots \kappa_{n-1}, \kappa_1 \dots \kappa_{n-2}, \dots$ are negative or positive keys. These keys will be positive until we remove a symbol from k'. Thus, the key checked before a negative key is found is k'.

If the attacked system does not support variable-length keys, removing symbols is not possible. In this case, instead of removing symbols, we change them. We iteratively check if the keys $\kappa_1 \dots \kappa'_n, \kappa_1 \dots \kappa'_{n-1}\kappa_n \dots$ are negative or positive keys, where $\kappa'_i \neq \kappa_i$. Similarly to before, if the first negative key found is $\kappa_1 \dots \kappa'_j \dots \kappa'_n$ then $k' = \kappa_1 \dots \kappa_j$.

Overall, the number of requests made is $O(|\kappa|)$.

SuRF-Hash SuRF-Hash complicates the attack, because modifying κ's suffix can change its hash value, leading to a key that is rejected by SuRF despite sharing the prefix k'. To address this problem, we assume SuRF's hash function *hash* is public knowledge. (This is a reasonable assumption, because the hash function's purpose is to reduce the FPR and not for security.) We perform essentially the same algorithm(s) as for SuRF-Base/Real, but we only query each modified key κ' if $hash(\kappa') = hash(\kappa)$. We are still essentially assured to find keys to query, because SuRF-Hash stores only a small subset of the hash bits, for space-efficiency reasons. For example, with the recommended 4 hash bits [65] and using 8-bit symbols, on average 1 in 16 symbols tried will yield a hash collision and thus a key usable by the *IdPrefix* algorithm.

Similarly, when trying to extend an identified prefix to a full key (step ③ in § 5.3.2), we can skip querying any candidate key whose hash does not match the false-positive key's hash.

7 Prefix Bloom filter prefix siphoning

This section instantiates prefix siphoning against LSM-trees using the prefix Bloom filter (PBF) [25]. We describe the PBF in § 7.1 and show its vulnerability in § 7.2.

7.1 Prefix Bloom filter primer

The PBF is a Bloom filter-based range filter that supports range queries for ranges expressible as fixed-prefix queries. While PBFs do not provide general range queries, they are currently deployed in real-world key-value stores such as RocksDB [30] and LittleTable [52].

A PBF consists of a Bloom filter and a predetermined prefix length, l. When a key k is inserted into the PBF, both k and its l-bit prefix are inserted into the Bloom filter.

PBF range queries must be for ranges of the form "all keys starting with α," where α is an l-bit string. They are answered by querying the Bloom filter for α. If this query responds false, the dataset does not contain keys within the target range.

The PBF answers point queries by querying the Bloom filter for the queried key. We remark that if the high-level system does not prioritize point query efficiency, the PBF can be configured to only store key prefixes. In this case, the PBF implements a point query for key k by querying its Bloom filter for k's l-bit prefix. This option reduces the PBF's memory consumption but increases the FPR of point queries. This PBF configuration does not affect the success of our attack, so we do not discuss it further.

7.2 Vulnerability of the PBF

The PBF has the characteristics defined in § 5.2. As with SuRF, C3(1) holds trivially. C3(2) holds because the PBF's FPR is based on its Bloom filter's FPR.

The PBF has an important property: it not only has the usual Bloom filter false positives caused by hash collisions but also has what we call *prefix false positives*. These occur when a PBF point query falsely returns positive for an input κ that is an l-bit prefix of a dataset key, simply because the Bloom filter stores both dataset keys and their l-bit prefixes. This property implies that C1 holds: with probability $1 - FPR$, an l-bit false-positive is actually the prefix of some stored key.

To show that C2 holds, we need only describe how to find prefix false positives (§ 7.2.1). Finding them makes the *IdPrefix* algorithm of C2 trivial: given an l-bit false positive κ, it outputs κ.

7.2.1 Finding l-bit false-positive keys (FindFPK)

The *FindFPK* algorithm first determines the length of key prefixes stored in the PBF, l, and then proceeds to guess prefix false positives. Crucially, finding l needs to be performed only once per attack. That is, when running the attack's rounds concurrently (§ 9), we run this step only once.

Once l is known, generating queries for uniformly random l-bit strings will find false-positive keys, similarly to the SuRF attack's *FindFPK* (§ 6.2.1). Given a set of false positive l-bit keys thus found, an expected fraction of $p/2^l$ will be prefix false positives, where p is the number of distinct l-bit prefixes of dataset keys. The remaining false positives will be hash-collision Bloom filter false positives. Because we cannot distinguish between the two types of false positives, the attack's later steps must try to extend all of them to full keys.

The crux of the *FindFPK* algorithm is to identify l. To this end, we rely on the PBF property that made it vulnerable in the first place. For any prefix length $l' \neq l$, the probability of an l'-bit key being a false positive is exactly the filter's FPR. Only for l-bit keys will we observe a "bump" in the probability of a random l-bit key being a false positive, due to the presence of prefix false positives.

Accordingly, the *FindFPK* algorithm first generates j queries for uniformly random keys of length l', for every non-trivial prefix length l' (e.g., $l' \geq 3$). It observes the fraction of false positives found and deduces that l is the length l' for which the fraction of false positives found is maximal.

8 Complexity analysis

The key factor determining prefix siphoning's effectiveness is the probability of *FindFPK* (step ① in § 5.3.2) guessing an *exploitable* key k, which is a false positive whose longest

shared prefix with stored keys is of length l, where l is a predetermined constant for which extending k into a full key is feasible (step ③).

The full version of this paper [39] includes a theoretical analysis of the SuRF and PBF attacks, which is omitted here due to space constraints. We analyze the case of uniformly random keys, which is the worst case for our attack. (If the key distribution is skewed, then (1) the guessing and full-key extraction steps can incorporate this knowledge; and (2) the prefixes SuRF stores are longer, so our attack will identify longer prefixes and thus extend them to full keys faster.)

The analysis derives the probability of *FindFPK* guessing an exploitable key. This determines the expected number of queries to guess an exploitable key or, equivalently, the number of keys we ultimately expect to extract after investing G guesses in *FindFPK*. These values also allow comparing the cost (in queries) of prefix siphoning to brute force search.

Under the realistic constraint that $|D| \ll 2^l$, where D is the dataset (e.g., $|D| = 500\,\text{M}$ and $l = 40$), we find that (1) prefix siphoning becomes more effective with growth in dataset size and better FPR—i.e., as the LSM-tree becomes more effective, so does prefix siphoning; and (2) prefix siphoning takes several orders of magnitude fewer queries to extract a key than an exhaustive brute force search.

9 Implementation issues

In previous sections, we assume the attacker can check if a key is a filter positive or negative key, based on measuring query response times. Here, we describe our implementation of this check.

The basic idea is simple. Prefix siphoning's preliminary phase (§ 5.3.1) derives a response time cutoff. Keys whose query response time is below this cutoff are considered negative; otherwise, they are considered positive. However, this cutoff only distinguishes between queries satisfied from memory and those involving I/Os. Once a query for a false-positive key completes, the I/O it performs reads the relevant SSTable into the in-memory page cache. Future queries for false-positive keys covered by this SSTable will thus get satisfied from memory.

To overcome this problem, we exploit the fact that the attack targets some production system, which is assumed to sustain heavy I/O load due its legitimate operation. This property implies that if the attacker *waits* after performing a false positive query, the SSTable brought in will be evicted from the page cache due to legitimate I/O traffic.

Unfortunately, waiting for even a few seconds after every query would make the attack impractical. We solve this challenge by performing attack rounds in a *concurrent, breadth-first* manner, as described below, instead of working depth-first (finding a false-positive key and proceeding to identify its prefix and then to extract the full key).

Step ① of § 5.3.2 (*FindFPK* execution) generates N random keys (false positive candidates) and measures a four-query average response time for each key to identify false-positive keys. The averages are computed in a breadth-first manner: there are four iterations, each of which performs one query for each key. Waiting for page cache evictions is done only between each iteration.

Step ② (*IdPrefix*) similarly executes iteratively, interleaving the next step of *IdPrefix* for each false-positive key in each iteration, until all invocations output a prefix. Again, waiting for page cache evictions is only done between iterations.

Step ③ (key extraction) likewise interleaves the searches extending each prefix. We optimize step ③'s general-case brute force suffix search by leveraging the fact that step ② outputs a set of prefixes. This enables us to discard short prefixes, so that step ③ only attempts to extend prefixes where the suffix search is feasible.

The interleaved execution of each step can be sped up using multi-core parallelization by assigning each core a subset of the N random keys, false-positive keys, or prefixes when executing step ①, ②, and ③, respectively, in the above described manner. This results in linear speedup (in the number of cores) of step execution time. Our implementation parallelizes step ③, whose execution time dominates the attack (§ 10.2.2), over 16 cores and leaves the other steps single-threaded.

10 Evaluation

In this section, we evaluate prefix siphoning attacks on SuRF and PBF in RocksDB. We demonstrate the attack's feasibility, successfully mounting it against a full-fledged RocksDB key-value store employing SuRF (§ 10.2).[3] We empirically analyze the SuRF attack's efficiency and sensitivity to data store size and filter FPR (§ 10.3). Consistent with our theoretical analysis, we find that the attack becomes more effective with growth in dataset size and better FPR—i.e., as the LSM-tree becomes more effective, so does prefix siphoning. Finally, we demonstrate the attack against the PBF (§ 10.4).

10.1 Experimental setup

Both clients and the attacked key-value store run on the same server. However, the time differences we exploit can be measured over the network using prior techniques (see § 4).

We use a server with two Intel Xeon Gold 6132 v6 (Skylake) processors, each of which has 14 2.6 GHz cores with two hyperthreads per core. The server is equipped with 192 GB DDR4 DRAM and two 0.5 TB NVMe SSDs. The server runs Ubuntu 18.04 and code is compiled with GCC 4.8.

RocksDB setup We use a version of RocksDB modified by the SuRF authors to employ SuRF [65]. The target RocksDB instance uses the NVMe devices as secondary storage. We use Linux `cgroup` to limit RocksDB's available DRAM to

[3] We use the SuRF's authors' implementation, https://github.com/efficient/SuRF.

2 GB. This configuration emulates an industrial-scale, I/O heavy key-value store setup, in which storage capacity far exceeds DRAM capacity.

The RocksDB engine stores 64-bit keys and 1000-byte values and the SuRF-Real variant. Unless noted otherwise, we use a datastore of 50 M uniformly random keys (generated using SHA1). We invoke RocksDB LSM-tree compaction after populating the datastore. We do this to emulate the compaction that naturally occurs in a real workload due to insertions, because our experiments perform only *get()*s.

Background load In all experiments, we emulate a realistic, loaded system by running 32 threads that constantly perform *get()* queries for random keys, with 50% of the queries targeting stored keys and 50% targeting non-present keys.

10.2 RocksDB+SuRF-Real key extraction

We implement the attack as described in § 9. § 10.2.1 evaluates the attack's first phase (§ 5.3.1), demonstrating that query response times can be used to distinguish negative from positive keys in practice, even in the presence of heavy background load. § 10.2.2 evaluates the attack's second phase, which extracts full keys, and compares it to a brute force search.

10.2.1 Negative/positive query time differences

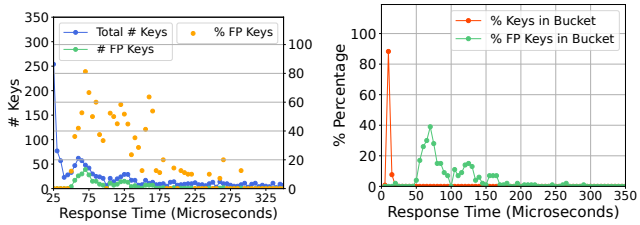
In this phase, the attacker performs 10 M *get()* queries for randomly generated keys to build the response time distribution. Table 1 shows the distribution of response times in terms of 5 microsecond buckets. The distribution is extremely skewed toward values $< 25\,\mu$s, which our attack therefore assumes are associated with negative keys.

To validate this assumption, Figure 2 visualizes the distribution while breaking the response times by queried key type (negative or false-positive). This breakdown is presented for analysis purposes; it is not available to the attacker. For readability, we present the breakdown in two ways. Figure 2(a) shows only the buckets $\geq 25\,\mu$s, which are otherwise dwarfed by the lower end of the distribution. We show both the number of keys (blue) and false-positive (green) keys in each bucket, and the percent of false-positive keys in each bucket (orange). Figure 2(b) shows the entire distribution, but bucket sizes (Y axis) are percentages instead of absolutes. For each bucket, we report the number of keys in the bucket as well as the percentage of false positives (out of all positives).

Figure 2(a) shows that the vast majority of false positive queries have a response time of 25–35 μs. Conversely, Figure 2(b) shows that this response time range contains over 50% of the false-positive keys. Overall, these results show that picking a cutoff point of 25 μs for distinguishing a negative from positive key—which is done based only on the distribution's shape, without knowledge of key types—yields a good distinguisher.

Bucket range (microseconds)	% of responses
< 5	0.77%
5 - 10	**88.3%**
$10 - 15$	7.65%
$15 - 20$	0.53%
$20 - 25$	0.05%
≥ 25	2.7%

Table 1: Distribution of query response times.



(a) Buckets $\geq 25\,\mu$s: Absolute number of queried keys

(b) All buckets: Percentage of queried keys.

Figure 2: Breakdown of query response time distribution.

10.2.2 Key extraction

The attack executes as described in § 9; specifically, wait is set to 20 seconds and each step is executed in a parallel, breadth-first manner, to minimize the amount of time spent waiting for page cache evictions. The attacker generates a set of 10 M random keys to find false-positive keys (step ① of § 5.3.2). The attacker next identifies the prefix each false-positive key shares with a stored key (step ②). Finally, the attacker discards every prefix of length < 40 bits and attempts to extend the remaining prefixes into full keys (step ③).

Figure 3 shows the number of keys extracted as a function of the number of total number of *get()* requests issued by the attack (aggregated over steps ①–③). The figure also compares the attack to an *idealized* attack, which uses internal RocksDB debugging counters to accurately determine the filters' responses for each queried key, instead of relying on query response times.

Because the idealized attack never incorrectly classifies a key, it identifies more false positives than the actual attack in step ①. It thus requires more queries in step ② to identify the shared prefixes of the keys provided to step ②, as there are more of them. Consequently, the idealized attack begins step ③ later (in terms of queries) than the actual attack, which is why its line is "shifted" compared to actual attack. For this reason, the idealized attack also requires more queries overall. Ultimately, however, the actual attack extracts only 74 fewer keys than the idealized version.

The idealized attack is also faster (in real time) than the actual attack, because it does not require waiting for page cache evictions. The actual attack's key extraction rate is $\approx$ 10 minutes/key, while the idealized attack achieves 0.2 minutes/key.

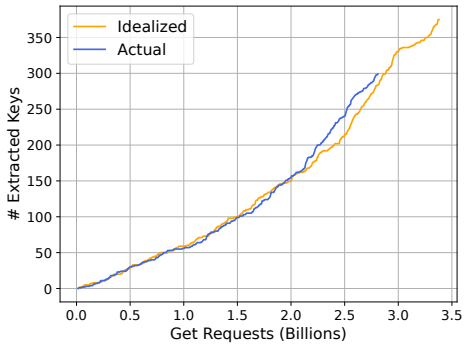


Figure 3: Actual vs. idealized prefix siphoning against SuRF-Real: Number of keys extracted as attack progresses.

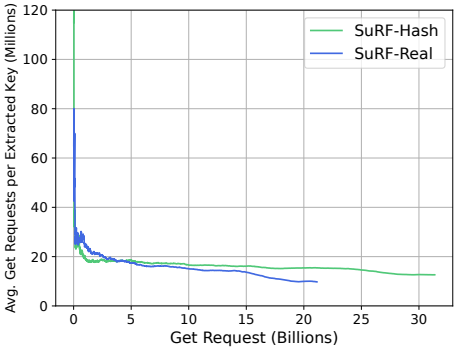

Figure 4: SuRF-Hash vs. SuRF-Real: Moving average of queries per extracted key as a function of attack progress (measured in queries).

attack step	# queries (millions)	queries/total (%)
① Find false positives	10M	0.35%
② Identify prefixes	0.025M	0.0009%
③ Extract keys	2581M	91.68%
Wasted	224M	7.9%

Table 2: Attack queries per stage. Wasted queries futilely attempt to extend an incorrectly identified prefix into a full key.

Table 2 shows a breakdown of the (actual) attack's queries across all three steps. The bulk of the attack is spent on step ③, extending prefixes into full keys. Our later analysis (§ 10.3.2) explains this number. The table also reports wasted queries, which are issued when the attack futilely tries to extract a key from an incorrect prefix, which was misidentified due to incorrectly classifying a key as a false-positive (based on its query response time). Additional wasted queries (not shown) are spent identifying prefixes of length < 40 bits in steps ①–②, which are then discarded. While over 90% of prefixes identified by steps ①–② are discarded, this waste is negligible, as they are discarded before the most expensive step.

Comparison to brute force We further evaluate a brute force attack, that randomly guesses keys until a stored key is found. We allow this attack to run for 10× more time than the prefix siphoning experiment—but it fails to guess a key. Unsurprisingly, brute force search for a large key space is infeasible.

SuRF-Hash vs. SuRF-Real SuRF-Hash complicates the attack. Compared to SuRF-Real with the same per-key space budget, SuRF-Hash replaces key bits (SuRF-Real's suffix bits) with hash value bits. This means that possible prefixes to identify are shorter and that the filter's FPR is lower, making the number of false positives identified in step ② lower. On the other hand, as discussed in § 6.2.2, when identifying the prefixes and performing key extraction, the attacker can use the false-positive key's hash value to ignore definitely incorrect guess—potentially improving the attack's efficiency.

To evaluate this trade-off, we compare idealized attacks against the same dataset, with RocksDB using either SuRF-Real with 8-bit suffixes or SuRF-Hash with 8-bit hashes. Thus, in SuRF-Hash, the suffix search space when extracting a key 256× larger than in SuRF-Real, but the attacker will ignore $255/256$ of its guesses on average. To compensate for SuRF-Hash's lower FPR, the initial false-positive key search of the SuRF-Hash attack uses 3× the number of candidate keys used for SuRF-Real. Figure 4 therefore compares the attacks' amortized cost, in terms of a moving average of queries per extracted key as a function of attack progress.[4] The SuRF-Hash attack's extra initial queries (for finding false positives) manifest as the peak of the per-key cost, when all these extra queries are amortized across only a handful of keys. The extra cost is eventually amortized away, into a per-key cost of 12 M vs. 10 M queries for SuRF-Hash vs. SuRF-Real, respectively. For this similar cost, the SuRF-Hash attack extracts 2490 keys vs. 2171 keys for the SuRF-Real attack.

10.3 Attack analysis

This section analyzes the attack's efficiency (§ 10.3.1) and sensitivity to data store size (§ 10.3.2) and filter FPR (§ 10.3.3).

10.3.1 Efficiency

Figure 5 shows the attack's efficiency, measured as average *get()*s per extracted key as a function of attack progress. We compare across three 50 M random 64-bit key sets to show the results are not a function of the specific key set.

The average number of queries per extracted key converges to about 9 M $\approx 2^{23}$. This indicates that the attack extracts keys with roughly the work required to search a 23-bit space—40992× better than a brute force search of the full key space ($2^{64}/50\,\text{M} \approx 2^{38.4}$). The attack also extracts a substantial number of keys (375, 419, and 423 keys).

[4] I.e., the Y axis reports the number of *get()*s issued divided by the number of keys extracted up to the current X-axis point.

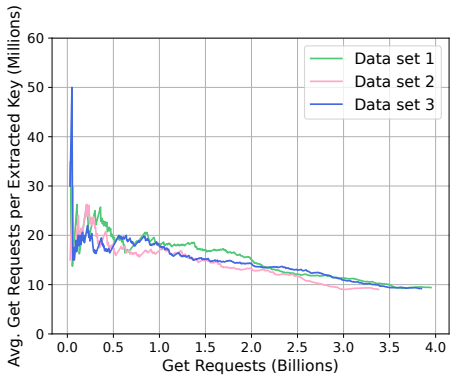

Figure 5: Attack efficiency: average number of *get()*s per extracted key as attack progresses.

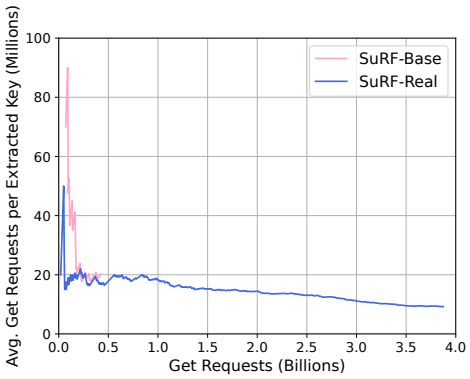

Figure 7: SuRF-Real vs. SuRF-Base: Moving average of queries per extracted key as a function of attack progress (measured in queries).

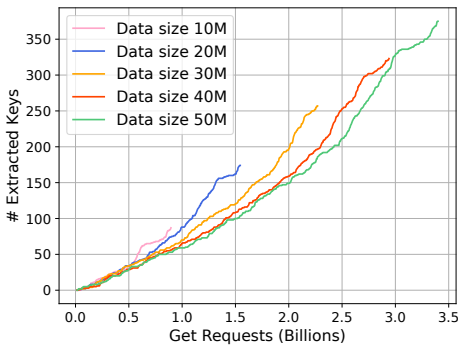

Figure 6: Idealized attack against SuRF-Real: Number of keys extracted for different dataset sizes.

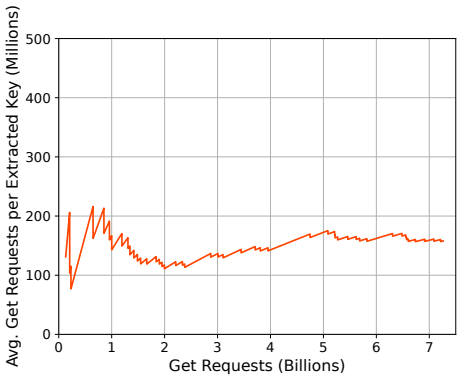

Figure 8: Idealized prefix siphoning against PBF ($l = 40$ bits).

10.3.2 Sensitivity to dataset size

To evaluate the attack's sensitivity to the dataset size, we progressively shrink our original 50 M key set into smaller subsets of size $c \cdot 10$ M keys for $c \in [1,5]$. We then perform an idealized attack against the system with each dataset, but using the same set of random keys for step ①, so any difference in attack behavior can related only to the datastore size and not the key distribution.

Figure 6 shows the number of keys extracted as the attack progresses. Prefix siphoning is more effective as the dataset size increases: it extracts ≈ 100 keys from the 10 M dataset, but almost 400 keys from the 50 M dataset.

10.3.3 Sensitivity to SuRF FPR

We show that prefix siphoning becomes more effective as SuRF's FPR improves, i.e., the attack becomes more harmful to the system as SuRF becomes more productive to the system. To demonstrate this effect, we compare idealized attacks against the same dataset, with RocksDB using either SuRF-Base or SuRF-Real. SuRF-Base stores shared key prefixes, padded to the next full byte (which adds 1–8 bits to the prefix). SuRF-Real does the same, plus stores a byte from the key's unique suffix, and thereby improves its FPR (see § 6.1).

We carry out the attacks against each SuRF variant using the same initial random key set, used to identify false-positive keys. Figure 7 reports the attack's amortized cost (queries per extracted key) as the attack progresses.

In both cases, the attack has similar efficiency of ≈ 10 M queries per extracted key, as evident from the similar slope of the two lines. However, the attack is more successful against SuRF-Real, where it extracts 420 keys, than against SuRF-Base, where is extracts 21 keys. The reason for the improved effectiveness is that SuRF-Real's extra key byte storage makes an initial false-positive key much more likely to have a prefix length of > 40 bits, resulting in more false positives making it to step ③.

The situation is similar with SuRF-Hash, which further improves the FPR over SuRF-Real (Figure 4). As mentioned in § 10.2.2, the idealized SuRF-Hash attack extracts 2490 keys vs. 2171 keys for the idealized SuRF-Real attack.

10.4 RocksDB+PBF key extraction

We evaluate an idealized prefix siphoning attack against RocksDB's PBF. We use a dataset of 50 M uniformly random 64-bit keys. We configure the PBF to store prefixes of length

$l = 40$ bits and to consume 18 bits/key (which is roughly the space usage of SuRF in our experiments).

Step ① (*FindFPK*) perform 1 M queries for uniformly random 40-bit keys, which result in 457 false-positive keys. The attack then attempts to extend these false positives into full keys. It eventually extracts 46 keys, which matches the expected number of prefix false positives observed in 1 M random guesses ($1\text{M} \cdot 50\,\text{M}/2^{40} = 45.4$). Figure 8 plots the attack's amortized cost (queries per extracted key) as the attack progresses. The PBF attack makes 160 M queries per extracted key, which is 20× more queries/key than the SuRF attack, but still three orders of magnitude better than a brute force search. The reason for this difference is that the PBF attack wastes effort trying to extend Bloom filter false positives that are not prefix false positives.

11 Mitigation

Here, we discuss approaches for mitigating prefix siphoning attacks. Unfortunately, every potential solution constitutes some trade-off, whether in query performance, memory efficiency, complexity, or other system aspects.

System-level approaches A system can block prefix siphoning attacks by only querying its key-value storage engine for keys the requesting user is allowed to access. This approach requires re-architecting the system so that a key's ACL is kept outside of the key-value store. In addition, a system can rate limit user requests, thereby slowing down prefix siphoning attacks. This approach is viable only if the system is not meant to handle a high rate of normal, benign requests.

Key-value store mitigation A key-value engine can block prefix siphoning by maintaining separate filters for point and range queries for each SSTable file. Unfortunately, this approach will double filter memory consumption. In addition, it will not block attacks that target range queries (which we believe are possible, and are currently exploring).

Filter-level mitigation A natural mitigation is for key-value stores to employ non-vulnerable range filters. Like the separate filter approach described above, this mitigation carries the risk of being vulnerable to future extensions of prefix siphoning to range queries.

In addition, the properties that make a range filter non-vulnerable to point query-based prefix siphoning may limit its utility in practice. For example, Rosetta (Robust Space-Time Optimized Range Filter) [45] is a range filter that does not conform to our vulnerable range filter characterization (§ 5.2), but it lacks support for variable-length keys, which are important in practice.

Rosetta uses Bloom filters for SuRF-like prefix-based filtering. Rosetta assumes a bound on the possible key length in bits, L. A Rosetta instance consists of L Bloom filters, $B_1, \ldots, B_L$. When a key k is inserted into the filter, each i-bit prefix is inserted into the i-th Bloom filter B_i. A Rosetta point query thus simply queries B_L, making Rosetta non-vulnerable to prefix siphoning.

The Rosetta paper does not specify how variable-length keys are handled. Its design is clearly incompatible with such keys if there is no predetermined bound on their size. Even if such a bound exists (and can thus be used for L), Rosetta requires every key to be padded to L bits, so that point queries function correctly. This requirement significantly increases the filter's memory consumption.

Encrypted key-value stores Disclosed keys reveal no sensitive information if they are stored encrypted in the storage engine. However, encrypting key-value pairs requires re-architecting the entire system so it can query on encrypted data [63, 64]. Most if not all deployed key-value stores do not support such encryption.

12 Related Work

Key-value store timing attacks Existing key-value store timing attacks aim to disclose stored values. These attacks work by exploiting external mechanisms such as memory deduplication [55] or memory compression [56], which can be disabled for protection. In contrast, prefix siphoning exploits a mechanism of the key-value store itself, which cannot be disabled for protection without suffering significant throughput degradation and additional I/O traffic.

Storage engine timing attacks Timing attacks mostly target cryptographic software rather than storage engines. Futoransky et al. [35] extract private keys from a MySQL database with a timing attack, but the attack relies on insertions of attacker-chosen data. Wang et al. [59] show a practical timing attack on a multi-user search system, such as Elasticsearch.

13 Conclusion

This paper shows that certain range filters make LSM-trees vulnerable to novel *prefix siphoning* timing attacks, which exploit differences in query response times to reveal keys and prefixes of keys stored in the LSM-tree. Our results show that key-value store performance improvements may trade security in exchange, and encourage practitioners and researchers to evaluate the security impact of their work. We also hope that our characterization of vulnerable range filters will spur research on more secure filters.

Acknowledgments

We extend our deepest thanks to Yuvraj Patel, the paper's shepherd, and the anonymous reviewers for their dedication and assistance in improving this paper and their valuable feedback. We thank Guy Khazma for his work on an earlier stage of this project.

EPF: Evil Packet Filter

Brown University

Abstract

The OS kernel is at the forefront of a system's security. Therefore, its own security is crucial for the correctness and integrity of user applications. With a plethora of bugs continuously discovered in OS kernel code, defenses and mitigations are essential for practical kernel security. One important defense strategy is to isolate user-controlled memory from kernel-accessible memory, in order to mitigate attacks like ret2usr and ret2dir. We present EPF (Evil Packet Filter): a new method for bypassing various (both deployed and proposed) kernel isolation techniques by abusing the BPF infrastructure of the Linux kernel: i.e., by leveraging BPF code, provided by unprivileged users/programs, as attack payloads. We demonstrate two different EPF instances, namely BPF-Reuse and BPF-ROP, which utilize malicious BPF payloads to mount privilege escalation attacks in both 32- and 64-bit x86 platforms. We also present the design, implementation, and evaluation of a set of defenses to enforce the isolation between BPF instructions and benign kernel data, and the integrity of BPF program execution, effectively providing protection against EPF-based attacks. Our implemented defenses show minimal overhead ($< 3\%$) in BPF-heavy tasks.

1 Introduction

The security of a computer system can only be as good as that of the underlying OS kernel. The kernel provides a relatively simplistic abstraction for programs to build on top of, and mediates their access to system resources. Hence, the confidentiality and integrity of user programs rely solely on the security of the OS kernel itself. Yet, the kernel is hard to defend, due to its unique execution model, and the sheer size and complexity of its code. With the development of automated kernel-code testing tools, such as syzkaller [13], thousands of bugs have been found across different OSes [12]. It is even pointed out that bugs are discovered faster than they are fixed [113]. The abundance of errors and vulnerabilities in OSes amplifies the importance of protection mechanisms that reduce the exploitation potential of kernel vulnerabilities.

Standard defenses, such as W^X [6] and ASLR [6], are also adopted by the Linux kernel, aiming to stop and mitigate code-injection- [64] and code-reuse-based [40] attacks. More specifically, these defenses aim to limit the attacker's ability to successfully mount an attack. However, attacks such as ret2usr [68], which completely encode their payloads in userspace, indicate that kernel exploitation is made significantly easier by the relatively *weak separation* between the kernel and userspace (as opposed to a user application, such as web server, where the interface between it and the clients is much more well-defined and limited). Similarly, protection mechanisms like SMEP [112] try to stop kernel attacks by limiting the attacker's ability to encode attack payloads in a kernel-accessible manner (more attacks and defenses in this direction are discussed in Section 2.1).

In this paper, we explore the possibility of abusing the *BPF infrastructure* in the Linux kernel—more specifically, by leveraging BPF programs as attack payloads. We have identified three properties that make BPF programs a promising candidate for such a task. First, BPF programs can be created by *unprivileged users*, and contain memory contents chosen by the user (such that they can be used to encode malicious contents). Second, BPF programs can be created in *large amounts*, such that during exploitation valid references to them can be constructed (e.g., by just guessing) with good probability. Third, BPF programs are created by users, but "*consumed*" by the OS kernel. Access to such payloads cannot be prevented by existing, strong kernel-user isolation mechanisms (e.g., XPFO [67]), because they cannot be differentiated from regular data that the kernel operates upon.

Yet, unlike previous techniques where the payload content is encoded inside regions acting effectively as "byte buffers", a BPF programs's in-memory representation has a non-trivial structure. To address this problem, we develop special code-reuse strategies, dubbed as *EPF*, to utilize payloads with the constraints introduced by the corresponding BPF structure. BPF programs can aid exploitation because they are not strongly-isolated from normal kernel data.

And to defend against such EPF-style attacks, we develop a set of defenses that enforce strong BPF-to-kernel isolation. Recognizing the fact that BPF is essentially a "virtual architecture", we follow a roadmap similar to that of isolating native code from pure data: (1) BPF code should not be read or written as regular, kernel data; (2) regular kernel data should not be executed as BPF code; and (3) BPF code should not be reused as semantically different BPF code.

To summarize, we make the following contributions:

- We introduce a novel, high-volume, undefended method to inject payloads in kernel space for aiding the exploitation of memory errors in kernel code, and we create systematic techniques to utilize them in different architectures. Our methods enable attacks that bypass state-of-the-art defenses that focus on enhancing kernel-user isolation.
- We develop defenses against exploitation that (ab)uses the BPF infrastructure by enforcing strong isolation between BPF code and regular kernel data, and the integrity of BPF execution under attack.
- We evaluate both our attacks and defenses. We create exploits using our techniques on four different real-world vulnerabilities. We integrate our defenses into Linux kernel and demonstrate low overhead ($< 3\%$) on BPF-heavy tasks.

2 Background

2.1 Kernel Exploitation and Defense

Exploitation is the process of tampering with a victim system/-software codebase by abusing vulnerabilities in it [95]. In the case of operating systems (OSes), because OS kernels are typically written in memory- and type-unsafe languages, like C, C++, and ASM, the most common approach to their exploitation entails abusing memory errors in kernel code [73,74,88,96]. In general, two are the dominant exploitation strategies (re: memory errors): *code-injection* [64] and *code-reuse* [40]. Code-injection leverages memory corruption vulnerabilities to place malicious code (i.e., *shellcode*) in the victim's address space before corrupting control data (e.g., *return address*, *function pointers*, *dispatch tables*) to steer execution to it. In contrast, code-reuse stitches together *existing* (i.e., benign) code snippets, in an out-of-context manner, to perform the respective (malicious) computation.

In addition to the above, there exist *kernel-specific* exploitation techniques that address unique challenges of the OS kernel setting. Throughout the evolution of kernel attacks and defenses, regarding memory errors, the ability to create attacker-controlled, exploit-time-accessible payloads has been at the forefront of the subject matter. For example, in *ret2usr* [68] attacks, the adversary first corrupts a code pointer, and then diverts the control flow to userspace code, tricking the kernel into executing malicious (shell)code with elevated privileges. Alternatively, a different flavor of such an attack employs code-reuse techniques (e.g., ROP [100]) with payloads placed in userspace [74, 77]. An essential property of ret2usr-like attacks is the placement of their payload (e.g., shellcode or code-reuse payload) in userspace.

To provide protection against exploits that follow the ret2usr approach, various defenses focus on stopping the respective payloads from being *accessible*. CPU features such as SMEP [112], SMAP [49], PXN [2], PAN [7], as well as software solutions such as kGuard [68], PaX's KERNEXEC [89] and UDEREF [90, 91], were introduced to prevent userland code/data from being executed/accessed freely by the OS kernel. Seeking new ways to provide payloads for exploiting kernel vulnerabilities, without accessing userspace, in the past we proposed to (ab)use the implicit memory sharing between userspace and the kernel: i.e., the `physmap` region [67].

For performance reasons, modern OS kernels keep a continuous mapping of the physical memory (or part of it) in kernel space, which naturally contains user-controlled content. In such attacks, dubbed *ret2dir*, the adversary tries to allocate enough physical pages containing the respective payload, and through the implicit sharing of `physmap`, the payload will be utilized/accessed in a later stage via code injection or reuse. To defend against ret2dir-based attacks, we introduced the concept of *XPFO* (eXclusive Page Frame Ownership) [67]. XPFO prevents the kernel from accessing any memory page that houses userland content, using a kernel (`physmap`-resident) address. Again, the defense impedes the attackers' ability to access their payload.

In this work, we show that unintended access and implicit sharing are not the only reliable sources of *payload injection*. As it turns out, the ability to "push" BPF programs [83] in kernel space provides the attacker with enough control over the contents of kernel memory, to the extent that BPF can be used as an *arbitrary* payload-encoding mechanism. As BPF programs are designed to *live in*, and *used by*, the OS kernel, such payloads bypass all defenses that rely on the strong isolation of kernel- from user-space [66].

2.2 BSD Packet Filter

Design and Usage The BSD Packet Filter (BPF) [83] was originally designed for *filtering* packets during network monitoring: by providing the kernel with "instructions" regarding how to filter packets, before delivering them to a monitoring process in userspace, BPF eliminates unnecessary data copying and context switching. The design and implementation of the Linux Socket Filter (LSF; i.e., our main subject of study) [60] was inspired heavily by BPF. However, it has recently evolved into a generic utility, acting as a *universal* in-kernel virtual machine [46]: its execution is strictly *sandboxed*, and no unintended *side-effects* escape confinement.

A wide range of kernel components, and applications, make use of the expressiveness and security provided by BPF. Docker [10], Firefox [9], and Chromium [1], as well as automated system call (syscall) filtering schemes, like `sysfilter` [52], Confine [55], and Chestnut [42], use `seccomp-BPF` [80] to specify syscall filtering policies. In addition, BPF programs can be attached to Kprobes (kernel probes) [105], giving rise to powerful kernel tracing tools [38], while BPF-based networking frameworks are developed to enable agile packet processing [15, 78]. Lastly, BPF programs have also been proposed to be used in FUSE (Filesystem in USErspace) [34] to reduce context switching overheads.

Features Two different flavors of BPF exist in Linux: classic BPF (cBPF); and extended BPF (eBPF). Internally, cBPF is converted to eBPF, and therefore only a single execution engine (for eBPF) exists nowadays [70]. cBPF programs are used for socket filtering (`setsockopt`), and syscall filtering (`prctl`, `seccomp`), while eBPF programs are managed with the `bpf` syscall, allowing kernel subsystems to implement different methods for attaching/invoking eBPF code.

cBPF is similar to the original BPF, with two general-purpose registers and 16 (addressable) scratch memory slots, all of which are 32-bit wide. In contrast, eBPF has 10 general-purpose, 64-bit registers, and is equipped with a set of helper functions to access either eBPF *maps* (i.e., a family of key/-value store data structures) or other, *internal functionality* (like getting the current process-ID or generating random numbers) [3]. eBPF maps can be made accessible from multiple eBPF programs or user processes [4].

Both cBPF and eBPF specify a RISC-like instruction set, allowing: (a) loading and storing operations (re: immediate values or scratch memory slots); (b) moving values between registers; (c) performing arithmetic and logical operations; and (d) branching. To guarantee termination, there is no *indirect* branching, and the branch instructions can only *jump forward*. In addition, eBPF provides specific instructions for invoking helper functions and other eBPF programs. JIT (Just-In-Time) compiling for eBPF [45] instructions, down to machine code, allows for performance gains [99], compared to using the eBPF interpreter. Lastly, popular tools have also added support for eBPF. LLVM supports BPF as a backend since v3.7 [81], so that developers can choose to write BPF programs using a syntax similar to C. Similarly, BCC [61] and `libbpf` [8] are frameworks that allow developers to easily create and interact with loaded BPF programs.

Security The isolation between the BPF runtime and OS kernel is crucial for the security of the latter. For performance reasons, BPF favors static, *ahead-of-time* checking (over dynamic, runtime checking), when enforcing such isolation. The static checker for cBPF ensures the following properties: (1) jumps (i.e., branches) do not go backwards; and (2) scratch space accesses target initialized locations only. Any program that cannot be statically verified by the checker is rejected. In case of packet filtering, the validity of access to a packet cannot be determined statically, as packet sizes may differ at runtime. Hence, such accesses will be translated to calling helper functions, and bounds are enforced at runtime.

The checker for eBPF is more complex [84]. Same as the cBPF checker, it needs to make sure that control flow does not go backwards. It also validates, and replaces, eBPF map and helper function references, and analyzes register value types, such that the corresponding operations lead to predictable memory accesses to safe locations. The verifier is known to be prone to errors, such as incorrect value range analysis [16, 17, 21] and insufficient protection against speculative execution-related vulnerabilities [19, 22]. Hence, the unprivileged `bpf` syscall is disabled by default [48] (`defconfig` in x86 Linux), while distributions are adopting a "on/off" choice [51, 106].

BPF has also been used as aid in the exploitation of *transient execution* vulnerabilities [72], as well as in settings that involve limited memory corruption capabilities (wrt spatial ranges and/or value choices) [63, 107]. Concerns regarding the former have led to removing the interpreter entirely, and always using JIT-compiled BPF, in certain settings, in order to reduce the risk of Spectre-like attacks (i.e., via `CONFIG_BPF_JIT_ALWAYS_ON` [103]). However, BPF JIT comes with its own set of security concerns.

First, because BPF JIT provides fine-grain control of native code (i.e., instructions) in kernel space, it is favored by specific transient-execution attacks [32, 71] (against the OS kernel). Second, it has been shown that the JIT engine can be used to facilitate *code injection* [82, 98], and hardening techniques such as *constant blinding* [36] and *code-offset randomization* [53] are added to counter these attacks. Lastly, the JIT compiler itself also suffers from errors. Nelson et al. [86] proposed the use of formal methods to ensure the correctness of JIT compilation, in which they report 82 bugs, demonstrating the difficulty of developing a correct (BPF) JIT compiler. The above issues have made the choice between the BPF interpreter and JIT compiler a difficult one, because both sides come with different security trade-offs. Notably, `defconfig` in x86 Linux, as well as popular distributions, like Debian, choose to keep the BPF interpreter compiled-in, which is what we assume in this work.

3 Threat Model

3.1 Adversarial Capabilities

We consider an attacker who is a local, *unprivileged* Linux user, aiming at escalating their privileges. More specifically:

Unprivileged Access The attacker is able to perform anything an unprivileged user can, like executing arbitrary code in userspace, invoking syscalls, accessing the filesystem, and interacting with OS interfaces (`procfs` [14], `sysfs` [11]).

BPF Functionality The attacker has the ability to *push* cBPF programs in kernel space. First, BPF should be enabled in the kernel. This is true for any Linux kernel compiled with

network support, because the BPF subsystem is turned on by `CONFIG_BPF`, which is selected by `CONFIG_NET` [104]. Second, the attacker should have access to the BPF infrastructure, which is always the case because the `setsockopt`, `seccomp`, and `prctl` syscalls are *not* privileged. Third, the interpreter needs to exist in kernel code, which means that `CONFIG_BPF_JIT_ALWAYS_ON` should be off (§2.2). We do not require the `bpf` syscall being available to the attacker, which can be used to create eBPF programs. Actually, the *unprivileged* `bpf` syscall is disabled in all major distributions [51, 106].

Memory Errors We also assume that the attacker has access to a (at least one) memory corruption vulnerability in kernel code, and that by abusing this vulnerability they are able to overwrite code and data pointers, either in a *temporal* (e.g., use-after-free [23, 24]) or *spatial* (e.g., out-of-bound access [27, 28]) manner. We do not assume any error, or bug, in the BPF interpreter, verifier, or JIT compiler. Although the correctness of these components is challenging [25, 26, 86], this is something orthogonal to our attack(s)/EPF.

3.2 Hardening Assumptions

On the kernel side, we assume that W^X [6] is enforced, such that code injection is not possible. In addition, we consider that the kernel is hardened against ret2usr attacks, using SMEP [112]/PXN [2] and SMAP [49]/PAN [7]. Furthermore, we assume that no implicit memory sharing can take place between userland processes and the OS kernel, and hence ret2dir attacks are not attainable. Note that this is a strong assumption, as currently Linux does not employ a comprehensive defense against ret2dir, like XPFO [67]. We also assume that the page tables are protected against tampering with page table integrity mechanisms, such as PT-Rand [50] or xMP [94]. Lastly, kernel ASLR [54] is orthogonal to our attack(s); if deployed, EPF leverages known techniques to bypass it (§7).

4 Evil Packet Filter

We use the term EPF (Evil Packet Filter) to refer to a set of attacks that (ab)use the BPF infrastructure for injecting malicious payloads in kernel space. EPF allows bypassing existing isolation mechanisms [7, 49], which prevent user-controlled content from aiding kernel exploitation (§3.2). Due to the nature of the in-memory representation of BPF programs, making use of them as an attack vector is quite challenging. First, we describe certain design/implementation details of BPF, how BPF programs are created, what malicious content can be "hidden" in them, and how an attacker can locate them. Then, we describe two EPF-based attacks: *BPF-Reuse* (EPF v1—variant 1) and *BPF-ROP* (EPF v2—variant 2).

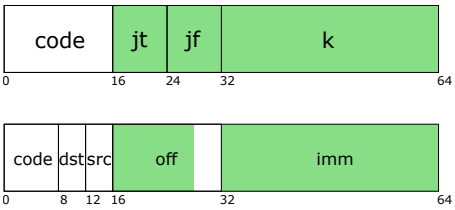

Figure 1: Fields and their sizes (in bits) in cBPF (top) and eBPF (bottom) instructions. Green regions are the parts of the instruction that can be controlled by an attacker.

4.1 Linux BPF Internals

BPF-code Management cBPF programs are primarily created via `setsockopt`, `prctl`, and `seccomp`, which can be used to "push" (cBPF) filtering code in kernel space; eBPF code can be copied in kernel space using the `bpf` syscall.

Both cBPF and eBPF programs are represented using the same data structure: that is, `struct bpf_prog`. We refer to this data structure as the "BPF program"; BPF programs pushed by `setsockopt`, `prctl`, and `seccomp` are considered 'cBPF', while those copied in kernel space by `bpf` are 'eBPF'. `struct bpf_prog` is always *page-aligned* when allocated. After a cBPF program is loaded into kernel space, the cBPF instruction array is duplicated, and stored separately—we call this instruction array as the *original cBPF code*. This code is referenced from `struct bpf_prog` by a member pointer `orig_prog`, allowing the corresponding process to retrieve the original cBPF code later (if needed). Then, the cBPF code is statically verified for safety, and translated *in-place*, becoming a *verified BPF program* (§2.2). Notably, the verification of cBPF programs is different from the one of eBPF programs, and after the cBPF instructions are translated to eBPF instructions, they are not verified again.

Lastly, a verified BPF program goes (optionally) through the process of being JIT-compiled (when `/proc/sys/net/core/bpf_jit_enable = 1`), while the memory permissions of pages that host the BPF program become *read-only*.

Data Structures The BPF program data structure (in the case of cBPF) consists of a header, which includes a pointer to the *interpreter* function, and a pointer to the original cBPF code, and an array of instructions. After verification, the array of instructions contains only eBPF code, due to the in-place cBPF⇝eBPF translation. (We refer to this array as the eBPF code. Notice that, internally, both cBPF and eBPF programs are represented with eBPF code.) BPF programs are allocated from the `vmalloc` region, whereas the original cBPF code is duplicated using `kmalloc` and lives in `physmap` [67].

In cBPF instructions (Figure 1, top), the `code` field is the opcode, defining the respective operation; `jt` and `jf` are two fields used for specifying where to jump if a predicate is true or false; and `k` is used for encoding immediates. Similarly, in eBPF instructions (Figure 1, bottom), both `src` and `dst` encode a number between 0–10, corresponding to one of the

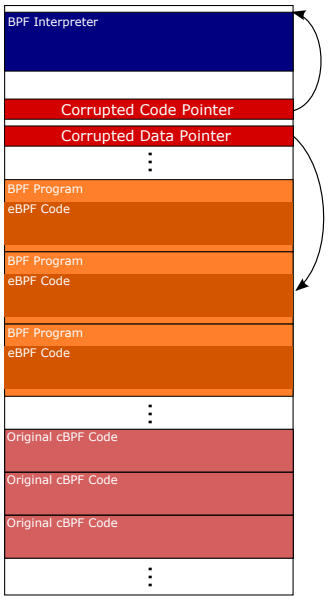

Figure 2: Memory layout during an EPF v1 (BPF-Reuse) attack. The corrupted code pointer points to the BPF interpreter function, and, at the time of its invocation, its argument points to one of the malicious BPF programs.

10 general-purpose registers or the frame pointer; the `off` field is used by memory load/store instructions, and jump instructions, to specify the offset of such operations; and `imm` stores the value of instructions that require an immediate.

Payload-encoding Challenges Ideally, the attacker would like the memory region they control to be of *arbitrary* size and content. However, this is not the case for BPF. Both cBPF and eBPF instructions correspond to 8 bytes, and not all bytes can take arbitrary values, because some of them have restrictions due to verification or translation. Only `imm` and `k` can be used in an *unconstrained* manner, and therefore we will only use these fields for EPF purposes—this corresponds to every other 4 bytes in the {c, e}BPF instruction array. Other fields can be *partially-controlled* or are only controllable iff the BPF program is constructed in a specific way. Hence, more fine-grain control is also possible (see Figure 1), but this is something that we do not explore for mounting an EPF attack.

BPF-code Spraying Although an attacker can control parts of a BPF program's content (both in the case of translated eBPF code and the original cBPF code), they still need to create *reliable references* to such BPF instructions. This can be achieved by *spraying*: i.e., saturating kernel space with BPF programs, and, as a result, a randomly-chosen location will likely contain (malicious) BPF code [67]. Both cBPF and eBPF code are page-aligned, and hence no additional care is needed to locate memory offsets within a page. In the Linux kernel, all allocated objects can be found in the `physmap` region, which maps the whole RAM.

Figure 3: A snippet of the same eBPF code interpreted from different offsets (above vs. below).

During our experimental evaluation (§6.2), we discovered that `setsockopt` is the most effective spraying apparatus: it can be used to saturate ≈80% of all RAM, if the attack can utilize both the translated eBPF code and the original cBPF code, or ≈40% when only one of the two can be used.

BPF Interpreter The interpreter function receives two arguments: a *context* pointer and an (eBPF) instruction pointer. Context is the input to the BPF program—for example, in packet filtering, context points to the respective network packet. The value of the context pointer is loaded onto eBPF register `R1`. (The interpreter will not use this value unless it is used by the BPF program.) The second argument points to the eBPF code that is assumed to be verified. Hence, the interpreter does not validate any (eBPF) operation during execution. Because of its expressiveness, and relatively few side-effects, the interpreter is useful, as a code-reuse target as we will demonstrate in our EPF v1 (BPF-Reuse) attack.

4.2 EPF v1 (BPF-Reuse)

As we explained earlier (§4.1), an attacker can reliably control a large portion of kernel space, by (ab)using the BPF infrastructure, but they can only inject arbitrary values on every *other* 4-byte word—and thus cannot encode traditional code-reuse (e.g., ROP) payloads, which would require controlling 8 consecutive bytes in 64-bit platforms, like x86-64. However, the Linux kernel contains a powerful subsystem that can be leveraged to perform malicious computations with relatively sparse memory control: i.e., the *BPF interpreter*.

Figure 2 depicts the memory layout during an EPF v1 (BPF-Reuse) attack. First, the attacker *encodes* their payload in *valid* BPF programs, and sprays them in kernel space. Then, using a memory corruption vulnerability, they overwrite a code pointer and redirect the control flow to the BPF interpreter. By carefully choosing the respective code-pointer value, the attacker can control the *context* in which the (overwritten) code pointer will be invoked, thereby allowing them to specify an *arbitrary eBPF instruction* to start the interpretation from (i.e., by selecting/controlling the second argument of the invoked function), when the control flow is redirected to the BPF interpreter. Finally, since the attacker has sprayed BPF programs in kernel memory, they can easily find their payload in the direct mapping (i.e., `physmap`) region, with high probability (see Section 6.2).

Eventually, the problem becomes: *Can the attacker embed malicious eBPF code inside a benign BPF program, which escalates their privilege upon execution?*

```
R0 = R0 ^ R0    /* R0 =     {0} */
R1 = R1 / R1    /* R1 =     {1} */
R0 += R1        /* R0 =     {1} */
R0 += R0        /* R0 =    {10} */
R0 += R0        /* R0 =   {100} */
R0 += R1        /* R0 =   {101} */
R0 += R0        /* R0 = {1010} */
R0 += R1        /* R0 = {1011} */
```

Listing 1: Register-only BPF instructions that load the value 11 (`1011` in binary) onto register `R0`. (Values in comments are shown in binary.)

The answer is *positive*. The attacker can offset the eBPF instruction pointer by, say, 4 bytes during the attack, so that the `imm` fields will be in the original locations of `code`, `dst`, `src`, and `off`. A snippet of our eBPF payload is shown in Figure 3. When executed normally, it is an array of instructions that load immediates. However, when executed from a +4b offset, the semantics of that instruction stream are completely different. In what follows, we explain how one can perform different computations under the aforementioned model.

Arithmetics and Register Manipulation All instructions that do not use immediates, such as those moving values, or doing arithmetic, between registers, can be embedded into the `imm` field, as unused immediates are ignored by the interpreter. All *unaligned* instructions shown in Figure 3 do not use any immediates. If the attacker wishes to use constant values, they first need to load the constant into a register, and then perform the respective operation(s) with registers. Loading *arbitrary constants* into a register, without using the `imm` field, can be done solely with arithmetic operations.

Despite not being able to encode arbitrary numbers into `imm`, the attacker can load a non-zero value into a register. Then, say, `div` a register by itself, which leaves the value `0x1` in the register, or `xor` a register with itself, resulting in a `0x0` value. Similar to Listing 1, starting from `R0 = 0x0` and `R1 = 0x1`, any constant can be obtained by repeatedly adding `R0` to itself, and (optionally) adding `R1` to `R0`.

Control Flow Register-based comparisons and jumps can be encoded as usual because they do not use immediates—so conditionals can be done easily. *Looping* is also possible in malicious eBPF code. `off` field is a *signed* 16-bit value: it is signed because the `ld` and `st` instructions can use negative offsets for memory accesses. The eBPF verifier statically checks for non-negative offsets in jumps, but at runtime the interpreter does not check for this property (§2.2).

Memory Access `ld` and `st` instructions can directly access the whole kernel memory. Normally this does not create a security issue because of the (register) range analysis performed by the static checker, which ensures that no such instruction will be performed on a register that (potentially) points outside of the desired bounds. However, similar to branching offsets, this property not enforced at runtime by the interpreter.

By combining the three aforementioned techniques, the attacker can embed malicious eBPF code inside a benign BPF program. With a piece of unverified eBPF code operating in kernel memory space, there are different ways to escalate privilege. In our exploits, we chose to locate `init_task`, a global symbol that is placed in the same linked list with all `task_structs`. Then, we iterate over all processes until we find the attacking process. Lastly, we overwrite the credentials of the attacking process with those of `init_task`, giving the attacking process the highest privilege.

Combining eBPF and cBPF When spraying BPF programs, the RAM can be filled close to full, but not with only the translated eBPF code. The original cBPF code, the user process, the sockets created to attach the BPF programs to, and the JITed eBPF (if enabled), also reside in physical memory and compete for space. It is possible to encode payloads in both eBPF code and in the original cBPF code, and greatly increase the effectiveness of spraying, which translates to a higher probability of successful exploitation.

The problem is that although the allocations are always page-aligned, eBPF code and cBPF code do not start from the same offset *within* their respective pages. For example, in Linux v5.10, the eBPF code starts at a `0x38`b offset, within its page, while cBPF code starts at the beginning of the page. This can be mitigated by using a technique similar to a `NOP`-sled [30]: the attacker encodes malicious eBPF instructions inside benign instructions by offsetting the starting point by 4 bytes. Hence, in the example above, the attacker can start the malicious eBPF code with 7 (`=0x38/8`) instructions that are `xor R9, R9`; these instructions have no effect on the malicious functionality. However, if the attacker now aims at byte `0x3c` within a random page, they will be hitting a memory location that contains either eBPF or cBPF code.

4.3 EPF v2 (BPF-ROP)

Although the memory layout of eBPF code forbids the attacker from embedding 64-bit pointers, it is still possible to do so on 32-bit platforms. This facilitates ROP [100] (or, in general, code-reuse [35, 40, 57]) attacks. We will demonstrate this on x86 by introducing EPF v2 (BPF-ROP). To initiate, say, a ROP attack, the attacker usually needs to overwrite a code pointer with a stack-pivoting gadget [93], moving the stack pointer to the payload, which is an array of code pointers pointing to other gadgets. An immediate strategy would be to use the eBPF code as the payload. Doing so would encounter two challenges: (a) not every 4 bytes can encode return addresses, and (b) such a stack would be read-only.

Since the attacker has control only over every 4 other bytes, some gadgets would make `%esp` point to the gaps in between. If the execution hits a `ret` instruction in this case, it will crash the kernel and terminate the attack. More specifically, if a gadget does not move the stack pointer by +4X bytes, where X is an *odd* number, then the attack will fail.

Access Type	Regular Data	BPF Programs	
		Aligned	Unaligned
Normal Access	Allowed	BPF-ISR	BPF-ISR
BPF Execution	BPF-NX	Allowed	BPF-CFI

Table 1: How regular memory accesses and BPF-code fetches are hardened by our defenses.

To overcome this, EPF v2 filters gadgets based on how they move the stack pointer. Namely, the attacker can use gadgets that have the form: `...; pop %reg; ret`, where the `pop` instruction offsets the return address to a correct location.

EPF v2 divides a ROP (or code-reuse) attack into two stages. The first stage uses stack lifting gadgets only, and bootstraps a new ROP payload for the second stage, at a writable memory area (preferably in the original stack). This strategy requires simpler semantics for the more restricted first stage ROP, which makes gadget-finding much easier. For example, the following is a set of gadgets that can be used to bootstrap a new ROP payload: (1) `pop %edx; pop %ecx; pop %ebx; ret`, (2) `dec %eax; pop %ebp; ret`, and (3) `mov %ecx, (%eax); pop %ebx; ret`. Assuming `%eax` points to a writable region, gadget (1) can load a constant in the BPF filter into register `%ecx`, and gadget (2) can move that value to the future stack; then gadget (3) moves the future stack pointer further down for the next value. In the second stage, the attacker can use arbitrary gadgets. There are a lot of options once the attacker reaches this point. A common practice is to invoke `commit_creds(prepare_kernel_cred(0))` [88]. The ROP representation of the above, in x86 Linux, is just three addresses on the stack: a gadget to clear `%eax`, the address of `prepare_kernel_cred`, and the address of `commit_creds`. (This would not be able to execute during the first stage, as it would require a writable stack.)

5 Hardening BPF against EPF-style Attacks

5.1 Goals and Objectives

Our attacks (EPF v1 and v2) have demonstrated design weaknesses in the BPF infrastructure on Linux. Specifically, they reveal the weak separation between BPF programs and regular kernel memory: arbitrary kernel objects can be used in lieu of eBPF instructions in BPF-Reuse (EPF v1); and BPF code is used as native code pointers in BPF-ROP (EPF v2). More importantly, the problem is exacerbated by the weak runtime checks performed by the eBPF interpreter.

Taking inspiration from hardening native code, we propose to enforce the following properties (shown in Table 1):

① **Prevent regular kernel data from being used as eBPF instructions.** From the perspective of the BPF execution engine, this is analogous to data being non-executable [6]. Without this guarantee, we cannot realistically enforce any property on BPF programs, since they can be counterfeited using regular data. This property stops BPF-Reuse that utilizes the original cBPF code.

② **Ensure that BPF execution starts from benign addresses.** This is similar to control-flow integrity (CFI) on native code [29]. Since all BPF jumps have hard-coded offsets, no indirect branching is possible. The only way to divert the intended BPF control flow is to start from an unintended/unaligned address. This property stops BPF-Reuse that utilizes eBPF code.

③ **Prevent eBPF instructions from being used as regular (control) data.** By isolating BPF programs from regular kernel data, regardless of the amount of BPF programs created, the kernel cannot be misled to access malicious payloads that are embedded inside BPF programs. This property stops BPF-ROP attacks.

Besides the above security goals, we also want the respective code changes to incur negligible runtime overhead.

```
u64 bpf_interpreter(struct bpf_prog *prog)
{
    ...
    enter_bpf_mode();
    check_bpf_cfi(prog);
    initialize_context();
    mask = prog->mask;
    ...
    insn = prog->insns;
select_insn:
    tmp_insn = *insn;
    check_bpf_nx(insn);
    check_bpf_mode();
    tmp_insn = unmask(tmp_insn, mask);
    execute_bpf_insn(tmp_insn);
    if (finished) {
        goto done;
    }
    else {
        insn++;
        goto select_insn;
    }
done:
    leave_bpf_mode();
    return result;
}
```

Listing 2: Pseudocode of the BPF interpreter, instrumented with our defenses against EPF.

5.2 Design

Shown in Listing 2 is a pseudocode implementation of the BPF interpreter; colored lines correspond to our defenses.

BPF-NX To achieve objective ①, we reserve a region in the kernel's address space that is used *exclusively* for allocating BPF programs (not cBPF code, as it is not interpreted).

The interpreter can tell the difference between eBPF code and normal data by just checking an address range (ln. 12[1]). The check is performed for every eBPF instruction load, which is analogous to how a CPU enforces that the instructions are fetched from an executable page. Such frequent checking is required because in a code-reuse attack, the attacker might branch to the middle of the interpreter and bypass any one-time check outside of the main execution loop. In such scenarios, we still need the interpreter to reject instructions from invalid memory ranges.

BPF-CFI Objective ② is essentially defending against code-reuse attacks in BPF programs. BPF-CFI is challenging since we cannot simply check the alignment of the eBPF instructions. Although our attack uses unaligned eBPF instructions for simplicity, it can still be dangerous to even start executing aligned eBPF instructions from the middle of the eBPF code, because the static verifier's security guarantees only hold for executions starting from the beginning of the eBPF code. So the interpreter needs to make sure that the instruction array begins from the correct position in the eBPF code. We add such a check at the beginning of the interpreter (ln. 5).

However, this is not enough. The integrity of the control-flow [29] of the whole interpreter (function) is also necessary. Otherwise, the security check can just be skipped by leveraging a code-reuse attack that starts the execution from the "middle" of the interpreter. Kernel-level CFI [47, 85] incurs some non-negligible overhead, because it protects all code, and cannot be scaled down to protect selected parts of the kernel. Instead, we introduce a *sentinel* variable that is not corruptible by normal execution. The sentinel is used to ensure the control-flow integrity of the interpreter. The sentinel is set at the start (ln. 4), indicating that the interpreter is properly executed; at the end (of the interpretation) the sentinel is cleared (ln. 24). The interpreter checks the sentinel on each eBPF instruction fetch (ln. 13) to ensure control-flow integrity. If the control flow enters the interpreter without going through the correct entry point (i.e., the beginning of the function), it will be caught before any eBPF instruction is executed.

BPF-ISR To achieve objective ③, an obvious solution is to make use of the separation we have done in BPF-NX: whenever the rest of the kernel wants to access normal data, check whether the data lives in a BPF region.

However, it would be inefficient to instrument every memory access the kernel makes. Instead, we adopt the idea of ISR (Instruction Set Randomization), a defense originally designed to counter code injection [33, 65, 101]. ISR is suitable in this case as it is very easy to implement in a software-based interpreter. Every time the attacker tries to allocate a BPF program, the in-memory representation is chosen randomly from one of 2^{32} possibilities. Under normal BPF execution, the mask is extracted at the beginning (ln. 7), then used to unmask every instruction during interpretation (ln. 14).

[1] All line numbers in this section refer to Listing 2.

The attacker can no longer benefit from tricking kernel code into accessing BPF programs as normal memory because the content is randomized and unpredictable.

5.3 Implementation

We implemented our defenses in x86-64 Linux.

BPF-NX In 64-bit Linux, there exist gaps in the kernel's address space that are not used. We reserve a 512GB *unused* region exclusively for BPF programs (`struct bpf_prog`). Originally, the BPF programs are allocated using `vmalloc`, which is a wrapper function around `__vmalloc_node_range`, whose parameters indicate the target range in which the memory is allocated from. `vmalloc` uses a *fixed* range, specified by `VMALLOC_START` and `VMALLOC_END`. To allocate in our reserved eBPF region, we add our own wrapper `bpf_vmalloc` that calls `__vmalloc_node_range` with the proper range. A small change to the page fault handler is also needed, because of the lazy propagation of changes in kernel page tables. The BPF program region needs to be handled similarly to `vmalloc`, where its page table entries are populated on-fault.

BPF-CFI We implement the sentinel variable using the `AC` flag in `RFLAGS`. This flag is the switch for SMAP: turning off the flag allows the CPU in supervisor mode to access user data. We assume that the interpreter itself is benign and does not need the protection against unintended user-space memory accesses. The sentinel variable is set by "turning off" SMAP, and cleared by turning it on. This way, the sentinel variable can easily be checked by an access to a user memory page. During kernel initialization, a dedicated memory page is marked as a user-mode page, and reserved for the access check. At the beginning of the interpreter, we execute the instruction `clac` to disable SMAP. Whenever the interpreter fetches an eBPF instruction, it also reads from the user-mode page, verifying that SMAP is indeed disabled. And at the end, the interpreter executes `stac` to re-enable SMAP.

For the check re: the starting point of the eBPF instruction array, we added 8 `0xff` bytes in `struct bpf_prog` as a *magic* number, which eBPF instructions cannot forge. By checking that this exists at the correct position inside the BPF program header, we assert that it is the right starting point.

BPF-ISR To implement ISR in the eBPF interpreter, we add a new field `mask` in `struct bpf_prog` to store the mask value for each BPF program. After a BPF program is initialized, all the pages are changed to read-only. Right before the permission change, we choose a random 4-byte value as mask, and `xor` the `imm` field in every eBPF instruction with our mask. This ensures that the memory content can not be arbitrarily chosen by the attacker. Since original cBPF code is also stored inside kernel memory, naturally it needs to be masked too. We do not mask the rest of the eBPF instructions because the attacker does not have much control over them. Lastly, the interpreter unmasks each instruction in the stack during the execution of the eBPF instructions.

CVE	Vulnerability Type	Context	Method
CVE-2021-43267	Heap overflow	Process	EPF v1
CVE-2017-7308	Heap overflow	Process	EPF v1
CVE-2016-8655	Use-after-free	Interrupt	EPF v1
CVE-2017-7308	Heap overflow	Process	EPF v2
CVE-2017-6074	Use-after-free	Process	EPF v2
CVE-2016-8655	Use-after-free	Interrupt	EPF v2
CVE-2013-2094	Arbitrary write	Process	EPF v2

Table 2: List of vulnerabilities exploited with EPF.

6 Evaluation

To evaluate EPF (§4), and the set of defenses we developed against it (§5), we used a host armed with a 16-core 3.7GHz Intel Xeon W-2145 CPU and 64GB RAM, running Ubuntu 18.04 LTS (64-bit).

In our evaluation we focused on the following questions:

- **RQ1:** Are EPF attacks realistic?
- **RQ2:** How effective is EPF-based payload injection? How does it compare to other methods?
- **RQ3:** How much overhead does our set of defenses against EPF introduce?

6.1 Effectiveness of EPF (RQ1)

To demonstrate the feasibility of EPF-style attacks, we applied BPF-Reuse and BPF-ROP on existing Linux vulnerabilities with publicly-available exploits (see Table 2).

For BPF-Reuse (EPF v1) we chose 3 vulnerabilities. CVE-2021-43267 and CVE-2017-7308 are heap overflow bugs; our exploit dereferences an overwritten code-pointer in process context. CVE-2016-8655 is a use-after-free bug; a controlled function-pointer is dereferenced in interrupt context. Our payload loops through the linked list of *all* `task_structs` and changes the credentials on the one with the proper `pid`, using the interpreter (§4.2)—as a result, our strategy works in both contexts. This shows the expressiveness and versatility of EPF-based exploitation.

For BPF-ROP (EPF v2) we chose 4 vulnerabilities that also cover interrupt and process contexts with different types of vulnerabilities; 3 vulnerabilities happen in process context, and the respective payloads are setup to invoke `commit_creds(prepare_kernel_cred(0))` (§4.3), whereas for the interrupt context scenario, the ROP payload marks the memory page(s) that host the BPF program itself as executable, and transfers control to (x86) shellcode that in encoded as valid BPF instructions. With native shellcode embedding, we also employ the same strategy of looping through active processes and performing privilege escalation.

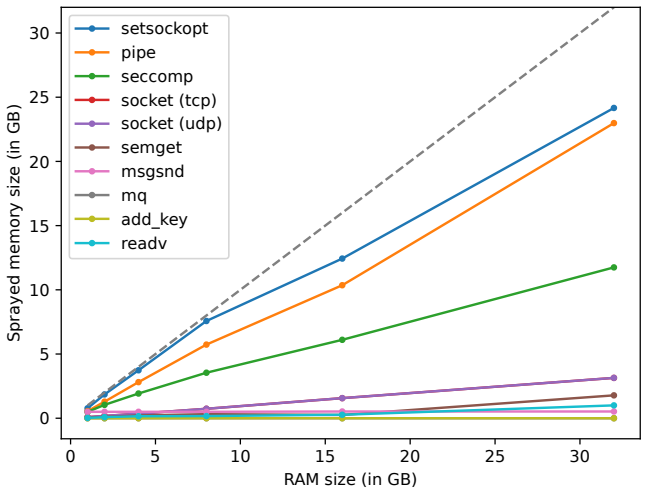

Figure 4: Effectiveness of spraying using different syscalls.

6.2 Spraying Effectiveness (RQ2)

We measured the effectiveness of EPF-based spraying and compared it to other methods. We found reasonable candidates for our comparison. Namely, we chose syscalls as spraying aids using the following three criteria:

• *Syscalls with variable-sized arguments*: In this case, we aim to find syscalls that copy variable-sized data into the kernel. This is done by filtering out syscalls that have a `const` pointer as argument, accompanied by a `size_t` or integer argument specifying the array size. This set includes `add_key` and `readv` (representing all vectorized I/O syscalls).

• *Syscalls returning writable file descriptors*: In this case, we aim to find syscalls that create file descriptors, which can later be used together with syscalls such as `write` to inject data into the kernel. As a result this set includes `pipe`, `bpf`, `socket`, and `landlock_create_ruleset`. The latter is not available in latest Debian (v11), and `bpf` is disabled for unprivileged users by default, so we exclude them.

• *Multiplexed syscalls*: In this case, we manually investigated syscalls with multiplexed arguments (e.g., `ioctl`, `fcntl`) and tried to find semantically similar syscalls for spraying. This set includes `setsockopt` and `seccomp`.

All our experiments took place on a Debian v11 (bullseye) VM, running on the benchmarking host, with its RAM size set at 1, 2, 4, 8, 16, and 32GB, respectively. Specifically, we first start a *monitor* process, which then forks a *sprayer* process and communicates with it via a set of Unix pipes. When the latter stops consuming additional memory, the monitor will spawn a new sprayer. For each method, the probability that the attacker can locate one of the sprayed objects is denoted as *success rate*. Lastly, the respective spraying method can bypass strong kernel-user isolation mechanisms (like XPFO [67]), unless we mention otherwise. As shown in Figure 4, creating cBPF (using `setsockopt` or `seccomp`) is among the most efficient methods.

setsockopt and seccomp We are using `setsockopt` with `SO_ATTACH_FILTER` to attach cBPF programs to sockets, and `SECCOMP_MODE_FILTER` to attach cBPF programs to processes. These two methods do not have quotas/limits set from the underlying kernel. In fact, if we keep allocating cBPF programs, the system will invoke the OOM-killer and try to reclaim memory at some point. If both the translated eBPF programs and the original cBPF copies are utilized (as described in Section 4.2), `setsockopt` can take up to 70% of all physical memory, while `seccomp` can take up to 34%; otherwise, the ratios reduce to 35% and 17%, respectively. In conclusion, spraying cBPF programs has a 70% or 35% success rate depending on the mode used, and the data structure allows controlling every 4 other bytes.

msgsnd The `msgget` syscall creates message queues for SysV-based IPC, and `msgsnd` adds messages to such queues. The maximum memory occupied by the messages is 500MB, regardless of the RAM size. The probability of locating sprayed content is 3%–24% (depending on the total RAM size) with continuous control over the sprayed region.

semget The `semget` syscall creates (SysV) semaphores. By generating 32K sets, each with 32K semaphores, the total limit will be reached. Each semaphore takes up 64 bytes of kernel memory, so the semaphores can consume ≈60GB of memory. But, a significant drawback of this approach is that of the 64-byte data structure only the semaphore variable can be controlled by the attacker, which is only 4 bytes. Therefore `semget` is not realistically useful.

pipe We create 20K Unix pipes for each sprayer process, and write exactly one page of content into each. This method can fill up to 60% of the total physical memory. Since the memory used to store pipes is page-aligned, this translates to 60% success rate, with complete attacker control. However, the sprayed content can be easily isolated using strong kernel-user separation mechanisms (e.g., XPFO).

mq By default, an unprivileged user can have 800KB of data stored in-kernel using POSIX message queues. The attacker will have less than 1% chance of locating the sprayed objects. Additionally, the sprayed content can also be isolated by strong kernel-user separation mechanisms, like XPFO.

socket We use the following strategy to spray with TCP sockets: for each process, create one TCP socket, send messages until it blocks, and then spawn as many processes as possible until socket creation fails. UDP sockets are different; they do not block with failed sending. Hence, we send until the occupied memory in `/proc/net/sockstat` does not change. In both cases, we are able to spray about 10% of the physical memory. This method has 10% success rate and allows for complete control over the sprayed region.

readv and add_key `readv` gives the attacker less than 2% success rate, controlling 6 out of every 8 bytes, while the total amount of memory that can be allocated by `add_key` is 20K bytes. So the success rate of the latter is less than 1%.

6.3 Hardening Overhead (RQ3)

We mainly evaluate our defenses on syscall filtering [80], socket filtering, and XDP [78] `skb` mode.

Syscall Filtering `sysfilter` [52] is an automated syscall filtering tool. It analyzes an application, creates the set of syscalls that the application needs, and then enforces it using `seccomp-bpf`. We evaluate the overhead our defenses incur on Nginx and Redis, when hardened by `sysfilter`, with no BPF-JIT, and the SSB mitigation disabled (by setting `SECCOMP_FILTER_FLAG_SPEC_ALLOW` [80]). The network requests in each test are sent over the loopback (`lo`) device. Both packages are installed from Ubuntu's repository.

To benchmark Nginx, we used `wrk` [56] with 2 running threads, each performing 128 connections, for 1 minute continuously. Nginx is configured to have 2 working processes. To maximize the time spent on BPF execution, we picked the smallest size of requested file from `sysfilter`, which is 1KB. Additionally, we manually inspected the CPU utilization, ensuring it was close to 100%. To benchmark Redis, we used `memtier` [97], spawning 2 worker threads, each with 128 clients, running for 1 minute continously. The ratio between `GET` and `SET` operations was set to 10:1, and each data object was 32 bytes. Again, we also made sure that the CPU utilization was close to 100%. Our results are shown in Figure 5. Our defenses introduce an additional 1.8% throughput decrease on Nginx, and 1.5% on Redis.

Socket Filtering We focus on the usage of socket filtering, similar to a traffic monitoring scenario. A simple traffic generator will send UDP packets in a tight loop, with a body size of 64 bytes to the DUT (device under test); and on the DUT there is a server that receives them. Both machines have 1GbE NICs, and the sending speed is tuned to be slightly higher than the processing capability of the DUT. We use small packets because large packet sizes will mask the BPF processing time.

To simulate a traffic monitor, we attach a raw socket to the ethernet interface and call `setsockopt` to attach a cBPF filter on the raw socket. We use a set of 6 different filter rules, similar to previous network monitoring studies [111], with some changes: (1) the rules are slightly modified to make sure our packets go through the maximum possible execution paths; and (2) we also modify the return instruction to always reject packets and not spend any time reading them, resulting in all overhead showing up on the receiving end.

The cBPF filters are described in the following (`PCAP`):

1. `""` (empty expression that allows everything)
2. `"ip"`
3. `"ip src net 10.116.70.0/24 and dst net 10.0.0.0/8"`
4. `"ip src or dst net 192.168.2.0/24"`
5. `"ip and udp port (10 or 11 or 12 or 13 or 14)"`
6. `"ip and (not udp port (80 or 25 or 143)) and not ip host ..."` (32 IPv4 addresses)

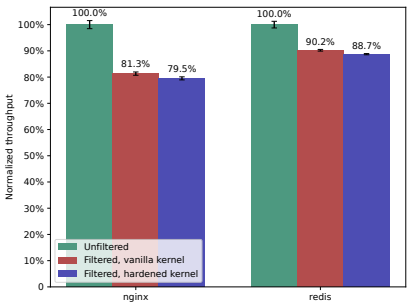

Figure 5: Normalized throughput between vanilla Linux and EPF-hardened Linux when running `seccomp`-protected Nginx and Redis.

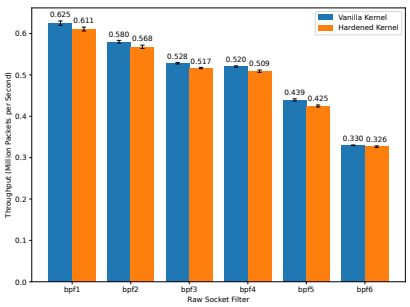

Figure 6: Traffic monitoring performance using different socket filters.

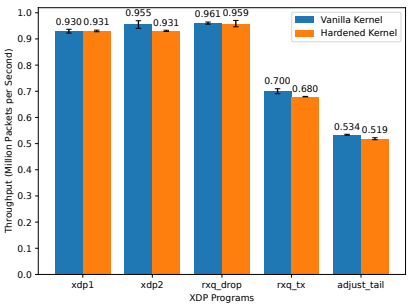

Figure 7: Throughput of XDP programs when run on vanilla kernel vs. an EPF-hardened kernel.

The results are shown in Figure 6; there is a 0.5%–3% reduction in the respective throughput.

XDP Since all cBPF programs are executed as eBPF programs, our defense affects interpreted eBPF programs too. XDP uses eBPF programs to passthrough, drop, re-transmit, or re-route incoming packets. In our experiment, we run XDP in `skb` mode, which executes eBPF programs when packet handling enters the device-agnostic part of the kernel, as the other modes require specific hardware. The experiment setup is the same as for socket filtering. To demonstrate the performance impact on eBPF programs, we run XDP programs (shown below) from the Linux source tree, similar to previous works [39, 59]. The XDP programs will intercept and run on every incoming packet generated by the UDP client.

- `xdp1`: Parse the IP header, count incoming packets and update a counter in a BPF map, then drop the packets.
- `xdp2`: Same as `xdp1`, but re-transmit the packets.
- `xdp_adjust_tail`: Change incoming packets into ICMP packets and send them back, keeping a total count in a BPF map.
- `rxq_info(drop)`: Count incoming packets for each receive queue and drop them.
- `rxq_info(tx)`: Count incoming packets for each receive queue and re-transmit them.

We tuned the traffic generator to send at a higher rate than the maximum throughput. Additionally, we pinned the NIC interrupts to one CPU core and manually verified that CPU utilization was close to 100%. The results are shown in Figure 7: we observed 0%–3% throughput degradation.

7 Discussion

BPF-CFI Considerations To implement BPF-CFI we utilize the `AC` flag, and, as we mentioned in Section 5.3, this flag also controls SMAP. We chose this approach because SMAP was designed to accommodate low-overhead switching.

However, this also means that during the execution of the BPF interpreter SMAP cannot prevent the interpreter from incorrectly accessing userspace data. At first glance this might be a security loss, but in fact the impact is very minimal. Firstly, this is a confined attack surface that is relatively easy to maintain, instead of a complicated invariance to be respected across the whole kernel codebase. Secondly, SMAP is designed to stop the kernel from incorrectly accessing user-controlled data during an attack, but the semantics of BPF programs already grant the interpreter access to user-controlled content such as BPF maps [5], context metadata, and more. In conclusion, SMAP does not provide notable security gains in the BPF interpreter context, while our defense provides better overall security by re-purposing this extension.

KASLR Bypass Although KASLR [54] is sometimes bypassed by arbitrary memory disclosure vulnerabilities, much weaker primitives exist that circumvent KASLR, including bounded memory disclosure vulnerabilities [18, 20, 44] and side-channel attacks [41, 58, 62, 76]. By spraying, our attacks can locate attacker-controlled objects *within the heap*. If the attacker deploys one of the methods to de-randomize KASLR, then they can find *where the heap is located at*. Combining these two capabilities, our attacks can work exactly the same as they would without KASLR.

8 Related Work

BPF JIT Spraying BPF JIT spraying [82, 98] is an exploitation technique that takes advantage of the BPF's JIT engine generating predictable code. By carefully crafting and spraying the JITed code, the attacker can control a piece of code in kernel context, which effectively nullifies defenses against ret2usr such as SMEP and PXN, and re-enables attacks that redirect control flow to user-controlled code—JITed BPF code. BPF-Reuse and BPF-ROP utilize the BPF program data structure itself and aim to control memory content.

Thereby turning BPF programs into a mechanism for injecting payloads for code-reuse attacks. Importantly, the targeted features and the goals of BPF JIT- vs. EPF-based spraying are completely different. Moreover, BPF JIT spraying is already defended against in recent Linux kernel [79], whereas BPF-Reuse and BPF-ROP bypass all existing isolation mechanisms, including XPFO [67], which is not yet deployed in mainline Linux.

eBPF-based Speculative Type Confusion Kirzner et al. [71] pointed out that the eBPF verifier performs extensive analyses, and safety checks, to ensure the execution of eBPF programs is sandboxed, but they did not take into account speculative execution paths. As a result, some eBPF programs deemed safe by the verifier can be vulnerable to transient execution attacks and leak confidential kernel data. The root cause is addressed by adding analyses that account for possible speculation [37]. Our attacks are possible due to a different underlying reason: BPF programs are a type of user-controlled memory object that cannot be easily isolated from the rest of kernel data, and they can be created in bulk.

Other Popular Kernel Exploitation Techniques In the post-ret2usr era, where defenses such as SMEP, SMAP, PXN, and PAN are present, kernel exploitation has evolved to allow for creating addressable payloads at exploitation time. Apart from ret2dir [67], which is discussed in Section 2.1, there are also two other popular strategies to bypass ret2usr defenses. The first strategy is careful heap manipulation that combines heap fengshui [102, 108] with elastic objects (systemized and termed by Chen et al. [43]), which results in disclosing the address of the user-controlled memory object that will become the attack payload. The strategy is used by some real-world exploits [87, 92], and takes advantage of the predictability of the heap layout, whereas EPF abuses the design of BPF functionality. The second strategy is calling functions inside the kernel, which can disable protection mechanisms. It is used by real-world exploits [75], as well as automated exploit generation frameworks [110]. The drawback is that it relies on how defense features are implemented.

After the payload is placed in kernel space, there are several ways to actually realize privilege escalation. One popular method is to overwrite the `modprobe_path` global variable [69], substituting an attacker-controlled binary to be executed with `root` privilege (instead of `/sbin/modprobe`). This is used by exploit authors and the CTF community [109, 114]. Another method is `ret2bpf` (termed by Jin et al. [63]), which is popular in ARM kernel exploits [31] because it does code-reuse using the BPF interpreter, significantly simplifying the search for code gadgets. It tricks the kernel to use attacker-controlled memory as BPF instructions, essentially doing "BPF-code injection", which notably can be defended against by BPF-NX. `ret2bpf` has similarities to BPF-Reuse, but, most importantly, it differs in the method of supplying the attack payload: `ret2bpf` requires the attacker to have the ability to create a payload in kernel space, whereas BPF-Reuse solves exactly this problem (i.e., payload injection).

9 Conclusion

In this paper, we have shown that BPF, a kernel subsystem that allows unprivileged users to push data structures, freely, onto the kernel address space, is inherently susceptible to attack-payload injection. We developed two attacks, BPF-Reuse (EPF v1) and BPF-ROP (EPF v2), and demonstrated how to inject certain payloads. Further, we showed the practicality, and effectiveness, of our attacks by combining them with real-world vulnerabilities to exploit the Linux kernel. We also developed comprehensive defenses that enforce the stronger isolation between BPF code and normal kernel data, and the integrity of BPF program execution, thwarting the abuse of the BPF infrastructure. Our defenses were evaluated on tasks that result in heavy BPF usage, and were shown to have negligible overhead.

Abstract

Virtual machines (VMs) are used for consolidation, isolation, and provisioning in the cloud, but applications with large working sets are impacted by the overheads of memory address translation in VMs. Existing translation approaches incur non-trivial overheads: (i) nested paging has a worst-case latency that increases with page table depth; and (ii) paravirtualized and shadow paging suffer from high hypervisor intervention costs when updating guest page tables.

We describe *translation pass-through* (TPT), a new memory virtualization mechanism that achieves near-native performance. TPT enables VMs to control virtual memory translation from guest-virtual to host-physical addresses using one-dimensional page tables. At the same time, inter-VM isolation is enforced by the host by exploiting new hardware support for physical memory tagging in commodity CPUs.

We prototype TPT by modifying the KVM/QEMU hypervisor and enlightening the Linux guest. We evaluate it by emulating the memory tagging mechanism of AMD CPUs. Our conservative performance estimates show that TPT achieves native performance for real-world data center applications, with speedups of up to 2.4× and 1.4× over nested and shadow paging, respectively.

1 Introduction

Virtualization plays a central role in cloud stacks. Many academic and industry efforts strive to bring its performance closer to that of native (bare-metal) execution [19, 23, 27, 29, 37, 51, 55, 68]. Nevertheless, memory address translation in virtual machines (VMs) introduces non-trivial performance overheads. Worse, these overheads are expected to grow as applications move to larger working set sizes [26, 45], and architectures evolve to use deeper page tables to support more physical memory [1].

Memory translation in VMs (also known as guests) is performed using one of two approaches, each with its own benefits and drawbacks. In *nested paging* (see Fig. 1a), as supported by Intel EPT [51] and AMD nPT [19], VMs self-manage page tables without involving the hypervisor (also known as the host). Nested paging, however, introduces overheads during address translation: it virtualizes guest physical addresses by combining guest page tables with an additional nested page table controlled by the hypervisor. This results in up to 6× more page table entry references than a native system [19] – the MMU must issue up to 24 memory accesses to the page tables, as opposed to 4 in a native system.

In contrast, *shadow paging* (see Fig. 1b) achieves near-native translation performance. However, the guest page table management becomes costly: the hypervisor synchronizes each guest page table with a host (or shadow) page table, which directly translates guest virtual addresses (GVAs) to host physical addresses (HPAs). This avoids the translation overheads of nested paging, but introduces expensive VM exceptions to keep the page tables synchronized — often in an application's critical path.

Despite sophisticated optimizations in today's systems, such as lazy page table shadowing [61] and partial walk caches [32], we observe that workloads see up to 2.4× and 1.4× slowdowns due to nested and shadow paging, respectively (see §6). These overheads are expected to grow in future systems: applications with larger working set sizes [26, 45] will have higher TLB miss rates; emerging workloads such as function-as-a-service (FaaS) and Kata containers [34] rely heavily on process creation inside VMs, adding to page table management overheads; and upcoming CPUs will feature deeper page table hierarchies, resulting in quadratic increases in nested page table traversal overheads [1].

We explore a new approach to memory address translation, *translation pass-through (TPT)*, which enables near-native virtual memory performance in VMs. With TPT, VMs directly control translations to their assigned physical memory, without the extra level of indirection of nested paging, and without the hypervisor interventions of shadow paging during guest page table modifications. TPT is enabled by new functionality in commodity CPUs for physical memory protection using *memory tags*, e.g., in AMD SEV-SNP [60] to support confidential computing features [22]. Our key observation is that this new type of physical memory protection can be leveraged

by hypervisors to efficiently enforce memory isolation between VMs, while allowing the VMs to manage direct guest-virtual to host-physical address translation (see Fig. 1c). Thus, TPT offers a new, more efficient point in the design space across hardware-virtualized, paravirtualized, and shadow virtual memory management.

TPT's gains in memory translation performance come from the fact that one-dimensional page walks in guest VMs, combined with hardware memory protection checks, are faster than the two-dimensional page walks using nested paging. Prior work [6, 7, 16] has shown that the overheads of tag checks can be hidden by performing them in parallel with memory accesses and translation. Recent performance results on AMD SEV-SNP CPUs with physical memory tags [60] corroborate the low-performance overhead for real-world workloads. In contrast, a nested page table walk requires extra steps that are inherently sequential, making it harder to optimize.

To realize TPT, we make the following contributions:

(1) VM isolation with hardware memory protection. TPT leverages MMU support to maintain the host's physical memory frame permissions using tags. By setting per-VM frame tags, we can safely allow VMs to manage direct guest-physical-to-host-physical page tables: the hypervisor ensures that a VM can only access host frames assigned to it, regardless of the host physical addresses in the VM's page tables ("Hypervisor" and "HW" layers in Fig. 1c). Existing AMD CPUs with SEV-SNP already support the host frame permissions we need for TPT; we cannot use SEV-SNP as-is because frame tags are coupled with nested paging and expensive memory encryption, but we would require only simple hardware changes: adding two registers to configure TPT, and enabling the frame tag functionality separately from the rest of SEV-SNP.

(2) Selective user-space translation. Enabling TPT for an entire VM would require a fundamental redesign of the boot process, memory management, and I/O in the guest OS. Fortunately, TPT's performance benefits are largest for user-space applications with large working sets, but are less so for small working-set applications or kernel-space (see §3). The guest OS thus enables TPT only in user-space execution of some processes, which are dynamically identified to take advantage of it. We achieve this by introducing a new type of *TPT page table* with GVA-to-HPA translations that are checked against the VM's host frame permissions, whereas guest kernel code and other non-TPT-enabled processes use the traditional *non-TPT page table* (similar to how PTI works [58]). This supports incremental deployments in which TPT and non-TPT processes and VMs co-exist on a host and with minimal guest OS changes, which simplifies the deployment of TPT.

(3) Hypervisor-compatible extensions. We describe a design for TPT that is compatible with existing hypervisors. TPT only requires modest changes to the KVM interface: it exposes the physical memory map to enlightened guests, and

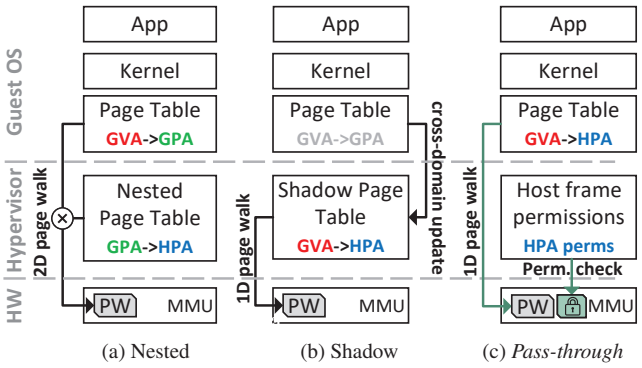

Figure 1: Existing (nested, shadow) and proposed pass-through paging approaches (GVA/GPA mean guest virtual/physical address; HVA/HPA mean host virtual/physical address; PW means page walk.)

extends the guest pvops backend in Linux to seamlessly incorporate the extra TPT page tables. Our design permits the hypervisor to retain control over guest physical memory without introducing performance penalties: the hypervisor can use existing memory ballooning techniques, and can forcibly reclaim host frames from uncooperative VMs. To support host frame reclamation and VM migration, the guest OS keeps a pair of synchronized TPT and non-TPT page tables, which we call *dual page tables*, for each TPT-enabled process; using pvops in the guest OS keeps synchronization transparent and with low overhead. Since a dual page table is always kept in sync, the hypervisor can force any guest process to utilize its non-TPT page table while a host frame reclamation or VM migration is underway.

We implement TPT using a Linux guest and KVM/QEMU hypervisor. We evaluate our TPT prototype using a commodity x86–64 CPU — which does not perform any host frame permission check, but can execute applications much larger than a traditional CPU simulator —, and assume an optimized MMU implementation that executes permission checks in parallel with page table traversal. We also model the performance of a naive MMU implementation where operations are executed in sequence by injecting additional delays in page table walks, and discuss how both approaches reasonably model the overheads that we should expect from a hardware implementation such as is contained in SEV-SNP.

Our results show that an optimized TPT implementation achieves native performance, and is 2× and 1.2× faster than nested paging and shadow paging, respectively, on a PageRank benchmark. Even with a naive MMU implementation, TPT exhibits a geometric mean slowdown of only 3% over native execution for a series of typical cloud workloads, including Memcached and kernel compile.

The TPT implementation is available as open source software at https://github.com/acsl-technion/TPT.

2 VM Address Translation

We discuss the properties of current memory virtualization approaches (§2.1) and motivate the opportunities offered by new hardware protection mechanisms in recent CPUs (§2.2).

2.1 Memory virtualization approaches

Current VMs use one of the three following mechanisms:

Shadow paging uses hypervisor-managed *shadow page tables*, shown in Fig. 1b, that directly translate a guest virtual addresses (GVA) to host physical addresses (HPA). The guest maintains its own page tables, but the hypervisor forces the MMU to use shadow page tables for address translation. Shadow paging thus offers native translation performance with a one-dimensional page walk.

The hypervisor typically write-protects guest page tables, such that *every guest write* to a guest page table traps into the hypervisor to update the shadow page table [4]. Modern implementations thus need to trap on guest page table writes and on privileged guest instructions, such as TLB flushes. Despite elaborate optimizations [61], shadow paging suffers from these high intrinsic costs for page table manipulation.

The performance of page table manipulation is critical for some workloads, such as function-as-a-service (FaaS). With FaaS, process initialization is on the critical path of function invocations, which includes page table manipulations [25]. To achieve strong isolation, FaaS runtimes are commonly deployed in VMs, e.g., Kata containers [34, 52], which makes page table management a performance-critical operation.

Paravirtualization of MMUs, e.g., in Xen-PV [14], predates hardware virtualization extensions. It can be seen as a variant of shadow paging in which traps are replaced by explicit hypercalls in the guest OS, used to request changes to the hypervisor-managed GPA-to-HPA page tables.

Paravirtualized page tables, however, are costly: hypercall overheads are of the same magnitude as the traps in shadow paging, requiring context switches between VMs and the hypervisor. While paravirtualization can batch modifications to reduce overheads, lazy shadow paging can achieve similar benefits. Therefore, only older hypervisors used paravirtualized page tables by default [12, 14], newer ones use optimized shadow paging and nested paging [13, 66, 73, 75].

Nested paging is a hardware-accelerated approach that performs GVA-to-HPA translation using two hierarchies of page tables: (i) guest (VM-controlled) page tables and (ii) host (hypervisor-controlled) page tables (see Fig. 2). The guest page tables translate GVA-to-GPA (guest physical addresses); the host ones translate GPA-to-HPA. Every GPA in a guest page table requires a GPA-to-HPA translation by the MMU. This procedure is called *two-dimensional page walks* [19].

A two-dimensional page walk multiplies the number of memory accesses per address translation. In the worst case, a single translation must access m levels of the guest page table (horizontal dimension in Fig. 2), where the GPA of each level

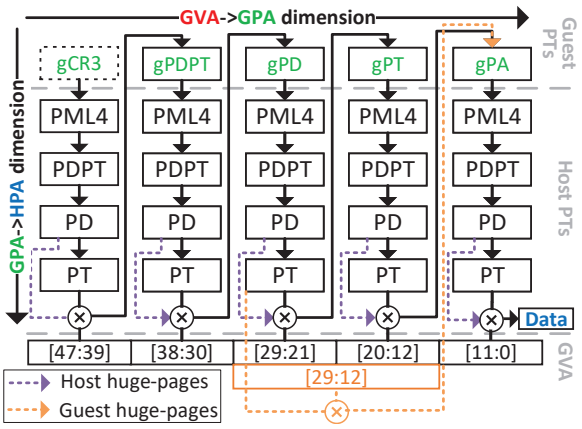

Figure 2: 2-D page table and page walk for nested paging

is first translated by accessing n levels of the host page table (vertical dimension), plus n and m accesses to the contents of the respective page tables: $nm+n+m$ memory accesses in total (e.g., 24 memory access in existing x86–64 processors using 4 KB pages, where $m=n=4$).

Several studies have reported that the overheads of two-dimensional page walks may account for over 30% of application execution time [19, 57]. With the growth in working set sizes and deeper radix page tables [1], this could lead to a quadratic increase in memory virtualization overheads.

Translation overheads can be reduced by using huge pages on the host and/or guest page tables. This bypasses part of the page walk, as shown in the dotted lines in Fig. 2. Their use, however, is not always feasible and may lead to under-utilization of memory due to internal fragmentation [54]. Hardware partial walk caches target similar optimizations but are typically less effective due to their reliance on spatial and temporal reuse [32].

Despite its higher translation costs, nested paging is often the preferred virtualization approach, because it enables guests to perform page table updates without hypervisor intervention while remaining compatible with full virtualization.

2.2 Hardware memory protection

Physical memory protection, recently introduced in commodity CPUs, offers a new hypervisor-controlled mechanism for memory isolation across VMs [60, 64]. AMD SEV-SNP [60] is one example of such technology, which utilizes both memory encryption and physical memory tagging to enhance VM isolation; other architectures, e.g., RISC-V, also offer mechanisms for physical memory protection [71].

In AMD SEV-SNP, the MMU checks each host physical memory access against a *host frame permission table* (called *RMP*) that identifies which VM can access each host frame. The RMP is a physically-contiguous array of memory that contains one entry per host frame. Each entry has a unique identifier of the VM that the host frame is assigned to. Since the MMU checks every HPA against the RMP, this ensures that VMs only access HPAs assigned to them.

RMP checks only happen during a TLB miss, and AMD's implementation has various optimizations to reduce their overhead: (1) RMP entries can be cached as regular data when accessed by the MMU during a page walk, minimizing RMP memory accesses (page table entries can be cached too); and (2) cache lines are extended with their RMP entry to eliminate RMP lookups on cached data.

To decide if it is possible to leverage such hardware memory protection features to accelerate address translation and page table manipulation in VMs, we can consider existing AMD SEV-SNP deployments. SEV-SNP is integrated into Microsoft's Azure cloud platform, and recent performance results show a low overhead for SEV-SNP-enabled VMs [48]. Since SEV-SNP performs both host frame tagging and cache line encryption, with the latter dominating performance overheads [49], using just host frame tagging as part of memory translation should have an even lower overhead (see §5.4).

3 Translation Pass-Through Design

Our design goals and key insights for TPT are as follows:

Native performance. Our solution should offer efficient translation in both current and future systems, where we expect existing memory virtualization approaches to not scale (see §2). Our insight is that, unlike the quadratic overhead of nested paging, VM translation with host physical memory tagging adds a single access to the tag for each page table level. Prior work has shown that such overheads can be largely hidden at the micro-architectural level [6, 7, 16] (see §5.4), and existing commercial results seem to indicate the same [48]. Thus, we make a choice to use tagged physical memory to achieve native translation performance in VMs.

Compatibility with hypervisors/guests. To facilitate adoption, our solution should avoid major changes to existing hypervisors and guest OSs. Achieving this is challenging, as memory translation is deeply ingrained in hypervisor and guest OS implementations. Paravirtualization is often used in virtualized environments in which full hardware virtualization is too complex to implement or too expensive [30, 50, 59]. Nevertheless, a fully paravirtualized memory management interface, such as Xen-PV [74], would require extensive changes to the guest OS, including the boot sequence, I/O layer, and kernel memory management.

To sidestep this complexity, our observation is that TPT's translation approach can be confined to user-space applications, which experience the highest gains. It can be enabled dynamically for each guest process at runtime. As we show in §5.2, TPT is not expected to benefit kernel performance. By limiting TPT use to user-space, we avoid changes to I/O management, guest system boot or guest memory management, and maintain compatibility with existing hypervisor interfaces and host memory management features, such as VM migration or host frame reclamation.

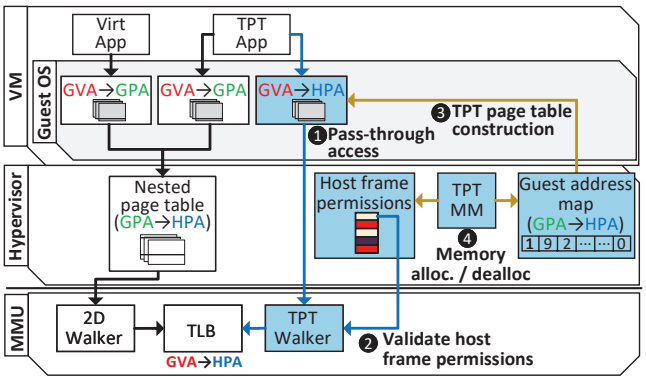

Figure 3: TPT prototype design (Extensions to hardware, hypervisor, and guest are shaded. Memory fast-path translation are blue arrows. Page table management are yellow arrows.)

3.1 Design overview

Fig. 3 shows the main components of our TPT prototype. As a starting point, we assume that the guest OS and hypervisor use nested paging by default; however, our design is general and also applicable to shadow paging (e.g., Linux supports both) or a hybrid system [27, 50]. Further, we assume the availability of hardware memory protection using host frame tags as used internally in AMD SEV-SNP (see §2).

By default, every guest process has a single non-TPT page table (as usual; see "Virt App" in Fig. 3), until the TPT prototype enables TPT on that process. At this point, the guest OS constructs and maintains *dual page tables* for that process, by keeping both a TPT and non-TPT page table in sync (see "TPT App"). We could instead have one or the other depending on whether we enabled TPT on each process, but maintaining dual page tables is inexpensive (evaluated in §6.3), keeps change complexity low, and makes host frame revocation simple to implement: e.g., during host frame reclamation or VM migration, the hypervisor can force all processes to use their non-TPT page table until the guest OS has "repaired" the corresponding TPT page tables (see § 3.2, 3.4 and 4.2).

The guest OS uses the non-TPT page table as the canonical representation of address translation. It only maintains a TPT page table for user-mode execution of processes for which it explicitly requested TPT (step ❶). When running with TPT, the guest updates both page tables, thus keeping them in sync.

To populate the TPT page table, the guest OS retrieves GPA-to-HPA translations from the "guest address map" (step ❸). The guest address map is a data structure used by a VM to know the mapping between its GPAs and the corresponding HPAs. The hypervisor maintains one guest address map for each VM, maps it as a read-only guest physical memory range when a VM boots, and updates it each time the hypervisor changes a guest-to-host physical memory assignment for that VM (step ❹). This approach minimizes changes to the hypervisor since we can reuse GPA faults and existing balloon drivers to manage host frames, and to update the corresponding guest address map and host frame permission table.

The design of dual page tables assumes that each hardware thread has registers pointing to both page tables (TPT and non-TPT), and that the hypervisor may force a VM to use its non-TPT page tables despite also having TPT page tables. We describe the necessary hardware extensions in §4.

3.2 Dual page tables in the guest OS

Every hardware thread has hardware support to access the dual page tables, by using separate page table pointer registers. This ensures compatibility: non-TPT VMs require no changes at all, and TPT-enabled VMs boot without changes — i.e., no TPT page-table is used. A TPT VM then dynamically enables TPT by providing a TPT page table, and can also disable it.

The guest OS enables TPT on a per-process basis, and for user-level code only, where TPT is most effective (see §5.2). TPT can be activated for a process based on an explicit user request. One could extend this with automated runtime policies, although this is out of the scope of this paper; e.g., by monitoring performance metrics such as TLB-miss rates, RSS values, and page-walk cycles.

The guest OS always operates on the canonical non-TPT page table, with its GVA-to-GPA translations, to avoid changes on existing components such as memory management abstractions and algorithms, e.g., to perform reverse virtual address lookups. Each time a non-TPT page table is modified, the guest OS efficiently reflects the changes to the corresponding TPT page table, if any. Entries in a TPT page table take the canonical GPA and translate it to the corresponding HPA using the added guest address map in step ❸, which provides "GPA→HPA" translations specific to this VM.

3.3 Page walks and host frame permissions

The hypervisor assigns a unique identifier to each VM, which is used in the host frame permissions table to mark which host frames are assigned to each VM. When the MMU traverses a TPT page table, it raises an exception into the hypervisor whenever the tag for the VM does not match that of an accessed host frame.

Note that a 4-level page walk in TPT incurs up to 9 memory accesses, but allows micro-architectural optimizations to hide permission checks (see §5.4). If we instead look at a 5-level page table, nested paging goes from 24 to 35 memory accesses, but TPT only goes from 9 to 11 memory accesses, highlighting the advantage of TPT when moving to upcoming architectures with larger physical memory spaces [1].

The behavior of a non-TPT page table is unchanged (see "GVA→GPA" in Fig. 3): a TLB miss triggers a traversal from the MMU, which performs a two-dimensional traversal when using a nested page table set by the hypervisor.

3.4 Host frame management in the hypervisor

The hypervisor tracks GPA→HPA assignments as usual: guest accesses to an unassigned guest frame trigger allocation and mapping into a host frame, i.e., via guest access to an unmapped page in the EPT.

These host frame assignments are captured by the hypervisor's TPT *memory manager* ("TPT-MM" in step ❹). It then updates the host frame permissions used by the MMU in step ❷ and the per-VM guest address map used by the guest OS in step ❸ (see §4.2 for more details).

The hypervisor reclaims host frames from a VM by using the existing balloon driver. When frames are released to the hypervisor, the latter updates the guest address map and host frame permissions accordingly, followed by the invalidation of the TLB entries using existing mechanisms – nested paging uses instruction `INVEPT` in x86–64, whereas shadow paging uses a reverse map to invalidate individual pages.

In some cases, the hypervisor must forcibly reclaim host frames without guest OS cooperation (e.g., the VM is uncooperative or its balloon driver is slow to respond). We design a protocol between the guest OS and hypervisor to handle this case: (1) the hypervisor forcibly disables the use of TPT page tables on that VM and injects a "TPT status" exception onto it. Since the guest has dual page tables, the processor will exclusively use the non-TPT page tables; (2) the hypervisor reclaims any host frames it needs from the VM as usual, removes them from the guest address map, and resets the host frame permissions; (3) the hypervisor resumes guest OS execution; (4) the guest OS gets the injected interrupt and "repairs" the affected page tables to ensure that they do not use the reclaimed host frames; and (5) the guest OS issues a hypercall to notify the hypervisor it can re-enable TPT.

VM migration is handled similarly. The hypervisor disables TPT during migration and notifies the guest OS upon completion by injecting the "TPT status" exception. At this point, the guest OS repairs its TPT page tables based on the new guest address map contents, and re-enables TPT.

Note that this protocol is only needed for TPT-enabled guest processes, which we expect to be a small fraction of all VMs and guest processes. It also only triggered in already expensive cases, such as forceful host frame reclamation, and VM migration. Failure to unmap reclaimed host frames is not a security issue: the VM does not have access to such frames through the host frame permissions, and guest access to an unassigned frame results in an exception in the hypervisor, which can allocate a new frame or terminate the VM.

3.5 I/O host frames and pass-through devices

The host frame permission table only covers the system's main memory address range, which prevents support for pass-through devices on TPT processes (e.g., a DPDK application with VM device pass-through [2, 24]).

To support such additional physical memory address ranges, TPT includes new privileged address range registers, which are configured by the hypervisor to grant a VM access to the selected ranges (selected during VM boot). These ranges are assigned to the executing VM, and the hypervisor exposes their HPAs through the guest address map. This mechanism operates similarly to x86 MTRRs [32] and AMD's IORRs [8].

Name	Description
TPT-cr3	Root TPT page table location (zero disables TPT)
cpuid leaf	Discovery for TPT support
tag_{base,end}	MSR w/ physical addr. of host frame permissions table
VMCS TPT-tag	Tag associated with VM (zero disables TPT)
VMCS TPT-IORR	Address range regs. for VM permissions to HPA ranges
TPT-fault	Exception for invalid permission access
TPT_enable	Hypercall to request TPT enable
TPT_status	Hypervisor-injected int. to signal TPT status change
TPT_addrmap	Virtual PCIe device with guest address map

Table 1: TPT interface added to CPU (Guest ISA (top); hypervisor ISA (middle); guest/hypervisor interface (bottom).)

4 Implementation

We implement a prototype of TPT for Linux 5.16 that consists of 1,700 lines of code (LoC) for the guest OS extensions, 500 LoC in the KVM hypervisor, and 700 LoC in QEMU to configure and start VMs (counted using CLOC [21]). Our prototype targets x86-64, but most changes are architecture-agnostic. Table 1 summarizes the changes visible at the ISA and guest/hypervisor interface, where VMCS identifies the VM hardware configuration fields. In particular, dual page tables are implemented by setting both cr3 and the new TPT-cr3 (which can be disabled by the hypervisor by setting VMCS field TPT-tag to zero).

4.1 Hypervisor extensions

Our hypervisor is based on Linux KVM/QEMU and supports shadow and nested paging by default.

Host frame permissions. The host frame permission table is located in contiguous host physical memory, spanning as many entries as frames in the host physical memory range. With 32-bit tags (already used by AMD SEV-SNP [60]), that corresponds to a 0.1% memory overhead.

The table is configured by the hypervisor, which sets registers tag_{base,end} (similar to AMD RMP_{BASE,END} [8]). In addition, the hypervisor provides a unique TPT identifier for each VM in VMCS field TPT-tag (checked against host frame permission table entries), or sets it to zero to disable TPT (e.g., when migrating a VM or forcing page reclamation).

Extra memory ranges are permissioned by the hypervisor via VMCS TPT-IORR (e.g., for user-level device passthrough; see §3.5), which are used when the requested address is outside the DRAM's physical address space.

Guest address map. The hypervisor generates a mapping for every VM to translate the VM's GPAs to their corresponding HPAs. Upon booting the VM, the hypervisor constructs the guest address and maps it as a read-only guest physical memory range in the VM. Each map is an array in the host virtual memory that covers the guest physical memory range and extra pass-through device ranges assigned to the VM (configured via QEMU). This map is exposed as a virtual PCIe device to VMs (TPT_addrmap), and the size of each map entry is 8 B per 4 KiB frame, resulting in 0.2% memory overhead.

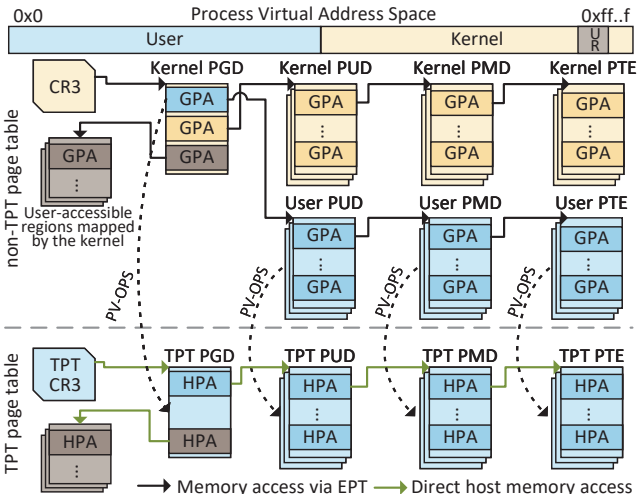

Figure 4: Dual page tables in guest OS (Changes in non-TPT page tables are synchronized to TPT page tables via pv_ops.)

We extend KVM's tdpmmu [63] to update the guest address map's contents when modifying GPA mappings without allocating hypervisor memory on unmapped guest sub-ranges.

4.2 Guest OS extensions

The guest OS changes are largely restricted to a new TPT-specific paravirtualization backend. The new features are activated when the guest OS kernel detects TPT support by the hypervisor (via a new cpuid leaf, configured by the hypervisor). After the discovery of TPT, the guest OS maps the TPT_addrmap device as a write-back (cacheable) memory range as its guest address map.[1]

To enable TPT for a process, the guest user writes to a new procfs entry, which triggers the construction of dual page tables. After the TPT page table has been created, the kernel puts the TPT page table into the new TPT-cr3 register to activate it when a process is rescheduled.

Dual page tables. Our guest OS maintains dual page tables, shown in Fig. 4, and the TPT page tables only cover addresses accessible in user-mode. The guest disables TPT every time it enters kernel-mode and re-enables it when exiting back into user-mode by writing into TPT-cr3 (similar to existing PTI logic [58]). Note that the regular cr3 register always points to the non-TPT page table, in case the hypervisor forcibly disables TPT (see §3.4 and §4.3).

To synchronize the dual page tables, the guest patches the page table operations via a new pv_ops backend when it detects TPT support. pv_ops is an existing Linux kernel API that abstracts core kernel operations in a guest OS to work optimally across different hypervisors, and is used by default on

[1] We modify the kernel's iomap to support cacheable accesses with the right PAT [56] memory attributes. Note that the virtual device's contents are backed by host memory.

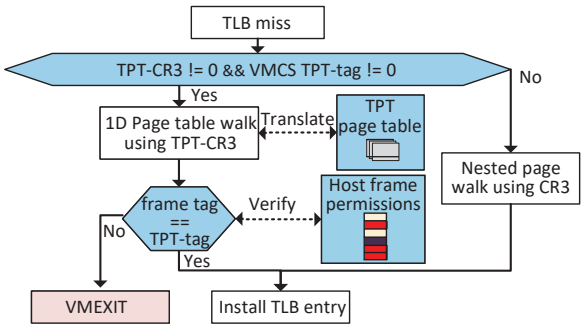

Figure 5: MMU logic to select TPT/non-TPT translation

most VMs. These core operations include page table manipulations, and the overhead of enabling this API is negligible – Linux leverages dynamic code patching to optimize calls to the hypervisor backend selected at boot time.

Every page table modification on a vanilla Linux guest uses GVAs and GPAs and goes through the `pv_ops` mechanism. TPT's `pv_ops` backend performs all requested changes as usual on the non-TPT page tables, but also synchronizes changes to user-accessible addresses with the corresponding TPT page table. Maintenance of dual page tables is therefore transparent to the guest kernel, and requires no more than 3 additional memory accesses to update the TPT page tables. First, the necessary GPA-to-HPA translation is retrieved from the guest address map. Next, the TPT page table entry is located by accessing the extended `mapping` field in `struct page` of the non-TPT page table. Finally, the TPT page table entry is updated with its new HPA value.

In most cases, the guest OS accesses a GPA before mapping it into a page table (e.g., when zeroing it), ensuring that a translation is available in its guest address map. In the few cases in which a GPA is not allocated to a HPA, the guest touches the page to force its presence, going through the pre-existing guest physical memory page-in logic of the hypervisor.

Huge page support. TPT supports huge page translation optimizations, which are used if a page is huge on both the guest and the host (note that the same happens with nested and shadow paging). Our backend adds 12 `pv_ops` functions to support TPT with huge pages.

4.3 MMU extensions

Fig. 5 shows how the hardware extensions for TPT work on a TLB miss. If `TPT-cr3` is supplied by the guest OS and the VMCS `TPT-tag` has not been zero-ed by the hypervisor (disabling TPT), the MMU uses the TPT approach for translation; otherwise, it falls back to using the VM's regular page table walk, e.g., via nested paging, as shown in the figure.

With TPT, the MMU takes each address in the page table from `TPT-cr3` as a HPA. The MMU obtains the HPA's assigned tag from the host frame permission table. It extracts the frame number from the HPA and uses it to index into the permission table. If the retrieved value matches the VMCS field `TPT-tag` (cached in an internal register), the MMU continues to the next page table level; otherwise, it raises a `TPT-fault` exception in the hypervisor. If the HPA falls into any of the VMCS `TPT-IORR` ranges, the MMU considers the HPA valid before accessing the host frame permission table.

Note that various micro-architectural optimizations are possible to perform host frame permission checks during TPT page table traversals, which are discussed in §5.

5 Discussion

Next, we discuss design alternatives, the limitations of the design, and how different design choices relate to them.

5.1 TPT with Xen-PV

TPT is not based on Xen-PV [74] due to performance and compatibility considerations.

To update guest page tables, Xen-PV employs a mechanism called direct-paging that exposes the GPA-to-HPA mappings per guest, similar to TPT's guest address map. However, unlike the TPT model, Xen-PV guests must perform costly hypercalls to update their own page tables. Xen-PV also requires all guest code to execute in ring-3, which introduces hypercall and VM traps to execute privileged guest instructions. Furthermore, Xen-PV exposes a *machine-wide* HPA-to-GPA mapping to *all of its guests*, which is required for page table management operations, and thus reduces inter-VM isolation.

From a compatibility perspective, TPT's KVM-based design is non-disruptive and allows gradual adoption: TPT's hypervisor supports both TPT and non-TPT guests, and TPT guests can run on non-TPT hypervisors (without TPT's benefits). TPT supports full hardware-based virtualization, and provides a modular and adaptable implementation.

5.2 Impact of TPT on kernel-mode

Our guest OS prototype uses TPT page tables during user-mode execution only. This is because Linux kernel-mode accesses have very small translation overheads: it maps all kernel memory using 1 GiB pages [28], making TPT's benefits in kernel mode marginal. In addition, kernel-mode TPT support would be more complex and intrusive: e.g., kernel mode has a linear map for the entire physical address space, and handles physical addresses, such as DMA and contiguous memory allocator (CMA), making the addition of two physical addressing modes (GPA and HPA) more cumbersome. We leave the exploration of kernel-mode TPT to future work.

We quantify the potential impact of kernel-mode support for TPT by measuring the performance of randomly accessing 100 GiB of memory in kernel-mode. We compare shadow paging (with direct GVA-to-HPA translations) and nested paging (with 1 GiB guest kernel pages) and confirm that TPT would provide limited benefits: nested is only 9% and 3% slower than shadow paging when using typical 4 KiB and 2 MiB host pages, respectively, whereas we see overheads of 1.5×–2.5× with the same random access pattern in a user-space application (which does not use 1 GiB pages).

5.3 Impact of TPT on memory de-duplication

By using a single, per-VM tag, TPT cannot support memory de-duplication across TPT processes on different VMs (e.g., via Linux KSM [9]). The same problem exists in AMD SEV-SNP, but is less severe in TPT because only TPT-enabled processes are subject to this limitation: all other processes and kernel-mode pages can still benefit from KSM. It would also be possible to change the hardware to assign multiple `TPT-tag` values to a single VM, and use tag mismatch exceptions to soft-multiplex a larger number.

5.4 Host frame permission check performance

TPT uses per-VM tags to check host frame permissions, something that is inspired by AMD's SEV-SNP [60]. TPT's hardware extensions are feasible with minor changes to AMD's SEV-SNP (described §4.3). Similar changes can be applied to other existing and upcoming architectures that support efficient host memory tag checks such as CHERI [72], RISC-V with PMP [71], and Arm [10, 33].

A naive MMU implementation would perform page table walks and host frame permission checks in sequence, issuing up to 9 memory accesses – a 2.7× improvement over the 24 accesses of nested paging. In practice, there are several micro-architectural optimizations to hide tag accesses and checks: (i) partial walk caches will skip intermediate host frame permission checks; (ii) tags can be embedded into the data they describe to avoid accesses; (iii) tags can be cached to reduce access times; and (iv) host frame permission accesses and checks can be overlapped with page table traversal. More specifically, AMD SEV-SNP embeds host frame tags into the data they tag within the cache hierarchy (reducing the number of accesses), and caches the tag table's contents in the regular cache hierarchy (reducing access latency). Note that some MMU implementations already use the L2$ to cache page table entries, and others have evaluated using a separate tag cache [33]. An optimized MMU implementation would hide permission check accesses by executing them in parallel to page table traversal, which can continue speculatively.

5.5 Security considerations

A malicious or faulty guest in TPT could produce page tables in which any of their levels point to an HPA not assigned to the executing VM (defined as an "incorrect HPA" from here on). An instruction that accesses memory through an incorrect HPA is never committed, but speculatively executing page table walks and permission checks in parallel could lead to potential side-channel attacks, where the page walker logic is used to prime cache lines not assigned to the executing VM.

Single-VM case. We can terminate any such VM that accesses incorrect HPAs, thus avoiding data leakage within a multi-core VM (e.g., to prime/probe cache lines separately).

Inter-VM case. Leakage could happen across colluding VMs: one VM may use the page walker to prime a cache line based on confidential data, and the other VM uses a prime/probe side-channel attack based on the line primed by the first VM [43, 78]. This is a super-set of the single-VM case above.

Such inter-VM side-channels already exist in current systems, since the micro-architectural mechanisms are the same. We can use VM termination, together with existing mitigations to resolve them, and therefore enable aggressive host frame permission check implementations: (1) immediate VM termination ensures that a channel has minimal bandwidth, and an operator can throttle VM creation when frame tag mismatch exceptions rise; (2) integrating VM tags into the cache hierarchy, as done by SEV-SNP, links permission checks and cache accesses, reducing the window of vulnerability to a single memory access (every page table walk access is tag-checked when the cache line is loaded); and (3) existing mitigation techniques are applicable to TPT, such as cache partitioning [42], or controlling the flow of micro-architectural information during speculative execution [36, 76].

Note that the guest address map exposes HPAs set by the hypervisor in response to memory usage of all VMs. This could be used as a side or covert channel between VMs, but the same is valid for memory ballooning or guest physical memory paging. The same, existing mitigations should be applied in all three cases, such as event frequency modulation.

6 Evaluation

Our evaluation demonstrates the performance gains of TPT over traditional virtualization mechanisms. To evaluate our TPT prototype, we conduct a functional emulation of its hardware capabilities on a commodity x86–64 machine, and assume that VMs only map and access their assigned pages.

Our evaluation platform cannot enforce frame tag checks in hardware, and we instead model the performance impact of the frame tag check hardware for two extreme points in the micro-architectural implementation space of the MMU (see *TPT-opt* and *TPT-naive* below). Using this approach, we assess the end-to-end impact of the proposed approach on large-scale workloads, since traditional CPU simulators would make their evaluation unfeasible. While AMD SEV-SNP already implements frame tag checks, we were unable to repurpose it to more directly evaluate TPT; this is because frame tag checks are coupled with nested paging and memory encryption, both of which introduce substantial overheads that we could not isolate.

6.1 Experimental methodology

Testbed. We use a server with 2× Intel Xeon Silver 4216 CPU and 512 GiB of memory (2× 256 GiB DDR4 2,933 GHz). It has an SR-IOV capable NIC (Mellanox ConnectX-4 Lx), which exposes dedicated virtual functions (VFs) for the host and VMs. Intel virtualization support (`VT-x`) and Intel virtualization for direct I/O access (`VT-d`) are enabled for VMs to have direct access to their dedicated VFs (using `vfio-pci` pass-through). Hyperthreading is disabled, the frequency governor is set to "performance", and "turbo" is disabled for

stable results. Both VMs and hypervisor run Ubuntu 20.04 with Linux kernel 5.16. VMs are managed by QEMU with KVM acceleration, have 16 vCPUs with 156 GiB of memory, and each vCPU is pinned to a separate physical core.

We use NUMA node 0 to evaluate both native and virtualized executions. NUMA node 1 executes client agents (without virtualization) for workloads that require requests over the network, which are passed to the physical NIC, and routed via the NIC's internal switch to the correct VF.

Hardware emulation and performance modeling. We emulate the proposed hardware extensions for TPT on the x86-64 platform in two ways:

(1) Host frame tag checks. Our base results execute on the commodity machine "as-is" and assume an optimized MMU implementation where host frame permission checks have no performance impact (*TPT-opt* below). This is a reasonable approximation as SEV-SNP has micro-architectural optimizations to hide the latency of host frame permission accesses (see §5.4), whereas traversal and check operations can be executed in parallel without compromising security (see §5.5).

We also model the performance of a naive MMU implementation where traversals and checks execute sequentially (*TPT-naive* below), resulting in an extra memory access on every page-walk cache miss. We obtain a conservative performance estimate of the naive MMU implementation by placing TPT page tables on a different NUMA node from the one with executing cores; this effectively doubles the access latency, from 81 ns to 161 ns, respectively, according to MLC [69]. A similar technique was used to model larger latencies in prior works [40,77]. This is a reasonable approximation on existing hardware since SEV-SNP avoids tag accesses by extending cache lines, and hides tag accesses by caching them (others have also proposed separate caches to avoid capacity conflicts [33]). Note that we cannot model the added memory bandwidth consumed by tag accesses, but other tagged systems show overheads below 2% on most applications, and as low as 8% in the worst case [33].

(2) MMU walker logic. Current platforms lack the necessary hardware for registers `cr3` and `TPT-cr3` and the additional MMU logic we propose to manage them, as shown in Fig. 5. We therefore emulate these extensions in software; we modify the hypervisor to intercept `cr3` operations in TPT processes, select between `cr3` or `TPT-cr3`, and enable EPT or TPT translation modes, respectively.

We add support in KVM for per-vCPU EPT control, and patch the guest OS PTI [58] assembly thunks to perform the following hypercalls when executing TPT processes:

(i) Kernel-to-user: disable EPT on the vCPU, set the guest's `cr3` to `TPT-cr3`, intercept and emulate guest `cr3` reads to return the guest's original `cr3` value (sometimes performed in exception handling during guest execution).

(ii) User-to-kernel: enable EPT on the vCPU, restore the guest's original `cr3` value, and disable `cr3` read interception.

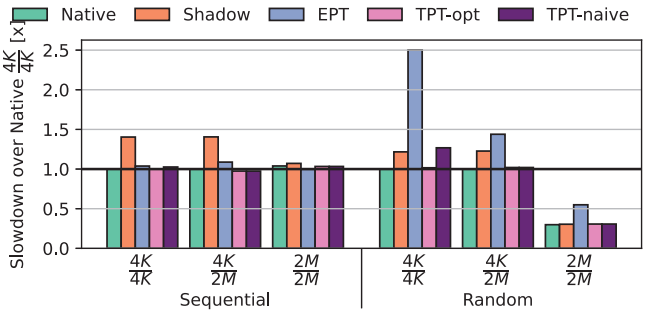

Figure 6: Relative slowdown for different translation mechanisms over native $\frac{4K}{4K}$ in memory access micro-benchmark (Lower is better.)

With a hardware implementation, the decision to use `cr3` or `TPT-cr3` would be performed by hardware with negligible cost. However, our software emulation has additional overheads for performing the additional hypercalls (via `VMCALL` and `VMEXIT`), which may dominate execution time on system call- or interrupt-heavy workloads (PTI is also only enabled for TPT).

We therefore report execution times after subtracting the software emulation overheads (time spent on new hypercalls performing EPT and `cr3` manipulations) from the application execution time. Note that most benchmarks do not invoke the hypercalls during the evaluation phase, and thus we do not remove the emulation overhead in such cases. For experiments that need the emulation hypercalls, such as the page table manipulation micro-benchmarks, we configure them to execute in a single physical CPU to maintain modeling correctness.

Configurations. We evaluate TPT's performance against the following system configurations:

(a) Native: Native execution, which serves as our ideal, upper bound on performance.

(b) Shadow: VM with shadow paging.

(c) EPT: VM with nested paging using Intel's extended page tables (EPT) mechanism.

(d) TPT-opt: VM with an optimized TPT implementation.

(e) TPT-naive: VM with a naive TPT implementation.

We evaluate each of the configurations under different host/guest page sizes: (1) $\frac{4K}{4K}$: guest OS uses base pages (4 KiB), and host backs VM with base pages (4 KiB); (2) $\frac{4K}{2M}$: guest OS uses base pages (4 KiB) and host backs VM with huge pages (2 MiB); and (3) $\frac{2M}{2M}$: guest uses huge pages (2 MiB) by enabling transparent huge pages (THP), and host backs VM with huge pages (2 MiB).

6.2 Memory translation

We create a single-thread memory micro-benchmark to assess TPT's impact on memory performance under different scenarios. Our benchmark allocates a 100 GiB buffer to serve as the target for memory read operations at a 64-bit granularity.

First, we evaluate the performance of sequential and ran-

Shadow	EPT	TPT-opt	TPT-naive
18.8×	5×	6.68×	6.68×

Table 2: Relative slowdown for different translation mechanisms over native $\frac{4K}{4K}$ when manipulating the guest page table using `mprotect` (Lower is better.)

dom memory accesses. Fig. 6 shows the relative slowdown of the evaluated system configurations over the native execution time. TPT-opt's performance matches that of Native, regardless of the memory page size, under both sequential and random access patterns. This is expected, as TPT-opt eliminates all virtualization-induced memory translation overheads due to its use of direct GVA-to-HPA page tables.

We also observe that EPT has the worst performance under the random access pattern due to its two-dimensional page walk on each TLB miss. Huge pages reduce, but do not eliminate the overhead of EPT, as the page walk is shortened due to the smaller size of the two-dimensional page walk [47].

TPT-naive only underperforms in random memory accesses under the $\frac{4K}{4K}$ configuration, where it exhibits a 1.25× relative slowdown over TPT-opt and Native. This is the result of the longer page walk duration on TLB misses, but it is still 2× faster than EPT under the same configuration.

Shadow exhibits a slowdown of 1.41× and 1.25× over Native for sequential and random memory accesses, respectively. The overheads stem from the extra time spent in the hypervisor due to page faults, which cause expensive VMEXITs. Although the guest OS page tables are populated, the shadow page tables are maintained by the host and updated lazily and on-demand: accesses to newly-mapped pages incur a page fault that is handled by the hypervisor, which in turn updates the shadow page tables and resumes guest execution.

Conclusions: TPT-opt exhibits native performance, outperforming both Shadow and EPT.

6.3 Page table management overheads

Raw page table manipulation. We evaluate the performance of page table modification under all configurations, as each incurs overheads from different sources. We measure the time taken to downgrade a single page from read-write to read-only via the `mprotect` system call.

Table 2 shows the results, normalized to Native execution. Shadow exhibits a slowdown of more than 18× over Native, as downgrading permissions in the page tables require TLB invalidations that are trapped by the host to amend the shadow page tables. EPT does not require interventions by the host and incurs a slowdown of 5× for a single page permission modification. This is the result of a single TLB entry invalidation in the guest (using instruction `INVLPG`), which invalidates *all* paging-structure translation caches of the current context, including the partial-walk caches (PWC) [8, 32, 47]. We corroborate this finding by observing an increase in the number of cycles the hardware page table walkers are active under the

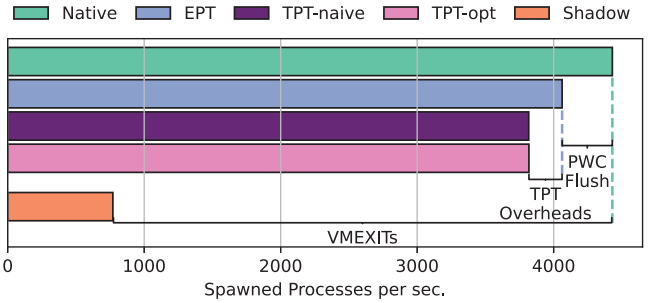

Figure 7: Spawn micro-benchmark for different translation mechanisms (Higher is better.)

Workload	Description	RSS
kcbench	Kernel compilation benchmark (v4.19) [35]	1 GiB
XSBench	Monte Carlo neutron transport algorithm [65]	99 GiB
Canneal	Optimization for chip design (PARSEC [20])	109 GiB
GUPS	Random integer updates in memory (HPCC [44])	129 GiB
PR	Page Rank (GAPBS [17]) on kron graph[2]	72 GiB
BFS	BFS Algorithm (GAPBS) on kron graph	70 GiB
CC	CC Algorithm (GAPBS) on kron graph	70 GiB
Memcached	Facebook ETC [11] (3×10^8 keys; mut. client [39])	108 GiB

Table 3: Application workloads and memory footprint

EPT configuration over Native (not shown).

TPT-opt exhibits a small overhead over EPT due to the additional operations to keep dual page tables in sync. Note that TPT-opt is also subject to the same cache invalidation overheads triggered by `INVLPG`, and TPT-naive has no additional overheads because page table contents are always accessed via non-TPT page tables in kernel space.

We perform the same experiment to measure the performance of mapping anonymous memory, by evaluating the `mmap` system call with the `MAP_POPULATE` flag. We do not observe a performance difference between the configurations, as the majority of time is spent on physical memory allocations and zeroing page contents.

TPT's extra logic to manipulate dual page tables has a small performance impact, and does not affect the end-to-end results on our evaluated applications (see §6.4). Such low overheads to synchronize modifications across page tables are corroborated by prior work [3, 53].

Process spawning. We evaluate the performance of Spawn from the Unixbench benchmark suite [67]. Spawn is a fork/wait-type workload, which measures the number of times a process can fork and reap a child that immediately exits.

Fig. 7 shows that EPT, TPT-opt, and TPT-naive are subjected to the adverse effects of PWC flushes as the `fork` system call performs TLB invalidations. The additional operations in TPT (maintaining dual page tables) lead to a 1.06× slowdown over EPT. In comparison, shadow incurs a 5.18× slowdown over EPT due to `VMEXIT`s induced by TLB invalidation and page faults.

[2] Kron graph [38] scale: 2^{29}, average degree: 16

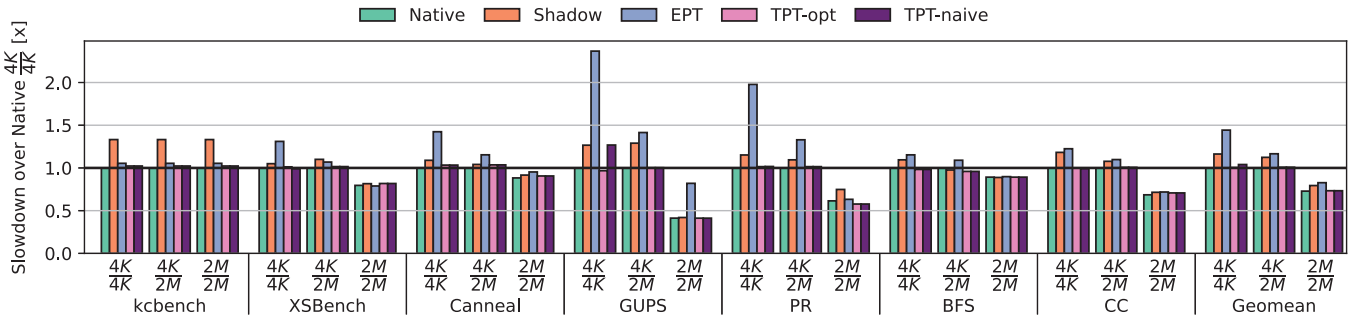

Figure 8: Relative slowdown on applications benchmarks over native $\frac{4K}{4K}$ (Lower is better.)

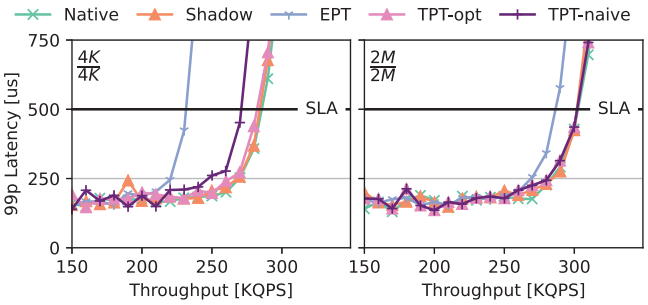

Figure 9: Memcached throughput-latency for different translation mechanisms (Lower is better.)

Conclusions: TPT enables substantially faster page table manipulations compared to Shadow by eliminating `VMEXITs`. It exhibits higher page table manipulation costs over EPT and native, but they have negligible impact on end-to-end application performance, as shown in §6.4.

6.4 Application benchmarks

We evaluate TPT on the application benchmarks listed in Table 3, which are commonly used to evaluate of data centers workloads [27, 53]. All benchmarks, apart from Memcached and kcbench, execute with 8 threads. We execute Memcached with a single thread because we do not have enough client cores to saturate more server threads. For maximum performance, Memcached uses the VMA [41] library for user-level I/O. We evaluate kcbench with a single thread because we need to model performance in the face of emulation hypercalls (as explained in §6.1).

Fig. 8 shows the relative slowdown of all the evaluated configurations over Native $\frac{4K}{4K}$. TPT-opt matches the performance of Native for all workloads, under all page size configurations. EPT exhibits significant slowdowns in workloads with random memory accesses, such as GUPS and PR. Overheads for Shadow are apparent in workloads that perform memory mappings, such as process spawning (kcbench), and dynamic memory allocation with page table modifications (CC and GUPS). TPT-naive exhibits a slowdown only on GUPS with the $\frac{4K}{4K}$ configuration, of 1.25×. GUPS is a random memory access benchmark, which correlates with our previous results for the random access micro-benchmark in Fig. 6. The geometric mean of the slowdown for TPT-naive is of just 3%.

Huge pages reduce the virtualization overheads of both EPT and Shadow, as well as improve the performance of Native execution, because they reduce TLB misses and page walk costs. Huge pages substantially decrease overheads in EPT as they reduce the number of steps on each dimension of the walk. EPT, however, still exhibits noticeable slowdowns with huge pages over TPT-opt and Native. Shadow's overheads with huge pages decrease, as 2 MiB mappings, compared to 4 KiB ones, induce less `VMEXITs` to sync the shadow page tables with the guest's page table mappings.

Memcached. We single out the Memcached benchmark, because it is latency-sensitive. Fig. 9 shows the throughput-latency graph of the 99th percentile of Memcached serving Facebook's ETC requests, with an SLA of 500 µs (following previous work [18]). Although the ETC access distribution is skewed, the keys are small in size and randomly distributed. This affects the overall access distribution of the workload, which exhibits a random memory access pattern.

EPT performs the worst due to the random memory accesses. Shadow, Native, and TPT-opt perform similarly in both page size configurations. This is expected because no new memory allocations occur during the measured portion of the workload. TPT-naive under the $\frac{4K}{4K}$ configuration crosses the SLA with 4% lower throughput than TPT-opt. The mean latency exhibits the same behavior as the 99th percentile, although the knee of the curves occurs at a higher throughput.

Conclusions: The performance of TPT matches Native, and systematically outperforms Shadow and EPT on all benchmarks where page table management or memory access performance dominates, respectively, even with huge pages.

6.5 Impact of 1 GiB huge pages

We now evaluate the same applications in §6.4 with EPT $\frac{2M}{1G}$, using 1 GiB host pages (typically unfeasible in a production system). The applications in Fig. 8 with 1 GiB pages only show a 2.5% speedup (geometric mean) compared to our previous EPT $\frac{2M}{2M}$ results, which would correspond to a 1.16× slowdown over Native and TPT-opt. In turn, Memcached's throughput only increases by 2.5% with 1 GiB pages, which

corresponds to a 1.04× slowdown over TPT-opt and Native.

Conclusions: Unlike TPT, 1GiB huge pages do not eliminate nested paging overheads completely.

6.6 Memory overheads

Guest. Non-TPT processes have no memory overheads, but TPT processes incur a small overhead to hold the TPT page tables. The TPT page tables only map the user space pages of the process and do not map the entire system memory and kernel space. A process with a sequential memory mapping of n pages incurs an additional $(1-\lfloor\frac{\text{page\_size}}{2\,\text{MiB}}\rfloor)\cdot\lceil\frac{n}{2^{36}}\rceil+\lceil\frac{n}{2^{27}}\rceil+\lceil\frac{n}{2^{18}}\rceil+\lceil\frac{n}{2^{9}}\rceil$. For example, a mapping of 1 GiB with 4 KiB pages incurs an extra 2 MiB-worth of TPT page tables.

Host. TPT's guest address map requires 8 B of host memory per GFN to hold the HFN. Therefore, a 64 GiB VM consumes 256 KiB or 128 MiB of host memory if the host utilizes 2 MiB or 4 KiB pages respectively (less than 0.2% in both cases).

Conclusions: TPT only adds small memory overheads in guests and hosts, making it practical for adoption.

7 Related Work

Prior work either attempts to improve existing virtualization mechanisms [27, 31, 46, 50, 53, 70], thus inheriting their shortcomings, or introduces invasive hardware changes, potentially changing the behavior of VMs compared to native execution [5–7, 15, 19, 23, 45, 55, 62].

Hardware-based virtualization. DVMT [6] proposes a software MMU architecture where applications/VMs can use their own address translation structures. DVMT also uses tag-based frame protection for isolation, but retains a two-dimensional translation approach in VMs, albeit with customizable translation structures on each dimension.

Sha et al. [19] propose new paging schemes for processors with software MMUs. The schemes reduce the page walk cost in nested paging by incorporating flat nested page table [5], or reduce the cost of updating guest page tables in shadow paging by intercepting TLB flushes. However, it introduces a software MMU and constraints to guest physical address space size, making it difficult to apply to modern machines and large memory sizes, respectively.

Several studies propose to redesign paging structures. Compromis [23] uses direct segments, but requires the reservation of variable-length physical memory areas for segments, which significantly compromises the flexibility of memory management in hypervisors. Chang et al. [55] propose to flatten 2 levels of page tables to reduce the cost of page walks by half. This approach increases the cost and complexity of managing page tables, and its cost reduction is limited. Nested Elastic Cuckoo Page Tables [62] utilize hashed page tables to reduce the nested page walk cost. However, replacing the existing radix page tables with hashed page tables requires significant changes to existing software and hardware ecosystems.

Caching and prefetching are also effective at hiding translation latency. Thomas et al. [15] explored new MMU caches, including today's partial walk caches in AMD and Intel processors. ASAP [45] reduces address translation latency by storing multiple page tables contiguously and introducing a hardware prefetcher for page walks. Caching does not fully eliminate the memory translation costs, and prefetching can result in mispredictions and numerous memory accesses to the page table when accessing large virtual memory areas. MMU caches and prefetching are directly applicable to TPT.

Improving virtualization. Agile paging [27] combines shadow and nested paging to reduce the hypervisor intervention cost on page table updates. It requires more memory accesses per TLB miss than native machines and TPT.

On-demand virtualization [31] enables virtualization dynamically to migrating bare-metal machines, and disables virtualization after the migration. This approach only applies to bare-metal machine migration, and cannot be generalized: it does not support more than a single VM in a bare-metal machine, and cannot enforce isolation between the VM and the hypervisor, because it relies on identity mappings (1:1) for nested translation between the VM and the hypervisor.

8 Conclusions

TPT is a new approach to memory virtualization, which achieves near-native translation performance for memory-intensive applications in VMs. In TPT, VMs regain control over their translation structures, while maintaining memory isolation across VMs by leveraging emerging physical memory protection technologies. TPT is compatible with both TPT and non-TPT guests, and can be selectively applied to processes running within any TPT-aware VM.

Efficient Memory Overcommitment for I/O Passthrough Enabled VMs via Fine-grained Page Meta-data Management

Yaohui Wang, Ben Luo, Yibin Shen
Alibaba Group

Abstract

In virtualization systems, guest memory overcommitment helps to improve the utilization of the host memory resource. However, the widely adopted I/O passthrough technique makes this task not intuitive since the hypervisor must avoid DMA (Direct Memory Access) failures when the I/O device accesses the guest memory. There already exist several solutions, for example, IOPF (I/O Page Fault) can fix DMA failures by allowing page fault triggered from the I/O device side, vIOMMU and coIOMMU avoid DMA failures by monitoring the DMA buffers in the guest. However, these solutions all face the performance concerns introduced by the memory backup/restore mechanism, *i.e.*, memory swapping. Some free page based methods (*e.g.*, Ballooning, Free Page Reporting, Hyperupcall) are free from memory swapping, but they either are not DMA-safe or introduce high guest communication overhead. In this paper, we propose V-Probe, a high-efficiency approach to achieve memory overcommitment for I/O passthrough enabled VMs. Using fine-grained page meta-data management, V-Probe allows the hypervisor to inspect and reclaim guest free pages actively and efficiently while guaranteeing DMA-safety. Experiments show that, for both memory reclamation and reallocation, the overhead of V-Probe is in the scale of microseconds, which is faster than Ballooning and IOPF based methods by two orders of magnitude. And our micro-benchmark and macro-benchmark show that V-Probe limits the performance impact of memory overcommitment to a low level.

1 Introduction

In virtualization systems, the total memory size of a VM (Virtual Machine) is commonly constant while it is running, but the working set of memory (*i.e.*, memory accessed actively) inside a VM is usually a subset of the total memory [11, 17, 36, 42, 47]. This results in the inefficiency of memory resource utilization [28, 39]. Memory overcommitment [4,6,7,9,19,26,37,40,44] helps to mitigate this problem. It reclaims cold memory (*i.e.*, memory not accessed recently) from a VM, and reallocates the memory to other VMs on demand to increase memory utilization.

However, the widely adopted I/O passthrough technique [3, 5, 12, 15, 26, 27, 41], which significantly reduces the overhead of I/O virtualization [1, 21, 24], requires the hypervisor to keep a fixed memory mapping for the VM during its life cycle to avoid potential DMA failures [4, 26, 40]. This highly limits the ability of memory overcommitment since the memory reclamation will change the memory mapping of a VM dynamically (Section 2).

Previous work tries to solve the contradiction between I/O passthrough and memory overcommitment in two different ways. The first is to introduce the IOPF (I/O Page Fault) mechanism [25, 26, 34]. It allows an I/O device to notify the hypervisor by triggering page faults when the target DMA buffer does not reside in the main memory. After the hypervisor repairs the IOPT (I/O Page Table) entry for the faulted IOVA (I/O Virtual Address), the device can replay the previously failed DMA request. The second is to monitor the guest DMA buffers using the PV (Para-virtualization) technique [4, 10, 11, 40, 44]. Such solutions include vIOMMU [4] and coIOMMU [40]. They use frontend drivers in the guest to inform the hypervisor with DMA buffer alloc/free events. With such knowledge, the hypervisor always keeps the memory mapping of the DMA buffers and thus prevents DMA failures.

Although the above solutions allow memory overcommitment to coexist with the I/O passthrough technique, they face several deficiencies. The first is the compatibility issue, which makes them currently less practical. For example, the IOPF solution requires designated hardware which is not widely supported by hardware manufacturers. And the coIOMMU solution needs changes to the guest OS and is still not supported by off-the-shelf OSes (*e.g.*, the Linux upstream). But even though the compatibility issue can be fixed over time (by evolving the hardware/software), the second issue – performance issue – is unavoidable. When doing memory reclamation/reallocation, these solutions need to backup/restore the

memory content using memory swapping [6, 20, 29, 30, 32]. The overhead it introduces not only slows down the memory reclamation process, but may also cause performance oscillations to the VM and hurts the VM's SLO [6, 49, 50].

While memory swapping is costly, reclaiming guest free pages [44, 45] is a good way to eliminate such overhead, since the content in free pages is meaningless. But because of the semantic gap in virtualization systems, free page reclamation methods usually rely on the communication with the frontend driver running inside the guest to obtain the knowledge of guest free pages. The guest communication introduces extra overhead and increases the response time for the memory reclamation requests (Section 5.1.2). The recently proposed free page inspecting method – Hyperupcall [7] – helps to eliminate such overhead. When doing memory reclamation, Hyperupcall allows the hypervisor to actively invoke the guest injected eBPF functions to inspect guest free pages. However, guaranteeing DMA-safety is a challenging task with this method. In Hyperupcall, since the guest is agnostic to the hypervisor's memory reclamation actions, it may allocate a free page, whose underlying physical page is reclaimed by the hypervisor, as a DMA buffer. Such behavior cannot be perceived by the hypervisor, so it does not have a chance to repair the memory mapping for the DMA buffer, which will further cause DMA failures (Section 2.2.3).

In this paper, we propose V-Probe to address the performance and DMA-safety challenges of memory overcommitment for I/O passthrough enabled VMs. V-Probe targets guest free pages to eliminate the costly overhead of memory swapping. Inspired by Hyperupcall [7], V-Probe uses guest injected helper functions to detect guest free pages actively, which avoids the communication overhead with the guest. But instead of using eBPF, V-Probe uses raw binary helper functions. This avoids the complex eBPF dependencies in the guest OS required by Hyperupcall. Such simplicity makes the deployment of the method easier. V-Probe uses the SFI (Software Fault Isolation) technique [13, 31, 38, 43, 48], which performs strict rule-based instruction-level checks to the injected binary, to prevent malicious code. Using fine-grained page meta-data management, V-Probe not only manages the memory mapping of the reclaimed free pages but also monitors their corresponding page meta-data. This allows V-Probe to react to guest memory allocation events and prevent potential DMA failures. Experiments show that the overhead of V-Probe is in the scale of microseconds. Compared to Ballooning and IOPF, it is faster by two orders of magnitude in both memory reclamation and reallocation. Our micro-benchmark and macro-benchmark show that V-Probe limits the performance impact of memory overcommitment to a low level.

We summarize our contribution as follows:

- We conduct a systematical study of previous VM memory overcommitment methods and characterize these methods in different aspects to provide an overview.
- We propose V-Probe, an efficient memory overcommitment method that targets guest free pages and guarantees DMA-safety for I/O passthrough enabled VMs.
- We evaluate the overhead of V-Probe, and assess its performance in both micro-benchmark and macro-benchmark tests. Results show that V-Probe achieves low overhead and limits the performance impact of memory overcommitment to a low level.

2 Motivation

2.1 I/O Passthrough & DMA-safety

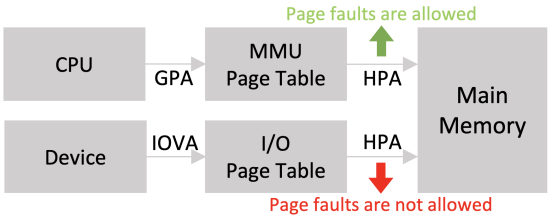

Figure 1: The address translation for CPU and I/O devices in modern hardware architectures. Page faults in the I/O device side will trigger DMA failures.

I/O passthrough, which allows the guest OS to directly interact with the underlying hardware, is widely used in virtualization systems [15, 16]. Using I/O passthrough, a peripheral device can directly access the guest memory through DMA without the intervention of the CPU. It significantly decreases the overhead of guest I/O operations and is also required by the emerging high-performance RDMA (Remote Direct Memory Access) applications [22, 23, 46]. This makes I/O passthrough an irreplaceable part of virtualization systems like the public cloud.

In the same way that the CPU MMU (Memory Management Unit) needs a page table to translate GPA (Guest Physical Address) to HPA (Host Physical Address), devices' DMA requests rely on the IOPT to translate IOVA (I/O Virtual Address, it is usually the same as GPA) to HPA. On the CPU side, if the accessed GPA does not have a valid page table entry, then a page fault will be triggered. The hypervisor will try to fix the memory mapping in the page table, and then resume the guest OS execution from where it triggers the page fault. On the device side, to add IOPF support, the device needs the ability to replay the once failed DMA request after the hypervisor fixes the invalid IOPT entry. But unfortunately, most off-the-shelf devices do not support such mechanism. So they require that all DMA requests must always succeed or they will result in DMA failure and crash of the guest OS (Figure 1). This implies that an I/O passthrough enabled VM has no tolerance to IOPT entry missing [4, 25, 26, 40].

Table 1: The characteristics of the memory reclamation methods from different dimensions.

Methods	DMA-safety	Hardware Compatibility	Guest Compatibility	Main Overhead
IOPF	DMA-safe	Dedicated hardware	No requirements	Memory swapping
vIOMMU	DMA-safe	General hardware	Frontend driver	Memory swapping
coIOMMU	DMA-safe	General hardware	Frontend driver	Memory swapping
Ballooning	DMA-safe	General hardware	Frontend driver	Guest communication
Free Page Reporting	DMA-unsafe	General hardware	Frontend driver	Guest communication
Hyperupcall	DMA-unsafe	General hardware	eBPF tool-chain	Extremely low overhead

In memory overcommitment, the MMU page table entry and the IOPT entry of the reclaimed page will both be invalidated after memory reclamation. As the hypervisor is agnostic to whether a page is used for DMA in the guest, the reclaimed page may be a DMA buffer. When a DMA request targeting the reclaimed DMA buffer arrives, the missing IOPT entry will cause DMA failure. To avoid potential DMA failures, the hypervisor needs to disable memory overcommitment, and statically pin the entire memory of a VM, *i.e.,* keep a fixed memory mapping for the VM during its life cycle.

2.2 Related Work

We discuss existing memory reclamation methods in the aspect of DMA-safety. We also characterize them in other important dimensions like compatibility and performance. We summarize them in Table 1.

2.2.1 I/O Page Fault

IOPF [25, 26, 34] is a hardware feature. When DMA failure occurs, IOPF allows a device to generate a page fault exception to the CPU, and replay the DMA request after the OS repairs the memory mapping. So by using IOPF, memory overcommitment is guaranteed to be DMA-safe.

As IOPF is transparent to the guest, it has no requirements for the guest OSes. However, it faces the issue of poor hardware compatibility as it requires designated hardware devices. Although the PCIe specification [34] has been extended to support IOPF since 2009, with the extensions of ATS (Address Translation Service) and PRI (Page Request Interface), the practice of such standard moves slowly. Currently, few off-the-shelf I/O device supports IOPF. Although manufacturers like AMD and Arm have introduced ATS and PRI to their SoC design [2, 8], the absence of PCIe devices that supports IOPF makes the IOPF call chain incomplete.

Even though the hardware compatibility issue can be fixed over time, the performance issue is unavoidable. Memory overcommitment depending on IOPF needs to backup/restore the memory content when doing memory reclamation/reallocation using memory swapping. Memory swapping introduces I/O overhead since the contents of the reclaimed memory are usually stored in storage media which is much slower than the main memory. Another method of memory swapping is memory compression. It introduces CPU overhead since the compress/decompress process is a heavy computing task. The overhead of memory swapping not only slows down the hypervisor's reaction to memory reclamation requests, but also causes performance oscillation to the VM and degrades the VM's SLO, especially when a VM faces a burst memory pressure and triggers a large number of page faults in a short time.

Meanwhile, the hypervisor's memory reclamation mechanism may also conflict with the memory reclamation inside the guest – The same memory page may be reclaimed twice, once by the guest and once by the hypervisor. In such a case, the guest's access to the memory page will trigger page faults twice, once trapped to the guest kernel and once to the hypervisor. This is the so-called *double paging* anomaly [14, 18, 33, 44] which introduces extra overhead to memory reclamation.

2.2.2 Monitoring DMA Buffers

Another way to avoid DMA failure is to monitor DMA buffer allocations in the guests. It implies two parts. First, when the hypervisor reclaims a guest page, the monitor tells whether it is a DMA buffer. Second, when the guest allocates a DMA buffer whose underlying page is reclaimed, the monitor notifies the hypervisor to fix the memory mapping in time. It is a software solution and does not rely on designated hardware.

vIOMMU [4] is one such solution. It exposes an emulated IOMMU (Input-output Memory Management Unit) to the guest and enables the hypervisor to intercept, monitor, and act upon DMA remapping operations. coIOMMU [40] is another one. It decouples the memory protection and pinning functionality in vIOMMU, which significantly improves the performance. But coIOMMU needs extensive changes to the guest OS, which results in the guest OS compatibility issue. At the same time, although monitoring guest DMA buffers guarantees DMA-safety, it still faces similar performance issues as the IOPF solution because of the need for memory swapping when doing memory reclamation/reallocation.

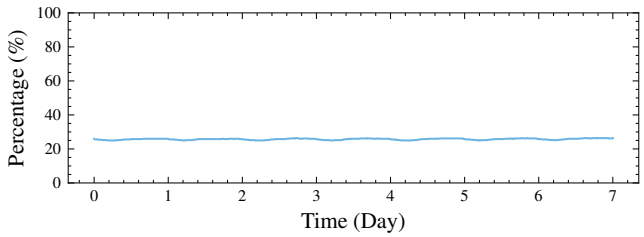

Figure 2: The free memory proportion of 10,000 VMs randomly sampled from the Alibaba cloud in one week period. The X-axis is the time, the Y-axis is the sum of the VMs' free memory size divided by the sum of the VMs' occupied memory size.

2.2.3 Free Page Reclamation

Free page reclamation targets on guest free pages. The quantity of guest free pages is considerable. Figure 2 shows the free memory proportion statistics of 10,000 VMs randomly sampled from the Alibaba cloud in one week period. As it shows, about 25.3% of the VMs' memory is free and this proportion is stable over time. At the same time, reclaiming free pages helps to eliminate the memory swapping overhead, since the contents of free pages are meaningless.

Ballooning [44] is a classical PV method that targets guest free page reclamation. It contains a frontend driver running in the guest, and a backend driver running in the hypervisor. The frontend driver can "inflate" to occupy the guest free pages and report them to the hypervisor, then the backend driver can reclaim those pages. The reclaimed GPA area is not allocatable in the guest until the hypervisor reallocates new pages for it. This can prevent reclaimed GPA areas to be used as DMA buffers, and thus avoids DMA failures.

However, the communication overhead between the frontend and backend drivers (Section 5.1.2) brings performance issues. Similar to the overhead introduced by memory swapping (Section 2.2.1), the communication overhead may also slow down the hypervisor's reaction to memory reclamation request, and cause VM performance oscillation [7, 9, 37].

Except for Ballooning, there are also other methods targeting free page reclamation. Free Page Reporting [45] allows the guest to report its free pages to the hypervisor periodically. And Hyperupcall [7], allows the hypervisor to inspect guest free pages without guest intervention. However, guaranteeing DMA-safety using these methods is a challenging task. As the memory reclamation action in these methods is transparent to the guest, the guest may allocate a free page, whose underlying physical page is reclaimed, as a DMA buffer. But the hypervisor will not be notified by this action, thus it does not have a chance to repair the memory mapping. So following DMA requests addressing this page will fail and cause DMA failures. Figure 3 illustrates the scenario. On the other hand, Free Page Reporting faces the problem of timeliness. Its frontend driver initiates the reporting procedure with a fixed delay (2 seconds in Linux's implementation) after the guest releases a high-order page. So the hypervisor's memory reclamation request may fail even if there are unreclaimed free pages in the guest.

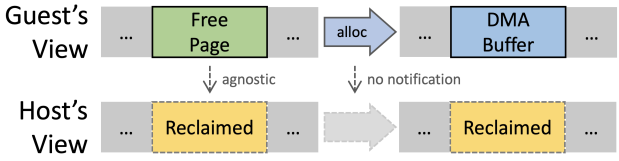

Figure 3: In guest free page reclamation, the hypervisor is agnostic to the DMA buffer allocation in the guest, and following DMA requests will cause DMA failures.

3 Approach

3.1 Design Goals

Based on our analysis in Section 2, we set our design goals as follows:

- **DMA-safety:** I/O passthrough is playing an irreplaceable part in today's virtualization systems since it significantly improves the guest I/O performance. The design should avoid DMA failures to make it safe for I/O passthrough enabled VMs.
- **Hardware Compatibility:** The design should not rely on IOPF as IOPF needs designated hardware. This ensures the solution is available for a large amount of existing hardware.
- **Guest Compatibility:** The design should be compatible with a wide range of commodity guest OSes. This makes sure the solution can be easily deployed to existing software systems.
- **Low Overhead:** The overhead of the solution should be as low as possible. This not only decreases the hypervisor's reaction time for memory requests and enables the hypervisor to take more aggressive memory reclamation decisions, but also limits the performance impact on the VMs and guarantees high VM SLO (Service-level Objective).

According to the summary in Table 1, memory reclamation methods that are unaware of the guest page allocation status (IOPF, vIOMMU, coIOMMU) require memory backup/restore for every reclaimed page, which introduces the overhead of memory swapping. However, obtaining knowledge of guest free pages usually needs communications to the frontend driver in the guest (Ballooning, Free Page Reporting), which introduces communication overhead. Hyperupcall

achieves low overhead, but it faces two challenges. First, as mentioned in Section 2.2.3, Hyperupcall is not DMA-safe. Although discarding guest communication makes the execution of Hyperupcall fast, this also means the guest is agnostic to the reclamation status of its free pages. The guest may allocate a reclaimed free page as a DMA buffer and the hypervisor is not notified by such behavior. It may not have a chance to fix the memory mapping before the DMA request arrives. Second, Hyperupcall relies on the complex toolchain of eBPF and needs modifications to the underlying LLVM compiler. This increases the deployment complexity of Hyperupcall, especially when adapting the toolchain to a variety of guest OSes in the public cloud.

Solving these challenges brings us to the solution of V-Probe. V-Probe is inspired by Hyperupcall. Like Hyperupcall, V-Probe allows the hypervisor to actively reclaim guest free pages without guest intervening. But V-Probe improves the programming model of Hyperupcall to overcome its complexity. More importantly, V-Probe proposes a novel fine-grained page meta-data management technique to guarantee DMA-safety.

3.2 V-Probe Overview

Figure 4 illustrates how V-Probe works. It contains three parts: (1) V-Probe injector, (2) V-Probe data manager, and (3) memory reclamation routine. Next, we will explain each part in detail.

3.2.1 V-Probe Injector

The V-Probe injector is a guest module. It only runs one time just after the guest finishes starting up. During its execution, it accomplishes two tasks: (1) page meta-data layout registration and (2) helper function registration.

In operating systems, like Linux, each physical page has a corresponding piece of page meta-data to record its usage state, *e.g.,* the reference count or the allocation status. And such meta-data is usually organized statically and continuously in ranges of the physical memory. In page meta-data layout registration, the guest first detects the GPA ranges where the page meta-data resides. Then it passes this information to the hypervisor through the registration API that V-Probe provides. As the hypervisor is aware of how GPA is translated to HPA, it can access the guest page meta-data precisely after obtaining the knowledge of guest page meta-data GPA ranges.

But only having access to the guest page meta-data is not enough, the hypervisor needs to understand the meanings of the bytes in it. So we need the helper functions which can parse the page meta-data. In helper function registration, the guest compiles the source codes of helper functions to hardware native binaries and injects them to the hypervisor through the registration API of V-Probe. As the formats of page meta-data can be different among guest OSes, the helper functions are guest-specific and need to be dynamically compiled in the guest.

3.2.2 V-Probe Data Manager

The V-Probe data manager runs in the hypervisor. It provides registration APIs for the V-Probe injector. The registered helper functions and page meta-data layout information are stored here. They help to recognize the status of each page in the guest when performing memory reclamation.

Since the hypervisor will directly call the helper functions via the injected binary code, we need a verifier to guarantee their integrity, *i.e.,* to prevent harmful codes injected from malicious guests. As the use case of the helper functions in V-Probe is limited to parsing guest page meta-data, the logic of the helper functions should be very simple. So the verifier uses strict rule-based restrictions to verify the injected binaries, which protects the hypervisor from security attacks without rejecting honest codes.

The V-Probe data manager also stores the information of the reclaimed memory set. Each record in the set represents a reclaimed guest memory area. Its content contains two dimensions: the reclaimed GFN (Guest Frame Number) range, and the GPA range for the corresponding page meta-data. This information is useful for page refaulting, which will be explained in the next subsection.

3.2.3 Memory Reclamation Routine

The memory reclamation routine is the core logic to reclaim free pages from the guest. Its execution is triggered by system events, like periodic timers, or memory pressure. After the preparation of the previous steps, the hypervisor can scan and parse guest page meta-data to inspect the status of each page.

V-Probe solves the DMA-safety problem via fine-grained page meta-data management. As shown in Figure 5, when reclaiming guest free pages, V-Probe not only invalidates the free pages' mapping in the MMU page table and the I/O page table but also modifies the page meta-data mapping in the MMU page table to read-only. The reclaimed memory set in V-Probe data manager will record the reclaimed GFN range, along with the GPA range of the corresponding page meta-data.

When the guest memory management system is going to allocate a page inside the reclaimed GFN ranges, it will first write to the corresponding page meta-data, *e.g.,* change the free flag. This will trigger a page fault on the CPU side as we have changed the memory mapping of the page meta-data to read-only after reclamation. The page fault notifies the hypervisor. Then the hypervisor looks for the corresponding record in the reclaimed memory set and recovers the memory mappings for both the pages and the page meta-data. This mechanism gives the hypervisor the chance to recover the

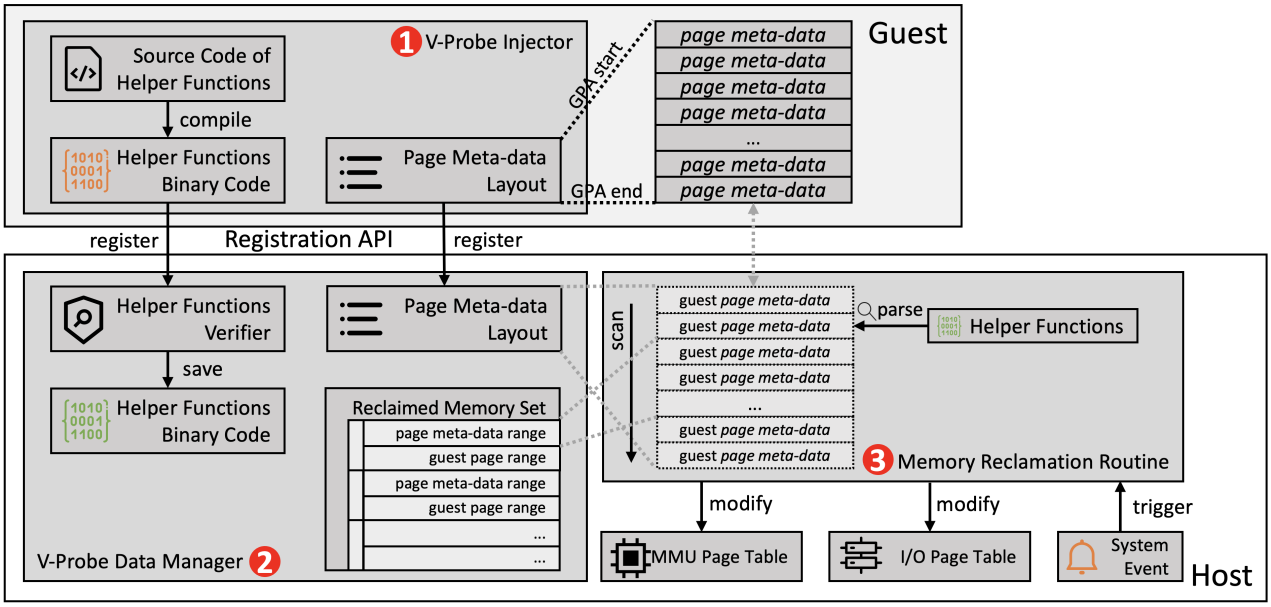

Figure 4: The design overview of V-Probe. It contains three parts: V-Probe injector, V-Probe data manager, and the memory reclamation routine. The V-Probe injector registers helper functions and page page-meta layout information to the V-Probe data manager. The code and data are used by the memory reclamation routine to inspect guest page status and reclaim free pages. The details of the design are explained in Section 3.2.

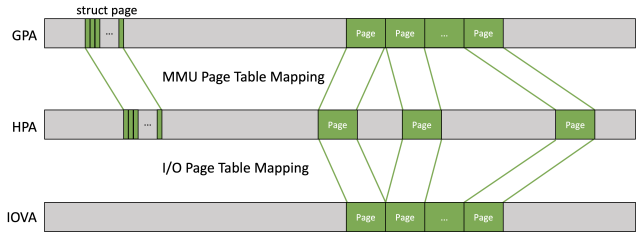
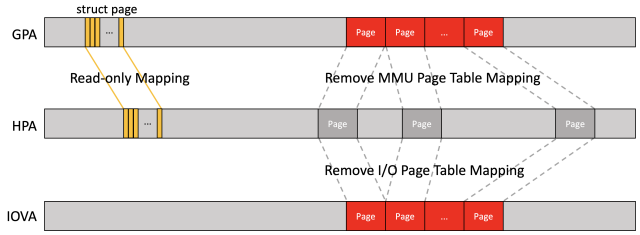


(a) Memory mapping before free page reclamation.



(b) Memory mapping after free page reclamation.

Figure 5: Memory mapping status before and after free page reclamation. During free page reclamation, V-Probe not only invalidates the page table entries for the reclaimed pages but also modifies the mapping of the page meta-data to read-only. This gives the hypervisor the chance to recover the memory mapping before the guest uses the page.

memory mapping before the guest uses the page, and thus it prevents DMA failures.

4 Implementation

In this section, we introduce the implementation details of V-Probe, which includes four parts: meta-data registration, helper function registration, memory reclamation routine, and page fault handler. We also explain the synchronization problem we face in V-Probe and how we solve this issue.

Our implementation of V-Probe is based on Linux, whose source code can be easily touched and modified. The hardware architecture is based on x86_64. The CPU we use is Intel® Xeon® Platinum 8163 CPU.

4.1 Meta-data Registration

The meta-data of pages in Linux is usually defined as type *struct page*. There are three kinds of *struct page* organization models in Linux, decided by one of the three compile configurations: `CONFIG_FLATMEM`, `CONFIG_DISCONTIGMEM` and `CONFIG_SPARSEMEM_VMEMMAP`. But no matter what the configuration is, the *struct page* data is organized linearly in ranges of continuous memory in the guest physical address space. V-Probe injector detects the *struct page* layout, indicating each *struct page* memory range with two dimensions: (1) the start and end GPA of the *struct page* memory range, and (2) the start and end GFN that are managed by the range

of *struct page*. V-Probe injector registers the information to the hypervisor, then the hypervisor can locate the *struct page* of each guest GFN.

4.2 Helper Functions Registration

```
noinline bool
page_free(struct page *page) {
        return PageBuddy(page);
}
```

```
8b 47 30          mov    0x30(%rdi),%eax
25 80 00 00 f0    and    $0xf0000080,%eax
3d 00 00 00 f0    cmp    $0xf0000000,%eax
0f 94 c0          sete   %al
c3                retq
```

(a) The source code and compiled binary of the helper function `page_free`. This function is used to parse whether a guest page is free. The function it calls (`PageBuddy`) is a Linux built-in function. The size of the compiled binary is only 17 bytes.

```
noinline unsigned long
page_order(struct page *page) {
    return page_private(page);
}
```

```
48 8b 47 28       mov 0x28(%rdi),%rax
c3                retq
```

(b) The source code and compiled binary of the helper function `page_order`. This function is used to parse how many free pages are adjacent to this page. The function it calls (`page_private`) is a Linux built-in function. The size of the compiled binary is only 5 bytes.

Figure 6: The source codes and their compiled binary of the two helper functions in V-Probe.

V-Probe relies on the helper functions to parse guest *struct page* and obtain the status of the pages. They are injected from the guest to the hypervisor after the guest finishes starting up. Since the formats of *struct page* vary from guests OSes, the helper functions need to be dynamically compiled in the guest.

Linux uses the buddy system [35] to manage free pages. It organizes free pages as blocks, and the size of one block is the order of 2. A buddy system block is identified by the leading *struct page* in the block, and it also records the order of the block. By parsing the *struct page*, *i.e.,* testing a specific bit or reading a specific field in it, we can decide whether a *struct page* is the leading one in a block, and get the order of the free page count in this block. In Linux, two kernel built-in functions, `PageBuddy` and `page_private`, help to do the parsing.

The two helper functions used in V-Probe are shown in Figure 6b: (1) `page_free`, which wraps the function `PageBuddy`, and (2) `page_order`, which wraps the function `page_private`. These two helper functions are short and simple, and the sizes of their binary code are also small: 17 bytes for `page_free` and 5 bytes for `page_order`. The definition of the helper functions requires the `noinline` decorator, to ensure they are not compiled to inline functions and can be called by the hypervisor in a function manner.

To avoid harmful codes injected from malicious guests, we need a verifier to guarantee the integrity of the helper function binary. We apply SFI to implement the verifier. As the logic of the helper functions used in V-Probe are very simple, simplified yet strict checking rules in SFI are enough to protect the hypervisor from security attacks without rejecting honest codes. These rules are as follows:

- Register `rdi` is read-only, register `rax` is read-write. Other registers are not allowed to be used.
- The function can only read a limited range of memory, which is usually the size of the guest *struct page*, pointed by the parameter stored in the `rdi` register.
- The function can not write to any main memory.
- No branch instruction or privileged instruction is allowed.
- The last instruction must be `retq`.
- The length of the binary is less than 64 bytes.

The above rules protect the hypervisor from being compromised by the injected code for two reasons. First, they make sure the helper functions obey the convention of a function call, and no branch nor privileged instructions are allowed. This implies the instructions inside the call will be executed sequentially, and the execution will finally return to the caller. Second, during the function call's execution, the accesses to registers and memory are strictly limited to avoid any host memory corruption. But note that these rules are highly related to the Intel X86_64 architecture. They need to be redesigned on other CPU platforms.

4.3 Memory Reclamation Routine

The memory reclamation routine is triggered by host events (like the memory pressure), and its execution is controlled by the hypervisor. Algorithm 1 shows the pseudocode of the procedure. It has two input parameters, *GUEST*, and *MIN_ORD*, which respectively indicate the target guest we try to reclaim memory from and the minimum order we want. The procedure iterates through each GFN in the guest (Line 2) and uses the two helper functions registered before, *GUEST.PAGE_FREE* and *GUEST.PAGE_ORD*, to check whether the guest page is free and what is the order in the buddy system (Lines 6-7). If it meets our requirements (Line 8), then we try to reclaim the corresponding pages (Lines

Algorithm 1 The procedure of memory reclamation

9-25). The core reclamation logic makes the *struct page* GPA range read-only (Line 10), invalidates the memory mapping in EPT (Extended Page Table) and IOMMU page table for the reclaimed GFN range (Lines 15-19), adds this range to the reclaimed set (Line 20), and finally, releases the reclaimed pages to the hypervisor (Line 21). Algorithm 1 uses the mutex (Line 9) and the page status double check logic (Lines 11-14) to avoid synchronization problems, which will be further explained in Section 4.5.

4.4 Page Fault Handler

Since we have modified the EPT mapping of the *struct page* GPA range to **read-only** for the reclaimed GFNs, when the guest tries to allocate these pages, it will **write** to the corresponding *struct page* to modify the bytes of page status flags. Thus a page fault is triggered. The pseudocode of the page fault handler is shown in Algorithm 2. It has two input parameters: $GUEST$ and GPA, which respectively indicate the guest and the accessed GPA that triggers the page fault. First, it calls *GetReclaimedRange* to find the reclaimed memory range responsible for GPA (Line 3). Then it allocates pages (Line 4), remaps the EPT and IOMMU page table for this range (Lines 5-6), removes the range from the guest's reclaimed memory set (Line 7), and resumes the EPT mapping of the *struct page* GPA range to **read-write** (Line 8).

Function *GetReclaimedRange* is simplified as a loop for ease of demonstration. We use the rbtree (Red-black Tree), which is an implementation of the binary search tree in Linux, to optimize the performance of memory range inserting, deleting, and searching.

4.5 Synchronization Problem

One challenge for the reclamation process is the synchronization problem: the guest may allocate the pages while we are reclaiming them, and the status of the guest *struct page* may change from "free" to "allocated" within the memory reclamation routine, which may cause inconsistency in the system.

Figure 7 show two cases to illustrate how the mutex and double-checking in Algorithm 1 (Lines 9-14) and Algorithm 2 (Line 2) avoids the racing conditions. In reclaim ①, if the guest allocates the free pages after the Hypervisor makes the corresponding *struct page* GPA range read-only, it will trigger page fault and the mutex will prevent the page fault handler to fix the memory mapping before the hypervisor finishes reclamation. This guarantees the atomicity of the memory reclamation process and the page fault handling. In reclaim ②, if the guest allocates the free page before the Hypervisor

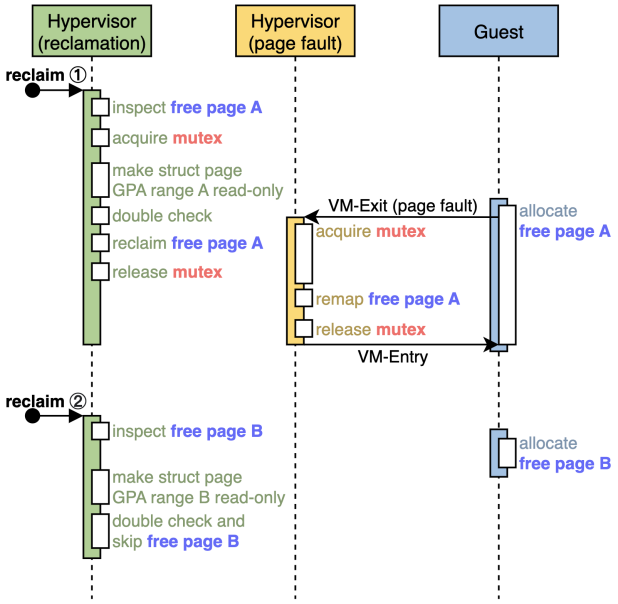

Figure 7: Two cases to illustrate how V-Probe solves the synchronization problem.

makes the corresponding *struct page* GPA range read-only, the double-checking will detect such behavior and skip the page, so as to avoid the inconsistency of the page status knowledge.

5 Evaluation

In this section, we conduct experiments to evaluate V-Probe in different aspects. First, we evaluate V-Probe's overhead in memory reclamation and reallocation tasks. Then we evaluate its impact on workload performance using both the micro-benchmark and macro-benchmark.

The experiments are based on the hardware architecture of Intel® Xeon® Platinum 8163 CPU. The hypervisor is based on QEMU and KVM. And the memory allocator manages the underlying memory of guest VMs in 2MB granularity. The guests in our experiments run Linux OS, each equipped with 2 CPU cores and 4GB main memory.

We use Ballooning and the IOPF based method for comparison. For simplicity, we will call the IOPF based method as IOPF in the following explanation. For memory reclamation and reallocation tasks, we compare V-Probe with both Ballooning and IOPF. For micro-benchmark and macro-benchmark tests, we only use IOPF for comparison. We do not use Ballooning for these benchmarks because the frontend driver of Ballooning will hold the reclaimed free pages and make them unallocatable in the guest. So if the memory usage of the task does not exceed the remaining allocatable memory in the guest, the performance will be the same as the baseline with no memory reclamation. On the other hand, if the memory usage of the task exceeds the remaining allocatable

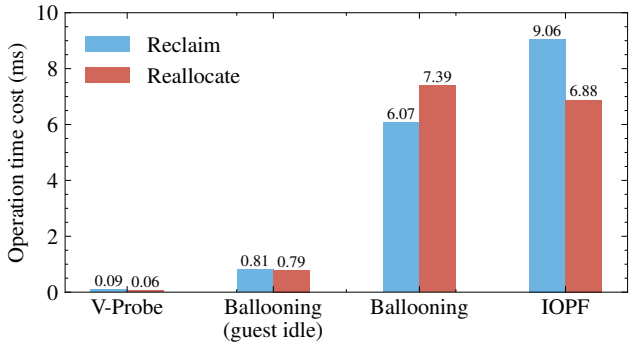

Figure 8: The time cost of V-Probe, Ballooning and IOPF to reclaim (reallocate) 2MB memory from (to) the guest. We run *sysbench* CPU workloads in the guest to emulate the guest's CPU stress.

memory in the guest, the guest will kill the task because of the OOM (Out of memory) error.

We reclaim 30% of the server's memory at the beginning of the each benchmark test. In practice, to avoid host memory insufficiency, the memory reclamation policies need to limit the quantity of memory reclaimed from each guest and the quantity of memory that can be reused by other VMs. 30% of memory reclamation is an extremely high value in practice. In this configuration, the benchmark results reveal the performance impact limit of V-Probe in a real-world environment.

Since IOPF is not commonly supported by off-the-shelf I/O devices, we implement IOPF by ourselves using FPGA-based SmartNIC. The storage media we use for memory swapping is a hard disk drive, with 250MB/s I/O throughput. Notice that other methods relying on memory swapping (vIOMMU, coIOMMU) share similar results with IOPF.

5.1 Overhead

5.1.1 Data Registration

The overall data registration process takes less than 1 second. The main overhead comes from the helper function compilation and page meta-data layout detection within the guest. The overhead of data transferring is small as the size of the registered data is only 232 bytes in our implementation, which includes the binaries of the helper functions, the page meta-data layout information, and the extra API-related fields. Also, as the helper functions are simple and small, the verification cost is negligible. Data registration only runs one time after the guest finishes starting up, and its overhead will not impact the following memory reclamation procedure.

5.1.2 Memory Reclamation and Reallocation

We evaluate the overhead of V-Probe in the memory reclamation (reallocation) task by measuring the time it takes to

reclaim (reallocate) 2MB memory from (to) the guest. For memory reclamation, the cost refers to the time elapsed between the initiation of the memory reclamation request and the moment the hypervisor releases the reclaimed memory back to the host. For memory reallocation, the cost refers to the time elapsed between the initiation of the memory reallocation request and the point at which the hypervisor establishes the new memory mapping.

We use Ballooning and IOPF for comparison. During memory reclamation (reallocation), we run *sysbench* CPU workloads in the guest to emulate the guest's CPU stress. Specifically, we run the command `'sysbench cpu -threads=$(nproc) -time=0 run'` in the guest to make all of the CPUs busy. We also assess the performance of Ballooning when the guest OS is idle, in order to determine the upper limit of its performance. For each measurement, we run the operation 10 times and present the average value as the result.

We will take the memory reclamation task as an example to analyze the experiment results. The memory reallocation task shares a similar analysis. As Figure 8 shows, V-Probe takes only 0.09ms to reclaim 2MB memory on average, while Ballooning and IOPF take 6.07ms and 6.88ms respectively. We analyze the reasons why V-Probe is two orders of magnitude faster than the other two methods as follows:

- Ballooning relies on the communication with the frontend driver running in the guest when reclaiming memory from it. The communication introduces a large delay, especially when the guest is busy with CPU intensive tasks, which reduces the chance for the thread of the frontend driver to gain CPU time slice. The overhead of communication (5.79ms) occupies 95.4% of the total overhead (6.07ms) when using Ballooning to reclaim 2MB memory. Even if the CPU is not busy in the guest, the communication overhead (0.53ms) also occupies 65.4% of the total overhead (0.81ms).

- IOPF relies on memory swapping to avoid guest memory corruption. Memory swapping introduces a large overhead of disk I/O (8.95ms), which occupies 98.8% of the total overhead (9.06ms).

- When triggered by events, V-Probe can use the injected helper functions to inspect the guest free pages actively, without the time-consuming communication with the guest. At the same time, since the reclaimed pages are free memory in the guest and do not contain valuable data, V-Probe does not need memory swapping, which avoids the disk I/O overhead.

The memory overhead of V-Probe's reclamation process is also small. For each reclaimed memory range, we allocate a 64B data structure to maintain the necessary data, which includes the start/end GPA of the *struct page* and the physical page, and other data-structure-specific fields. The overhead is 64B/2MB = 0.031‰ for a 2MB area and 64B/4MB = 0.015‰ for a 4MB area.

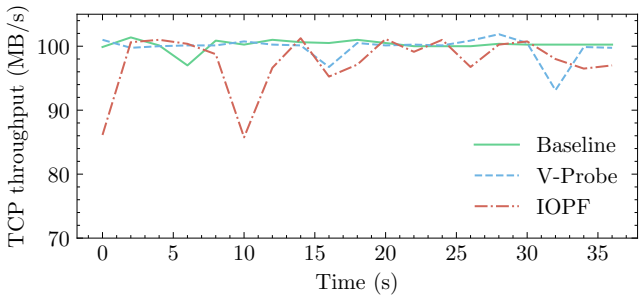

Figure 9: The TCP throughput of the baseline, V-Probe, and IOPF.

5.2 Micro-benchmark

The micro-benchmarks in our evaluation include TCP throughput and UDP latency, as these two metrics are critical for many important applications (*e.g.*, file servers, databases, and key-value stores). The evaluation requires a client-server experiment setting. We measure the performance impact of V-Probe on these metrics when a large amount of memory is reclaimed from the server side and high memory footprint is triggered by the network stream. We compare V-Probe with the baseline (*i.e.,* no memory is reclaimed from the guest) and IOPF.

Although there exist many network performance benchmark tools (*e.g.*, *netperf*), they only focus on the efficiency of the network stack and have a low memory footprint, which means they cannot cover the logic of the memory refault logic (*i.e.*, trigger page fault and reallocate memory). So we design and implement our own micro-benchmarks, which have a high memory footprint while measuring the TCP throughput and UDP latency.

5.2.1 TCP Throughput

To evaluate TCP throughput, we run a client and a server in two separate VMs, both equipped with 2 CPU cores and 4GB main memory. The server serves a 4GB file and the client will download the file when running the experiment. 30% of the server's memory is reclaimed at the beginning of the test. When the client downloads the file, the server will read the file from the disk to the in-memory page cache. As Linux drops the page cache in an on-demand manner, the server will fill the memory with the page cache until the memory is insufficient. This implements a high memory footprint of the experiment and will trigger page refault in the serve. We record the download speed as the TCP throughput.

Figure 9 shows the throughput changes over time in different settings. As the figure shows, the throughput fluctuation

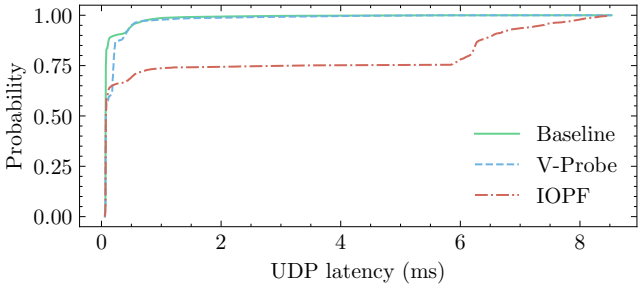

Figure 10: The CDF of the UDP latency when applying the baseline, V-Probe and IOPF.

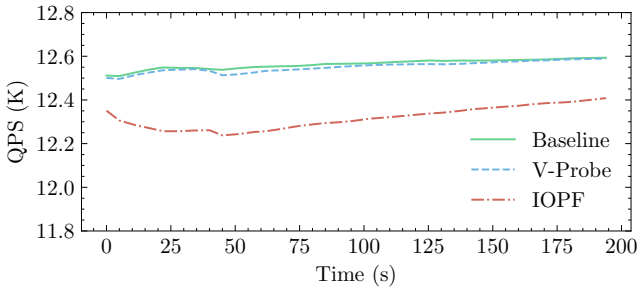

Figure 11: The Redis QPS when applying baseline, V-Probe, and IOPF.

of the baseline and V-Probe are smaller than that of IOPF. The minimum throughput of the baseline, V-Probe and IOPF are 97MB/s, 93.1MB/s, and 85.8MB/s respectively. And the average value is 100.2MB/s, 99.8MB/s, and 97.5MB/s respectively. These results show that V-Probe may degrade the TCP throughput slightly compared with the baseline, but it is much better than IOPF.

5.2.2 UDP Latency

To evaluate UDP latency, we run a client and a server in two separate VMs, both equipped with 2 CPU cores and 4GB main memory. 30% of the server's memory is reclaimed at the beginning of the test. The logic of the UDP server is quite simple: It listens on a port, accepts a UDP connection request, allocates a 2MB buffer and accesses it, then sends a response back to the client. This is to simulate a UDP application with a high memory footprint. Allocating and accessing buffers may cause page faults and page reallocations if the underlying memory is reclaimed by the hypervisor. The UDP client records the latency of each request as the results.

Figure 10 shows the CDF (Cumulative Distribution Function) of different settings. The 90th percentile latency of the baseline, V-Probe and IOPF is 0.23ms, 0.39ms and 6.55ms respectively, and the 99th percentile latency is 1.36ms, 2.43ms and 8.27ms respectively. The overhead of V-Probe is 69.6% and 79.4% in the 90th and 99th percentile latency, respectively, when compared to the baseline. However, it significantly outperforms IOPF, which introduces approximately 27X and 5X overhead in the 90th and 99th percentile latency.

5.3 Macro-benchmark

We use Redis, a widely used in-memory key-value database as the macro-benchmark to evaluate V-Probe. We run a client and a server in two separate VMs, both equipped with 2 CPU cores and 4GB main memory. At the beginning of the experiment, we remove all the data from the Redis server database and reclaim 30% memory from the server. The client runs `redis-benchmark`, the official Redis benchmark tool, to continuously send `SET` commands to the server. The `SET` command will randomly write key-value pairs to the in-memory database. There are 1,000,000 random keys, and the value size of each `SET` operation is 2KB. We record the QPS (queries per second) and the operation latency during the test. We only test the `SET` workload because V-Probe is a free-page-based method, and data insertion is necessary to trigger guest page allocation, and thus necessary to trigger V-Probe's memory reallocation. If we use the `GET` workload to evaluate V-Probe, the data in Redis will always stay in the main memory, with no page fault or memory reallocation operations will not utilize the functionality of V-Probe.

Figure 11 shows the QPS over time in the different settings. As it shows, the result of V-Probe (12.55K) is close to the baseline (12.56K). And the result of IOPF (12.31K) is about 2% lower than the other two. For the tail latency of each operation (not shown in the figure), the baseline and V-Probe exhibit a 99.99th percentile latency of 1ms, while the IOPF exhibits a noticeably higher 99.99th percentile latency of 7ms (the precision of the latency data is limited to the `redis-benchmark` tool). This indicates the Redis performance while applying V-Probe for memory reclamation is close to the case with no memory reclamation and better than applying IOPF.

6 Discussion

6.1 Compatibility

In this paper, we present a Linux-based implementation of V-Probe which is highly straightforward for two reasons. First, the V-Probe injector, including the helper functions, is lightweight (140 LOC (Lines of Code)), and it is dynamically compiled after the startup of the guest. This means that the V-Probe injector does not need to change for different releases of the Linux kernel. Second, V-Probe does not hack any API in the guest OS. This implies that V-Probe does not enforce any changes on the guest OS and retains full compatibility for guest OSes.

V-Probe relies on the continuous arrangement of the guest page meta-data. Accordingly, while in this paper we examine

a Linux-based implementation of V-Probe, the adoption of V-Probe is similar in Unix-like OSes that use a similar memory management mechanism to Linux. For example, FreeBSD uses ranges of *struct vm_page* (like *struct page* in Linux) to arrange the page meta-data and uses the buddy system to manage them.

V-Probe introduces about 1,300 LOC to the hypervisor, as the logic of V-Probe on the hypervisor side is much more complex. But this does not impact the practice of V-Probe as most of the cloud providers use customized hypervisors, and V-Probe can be easily integrated into these software systems.

V-Probe introduces high hardware compatibility as it only relies on the basic virtualization features of the CPU. These features are widely supported by popular CPU platforms such as Intel, AMD, Arm, and RISC-V. Furthermore, V-Probe does not rely on IOPF which is not commonly supported by off-the-shelf I/O devices.

6.2 Fine-grained Page Meta-data Management

Using fine-grained page meta-data management, V-Probe can effectively avoid DMA failures in I/O passthrough enables VMs. At the same time, the idea of fine-grained page meta-data management can also be combined with other free page reclamation methods to avoid DMA failures. For example, in Free Page Reporting, except for the free pages, the guest can also report the page meta-data to the hypervisor. So by managing the access mode of the guest page meta-data's GPA range, Free Page Reporting can avoid DMA failures in the same way V-Probe does. But unlike V-Probe, which uses helper functions to inspect guest free pages without notifying the guest, these methods rely on the frontend drivers to obtain the guest page status, which means the guest communication overhead is unavoidable.

6.3 Threats to Validity

There are two threats to the validity of our work. First, this paper defines and examines an example implementation of the V-Probe design that is specific to Intel X86_64 architecture and Linux-based OSes. Therefore, architecture-based and OS-based assumptions of this example implantation would need to be adjusted when moving to other architectures and OS types. However, since V-Probe relies on the continuous arrangement of the guest page meta-data, V-Probe may not apply to the OSes that use different ways to arrange the page meta-data.

Second, when reclaiming free pages, V-Probe needs to modify the memory mapping for the page meta-data GPA range. But since memory mapping is by the granularity of pages, the meta-data should reside on the same physical page. So V-Probe can only reclaim continuous free pages in batches. As a result, guest free page fragmentation may weaken the memory reclamation effect of V-Probe. But free page fragmentation in the guests is usually caused by high memory pressure, which suggests the system not to reclaim memory from them. Also, this problem can be mitigated by the memory compaction functionality in the guest OS.

7 Conclusion

In this paper, we conduct a systematic survey of previous VM memory reclamation methods and analyze their relationship with the widely deployed I/O passthrough technique. Based on the analysis, We propose V-Probe, a non-intrusion and efficient approach to achieve memory overcommitment for I/O passthrough enabled VMs. Using fine-grained page meta-data management, V-Probe enables the hypervisor to actively inspect and reclaim the guest free pages while guaranteeing DMA-safety. We implement V-Probe and evaluate its efficiency in different aspects. Experiment results show that the overhead of V-Probe is on the micro-second scale and it has low performance impact on the guest workload. It also has high compatibility with different hardware platforms and a wide range of Linux kernel releases, which simplifies the deployment.

Abstract

Latency predictability of storage is one important QoS target of the public clouds. Although modern storage virtualization techniques are devoted to providing fast and scalable storage for clouds, these works usually concentrate exclusively on giving high IOPS throughput without eliminating the device-level interference between multi-tenant virtualized devices and providing latency predictability for cloud tenants when the cloud infrastructures virtualize millions of the current commercially-available but unpredictable NVMe SSDs.

To resolve this issue, we propose a novel local storage virtualization system called LPNS to provide latency-predictable QoS control for hybrid-deployed local cloud storage, including virtualized machines, containers, and bare-metal cloud services. The OS-level NVMe virtualization LPNS designs reliable self-feedback control, flexible I/O queue and command scheduling, scalable polling design, and involves a deterministic network calculus-based formalization method to give upper bounds to virtualized device latency. The evaluation demonstrates that LPNS can achieve up to 18.72× latency optimization of the mainstream NVMe virtualization with strong latency bounds. LPNS can also increase up to 1.45× additional throughput and a better latency bound than the state-of-the-art storage latency control systems.

1 Introduction

Storage virtualization [23, 63] is critical to optimize limited hardware utilization and simplify storage management by providing consistent and straightforward I/O management interfaces in cloud systems. Since NVMe devices deployed in cloud platforms are usually inadequately utilized in terms of throughput [34, 35, 52], most previous works concentrated exclusively on achieving high-throughput targets, including software-level virtualization such as SPDK [25] and MDev-NVMe [55], the hardware-assisted virtualization such as the direct pass-through [70] and Single Root I/O Virtualization (SR-IOV) [14], and hardware/software co-design researches such as LeapIO [41] and FVM [37]. However, when more latency-critical businesses, in addition to the throughput-intensive businesses, have been migrating to the public cloud [12] for performance benefit, a fundamental contradiction between predictable latency and efficiency of the device sharing occurs when cloud platforms integrate storage virtualization: On the one hand, cloud service providers (CSP) tend to oversubscribe infrastructures by sharing them among multiple tenants to achieve better Input/Output Operations Per Second (IOPS) performance and higher energy efficiency [28, 44, 45]. On the other hand, the latency-critical tenants expect exclusive performance to ensure the latency bound of their services without worrying about interference from other guest machines that share the same NVMe SSD, i.e., latency-predictable Quality of Service (QoS).

The mainstream storage solutions can usually ensure high total throughput [25, 37, 41, 55, 57, 70] or fair bandwidth sharing [21, 71] but lack support for latency performance isolation between multi-tenant virtualized storage. For example, we quote a contention scenario where two virtual machines (VM1, VM2) share one Optane P5800X SSD [24] by using SPDK, and we use Figure 1 to show how the interference between these VMs hurts the average latency performance. In VM1, an IOPS-lightweight but latency-sensitive workload runs with a service level of agreement (SLA) at 30μs latency, while VM2 generates a throughput-intensive workload every 10 seconds as a competitor. Unfortunately, VM1 suffers a severe performance thrashing of over 250% additional latency as the workload weight of VM2 fluctuates, missing the SLA during its running time. The reason for this phenomenon is that the general storage controller naively handles all hardware queues used by different processes in a round-robin fashion [66], so the hardware queues are saturated with the I/O commands of the workload $w2$, resulting in a long queue operation time and unpredictable latency of $w1$.

In order to solve the performance interference issue and provide latency-predictable QoS, we propose LPNS, an NVMe virtualization solution that provides latency-predictable virtualized storage in NVMe virtualization and sharing scenarios. LPNS replaces the original static I/O queue allocation be-

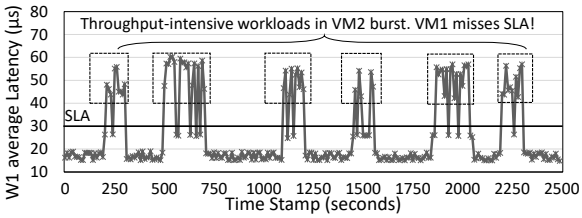

Figure 1: The workload $w1$ in the VM1 interfered by intensive workloads $w2$ in the VM2 sharing the same SSD. The $w1$'s average latency misses the 30μs SLA.

tween hardware and virtualized devices with dynamic queue scheduling. LPNS introduces a fine-grained I/O command scheduling to throttle the competing throughput-intensive workloads to constrain the latency of latency-sensitive workloads. Moreover, we have pioneered the introduction of deterministic network calculus [5, 38] into LPNS to provide mathematical modeling for the latency predictability of virtualized storage, giving a definite latency bound by abstracting the arrival/service curves for storage systems. The experiments show that LPNS can guarantee the latency-predictable QoS and achieve up to **11.57/18.72**× latency optimization over the SPDK/SR-IOV by eliminating the device-level interference. LPNS can also achieve better latency bounds (50μs) than the state-of-the-art mechanism K2 [48] (80μs) for real-world I/O trace on P5800X and increase up to **1.45**× additional total throughput over K2 (**1.61GB/s**, equivalent to **47.66%** of the maximum throughput of a P5800X SSD).

To sum up, we make the following contributions:

(1) We analyze the device-level latency interference of the commercially-available but unpredictable NVMe SSDs, and we argue the significance of overcoming this interference from the OS-level storage virtualization design aspects.

(2) We design LPNS, the first OS-level NVMe virtualization solution with latency-predictable QoS enhancement for unpredictable NVMe SSDs in clouds. LPNS designs a self-feedback mechanism that adaptively provides predictable latency according to the workload distributions of multi-tenant VMs. LPNS involves deterministic network calculus to verify the latency upper bound.

(3) We implement LPNS based on mediated pass-through to enhance the original Linux NVMe driver in providing latency-predictable QoS for hybrid-deployed local virtualized and cloud-native storage. All the CSPs can directly use the OS-level LPNS to provide latency-predictable NVMe storage virtualization and sharing without hardware modification and purchase costs.

(4) The evaluations prove the effectiveness of the latency-predictable QoS control of LPNS, compared with previous storage virtualization and other latency QoS control solutions.

The rest of the paper is organized as follows: Section 2 introduces the technical backgrounds of NVMe, cloud storage, and network calculus. Section 3 introduces the motivation for designing scalable and latency-predicable cloud storage virtualization. Section 4 describes the design and implementation of LPNS. Section 5 demonstrates the evaluation results of LPNS. Section 6 introduces the related works, and Section 7 concludes this paper.

2 Background and Motivation

2.1 NVMe Storage

The NVMe SSDs are now widely used in public clouds. The NVMe specification [51] is an efficient and scalable interface designed for high-performance SSDs. NVMe supports up to 65,535 I/O queues whose depth can be up to 65,535. Specifically, each queue pair contains a submission queue (SQ) and a completion queue (CQ). During each I/O execution, the host OS stores IO commands into the SQ and rings the doorbell, and the completion messages are placed into the corresponding CQ by the SSD controller. With the high-parallel SQ/CQ interaction between the host and the SSD controller, NVMe SSDs can obtain high throughput and micro-second-level latency advantages over the traditional interfaces [9], wherein both throughput and latency are extremely significant and mutually restrictive QoS targets of the cloud storage systems.

2.2 Local NVMe Storage for Cloud Services

For better performance and resource utilization, public cloud infrastructures usually adopt two types of solutions to manage their millions of NVMe SSDs. One is running cloud instances or workloads directly on the native servers and using the local storage; another is providing efficient data access to a remote storage pool or dedicated storage servers [36, 41, 46].

However, not all cloud services prefer remote storage solutions, for example, Elastic Compute Services (ECS). We infer there are three main reasons: (1) The remote storage performance is influenced not only by the storage system but also by network devices, which introduces an additional bottleneck of latency performance incurred by the network. (2) Remote storage uses expensive network devices, incurring additional purchase costs to cloud infrastructures and finally hurting the interests of the cloud tenants. (3) Cloud tenants may lease the bare-metal servers or services to customize their own distributed computing and storage clusters, which conflicts with the remote storage architectures.

In contrast, the local storage technique route can provide fast and cheap storage for the public clouds with the widely-used storage virtualization [7, 25, 37, 55, 57, 70]. For example, MDev-NVMe [55] proposes a novel I/O queue pass-through of NVMe hardware queue resources to achieve near-native performance for cloud instance storage. Moreover, local storage virtualization is more flexible in providing QoS guarantees for cloud services, especially the latency-sensitive services that suffer the performance unpredictability of network systems. Therefore, in this paper, we aim to provide latency-predictable virtualized storage services by following the local

storage virtualization technique route.

2.3 Deterministic Network Calculus

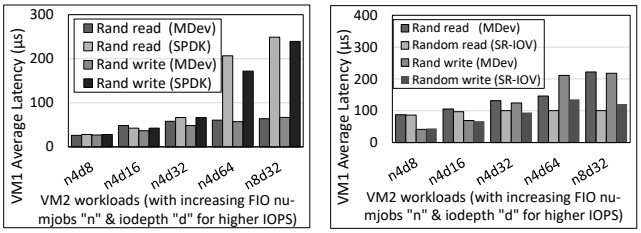
Deterministic Network Calculus (DNC) [38] is used to calculate theoretical worst-case performance guarantees for networks of queues and schedulers, which is commonly used for communication networks to provide predictable latency in typical deterministic queuing systems [13, 40, 59, 65, 69]. The theory's three basic concepts are suitable for providing predictable-latency performance in NVMe virtualization: the arrival curve, the service curve, and the virtual delay. The arrival curve expresses the upper bounds of the number of events that come from the sources over any time. The service curve refers to the guarantee of flows offered by the system and describes the service capability of the system. For a definite system, if the arrival curve and service curve are determined, the virtual delay referring to the delay that an event arriving at a particular time will suffer, can be deduced. The deterministic network calculus proves that the maximum horizontal distance between a workload's arrival curve and service curve is a tight worst-case bound on latency.

According to the NVMe specification and the I/O performance and behavior of the commercial-available NVMe SSDs, we can make a performance assumption that the processing capability of the modern NVMe SSD is stable and constant at most of their working time except during garbage collection and the SSDs serve the I/O command processing in First-In-First-Out (FIFO) policies. Moreover, for the multi-tenant virtual devices sharing the same NVMe SSD, we assume that throughput-intensive workloads can use the maximum queue depth and latency-sensitive processes use a queue depth of 1. The arrival curve refers to the actual IOPS of VM workloads, which determines the commands rate of multiple-tenant workloads that the SSD receives. The service curve guarantees the least command rate that the SSD can process during a busy period. The virtual delay is precisely the I/O latency of the latency-sensitive workload, which is the focus of our attention for latency-predictable QoS in storage virtualization.

3 Motivation

The clouds aim to provide **latency-predictable Storage QoS** for VMs so their virtual storage devices can have a latency bound for storage I/O operations. However, state-of-the-art storage virtualization [14, 25, 37, 41, 55] cannot solve the device-side latency interference issue and cannot provide latency-predictable QoS. The **device-side latency interference** refers to a phenomenon that the guarantee for the VM with latency-predictable QoS fails when multiple VMs without latency-predictable QoS run throughput-intensive workloads and compete for the same underlying NVMe SSD, incurring the latency deterioration, unbounded latency, and the miss of latency QoS (or SLA) just like the Figure 1 example.

However, even the state-of-the-art NVMe virtualization techniques (including SPDK, SR-IOV, and MDev-NVMe) neglect the importance of eliminating performance interference in multi-tenant storage-sharing scenarios. The more intensive the competitor's workload is, the more severe performance interference happens. We use MDev-NVMe and SPDK vhost-blk to share one Intel Optane P5800X SSD into two virtualized devices. We also use one SR-IOV-capable Samsung PM1735 to build two VFs and use MDev-NVMe as a comparison. In the test cases, VM1 runs a latency-sensitive workload (an FIO [26] random read or write benchmark with *iodepth=1, numjobs=1*), with a growing-intensive 4K random write workload in VM2 by increasing the *numjobs* and *iodepth* parameters of FIO. We separately show the latency performance of the latency-sensitive workload of VM1 in Figure 2, which shows that there is an up to 4.7× latency overhead in MDev-NVMe, 16.5 × overhead in SPDK, and up to 6.1× overhead in SR-IOV over the VM1 workload.



(a) Intel Optane P5800X (b) Samsung PM1735

Figure 2: Latency interference between two virtualized devices with the state-of-the-art NVMe virtualization. (If VM1 monopolizes one P5800X, the read/write latency of the VM1 workload is 11.9/13.1μs with MDev and 11.9/13.3μs with SPDK. If VM1 monopolizes one PM1735, the read/write latency is 71.9/17.6μs on MDev and 74.9/19.9μs with SR-IOV.)

We further analyze the latency distribution of different I/O phases of NVMe virtualization. We choose MDev-NVMe as a representative to virtualize a P5800X and summarize the results in Table 1. We find that the VM1's average latency on the NVMe controller grows from 62.5% to **93.0%** of the total latency with the increasing IOPS of the VM2 workload. This phenomenon proves that more severe I/O congestion happens when more commands from the competitor workloads simultaneously arrive at the SSD controller and savagely preempt the resources, causing a worse latency bound to the latency-sensitive workloads. Since the hardware/software co-designed virtualization [37, 41] usually attaches standard and unpredictable NVMe SSDs to an accelerator card, we can deduce that these solutions still meet this device-side latency interference and fail to reach latency-predictable QoS.

To overcome the device-level latency interference, we aim to design latency-predictable QoS control for NVMe virtualization. Previous works (summarized in Table 2) usually redesign the Flash Translation Layer (FTL) in the SSD con-

Table 1: VM1 latency distribution in different phases

I/O phase \ VM2 IOPS	50K	250K	500K
Guest OS submit commands	2.8%	1.9%	1.1%
Virtual SQ	1.9%	1.9%	0.8%
Physical SQ	1.4%	1.1%	0.4%
SSD controller	**62.5%**	**80.1%**	**93.0%**
Virtual CQ	23.0%	10.2%	2.9%
Virtual Interrupt handling	8.4%	4.8%	1.7%

troller [29,31,53,66] or introduce additional logic into the host software stack [21,48,71] to achieve reliable high-throughput or fair-bandwidth QoS control. FinNVMe [54] local NVMe virtualization designs fine-grained queue-level scheduling to achieve state-of-the-art throughput-oriented QoS control for virtualized devices. For predictable latency, Prioritymeister [74] automatically and proactively configures workload priorities and rate limits to provide tail Latency QoS for shared networked storage. K2 [48] uses work-constraining scheduling to trade reduced throughput for lower latency bound, which is the state-of-the-art latency QoS control among the previous solutions [15,22,29,30,33,36,50,61,64] for native storage. However, Prioritymeister and K2 lack the customized design for NVMe virtualization in multi-tenant cloud storage systems. Moreover, K2 sacrifices too much throughput (up to **2.27GB/s,** equivalent to **47.66%** of the maximum throughput of the P5800X SSD in Section 5 experiments) when reaching predictable latency.

4 LPNS Design and Implementation

4.1 System Overview

Motivated by the analysis of device-side latency interference, we aim to provide predictable latency and overcome the interference problems from the aspect of the OS-level NVMe virtualization design. The QoS levels of different VMs should be determined at initialization and can only be changed when storage service tenants agree. Since the strict predictability generalizing the notion of isolation comes at the overall throughput expense, we should give an upper bound to the latency of NVMe virtualization under definite system settings with a slight total throughput loss of the SSD.

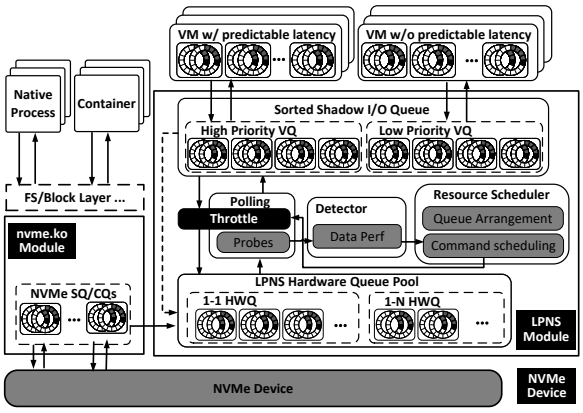

Figure 3: The system architecture of LPNS.

Scalable architecture. We briefly introduce the LPNS architecture in Figure 3. LPNS is designed based on mediated pass-through [27], which has been proven to be excellent in both performance and scalability [54,55,67]. LPNS is implemented as a kernel module to provide virtualized storage with full NVMe features to guest VMs, and it can coexist and cooperate with the original *nvme.ko* module (the NVMe driver) to support the **hybrid deployment of host processes, containers, VMs on each single NVMe SSD**. So it is cheaper, more flexible, and user-friendly for cloud vendors to use LPNS than SR-IOV-capable SSDs or the hardware/software co-designed solutions. Specifically, LPNS designs a performance detector, a queue scheduler, and a command scheduler for predictable latency enhancement, and it provides a flexible polling mechanism for better virtualization scalability.

Full virtualization. LPNS inherits the advantages of physical I/O queues pass-through and active I/O polling from the previous NVMe mediated pass-through solution [55]. LPNS supports full virtualization and does not modify the guest drivers. In the hypervisor (kernel module), the hardware I/O queues (HWQs) can be directly passed-through to VMs, so I/O commands from VMs can be stored in the HWQs through fast I/O paths. The hypervisor maintains a virtual IOMMU structure in shared memory for translating the GPA (Guest Physical Address) of different virtual devices into the IOVA (IO virtual address) of the underlying SSD. Cloud vendors can create partitions and bind each partition with a virtualized storage device with the hypervisor, and the hypervisor can easily do LBA translation between guest and host OS based on the partition information.

Self-feedback QoS control. LPNS has the ability to distinguish QoS targets of VMs to provide latency-predictable QoS. The hypervisor gives each virtual storage a tag when creating the VM to recognize if the workload from this VM should be provided with a predictable latency guarantee [1]. LPNS can periodically trigger resource scheduling between VMs based on runtime performance detection. We place a

[1]We use SVM to represent the VM with latency-predictable QoS guarantees, and use IVM to represent the VM without latency-predictable QoS.

performance probe in the polling thread to periodically collect the index, submission, and completion timestamps of all virtual I/O commands, along with real-time submission and completion command counts. With these statistics, LPNS can calculate the primary execution time of every command and the average latency within a time interval for the scheduler to enhance predictable latency and build an entire self-feedback QoS control system. Specifically, we choose 10 ms as a monitoring interval and 200 ms as a scheduling period in the current implementation.

Flexible and scalable polling. LPNS uses polling threads to process I/O commands and poll the virtual SQ (VSQ) tail, the HWQs, and the virtual CQ (VCQ) head of all VMs for better I/O performance. To reach a balance between performance optimization and CPU overhead, LPNS can arrange only one polling thread for all IVMs, and the thread can fully utilize the high throughput ability of the NVMe SSD; or arrange one dedicated polling thread for each SVM to reach a predictable latency (performance discussed in §4.5). All the polling threads are adaptively triggered on or off according to runtime workload detection of the VMs to reduce unnecessary CPU overhead.

Hardware queue pools (§4.2.) LPNS designs an I/O queue scheduling mechanism with a dynamic queue allocation to achieve a flexible mapping and multiplexing of hardware I/O queue resources. All HWQs are organized into a queue pool as two types of queues, wherein the 1-1 HWQs are exclusive queues for one single VM, and the 1-N HWQs are the shared queues for multiple VMs. The hypervisor implements an HWQ scheduler as a global controller for the HWQ resources. The queue scheduler can periodically schedule the 1-N HWQs between VMs for better virtualization scalability.

I/O command throttling (§4.3.) We implement a virtual I/O command throttling mechanism in the LPNS hypervisor to control the I/O path of each VM and eliminate the device-level latency interference at the OS level. The polling threads can perform the throttling between VMs from the global view. Specifically, the hypervisor provides an interface to adjust the threshold for command throttling, which can control the I/O rate received by the hardware at each scheduling period to reach predictable latency guarantees. The I/O command throttling follows the constraint of deterministic network calculus.

4.2 Scalable I/O Queue Handling

Since previous NVMe virtualization solutions usually use static I/O queue shadowing between virtualized devices and the hardware SSD, the total number of HWQs exposed by the SSD will limit the maximum number of VMs sharing the same underlying SSD. To increase the virtualization scalability, LPNS supports the flexible remapping between HWQs and virtual queues (VQ). Specifically, LPNS can allocate any number of the HWQs (but less than the maximum number of HWQs exposed by the SSD controller) from the *nvme.ko* kernel module into a **Hardware Queue Pool** for I/O queue scheduling, and the rest HWQs can be used by the native applications and containers.

We design an **I/O queue scheduler** to manage the Time Division Multiplexing (TDM) [16] of the HWQs in the **Hardware Queue Pool**. We abstract the HWQs of the pool into two types: 1-1 HWQs and 1-N HWQs. An 1-1 HWQ refers to an HWQ that can only be bound to one VQ. The 1-N HWQs refer to the I/O queues to maintain the necessary I/O capabilities for the other multiple VQs. The total number of 1-1 and 1-N HWQs should be configured when the host system initializes the LPNS module. Specifically, the configuration will not directly change the priority of these HWQs, so it can still work when using the NVMe Weighted-Round-Robin-with-urgent-priority (WRR) feature of the HWQs.

When multiple SVMs and IVMs share the same underlying SSD, LPNS only assign 1-1 HWQs to the SVMs for better latency performance, so the number of 1-1 HWQs should not be less than the number of total VQs owned by all the SVMs. The queue scheduler can schedule the idle 1-1 HWQs and all the 1-N HWQs among the other IVMs.

Since LPNS can monitor and collect real-time performance and workload data of VMs in each period, the I/O queue scheduler follows a hierarchical **workload-aware HWQ scheduling** policy wherein it takes the QoS target and runtime workloads of VMs as the algorithm inputs. The scheduling mainly consists of a hierarchical VQ weight calculating phase and an HWQ switching phase. During each scheduling period, the scheduler first respectively calculates the weight of VQs of all VMs. For any SVM VQ, the weight is set as 0 or the top weight, depending on if this VQ is empty or not. For the VQs of IVMs, their weights are equal to the number of their backlogged commands so that VQs with heavier workloads can get higher priority to be drained quickly. The HWQ switching phase works after the weight updating phase. It sorts the weights of all VQs in descending order, and those high-priority VQs will first use 1-1 HWQs, and the low-priority VQs will be bound to 1-N queues. After switching, the I/O queue scheduler will sleep until the next period.

When one 1-1 HWQ needs to switch to a new VQ, it may still have unfinished commands from the former VQ. Direct forwarding of these stranded commands in VSQs will cause an I/O error because the completion message cannot be handled correctly. So we design a seamless switching mechanism in the I/O queue scheduler. Specifically, LPNS extends the virtual NVMe command structure with an index of the VM to enable the HWQs to interact with different VQs from different VMs simultaneously in the seamless switching. When we want to unbind a 1-1 HWQ from a VQ, the VQ should be bound to another backup 1-N HWQ before the commands in the 1-1 HWQ are executed by the SSD. During the switching, both the 1-1 HWQ and the backup 1-N HWQ can write back the completion information into the original VCQs. Specifically, the VCQ should be locked to ensure data consistency

when two HWQs access the same VCQ simultaneously. The seamless switching operations run in the background, and each VQ can continuously send commands to an HWQ without the perception of queue scheduling operations until a new HWQ-VQ binding relationship is established. So it will not disturb the high-parallel fetch of I/O commands from VMs.

4.3 I/O Command Throttling

We design a fine-grained I/O command throttling in LPNS and involve a deterministic network calculus to provide a latency bound of the I/O command for multi-tenant shared virtualized storage. Network calculus has been proven effective in providing latency control for shared network storage systems in previous research, such as Prioritymeister [74]. In our LPNS, we use deterministic network calculus to help to solve the intensive resource and performance competition for different virtual devices sharing the same SSD so that a storage hypervisor can directly eliminate the device-level latency interference from the OS and virtualization layer by scheduling queue resources between different virtual devices and control the I/O command throttling inside a kernel module.

The deterministic network calculus gives a definite bound to the command latency by abstracting the arrival and service curves for storage systems. We can fix the I/O block size to the most widely-used 4K for simplification of the predictable latency deduction. The arrival curve expresses the upper bounds of the number of events from the sources over any time. It refers to the I/O command submission rate by all VMs in our system. The service curve refers to the guarantee of flows offered by LPNS wherein it describes the I/O capability of the NVMe devices. The service curve may be modified by internal functions (like garbage collection and block relocation) of SSDs, so we simplify the mathematical model of LPNS by concentrating on the normal working time without triggering internal functions. And we believe LPNS can cooperate with some future SSDs, such as AutoSSD [31], that try to control the tail latency inside the SSD controller so that LPNS can provide a more robust latency-predictable storage virtualization on the future NVMe SSDs. Once the arrival and service curve of an NVMe SSD is determined, we can deduce the virtual delay at a particular time t, which is the latency bound of SVMs in LPNS virtualization.

Arrival Curve. If the total command submission rate of an intensive VM exceeds θ times the slowest submission rate of a VM with predictable latency QoS guarantee, its I/O will be suspended. The polling threads in the hypervisor of LPNS can trigger the suspension based on the command count of each VM recorded by the performance detector. Using this I/O command throttling threshold is incredibly effective in guaranteeing the latency stability of the VMs with predictable latency guarantees because we can control the command submission rate precisely as we expect. Suppose there are j VMs with intensive workloads co-running with i VMs running latency-sensitive workloads whose IOPS is p and its command queue depth d , the real-time total command submission rate sent to the SSD hardware is:

$$v = p \cdot (j \cdot \theta + i), \tag{1}$$

where the I/O command submission rate v of LPNS is proportional to the IOPS of latency-sensitive workloads.

Similarly, we can get the number of commands b that the sources can send at one time:

$$b = d \cdot (j \cdot \theta + i). \tag{2}$$

Then we formulate the arrival curve of LPNS as:

$$\alpha(t) = v \cdot t + b = (p \cdot (j \cdot \theta + i)) \cdot t + d \cdot (j \cdot \theta + i). \tag{3}$$

Service Curve. The service curve is straightforward because the processing capability of the NVMe SSD is constant (according to the types of NVMe SSDs). We use R to represent the parallel speed of which the hardware processes random write commands per second (since most SSDs has lower random write performance than random read), and L_h to represent the minimum completion latency of an I/O command. So the service curve is:

$$\beta(t) = R \cdot t + L_h. \tag{4}$$

Latency Upper Bound. Call $\Delta(t) = \inf\{\tau \geq 0 : \alpha(t) \leq \beta(t+\tau)\}$. Let $h(\alpha,\beta)$ be the supremum of all values of $\Delta(t)$, then the virtual delay for all t satisfies: $L(t) <= h(\alpha,\beta)$. Given the arrival curve and service curve of LPNS above, we deduce the upper bound of latency $L_{\max}$ as (according to [5, 38]):

$$L_{\max} \leqslant b/R + L_h = d \cdot (j \cdot \theta + i)/R + L_h, \tag{5}$$

where we let $\Omega = j \cdot \theta + i$ to control the predictable latency performance of a latency-sensitive workload p and the total submission rate (which can finally decide the total throughput) on each type of the NVMe SSDs. Specifically, LPNS can adaptively change the θ parameter with the numbers of VMs (i and j) when the performance detector checks if each VM generates active I/O operations when the Ω is determined.

The choice of threshold Ω is essential to the effect of throttling in the real-world system. A smaller Ω value can provide better predictability, but it restricts the throughput of the VMs running throughput-intensive workloads without predictable latency requirements. So the most proper alternative of Ω should be figured out by the optimal upper limit of the hardware processing speed, which needs to be specified and updated by the system administrator because different NVMe SSD may have various R/W performances. Moreover, the requirements for the latency QoS level of each latency-sensitive workload can be stricter and looser in practice, so as the constraints for Ω. Therefore, LPNS can let VMs introduce a tenant-defined latency target in advance and help to tune the Ω parameter. And the decision-maker can increase

or decrease Ω by comparing the detected latency with the target during the running time for a better trade-off between throughput and predictable latency. In the evaluation section, we will verify the effectiveness of this latency bound through adequate experiments on different types of NVMe SSDs.

4.4 Latency-Predictable I/O Processing

We use Figure 4 to represent how LPNS enhances latency-predictable I/O processing of the SVMs. The left part of this figure shows the I/O path of a VM with the latency-predictable QoS (the SVM). The LPNS module maintains the shadow I/O queue data structure (directly corresponding to the virtual queue) for each virtual storage in the shared memory between the host kernel and QEMU, which can store I/O commands from guest SQs and generate completion messages into the guest CQs. When guest applications generate I/O operation on the virtualized storage (❶), the command will be stored in the shadow I/O queue. The polling thread will immediately poll the head of the queue (❷), and translate the DMA and LBA addresses in commands, store it into the 1-1 HWQ, and finally ring the hardware doorbell register. (❸) - (❺) represents the process that the SSD controller fetches command, generates DMA, and stores the completion messages into HWQs. The polling thread will continuously check if the doorbell register of the hardware CQs updates to accelerate the I/O operation instead of waiting for the SSD controller to inject interrupts (❻). And the polling thread will compose the completion message of the VMs and store the message into the shadow queue (❼), and inject a virtual interrupt into the VM. Finally, the guest VM driver can complete the I/O operation (❽).

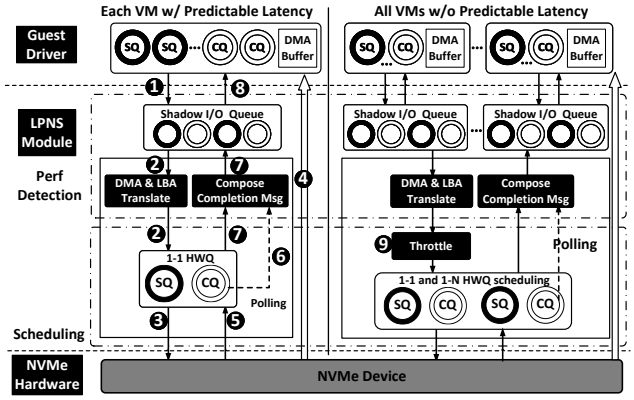

Figure 4: I/O work flow of LPNS virtualized storage.

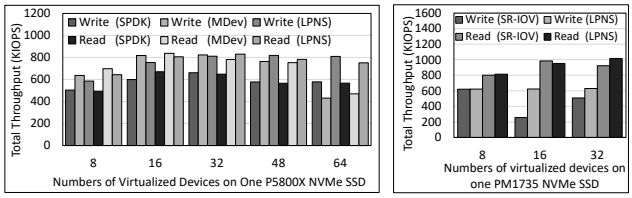
The right part of Figure 4 shows that the IVMs get the HWQ resources from HWQ scheduling, and the polling thread can throttle the command distribution from the VQ to HWQ (where ❾ replaces the ❷). With the I/O path designs, the intensive workloads in these VMs will not hurt the latency of the VM with the predictable latency guarantees because of the device-level latency interference.

4.5 Discussion

Polling effectiveness. We discuss the polling effectiveness of LPNS by comparing the throughput of LPNS with MDev-NVMe, SPDK, and SR-IOV when multiple VMs share a P5800X/PM1735 SSD. Figure 5 demonstrates the total throughput where increasing numbers of VMs running an FIO workload with the "*numjobs*=1, *iodepth*=1" parameters share the same NVMe SSD. The results prove that LPNS can fully utilize the P5800X or PM1735 for multiple IVMs with only one polling thread and provide better scalability than MDev-NVMe, SPDK, and SR-IOV.



(a) Intel Optane P5800X (b) Samsung PM1735

Figure 5: Polling effectiveness for high throughput (SPDK and LPNS both use one polling thread shared by all VMs.)

We also run an FIO test with "*numjobs*=1 or 4, *iodepth*=1" on the host OS and inside a VM with MDev-NVMe, SPDK and SR-IOV. Figure 6 demonstrates how one dedicated polling thread can achieve promising and near-native average latency.

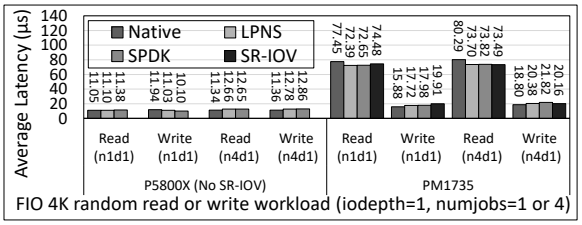


Figure 6: One dedicated polling thread for one SVM.

Performance overhead. In the self-feedback QoS control, each polling thread uses a two-phase array to achieve real-time performance data feedback for the SVMs. While the thread reads data from one phase of the array for computation, the probes record current I/O data into the other phase. It is lock-free, and only a writing-array operation is added into the origin command execution time. So the performance overhead of our self-feedback mechanism is negligible. Figure 5 and 6 prove that the active polling in LPNS can ensure no utilization overhead of the total IOPS and near-native idle latency performance for SVMs.

Resource overhead. (1) The choices of the performance detection are critical for resource overhead. The detection exacerbates kernel memory consumption because tens of thousand of commands can occupy hundreds of KBs of memory to store the performance data. Therefore, we cut the one-period detection into 10 ms intervals (much shorter than the scheduling period), we can calculate the average command latency for each interval, and finally sum up the results of a whole

period so we can reduce kernel memory overhead. (2) The polling threads in LPNS can be adaptively turned into an idle status when there are no I/O operations generated from the guest machines in a recent 500 ms. When performance detection finds there are burst I/O operations, LPNS will turn on the polling thread immediately. This helps reduce the CPU overhead of polling.

Limitation. The deterministic network calculus of LPNS needs tunning when cloud workloads use different NVMe SSDs or block sizes instead of the most commonly-used 4K. Also, for the SSDs whose random write IOPS is much lower than random read, the deterministic network calculus will be more strict to provide latency bound, and LPNS may sacrifice more throughput performance than when running LPNS on SSDs with equivalent random read and write performance, such as Intel Optane NVMe SSDs.

5 Evaluation

In this section, we evaluate LPNS on different NVMe SSDs and compare LPNS with several famous related works.

Firstly, we want to compare LPNS with mainstream NVMe virtualization solutions. We start with the following NVMe virtualization mechanisms: MDev-NVMe, VirtIO, SPDK with *vhost-blk* interfaces, and SR-IOV [2].

We also compare LPNS with state-of-the-art QoS control systems, MQFQ, D2FQ, and K2. Specifically, (1) we build a K2 kernel module with its source code [68]; (2) We implement MQFQ with 1125 Lines of Code according to the description in [21] since the original source [20] is no longer accessible. (3) We modify 19 lines of the D2FQ source codes [62] for bug fixing according to the description in [71].

5.1 Experiment Setup

Hardware configuration. We evaluate LPNS on two servers. One server has two 20-core Intel Xeon Gold 6248 CPUs (2.5GHz), 384GB DDR4 memory, and one 400GB Optane P5800X SSD [24]. Another server has two 20-core Intel Xeon Gold 6230 CPUs (2.1GHz), 128GB DDR4 memory, and one 1.6TB SR-IOV-capable Samsung PM1735 SSD [58]. The parameters Ω we choose for the P5800X and PM1735 are 190 and 100 (the choices are discussed in §5.5.)

System configuration. We implement LPNS based on Linux kernel 5.0.0. The two host servers run a Ubuntu 18.04.3 LTS 64bit OS and boot VMs with the same OS image version based on KVM/QEMU. There are different numbers of SVMs and IVMs in micro and real-world benchmarks. Each VM has 4 VCPUs, 4GB memory, 40GB virtual NVMe storage, and 4VQs equal to the number of VCPUs. Each virtual storage is created on a logical partition of the SSD, and the VM uses the original NVMe driver of Linux. In all experiments, the total number of HWQs used for virtualization is less than the total number of VQs to mimic a resource shortage scenario in the real-world cloud environments.

Workload configuration. The micro-workloads are generated by FIO [26], which is widely used in both industry and research. The FIO version is 3.1, and *libaio* is selected as the default I/O engine. We set the I/O mode as Direct I/O. We set the block size of random read/write as 4K. In application benchmarks, we first replay the webuser service of open-sourced production systems at Florida International University (FIU) [6]. We also use YCSB [8] as another application benchmark and choose RocksDB [3] to test the I/O performance of K-V store. The YCSB version is 0.17.0, and we use the embedded RocksDB database of YCSB [2].

5.2 Micro Benchmarks

In the micro benchmarks, we let one SVM to share a P5800X SSD with one or multiple IVMs on LPNS, MDev-NVMe, SPDK with *vhost-blk*, and VirtIO. We also compare LPNS with MDev-NVMe and SR-IOV on a PM1735. In each test case, the SVM runs the lightest FIO workloads in a general sense by setting both the two standard decisive FIO parameters “numjobs" and “iodepth" as 1 (n1d1). The other IVMs run throughput-insensitive workloads as competitors, and we let their workloads grow from as light as the SVM to heavy enough to reach the throughput limit of the SSD by increasing the “numjobs" and “iodepth" parameters. We observe the latency of the “n1d1" workload in the SVM when the SVM faces serious interference.

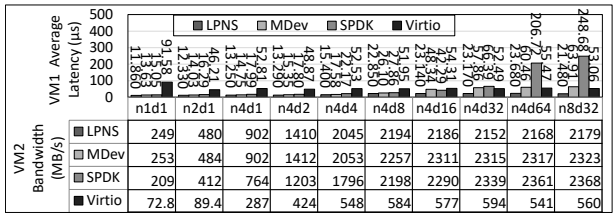
The micro benchmark results are demonstrated in Figure 7. Firstly, we let one SVM (VM1) and IVM (VM2) to share one underlying P5800X or PM1735 SSD and show the performance results in Figure 7a to 7d. The bar charts in the upper part of the sub-figures represent the latency performance of the FIO n1d1 workload in VM1, and the tables in the lower part are the throughput of the competitor workloads of VM2 in the same test cases. We also let one SVM (VM1) and multiple (2-7) IVMs to share the same SSD and demonstrate the latency of the VM1 workload in Figure 7e.

P5800X. We let the VM1 and the VM2 share one P5800X SSD, and the performance of 4K random read and write test cases are depicted in Figure 7a and 7b. Optane SSDs use 3D XPoint technology [17] (the most advanced storage medium), and their hardware controllers usually have stable storage service capability in latency and throughput, which is more friendly to latency-predictable systems. Because Optane SSDs also have similar random read and write performance, the results shown in Figure 7a and 7b have similar features.

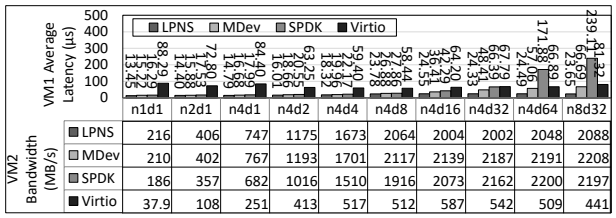
LPNS can bound the latency of VM1 workload at a low level (less than 25 μs) in both 4K random read and write cases. LPNS can only sacrifice the throughput of VM2 workload within 7.0% of MDev-NVMe and within 8.2% of SPDK when VM2 runs n464 or n832 cases, and in most cases, the sacrifices

[2]The hardware/software co-designed FVM [37] and LeapIO [41] are not open-sourced and available.

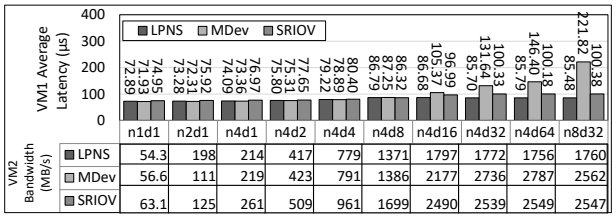
are less than 1%. Moreover, LPNS successfully eliminates the device-level interference observed in Figure 2.



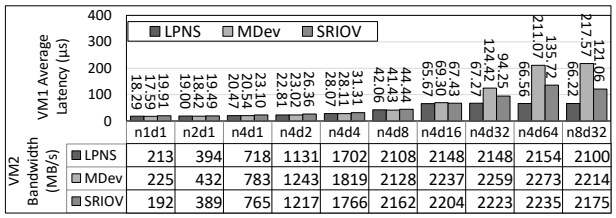
(a) One SVM & One IVM, 4K random read (P5800X).



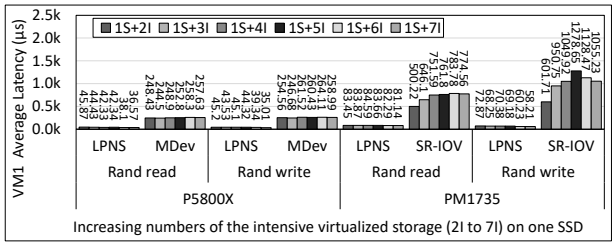
(b) One SVM & One IVM, 4K random write (P5800X).



(c) One SVM & One IVM, 4K random read (PM1735).



(d) One SVM & One IVM, 4K random write (PM1735).



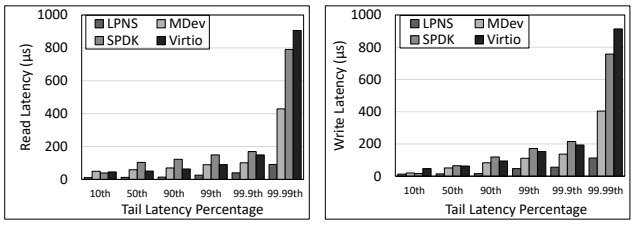
(e) One SVM & Multiple IVMs (P5800X & PM1735)

Figure 7: The average latency of LPNS compared with the other NVMe virtualization on P5800X and PM1735.

In MDev-NVMe and SPDK, the increasing throughput of the competitor workload in VM2 will lead to latency deterioration of the VM1 workload. For example, when using n4d64 or n8d32 parameters, LPNS can reach up to **11.57/2.98**× latency optimization over SPDK/MDev-NVMe. The main reason is that their polling threads cannot provide strong performance isolation between different virtualized devices to overcome latency interference. VirtIO can obtain stable average latency and better latency bound for VM1 than SPDK, but the VM1 latency and VM2 throughput are not comparable with LPNS because VirtIO is generic virtualization for block devices and not optimized for NVMe.

Figure 7e shows that LPNS can provide latency-predictable QoS with promising scalability for the SVM when we increase the number of IVMs from 2 to 7. The latency results of VM1 are very stable and low, and bounded by **50** μs, which can achieve up to 7.40× latency optimization of MDev-NVMe.

Figure 8 demonstrate the tail latency of the n8d32 test cases in Figure 7a and 7b. LPNS can reach up to 3.84/6.70× optimization of 99.9th/99.99th 4K random read tail latency of SPDK and 3.73/9.96× optimization of 99.9th/99.99th 4K random write tail latency of SPDK.



(a) Random Read Tail Latency (b) Random Write Tail Latency

Figure 8: Tail Latency of micro benchmarks on P5800X .

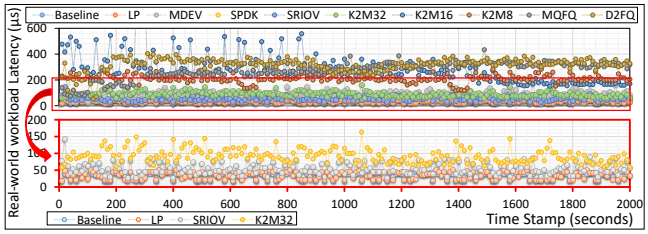
PM1735. We let the VM1 and the VM2 share one PM1735 SSD, and the performance results are shown in Figure 7c and 7d. These results show that LPNS can provide better latency than MDev-NVMe and SR-IOV in all cases and achieve up to 3.27× latency optimization. Moreover, when we increase the number of IVMs from 2 to 7 on PM1735, the IVMs cause serious latency interference on the VM1 when using SR-IOV. LPNS can bound the VM1 workload's latency under **90**μs, with up to **18.72**× latency optimization over SR-IOV. To be mentioned, the throughput performance loss of IVMs on PM1735 is worse than P5800X, which is less than 7.07% in the 4K random write cases, but up to 31.11% in the 4K random read cases. The main reason is that the random read service capability of the PM1735 controller is much better than the random write, and LPNS must choose a more conservative configuration to ensure latency-predictable QoS but incur more throughput loss.

In general, LPNS can perform better in both latency bound and low throughput loss than VirtIO. LPNS can provide ultra-low latency and ensure latency-predictable QoS compared to MDev-NVMe, SPDK, and SR-IOV.

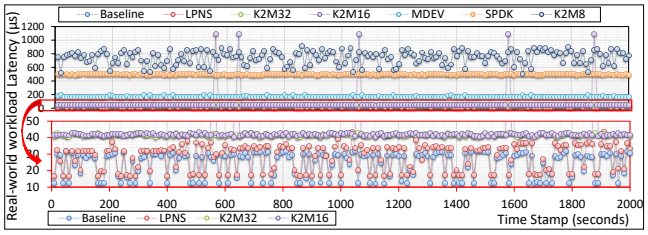
5.3 Real-world I/O trace Replay

In the real-world I/O trace replay, we run a *webuser* workload in the SVM(s) and let the SVM share one Optane P5800X and PM1735 SSD with one or multiple IVMs running intensive workloads (FIO 4K random write with *numjobs=4* and *iodepth=32*). The raw data of the latency-sensitive *webuser* server comes from [6]. We extract the throughput and the proportion of reading and writing operations from the raw data.

The running time of each *webuser* test case is 2000 seconds, and we report latency results every 10 seconds.



(a) Samsung PM1735.



(b) Intel Optane P5800X.

Figure 9: The latency of real-workload *webuser* on LPNS, MDev-NVMe, SPDK, MQFQ, D2FQ, and K2 with 32, 16, and 8 *max_inflight* when 4 VMs share one NVMe SSD (VM1 is an SVM and VM2-4 are IVMs), compared with a baseline that only VM1 monopolizes the NVMe SSD. The lower-part charts in the figures are the enlargement of the data from the red boxes of the upper-part charts.

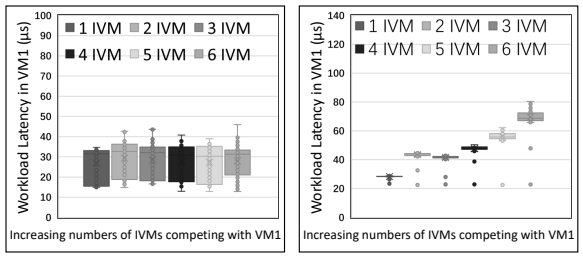
We choose MDev-NVMe and SPDK with *vhost-blk* as the representative of the state-of-the-art virtualization, and we design eight groups of experiments with different numbers of SVM (s) and IVM(s), including "1SVM & 1IVM" to "1SVM & 6IVM", "2SVM & 2IVM", and "3SVM & 1IVM".

We choose K2, MQFQ, and D2FQ for comparison. Since LPNS, MDev-NVMe, and SPDK can prove near-native latency for each virtualized storage and K2, MQFQ, and D2FQ are not designed for NVMe virtualization, we deduce that this latency performance comparison are typical and persuasive. We build the K2 module and *insmod k2-scheduler* into the original 4.15.0-175-generic kernel of the public Ubuntu 18.04 system. We implement MQFQ and D2FQ in a Linux 5.3.10 kernel. We run the same real-world *webuser* workloads and intensive FIO random write workloads on the host OS, just like inside the SVM(s) and IVM(s). We use the `ionice` [10] commands to give the *webuser* a high priority for latency QoS control on K2, MQFQ, and D2FQ scheduler. Specifically, we configure the *max_inflight* parameters of K2 as 32, 16, and 8, and the parameters of MQFQ and D2FQ are set as default values according to the papers.

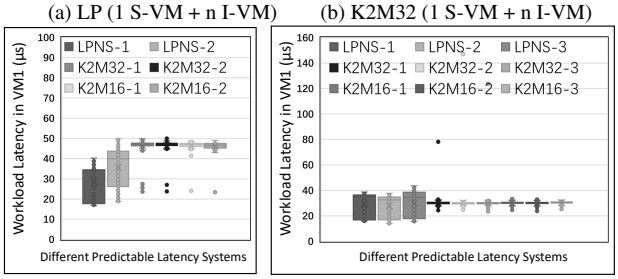
Latency fluctuation. We firstly choose the "1 SVM & 3 IVMs" cases on PM1735 and P5800X as a typical example of all the cases to show the overall latency control effects of the related works compared with a baseline where only VM1 running the *webuser* monopolizes the entire SSD. We demonstrate the latency results of the *webuser* in Figure 9.

On both PM1735 and P5800X SSD, the latency of LPNS can nearly coincide with the baseline fluctuation line, and it successfully ensures the *webuser*'s latency-predictable QoS. SR-IOV and K2 can also provide better latency performance than MQFQ, D2FQ, and SPDK because the main purpose of MQFQ and D2FQ is to reach a fair queue scheduling and SPDK does not involve reliable performance isolation. On P5800X, K2 with *max_inflight=32* can successfully bound the latency within **50**μs. However, SR-IOV and K2 cannot bound latency within 50μs level as LPNS does on PM1735.

Latency interference elimination. We count the latency distributions of the eight groups of LPNS and K2 (providing better latency bound effect in the example case) in Figure 10 with box charts.



(a) LP (1 S-VM + n I-VM) (b) K2M32 (1 S-VM + n I-VM)



(c) 2 S-VM+2 I-VM (d) 3 S-VM+1 I-VM

Figure 10: The latency distribution results of test cases where different numbers of SVMs and IVMs share one P5800X SSD on the LPNS system or on a system using K2.

In general, LPNS can bound the latency by 50 μs in all the test cases. K2 can bound the latency by 50 μs when there are small numbers (1∼4) of IVMs. However, the outliers of latency results in the box chart prove that the latency of VM1 *webuser* workload grows over 50 μs on K2 with *max_inflight=32* when there are more than 5 IVM as competitors. When there are more SVM but less IVM (for example, Figure 10c and 10d), K2 with *max_inflight=32 or 16* can effectively bound the latency by 50 μs just as LPNS does.

Throughput sacrifice. Figure 11 demonstrates the total throughput of the IVM(s) that compete for resources with the SVM in the "1SVM & 1IVM" to "1SVM & 6IVM" cases. We choose the maximum throughput of the P5800X as the baseline. LPNS throughput loss to MDev-NVMe is 18.46% in average and less than 19.88%. Figure 11 also proves that LPNS can reach latency-predictable QoS with less throughput loss of the IVMs than K2 when multiple VMs share the one SSD. For example, when there are 6 IVMs (or 6 native inten-

sive workloads), LPNS can increase up to **1.45** × additional total throughput over K2 with *max_inflight=32* (equivalent to **47.66% of the maximum throughput** of the P5800X SSD.)

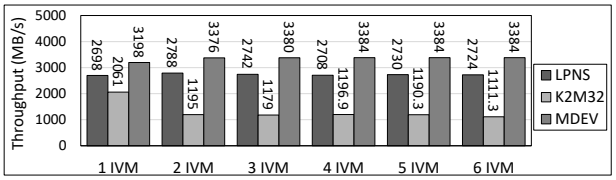


Figure 11: The total throughput of the one to six IVMs (or native workloads) on LPNS and K2 (*max_inflight=32*) in Figure 10a and 10b (MDev-NVMe as the baseline).

We deduce that LPNS will be an excellent choice to achieve their latency-predictable QoS with less sacrifice of the SSD maximum throughput when cloud vendors want to increase the scalability of virtualized devices on each single SSD with heavier over-subscription of storage resources.

5.4 YCSB Key-Value Store on RocksDB

We use the YCSB to generate K-V store workloads on the RocksDB databases in one SVM, and use several IVMs running intensive FIO random read/write workloads to generate serious interference and demonstrate that LPNS can provide latency-predictability for K-V store applications. Specifically, we build an `ext4` [1] file system on the virtualized NVMe storage device in the SVM to run the RocksDB database. We run the generic configuration of YCSB from the `workloada` to `workloadf`, which uses Zipfian [18] distributions. We set up 20M requests on 4GB database by enlarging the "recordcount" and "operationcount".

Figure 12 demonstrates the average latency performance results of YCSB benchmarks on the RocksDB databases, including the baseline where the benchmark monopolizes the entire P5800X SSD, or using MDev to support 1SVM +3IVM, or using LPNS to support 1SVM +3IVM. In the six YCSB tests, LPNS can efficiently reduce the latency interference from the IVMs and provide promising average latency performance for the Read, Update, Insert, or Scan operations. For example, the YCSB-A and YCSB-B workloads are identical mix Read and Update operations, which will bring challenges to the latency QoS control systems. The results prove that LPNS can achieve up to **7.41** × latency optimization of MDev-NVMe in the YCSB-B workloads. In YCSB-C, E, and F, MDev-NVMe and LPNS can provide latency similar to the monopolized baselines. We infer the reasons: YCSB-C is a 100% read case, which is very friendly to the cache systems, so it is not seriously interfered by the device-level congestion; YCSB-E and YCSB-F are more performance-critical about the computation ability of the K-V store databases, so the storage system is not a performance bottleneck in these cases.

In Table 3, we count the tail latency results of YCSB-A and YCSB-B benchmarks of MDev-NVMe and LPNS from Figure 12. From these results, we can find that LPNS can

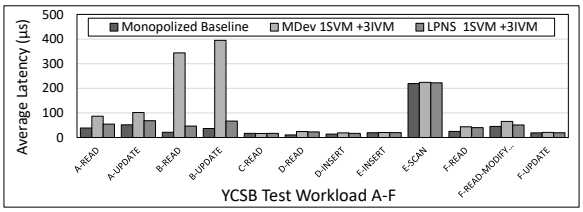

Figure 12: The average latency of YCSB A to F workloads.

achieve up to 4.44 × optimization of the 95th tail latency and up to 4.27 × optimization of the 99th tail latency compared with MDev-NVMe, which can provide the most advanced tail latency among the traditional NVMe virtualization in the Section 5.2 experiments.

Table 3: YCSB tail latency in YCSB-A and YCSB-B

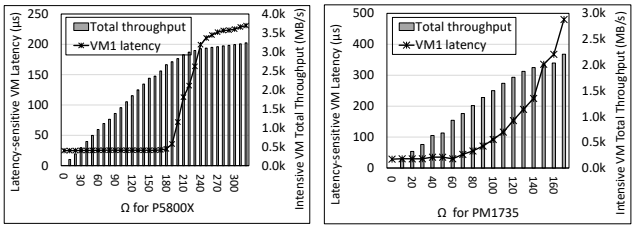
		Read		Update	
		MDev	LPNS	MDev	LPNS
YCSB-A	P95 (us)	419	242	453	260
	P99 (us)	896	366	934	399
YCSB-B	P95 (us)	907	204	961	225
	P99 (us)	969	317	1060	358

With these experimental results, we imply that LPNS can provide latency-predictable QoS for the latency-sensitive applications such as the K-V store databases in cloud services.

5.5 Predictability Trade-off

We discuss the trade-off between latency and throughput to guide the choice of the proper predicted value, which refers to the value of the I/O command scheduling parameter Ω in LPNS. The Ω value is related with the hardware SSD and can be flexibly determined by the cloud storage administrators to make an optimal alternative according to the hardware and workload scenarios. We observe the latency performance of SVM and the total throughput of IVMs to evaluate the effect of different Ω values and choose the proper Ω.

Figure 13 plots the latency of VM1 (SVM) and total throughput of IVMs at different Ω values on the P5800X and PM1735 SSDs. We use the dot lines to indicate the latency performance and bars to indicate the total throughput performance.



(a) Intel Optane P5800X. (b) Samsung PM1735.

Figure 13: Performance trade-off for different SSDs.

On P5800X, the R is 800K IOPS (0.8 iopμs) and L_h of the workload is 11.05 μs (measured when there is only one workload that monopolizes the SSD). When we choose Ω as 10, the latency can be bounded within 23.55μs according to Eq. 5, which matches the results in Figure 13a.

However, when Ω is smaller than 160, keeping decreasing Ω can not significantly improve the latency, but the throughput will continue to decline. When Ω is larger than 240, keeping increasing Ω is also uneconomic because the throughput is close to the ceiling while the latency is still growing. So an appropriate Ω value must be between 160 and 240, depending on the trade-off between the latency requirements and the acceptability of bandwidth degradation. We choose **190** on P5800X in all our experiments to bound the latency in micro and application benchmarks and get a balance between the latency bound (**50**μs) and the throughput sacrifice. With these configurations, we use Figure 14 to prove that LPNS can successfully bound the latency of the workload in Figure 1.

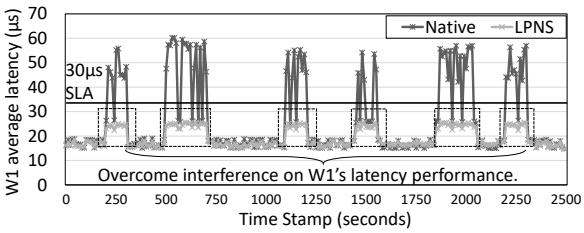


Figure 14: Latency bounded within 30μs without SLA miss.

Compared with P5800X, it is more difficult to reach a promising balance between latency and throughput on the PM1735. The Ω parameter when Ω is smaller than 60, keeping decreasing Ω can not significantly improve the predictable latency but only decline the throughput. And when we choose larger Ω, the latency grows faster than on P5800X. We finally choose **100** as the Ω to provide an upper bound of latency at **100**μs for the latency-sensitive workloads on PM1735. However, it will incur more serious throughput loss than using LPNS on P5800X. And this will be one of our future work to reach a better balance of latency prediction and throughput by upgrading our design and implementation.

6 Related Work

Local NVMe virtualization. The state-of-art local NVMe virtualization mechanisms include para-virtualization *VirtIO* [57], a userspace NVMe driver *VFIO* [70], and SPDK [25], MDev-NVMe [55], FinNVMe [54], FVM [37]. *VirtIO* is an I/O para-virtualization framework, which provides an abstraction of a set of common simulation devices suffers from the poor performance of virtualized devices. Fam Zheng [73] used *VFIO* to implement the NVMe driver to work with the modified user-space NVMe driver in Qemu. The SPDK is a userspace and lockless NVMe driver that provides an efficient and scalable interface to access various storage devices. MDev-NVMe uses mediated pass-through and the active polling mode to achieve high I/O performance. FVM implements a storage virtualization layer on an FPGA card to offload virtualization overhead, and FVM can ensure high throughput but incurs about 25% latency overhead over native performance.

Storage QoS. Many researches concentrate on NVMe resource sharing and scheduling by modifying the device controller or host software stack [4, 11, 19, 32, 39, 42, 43, 56, 60, 72]. FIOS [53] achieves the fairness of resource sharing through the per-task timeslices. AutoSSD [31] employs a self-management mechanism to schedule device-internal background jobs to prevent the SSD from falling into a critical condition that causes long tail latency. PartFTL [49] splits flash storage into separate read and write sets to ensure writes never block reads. FLIN [66] is a lightweight transaction scheduler using a three-stage scheduling algorithm to provide fairness, implemented within the SSD controller firmware. For performance isolation [15, 22, 30, 33, 36, 50, 61, 64] and QoS, workload-aware budget compensation (WA-BC) [29] provides a device-level scheduler with SR-IOV for performance isolation and fairness among multiple VMs by penalizing noisy neighbors. Differentiated Storage Services [47] propose an I/O classification architecture to close the gap between computer systems and storage systems, and improve end-to-end performance, reliability, and security of storage. More recent schedulers have evolved to guarantee isolation at OS-level without modification to the hardware. K2 [48] is a lightweight and device-agnostic I/O scheduler for Linux targeting NVMe-attached storage. Multi-Queue Fair Queueing (MQFQ) [21] is a fair and work-conserving scheduler for multi-queue systems. D2FQ [71] uses the device-side scheduling feature (NVMe WRR) to reach low-CPU-overhead fair queue scheduling.

7 Conclusion

In this paper, we propose LPNS, a latency-predictable NVMe virtualization mechanism for local cloud storage. Based on the mediated pass-through mechanism, LPNS retains high virtualization performance with I/O queue and command scheduling. To prove latency-predictable QoS, we model LPNS as a deterministic queuing system and deduce the latency upper bound referring to the deterministic network calculus. The evaluations demonstrate that LPNS can achieve the goal of latency predictability and prove to be an efficient cloud storage virtualization mechanism. In our future work, we will also improve the balance between latency prediction and throughput on more types of NVMe SSDs, and we are devoted to integrating LPNS into a hardware/software co-designed solution to offload overhead and improve scheduling efficiency.

P²CACHE: Exploring Tiered Memory for In-Kernel File Systems Caching

Zhen Lin*, Lingfeng Xiang†, Jia Rao†, Hui Lu*
*Binghamton University, †The University of Texas at Arlington

Abstract

Fast, byte-addressable persistent memory (PM) is becoming a reality in products. However, porting legacy kernel file systems to fully support PM requires substantial effort and encounters the challenge of bridging the gap between block-based access granularity and byte-addressability. Moreover, new PM-specific file systems remain far from production-ready, preventing them from being widely used. In this paper, we propose **P²CACHE**, a novel in-kernel caching mechanism to explore how legacy kernel file systems can effectively evolve in the face of fast, byte-addressable PM. P²CACHE exploits a read/write-distinguishable memory hierarchy upon a tiered memory system involving both PM and DRAM. P²CACHE leverages PM to serve all write requests for instant data durability and strong crash consistency while using DRAM to serve most read I/Os for high I/O performance. Further, P²CACHE employs a simple yet effective synchronization model between PM and DRAM by leveraging device-level parallelism. Our evaluation shows that P²CACHE can significantly increase the performance of legacy kernel file systems – e.g., by 200x for RocksDB on Ext4 – meanwhile equipping them with instant data durability and strong crash consistency, similar to PM-specialized file systems.

1 Introduction

Rapid changes in storage technologies, ranging from rotating hard disk drives (HDD) to NAND-based solid-state drives (SSD), Non-Volatile Memory Express (NVMe) [9], and Storage Class Memory (SCM) [10], play an essential role in driving the evolution of kernel file systems, such as Ext4 [35], Btrfs [37], and XFS [24]. Features have been continuously added to accommodate new and unique characteristics of storage devices. Examples include I/O schedulers designed for different types of storage media [21, 31, 39], concurrency and scalability support for high-speed storage on multi-core systems [17, 20], and the introduction of direct access mode (DAX) for byte-addressable SCM [5, 22].

However, the evolution of kernel file systems hits a plateau in light of emerging *fast, byte-addressable* storage [9, 10]. Kernel file systems are inherently built with the assumption of *slow, block-addressable* storage devices (e.g., HDD/SSD) sitting below. The layered in-kernel storage stack transforms I/O requests from applications to block operations for storage devices. As storage devices become faster, the overhead of the layered storage stack becomes more significant. For example, software contributes 50% of the read latency on a low latency (3 us) NVMe SSD [45]. The software overhead becomes even more dominant as storage devices become faster and closer to the CPU. Intel's Optane Persistent Memory [10] sitting on the memory bus incurs read latency as low as ∼170 ns [44].

To address this pressing challenge, some approaches tended to discard traditional kernel file systems. Indeed, a batch of new file systems [5, 18, 19, 23, 27, 28, 40, 42, 43] has been proposed – i.e., tailored for persistent memory (PM) [10] – and achieved high I/O bandwidth, low I/O latency, and strong crash consistency. Other approaches bypassed the kernel storage stack by exposing PM or low-latency SSDs directly to applications with userspace libraries [2] or file systems [32]. However, such new file systems and storage mechanisms may take a long time to mature and become production-ready – e.g., before having sufficient features and bug fixings.

We, instead, seek to answer the question: Can existing *well-tested, production-ready* kernel file systems effectively evolve to harness performance benefits and new characteristics of emerging storage technologies, achieving the same properties as those device-specialized file systems while requiring *no* application modifications and radical system redesign?

To answer this question, we gather the main insights from PM/SSD-specialized approaches that focus on minimizing system software overhead. First, maximizing the performance advantages of fast storage devices involves avoiding as much work as possible in the critical path. For example, approaches like SplitFS [27] and Strata [28] use a userspace library to handle data (and metadata) operations directly, which are then asynchronously processed by the kernel file system. Second, fast storage devices, along with a lightweight journaling/logging mechanism, can enable strong consistency with little overhead. For instance, NOVA [43] ensures that each file system update is synchronously persisted in an atomic manner.

Third, PM or modern NVMe SSD, with the advent of the high-speed CPU-to-device interconnect technology like Compute Express Link [4], provide a *memory-like, byte-addressable* interface [26], offering new design and optimization opportunities, including efficient handling of small writes for file system updates without write amplification.

These insights lead us to reap fast, byte-addressable storage for legacy kernel file systems with a novel in-kernel caching mechanism, **P²CACHE**. P²CACHE exploits a new *read/write-distinguishable memory hierarchy* within a tiered memory system involving both PM and DRAM. P²CACHE leverages fast PM to serve *all* write requests for instant data durability and strong crash consistency while using DRAM to serve *most* read I/Os for high I/O performance because DRAM's read performance remains significantly higher than PM.

P²CACHE first introduces a *persistent cache* located below the VFS layer. The persistent cache uses PM to quickly and synchronously persist/buffer file system metadata/data updates, guaranteeing instant data durability and strong crash consistency. The buffered operations are then asynchronously applied to underlying kernel file systems via the existing I/O interface, ensuring compatibility with kernel file systems. The persistent cache is built upon a lightweight operation log that captures minimal operations (i.e., file system updates from the VFS) and records them in a write-ahead log. It leverages PM's byte-addressability to efficiently persist metadata/data updates without costly, block-based Copy-on-Write (CoW) (commonly used in PM-based approaches [19,23,43]) – by decoupling the copy operation from the write operation, where a write operation (of any size) is synchronously recorded while the data copy is performed asynchronously.

P²CACHE further advances the *page cache* to serve most reads via faster but volatile DRAM. To allow the two caches – namely, the persistent cache and page cache – to work collaboratively and efficiently, P²CACHE leverages "device-level" parallelism. Specifically, we observe that the I/O latency of writing data to both PM and DRAM (at the same time) is almost the same as that of writing data to PM only, because the latency of the (extra) copy to DRAM is hidden (overlapped) by the *parallel-but-slower* PM write. This leads us to adopt a simple and effective *inclusive cache model*, where multiple copies of the same data are stored across the tiered memory, and the topmost layer (i.e., DRAM) always contains the latest version. The inclusive cache model simplifies the synchronization between the two caches: For writes, P²CACHE updates both caches; for reads, P²CACHE searches from the page cache, persistent cache, and underlying file systems sequentially until it first finds the data.

The benefits of P²CACHE are manifold: (1) P²CACHE requires *no* modifications to user applications, libraries, or kernel file systems while leveraging fast storage technologies to provide high I/O performance, high I/O concurrency, instant data durability, and strong consistency for legacy kernel file systems. Meanwhile, kernel file systems can still operate with their own (slow) storage devices (e.g., HDD/SSD). (2) P²CACHE does not provide complex file system functionalities (e.g., maintaining in-memory/on-disk data structures or disk block management). Instead, it focuses on efficiently persisting and buffering file system updates using PM as a persistent cache. It is extremely lightweight and enables legacy kernel file systems to achieve higher performance than PM-specialized file systems (e.g., NOVA [43]). (3) Unlike existing PM-based approaches that fully bypass DRAM (or page cache), P²CACHE leverages DRAM to maximize I/O performance – i.e., although PM has similar write latency as DRAM, there is a considerable latency gap for reads (e.g., 3x slower [44]). (4) Persistently buffering file system operations (i.e., metadata/data) enables new system optimizations. For example, P²CACHE accelerates the performance of a *cold-start* file system (e.g., after re-mounting or recovering from a system crash) by quickly re-building its in-memory cache (e.g., dentry cache) from the persistent cache.

We have implemented P²CACHE as a Linux kernel module interfacing with the VFS layer. Our evaluation with microbenchmarks and applications shows that the read/write-distinguishable memory hierarchy allows P²CACHE to significantly increase the performance of legacy file systems (e.g., Ext4) by up to 200x for RocksDB [1] while providing instant data durability and strong crash consistency. P²CACHE also achieves higher I/O performance than existing PM-specialized file systems, e.g., by up to 70% for RocksDB to NOVA [43].

2 Motivation

2.1 Fast Storage and Interconnect

Enabled by new storage technologies, such as 3D XPoint [12], NVMe SSDs over the PCIe bus achieve much higher bandwidth (e.g., 8 GB/s under the 70/30 mixed read/write case) and lower latency (e.g., as low as 3μs) [45] than before.

Further, byte-addressable persistent memory (PM) has been commercially available in a DIMM package on the memory bus, e.g., Intel Optane DC persistent memory [10]. PM allows programs to directly access data in non-volatile memory from the CPU using `load` and `store` instructions. PM offers approximately an order of magnitude higher capacity than DRAM (e.g., 8x capacity in Optane DIMMs) and within an order of magnitude performance of DRAM [44] (e.g., as low as 80 ns for write latency and 170 ns for read latency).

Despite Intel discontinuing its Optane product, the storage community is actively embracing high-speed CPU-to-device interconnect technologies [11], such as Compute Express Link (CXL) [4]. CXL provides a more general, unified interface to disaggregate various types of storage devices (e.g., DRAM, PM, and PCIe devices) directly to the CPU. CXL has the potential to offer a memory-like, byte-addressable alternative (i.e., via `load` and `store` instructions) to PCIe storage's block interface with minor modifications [26]. We envision that this trend will continue – storage devices will be increasingly faster with higher bandwidth and lower latency and offer byte-addressability via a memory-like interface. Although our

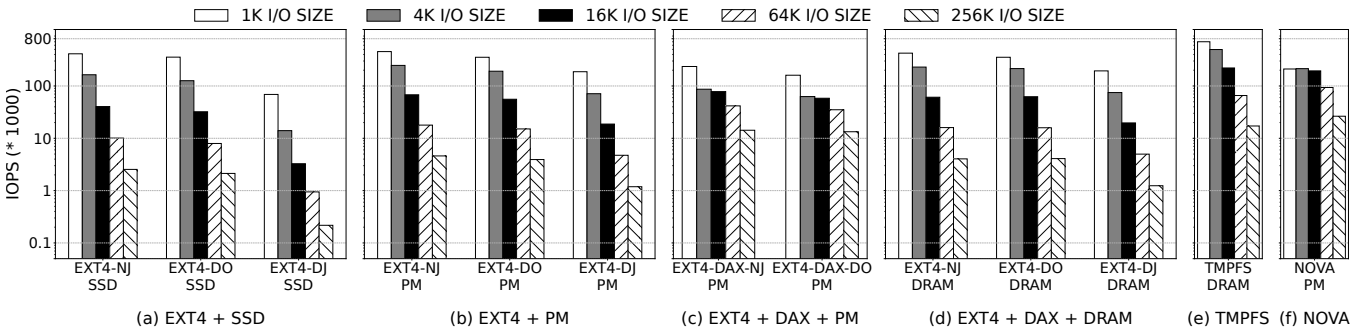

Figure 1: I/O performance comparisons for writes between cases with the combination of (1) distinct file systems: EXT4, EXT4-DAX, tmpfs, and NOVA; (2) journaling mode: no journal (NJ), data order (DO), and data journal (DJ); (3) storage medium: SSD, PM, and DRAM; and (4) various I/O sizes: 1 KB, 4 KB, 16 KB, 64 KB, and 256 KB.

work focuses on DIMM-based PM, it sheds light on bridging the gap between (1) byte-addressability, (2) a user-friendly and backward-compatible programming interface in PM and future CXL memory, and (3) the inherent differences between PM and traditional DRAM-based memory.

2.2 Kernel File Systems

Kernel file systems [7, 24, 29, 35, 37] have undergone continuous development and evolution, with the addition of features, bug fixes, and improvements in performance and reliability. For example, Ext4, the default general-purpose file system in most Linux distributions, was initially released in 2001.

The in-kernel storage stack converts I/O requests from applications into block operations that are persisted to storage devices through multiple software layers – i.e., the virtual file system (VFS), kernel file systems, generic block layers, journaling, and device drivers. While the layered design of the storage stack works well with slow underlying storage devices, such as HDD/SSD, it introduces nontrivial software overhead that becomes more pronounced as storage devices become faster. For example, in the case of low latency (3 us) NVMe SSD, software contributes 50% to read latency [45]. Our study on faster devices confirms this observation. *Observation 1: The in-kernel storage stack becomes the dominant storage bottleneck, rendering traditional kernel file systems unable to fully explore the potential of fast storage devices*. As depicted in Figure 1 (a), (b), and (d), Ext4 demonstrates only a marginal improvement in I/O performance (for writes) with PM (or even DRAM [1]) compared to SSD, despite the considerably faster speeds of PM/DRAM over SSD.

Virtual file system: Not all in-kernel storage layers contribute equally to the storage software overhead. The VFS, sitting atop the storage stack, incurs less than 10% of the overall software overhead [45]. Further, `tmpfs`, a lightweight kernel file system that works atop DRAM, achieves the highest performance (Figure 1(e)), indicating that a thin file system beneath the VFS can still leverage the benefits of fast storage media. On the other hand, the VFS implements key file system abstractions (e.g., `inodes` to represent metadata of on-disk files/directories) and functionalities (e.g., `pathname lookup` to locate a file/directory given a path name and `dcache` to cache such mappings in DRAM for quick lookup), commonly used by underlying file systems. *Observation 2: A storage layer (e.g., a persistent cache or page cache) – sitting below the VFS – can reuse VFS's rich functionality while being slim.*

Page cache: Because traditional disk accesses (e.g., HDD or SSD) are significantly slower than DRAM accesses, the operating system (OS) keeps frequently-accessed disk blocks in a dedicated region of DRAM, namely the *page cache*. The page cache reduces the number of disk accesses and speeds up I/O performance. However, as data updates are first applied to the page cache and later flushed to the storage, data modifications may not immediately reflect in the backing storage in case of sudden system crashes or power losses. This could cause an on-disk file system to enter an *inconsistent* state [34].

Journaling: To provide consistent and recoverable updates for metadata and/or data, kernel file systems often use *journaling* techniques. For example, Linux Ext4 employs the journaling block device version 2 (JBD2) [15], which implements a write-ahead log to record updates to a journal area before applying them to the corresponding file system locations. In the event of system failures, it replays the journal to restore the file system to a consistent state. JBD2 operates with three journaling modes: writeback, ordered, and data modes, providing trade-offs between performance and consistency. In writeback and ordered modes, only the metadata is journaled. However, the ordered mode (i.e., the default option) imposes an ordering requirement that data must be completed before the associated metadata is committed. This ordering constraint ensures stronger file system consistency than writeback, albeit with increased journaling latency [36]. On the other hand, the data mode journals both data and metadata, offering the highest level of consistency at the expense of the highest performance overhead.

Observation 3: Journaling places a serious impediment to the high performance of kernel file systems and can offset the performance benefits provided by the page cache. Figure 1 (a) and (b) show that in the ordered journal mode, the write performance under SSD and PM drops by ∼20% compared

[1] We used DRAM to emulate fast storage devices.

to the "no journal mode". The "data mode" substantially diminishes the write performance to only ∼10% of the no journal mode for SSD and ∼30% for PM. It is because (1) journaling requires writing metadata/data *twice*[2]: one to the log area and one to the file system location; though journaling is performed asynchronously, it can be frequently invoked by a background thread, competing for system resources with user applications. (2) JBD2 operates at the *block level* beneath the file system layer, recording all modified metadata/data blocks in a block unit within the journal area, even if only a small portion of the metadata/data blocks is modified (i.e., the small write case) – causing *write amplification*. (3) JBD2 journals all file system updates with a single kernel thread, limiting its scalability. In addition, the existing journaling scheme cannot ensure instant data durability. Instead, it relies on an explicit synchronous operation from users (e.g., `fsync()` or `fdatasync()`) for instant data durability.

2.3 Related Work

A large body of work has been recently proposed to exploit performance benefits and unique characteristics of fast storage technologies. We categorize them as two groups:

PM-specialized file systems: Many PM-specialized file systems have been studied [5, 18, 19, 23, 27, 28, 40, 42, 43]. They are tailored for the fast, byte-addressable PM to address challenges in write ordering and update atomicity, providing various levels of data/metadata consistency. For instance, BPFS [19] leveraged shadow paging for metadata/data consistency; PMFS [23] used journaling for metadata update atomicity, while performing in-place update for data (no atomicity and consistency); and NOVA [43] adopted a per-inode log-structured file system that offers synchronous persistence. Figure 1 (f) shows that NOVA achieves higher performance than Ext4 with the data journal mode (i.e., EXT4-DJ in Figure 1 (b)), while ensuring strong consistency. User-level PM-specialized file systems have been proposed to mitigate the overhead of system calls: Aerie [40] implemented a POSIX-like file system in userspace; Strata [28] appended updates to a userspace per-process log; and SplitFS [27] used a userspace library to handle data operations while still relying on the kernel-level file system to handle metadata operations.

Observation 4: the process of adapting existing storage systems to PM-specialized file systems remains in its early days. Making any of those projects production-ready needs substantial effort (and years) to achieve a combination of high performance, strong consistency, and comprehensive data protection. In addition, PM-specialized file systems unanimously bypass DRAM. While eliminating DRAM simplifies system design by allowing direct access to PM and avoiding synchronization complexity between PM and DRAM, it results in sub-optimal I/O performance. For example, the read latency of Intel Optane PM is *2x-3x* higher than that of DRAM, while the write bandwidth is only *1/6* [44]. Further compounding this situation, PM-specialized file systems usually trade I/O performance for write atomicity and consistency, for example, via log-structured file system techniques (cumbersome to reads) or shadow paging (causing write amplification) [19,43]. Figure 1 (f) shows that using Copy-on-Write (CoW) in NOVA to ensure data consistency incurs nontrivial overhead and proves detrimental to small writes (e.g., 1 KB).

[2]Although P^{2}CACHE also writes metadata and data twice, it has a very lightweight design with low overhead.

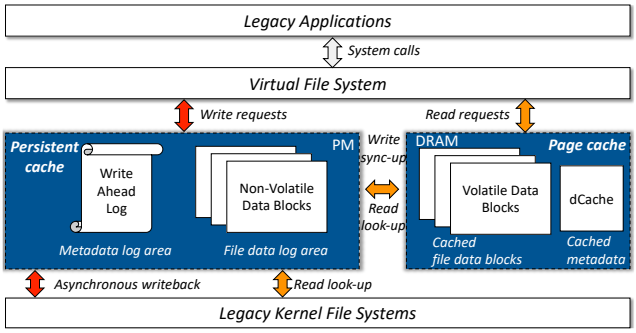

Figure 2: Overview of P^{2}CACHE.

PM-enhanced file systems: A straightforward approach for traditional block-based kernel file systems to adopt PM is to extend them with Direct Access (DAX), such as Ext4-DAX and XFS-DAX [5]. DAX-enabled kernel file systems bypass the page cache and perform reads/writes directly to PM. However, DAX-enabled file systems still operate at the block level and cannot explore PM's byte-addressability and its performance benefits. Figure 1 (c) shows that Ext4-DAX in the data-order mode achieves less than 50% of the performance of NOVA. Further, Ext4-DAX lacks support for the data journal mode and does not provide strong crash consistency.

Mostly related to P^{2}CACHE, efforts that explored the non-volatile nature of PM in building a cache layer have been conducted [30, 38]. They united either the journaling and caching [30] or the storage and caching [38] functionalities into a single cache layer. However, they are limited due to (1) like PM-specialized file systems, they eliminate DRAM despite its significant performance benefits for reads; (2) they only focus on caching data, while metadata operations remain on the slow path. Note that metadata can take up more than 50% of file system operations [3]; (3) they remain working at the block level (e.g., block-based CoW for data journaling or read-modify-write for partial writes), failing to leverage the byte-addressability of PM. *Observation 5: It is vital to have an OS caching approach that recognizes both data and metadata and distinct characteristics between PM and DRAM*.

3 P^{2}CACHE

We introduce P^{2}CACHE, a novel in-kernel caching mechanism. The goal of P^{2}CACHE is to enable the key properties of PM-specialized file systems for legacy kernel file systems, including instant data durability, strong consistency, high performance, and high concurrency while requiring *no* modifications to user applications, libraries, and kernel file systems. As illustrated in Figure 2, the key idea behind P^{2}CACHE is to

exploit a read/write-distinguishable memory hierarchy within the tiered PM/DRAM system, where P^{2}CACHE leverages fast PM to serve all write requests for instant data durability and strong crash consistency, while relying on DRAM to handle most read I/Os for high performance. P^{2}CACHE comprises two key kernel components: a persistent cache (Section 3.2) and a page cache (Section 3.3). Based on the observations in Section 2, P^{2}CACHE adopts the following key design choices.

3.1 Design Overview

A read/write-distinguishable memory hierarchy: We share the same observation as [41] that *the (modern) storage hierarchy is not a hierarchy* given the advent of fast, byte-addressable storage like PM. Unlike a traditional hierarchy where all I/O requests are first handled by the upper performance layer(s) and then consumed by the lower capacity layer(s), P^{2}CACHE distinguishes read and write operations in the PM/DRAM memory hierarchy with the goal to allow PM to handle all write requests while DRAM to serve most read I/Os because (1) P^{2}CACHE must persist each update in PM for instant data durability and strong crash consistency; and (2) DRAM's read performance is significantly higher than PM. To achieve this, P^{2}CACHE employs the following read/write strategies: (1) All writes are directed to PM, with a copy of the data modification also made in DRAM. It ensures that both PM and DRAM have the same data version. (2) Reads are first served from DRAM. If not found, P^{2}CACHE searches PM and underlying file systems. While P^{2}CACHE writes data to both PM and DRAM, it leverages *device-level parallelism* with *little* performance degradation – the latency of each data copy to DRAM is hidden by the parallel (slower) PM write.

A lightweight operation log: To harness the high performance of PM, P^{2}CACHE minimizes the operations in the critical path that involves PM. As shown in Figure 2, P^{2}CACHE's persistent cache resides at an early I/O layer, just below the VFS to leverage its general file system abstractions and functionalities while being slim. The role of the persistent cache is to capture all file system updates from the VFS (e.g., data overwrites/appends and metadata updates) and quickly, atomically persist them in an operation log stored in PM.

A PM-optimized logging mechanism: P^{2}CACHE's operation log in PM consists of two log areas: one for metadata updates and one for file data updates. First, P^{2}CACHE uses fixed-sized log entries (e.g., 64 bytes) to record metadata updates in the *metadata log area*. For data updates, P^{2}CACHE uses different strategies: (1) For *unaligned* overwrites (i.e., covering one or spanning across two *partial* data blocks), P^{2}CACHE directly appends the data to the end of its metadata update log entry for fast persistence. (2) For *aligned* overwrites (i.e., covering one or multiple contiguous full data blocks), P^{2}CACHE allocates free data blocks in the *file data log area* to store the data. (3) For *data appends*, P^{2}CACHE simply stores the appended data at the end of its data blocks in the file data log area (allocating additional blocks, if necessary). This approach ensures data consistency by never overwriting any old

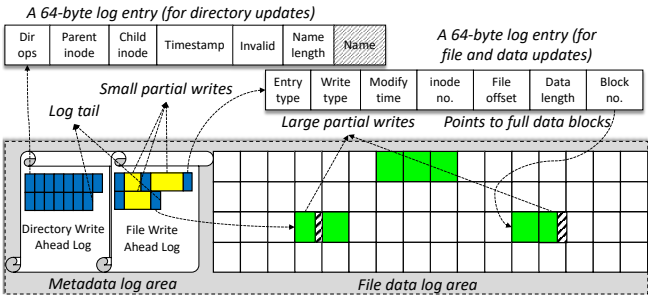

Figure 3: The layout of one CPU core's PM space.

data before the commit stage and avoiding the costly CoW operations commonly employed in other PM-based solutions.

Fast reads via in-DRAM indexes: While P^{2}CACHE's persistent cache benefits writes, it challenges reads. For example, a read operation may involve data scattered across various locations, and P^{2}CACHE may even create "holes" in the data blocks (in PM and/or DRAM) due to partial overwrites that are not aligned with the block size. To ensure fast reads, P^{2}CACHE leverages *in-DRAM* indexes to facilitate data search, including indexes for (1) log entries in PM's metadata log; (2) data blocks in PM's file data log area; (3) data blocks in the page cache; and (4) partial-write slots in the page cache. These indexes enable the rapid assembly of read content, even when it is distributed across multiple storage media. Importantly, these indexes reside exclusively in DRAM and can be quickly reconstructed from the persistent cache, such as during a system reboot or recovery.

3.2 Write-centric Persistent Cache

To achieve high performance, it is crucial to defer "writes" to slow storage for as long as possible. This is precisely why most kernel file systems employ DRAM-based caches, such as dcache for metadata and the page cache for file data, to expedite I/O operations. As depicted in Figure 2, P^{2}CACHE introduces a new OS component, a PM-based *persistent cache*, positioned beneath the VFS and above any legacy kernel file systems. It interfaces with the VFS to efficiently persist updates to file system data and metadata, ensuring crash consistency and quickly responding to user applications. Meanwhile, P^{2}CACHE relies on mature, well-tested underlying kernel file systems for data organization and management – i.e., the persisted metadata/data update operations in the persistent cache are eventually flushed back to underlying file systems.

3.2.1 Layout of PM

Operation log: P^{2}CACHE's persistent cache captures and records file system operations related to writes (i.e., metadata/data updates) in a PM-backed write-ahead operation log (WAL). As illustrated in Figure 3, a WAL is implemented as a circular buffer consisting of fixed-size log entries. As there are two types of operations, directory operations and file operations, P^{2}CACHE builds two WALs: the directory write-ahead-log (dWAL) and the file write-ahead-log (fWAL). To improve the concurrency of P^{2}CACHE, each CPU core has its own WALs to log updates on that core independently.

	VFS Interface
Directory	create(), link(), unlink(), symlink(), mkdir(), rmdir(), mknod(), update_time(), setattr(), rename()
File	write(), write_iter(), fsync(), flush() open() (access time might need to updated)

Table 1: Interface exposed by VFS for metadata/data updates.

Algorithm 1 Atomically persisting file system updates

```
1:  function PERSISTENCE(operation)
2:      log_entry := create_a_log_entry(operation);
3:      if is_directory_op then
4:          write_to_dWAL(log_entry);
5:      else
6:          write_to_fWAL(log_entry);
7:          data_persistence(log_entry);   //Section 3.2.3
8:      end if
9:      update_in_DRAM_indexes();      //Section 3.3.2
10:     sfence();
11:     update_log_tail();
12:     sfence();
13: end function
```

PM space management: P^{2}CACHE partitions the PM space into n groups, where n is the number of CPU cores. Each group is further divided into two main areas: the *metadata log area* for storing dWALs and fWALs and the *file data log area* for storing data updates, as depicted in Figure 3. In systems with multiple PM DIMMs, P^{2}CACHE employs the *interleaved* mode, which distributes contiguous data blocks across the DIMMs in an interleaved manner. The management of PM space allows P^{2}CACHE to achieve high concurrency: (1) P^{2}CACHE-related tasks can be independently handled on different cores; (2) Sequential reads/writes can be concurrently served by multiple PM DIMMs. While file and directory operations can be processed by different cores and stored across multiple WALs, these operations are inherently ordered by their time of occurrence. Each operation log entry in the WAL contains a timestamp, as depicted in Figure 3. This guarantees that logged operations are later consumed by the underlying file system in the exact order in which they were issued by user applications. P^{2}CACHE relies on the VFS to prevent conflicts arising from concurrent updates to the same directory or file (via the per-inode read-write lock). For example, while one thread is writing data to a file, all other threads attempting to read from or write to the same file must wait. As a result, writes to the same file are recorded sequentially across the WALs, and their orders are determined by their timestamps.

3.2.2 Durability and Crash Consistency

Instant metadata/data durability: Using the PM-backed operation log, P^{2}CACHE first ensures instant *data/metadata durability*. Any metadata/data updates are captured by the persistent cache and *synchronously* persisted in the WALs. P^{2}CACHE captures these updates via the VFS-exposed interface as listed in Table 1. For each update, one or more log entries are synchronously created to store such an update operation in either the dWAL or the fWAL for metadata durability. If the operation involves the file data update (e.g., `write()`), new data should also be synchronously stored for data durability (more details in Section 3.2.3). Note that achieving instant metadata/data durability in traditional kernel file systems requires user applications to explicitly invoke synchronous operations, such as `fsync()` or `fdatasync()`. For example, most database systems use `fsync()` to ensure immediate data durability. In contrast, with P^{2}CACHE's instant data durability, (1) those `fsync()` issued by legacy applications can be immediately returned; (2) P^{2}CACHE-aware applications can eliminate `fsync()`; the return of a file operation indicates that both metadata and data have been persisted.

Strong crash consistency: P^{2}CACHE further provides *strong crash consistency* similar to PM-specialized file systems [43]. P^{2}CACHE achieves this by ensuring that each file operation is *atomic* – i.e., updates made by the operation are committed in an all-or-none fashion. As described in Algorithm 1, for a *metadata* update, P^{2}CACHE appends the operation to the end of the dWAL/fWAL by creating a log entry (size of 64 bytes). Then, P^{2}CACHE atomically updates the log tail to commit the metadata update. For a *data* update, P^{2}CACHE first appends the operation in the fWAL. Depending on the type of the writes (partial or full-block), P^{2}CACHE stores the file data either to the fWAL by creating log entries or in the file data log area by allocating free data blocks (Section 3.2.3). Finally, the log tail will be updated to commit the data update. Note that as Optane PM only guarantees atomicity for an 8-byte update, ensuring the atomicity of updates larger than 8 bytes (e.g., metadata/data updates) requires P^{2}CACHE to atomically move the log tail to the end of the dWAL/fWAL, thus committing the update. To ensure correct write ordering and prevent the tail update from occurring before the metadata/data update, P^{2}CACHE uses two `sfence` instructions: one after WALs or file data are written, and one after the log tail is updated.

Compared to in-kernel file system journaling (e.g., JBD2), which offers "relaxed" consistency, P^{2}CACHE's strong consistency provides the following benefits: (1) Each file operation mostly involves updating a small log entry (e.g., 64 bytes), which is much lightweight, whereas JBD2 needs a complex transaction operation involving multiple (4 KB) blocks, such as a journal header, multiple descriptor blocks, and a journal commit block. (2) Since the logs in P^{2}CACHE are committed to PM, they are persistent. As PM has a much larger capacity (than DRAM), persisted data can stay for quite a long time. Hence, P^{2}CACHE can defer "writes" to the underlying slow file systems and storage devices as long as possible. (3) Once operations are asynchronously consumed by the underlying file system, many optimizations can be employed, such as coalescing repeated writes and removing obsolete data, similar to [28]. (4) As shown in Section 4, P^{2}CACHE (though with strong consistency) achieves much higher performance than legacy kernel file systems (with relaxed consistency) because P^{2}CACHE significantly mitigates software overhead.

While P^{2}CACHE can implement "relaxed" consistency by placing WALs in DRAM first and asynchronously flushing

them back to PM, its current focus lies in providing strong (synchronous) consistency to kernel file systems. Further, P^{2}CACHE does not support atomic `mmap`, as "mmapped" I/Os bypass the VFS and access "mmapped" files directly via `load`/`store` instructions. Currently, P^{2}CACHE relies on user applications to achieve instant data durability and strong consistency for `mmap`, while a modified (or new) `mmap` interface for update atomicity is our ongoing investigation.

3.2.3 Fine-grained, Highly-efficient Data Logging

Compared to metadata, persisting data operations can incur much higher overhead. To mitigate such overhead, P^{2}CACHE invents a fine-grained, highly-efficient data logging mechanism that leverages PM's byte-addressability.

To ensure consistency, one should never overwrite old data before committing its new update. Otherwise, if a crash happens in the middle of an overwrite, it may corrupt the old data, causing inconsistency. To consistently persist a file data update, an intuitive approach is to allocate *free* data blocks in PM for storing the new file data, record the addresses of these blocks, and finally commit the data update. Up to this point, the data blocks that store old data can be released. Reclaiming these blocks can be done asynchronously (Section 3.4).

Note that if the updated file data *aligns* perfectly with one or multiple block boundaries (e.g., 4 KB), no data copying is required. In this case, the new file data blocks simply replace the old data blocks once the update is committed. If the updated file data does not align with the data blocks, *partial updates* are involved. Existing approaches [19, 23, 43] use a CoW strategy to copy the old data to a new data block and then apply the partial updates. Unfortunately, this approach leads to write amplification and long write latency.

P^{2}CACHE addresses this issue by decoupling (and delaying) "copy" from "write" in a CoW operation, named *decoupled CoW*. Decoupled CoW distinguishes writes of different sizes. As depicted in Figure 3, there are two types of partial writes: (1) For a *small* partial write (< 2KB, assuming a block size of 4 KB), P^{2}CACHE first appends the write operation log entry to the end of the fWAL and then directly appends the data content after the log entry. Finally, P^{2}CACHE atomically updates the log tail to the end of the data content to commit the update. (2) For a *large* partial write ($\geq$ 2KB and < 4KB), P^{2}CACHE instead allocates a free block to store the content of the partial write. Similar to NOVA [43], P^{2}CACHE employs a red-black tree for tracking and allocating free blocks.

In both the aforementioned cases, P^{2}CACHE does *not* copy the old data in the write path, neither does it in the read path – P^{2}CACHE devises an approach to efficiently assemble distinct partial updates during reads (Section 3.3.2). P^{2}CACHE performs data copying to convert a partially updated block to a full block at any later time. For instance, when reclaiming space in PM (Section 3.4), P^{2}CACHE copies small partial writes from the fWAL to their data blocks in the file data log area, or fills the missing portion in the data block of the large partial write with old data. If such data blocks do not exist in PM, a read-modify-write (RMW) operation is invoked to copy the required data from the underlying file system.

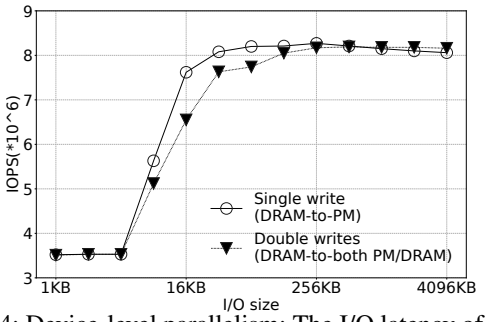

Figure 4: Device-level parallelism: The I/O latency of writing data to both PM and DRAM (i.e., one sfence after two writes: one to PM, and one to DRAM) is almost the same as that of writing data to PM only (i.e., one sfence after each PM write).

The decoupled CoW approach allows P^{2}CACHE to quickly persist partial updates by leveraging PM's byte-addressability. Real-world I/O traces show that a significant number of partial updates, ranging from 30% to 90% [33], commonly exist. In addition, by distinguishing writes by their sizes, P^{2}CACHE ensures that it requires copying *at most* half a block of data (e.g., 2KB with a block size of 4KB): P^{2}CACHE either copies the data of small partial writes (< 2KB) to their data blocks or the unmodified portion of old data (< 2KB) to the data blocks of large partial writes (> 2KB). Section 4 demonstrates that P^{2}CACHE, with the fine-grained data logging mechanism, achieves much higher performance for small writes than NOVA [43], a leading PM-specialized file system.

3.3 Read-centric Page Cache

P^{2}CACHE advances the page cache to handle most read I/Os in the tiered PM/DRAM hierarchy. P^{2}CACHE's page cache is a separate implementation other than the native page cache. It does not impact the behaviors of non-P^{2}CACHE supported kernel file systems, which still access the native page cache. To allow the persistent cache and P^{2}CACHE's read-centric page cache to work efficiently without comprising strong consistency, P^{2}CACHE employs a simple-and-effective *inclusive cache model* to exploit *device-level* parallelism.

3.3.1 Inclusive Cache Model

Similar to traditional caching mechanisms, P^{2}CACHE strives to maximize the hit ratio of the DRAM-based page cache. P^{2}CACHE employs an *inclusive cache model* where multiple copies of the same data can be stored across the tiered memory, and the topmost layer (i.e., DRAM) always contains the latest data version. It works as follows: (1) Given a *write* access, it will be persisted by the persistent cache (Section 3.2.2); meanwhile, a data copy will be made to the page cache before committing the update in PM. In this way, P^{2}CACHE allows the page cache to always have the latest version of all cached data. (2) Given a read access, P^{2}CACHE searches from the page cache (in DRAM), then the persistent cache (in PM), and finally the underlying file system until

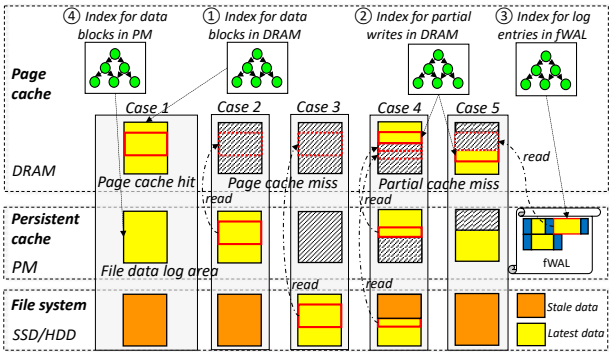

Figure 5: Fast read assembling via in-DRAM indexes.

it finds the data. For a page cache miss (e.g., the first time read or due to page eviction), the required data must be transferred either from the persistent cache or the underlying file system to the page cache, but data are never moved from the underlying file system to the persistent cache. (3) P^{2}CACHE uses LRU for cached page replacement, though other policies also apply. Evicted (dirtied) pages are dropped because any modifications have been recorded in the persistent cache.

Although P^{2}CACHE involves "double writes" for each data update, these two writes can be performed *in parallel* as they target separate devices: one for PM and one for DRAM. P^{2}CACHE can benefit from *device-level parallelism*. Figure 4 shows that the bandwidth (and latency) under "double writes" (i.e., writing to DRAM and PM at the same time) is very close to the "single-write" case (i.e., writing to PM only), indicating that the slower PM hides the latency of the extra data copy to DRAM as long as these two writes overlap each other. This way, P^{2}CACHE trades DRAM's bandwidth for simple synchronization between the two caches leading to a simplified read path. Note that DRAM has a much higher write bandwidth than PM (e.g., 6x [44]). Similar to the native page cache, P^{2}CACHE's page cache only uses "idle" DRAM and can grow/shrink. As all data on DRAM are in sync with PM, when the system memory pressure is high, the DRAM used by P^{2}CACHE can be reclaimed for other applications.

3.3.2 Fast Reads

While P^{2}CACHE's data logging (Section 3.2.3) greatly sharpens the write path, it brings new challenges to the read path due to: (1) While an operation log is efficient for updates, but not anymore for searching data (in the event of a page cache miss); (2) Decoupled CoW could leave holes in a page cache's data block – i.e., regions that are neither written by applications nor fetched from PM or underlying file systems.

In-DRAM indexes: To address these challenges, P^{2}CACHE uses in-DRAM indexes. P^{2}CACHE leverages Linux kernel's `XArray` – a memory-efficient, parallelizable treed data structure that performs lookups without locking – to create four per-`inode`, in-DRAM indexes (Figure 5) to track ① data blocks in the page cache; ② partial-write slots in the page cache; ③ log entries in the fWAL; and ④ data blocks in PM's file data log area. In consequence, in the *write* path, before committing a data update, P^{2}CACHE needs to insert the mapping information – between the updated data range and the log entry in the fWAL – in index ③. If a data block in the file data log area or the page cache has been allocated, index ④ or ① should be updated. If such an update involves a partial write, the offset and length of the partial write should be stored in index ②.

Assembling data for reads: With these in-DRAM indexes, the data content of a read request, specified by `offset` and `length`, can be quickly assembled as follows:

First, P^{2}CACHE uses the `offset` to query its per-inode index ① to check whether the data has been *fully* cached in the data block(s) of the page cache. If so, P^{2}CACHE returns the data of the requested length to user applications directly (e.g., case 1 in Figure 5). Otherwise, P^{2}CACHE uses the 2-tuple key `{offset, length}` to query index ② to check whether one or more partial slots in the range of the requested data exist in the page cache (e.g., case 4 & 5). If the aggregated partial slots do not cover the whole requested data, P^{2}CACHE moves to the persistent cache for the missing slots (e.g., case 4 & 5).

P^{2}CACHE uses the same 2-tuple key `{offset, length}` to query index ③ to get all log entries belonging to the queried data range, some of which may contain small partial writes (e.g., case 5). Further, by providing the `offset`, P^{2}CACHE retrieves the data block(s) stored in the file data log area via index ④ (e.g., case 2 & 4). Then, P^{2}CACHE copies the needed (missing) data slots – from the combined small partial writes (from the fWAL) and large partial writes (from PM's data blocks) – to the page cache (e.g., case 2, 4 & 5). If, unfortunately, there are still uncovered "holes" (e.g., case 3 & 4), P^{2}CACHE contacts the underlying file system for reading the needed data blocks to the page cache, taking longer time.

3.4 System Recovery and Digest

Rebuilding cache: P^{2}CACHE updates the log tail to commit operation-related records (Algorithm 1), indicating that all records preceding the log tail are considered valid. In case of a system crash or system remount, P^{2}CACHE discards any uncommitted records in the operation log (WALs). During system recovery/remount, *to facilitate fast reads*, P^{2}CACHE needs to scan the logs and build (1) two in-DRAM indexes, i.e., index ③ and index ④ (Section 3.3.2) and (2) a hash table (i.e., `dCache`). The process of scanning and building is considerably quick because logs are typically small (no data scanning is needed) and stored in fast PM. Table 2 shows that given a practical setup – for instance, with 10 thousand opened directories/files and 1 million log entries (typically multiple updates target one directory/file) – P^{2}CACHE uses a single core to recover index ③ within 33 ms while less than 17 ms to rebuild `dCache`. Moreover, the recovery of in-DRAM indexes can be made in parallel due to the design of per-core WALs – the time to rebuild ③ drops to 14 ms with 8 cores.

Digesting cache: P^{2}CACHE applies cached operations in PM to underlying file systems *asynchronously* via the existing I/O interface, namely the digest process [28]. The large capacity

# of log entries/files	10^4	10^5	10^6	10^7
Rebuild dCache (ms)	16.52	95.57	904.84	8009.02
Rebuild index ③ (ms)	0.89	4.44	32.92	320.50

Table 2: Time to rebuild dCache and in-DRAM indexes.

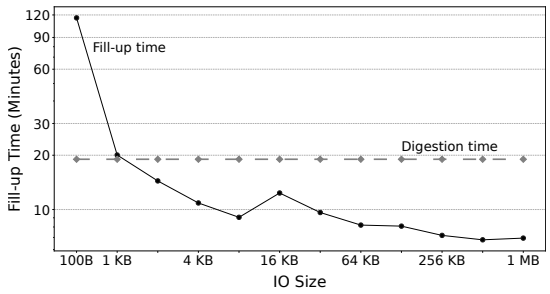

Figure 6: P^{2}CACHE filling-up time: P^{2}CACHE operates on a 512-GB PM, while the kernel file system (Ext4) runs upon one 2-TB SSD. A (sequential) write-intensive workload from Filebench [6] with 8 threads continuously issues I/O requests of various sizes at *maximum* speed. The PM's speed determines the cache fill-up time (the solid line), while the SSD's speed determines the digestion time (the dashed line). The digest process can merge adjacent write requests in the persistent cache and create large sequential I/Os writing to SSD.

of PM provides more flexibility to P^{2}CACHE by preventing the contention between the digest process and the normal working process. P^{2}CACHE digests operations during system idleness upon two conditions: the usage of PM space is high (e.g., more than 80%) or the number of log entries is large (e.g., more than 10 million). During the digest process, P^{2}CACHE relies on the return of `fsync` (after each operation) to ensure that metadata/data has been persisted and committed. A system crash may also occur during digest; P^{2}CACHE simply re-applies uncommitted operations. Similar to [28], P^{2}CACHE applies optimizations to coalesce multiple updates to the same file/directory during the digest process.

Filling cache: Given that (1) PM is generally faster than the storage devices on which the underlying kernel file systems operate (e.g., HDD/SSD) and (2) the speed of the digest process is mainly limited by the kernel file system's storage devices, the persistent cache of P^{2}CACHE can reach its full capacity. As a concrete example, Figure 6 shows the time required to fill up the persistent cache. When the persistent cache is full, P^{2}CACHE's current strategy is to throttle foreground I/O threads till the digest process reclaims enough space from PM (e.g., 20%). We note that as long as the *average* I/O rate is lower than the speed of the kernel file system's storage devices – or the fill-up time (the solid line in Figure 6) exceeds the digestion time (the dashed line) – the digest process can write back data timely. In practice, the occurrence of P^{2}CACHE reaching PM's full capacity is expected to be less frequent because (1) PM could be large (further CXL can aggregate even larger PM), and (2) I/O requests in a production environment arrive at moderate rates [38], typically lower than the speed of the kernel file system's storage devices.

4 Evaluation

We have implemented P^{2}CACHE as a Linux kernel module with ∼2000 lines of kernel code. P^{2}CACHE is available at https://github.com/YesZhen/P2CACHE. As an independent kernel module, P^{2}CACHE can be easily (un-)loaded without modifying other kernel components. P^{2}CACHE has passed all the test cases (∼7,000) of Linux official POSIX file system test suite [13], demonstrating P^{2}CACHE's POSIX compliance.

We have evaluated the effectiveness of P^{2}CACHE. Results from microbenchmarks demonstrate that (1) P^{2}CACHE accelerates metadata operations by *∼200x* against kernel file systems (e.g., Ext4 with `fsync`) and *3.5x* against PM-specialized file systems (e.g., NOVA). (2) P^{2}CACHE yields much higher write performance, particularly for *small, partial* writes – e.g., by *6.8x* than NOVA and *1,000x* than Ext4 (with `fdatasync`) for 1 KB writes. (3) P^{2}CACHE can leverage the DRAM-based page cache to achieve higher read performance – by *1.5x* than NOVA. The performance benefits brought by P^{2}CACHE further contribute to the improved application-level performance – e.g., by *72%* to NOVA for RocksDB's `insert` operations.

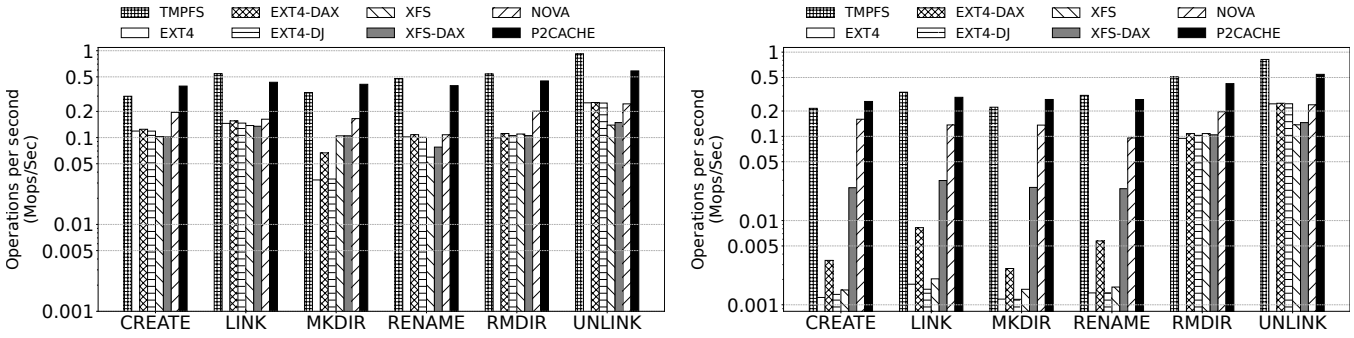
Experimental setup: The experiments were conducted on an ASUS RS700-E10-RS12U server equipped, with two 12-core Intel Xeon Gold 5317 processors (3.0 GHz and 18M Cache) with 2 NUMA nodes each with 256 GB DRAM. Hyperthreading was disabled while turbo boost was enabled. We installed four 128 GB (totaling 512 GB) Intel Optane 200 series persistent memory for each NUMA node and one 2-TB Samsung PM883 SSD. Since our focus is not on the NUMA effect, all experiments were conducted on one NUMA node.

We evaluated P^{2}CACHE on the Linux kernel 5.4, comparing it with (1) two kernel file systems, Ext4 and XFS, both operating on the SSD with the default metadata journaling mode and the data journaling mode for Ext4 (i.e., Ext4-DJ); (2) two PM-enhanced file systems, Ext4-DAX [5] and XFS-DAX [25], operating on PM; and (3) one PM-specialized file system, NOVA [43] (in strict mode) also operating on PM. We tested P^{2}CACHE atop Ext4 as the underlying kernel file system, though P^{2}CACHE can run atop any kernel file system. We evaluated P^{2}CACHE with both microbenchmarks and real-world applications. We have developed our own microbenchmarks to delicately generate desired I/O requests and patterns to test various design aspects of P^{2}CACHE. We selected three representative real-world applications for testing: Filebench [6], RocksDB [1], and MinIO [14].

4.1 Microbenchmarks

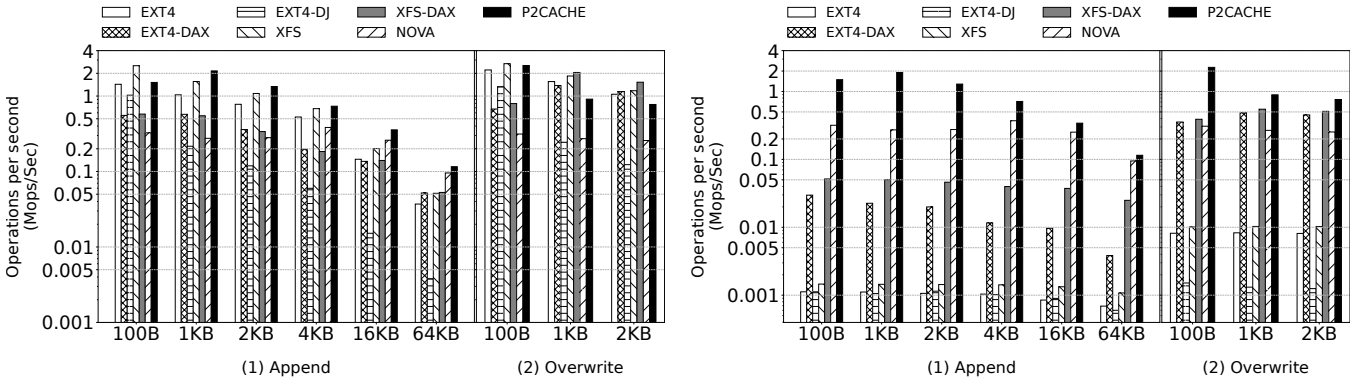
Metadata operations: We first show how P^{2}CACHE benefits metadata operations. We chose the six most complex ones in Figure 1, i.e., `create`, `link`, `mkdir`, `rename`, `rmdir`, and `unlink`. For each type of metadata, our micro-benchmark kept issuing the operations sequentially – i.e., the subsequent one was issued upon the completion of the previous one.

Figure 7a shows that P^{2}CACHE significantly accelerates the speed of all six metadata operations compared to all other cases, except for `tmpfs`. For example, for the most complex



(a) Without `fsync`. (b) With `fsync`.

Figure 7: P^{2}CACHE significantly accelerates metadata operations as against other cases except for `TMPFS`.



(a) Without `fdatasync`. (b) With `fdatasync`.

Figure 8: P^{2}CACHE accelerates data operations, especially for small, partial writes, as against other cases.

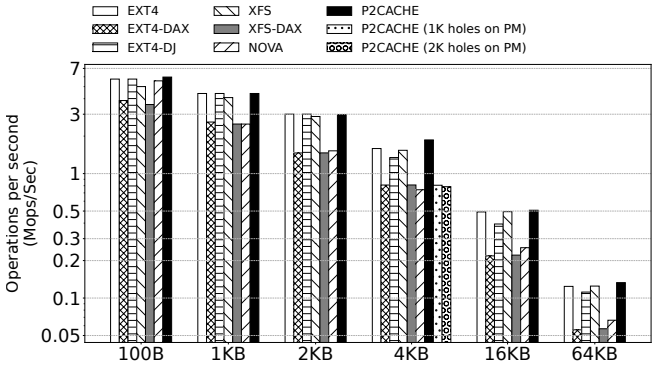


Figure 9: Comparisons of performance for reads.

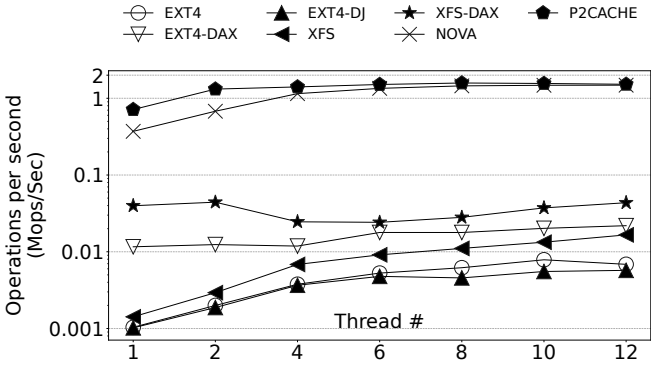

Figure 10: Scalability test with 4 KB append operations.

operation `rename` (i.e., involving multiple inodes), P^{2}CACHE achieves *∼4x* the performance of NOVA and Ext4 (in terms of operations/second). It is because P^{2}CACHE keeps the critical path (involving PM) extremely short by simply storing a log entry that represents the `rename` operation in the dWAL. In contrast, NOVA requires the creation of multiple logs and updates to multiple log entries, while Ext4 involves more operations (i.e., first `unlink` and then `link`). As another example, P^{2}CACHE enhances the performance of `mkdir` by a factor of *12x* and *6x* compared to Ext4 and Ext4-DAX. Figure 7a also shows that the performance gap between P^{2}CACHE and `tmpfs` is narrow – `tmpfs` is an extremely simple kernel file system that works upon DRAM. P^{2}CACHE is mostly within *80%* the performance of `tmpfs`; P^{2}CACHE even outperforms `tmpfs` for `create` (1.3x) and `mkdir` (1.25x). The main reason lies in that, instead of using the default heavyweight "inode_init_always" function, P^{2}CACHE implements its optimized one by initializing (fewer) needed fields. Again, as a caching mechanism, P^{2}CACHE can be lighter than full-fledged file systems, even including `tmpfs`.

Figure 7b shows a *strong consistency* scenario by issuing `fsync` after each metadata operation. Note that P^{2}CACHE and NOVA provide strong consistency in nature; they return `fsync` without any action. With strong consistency, ex-

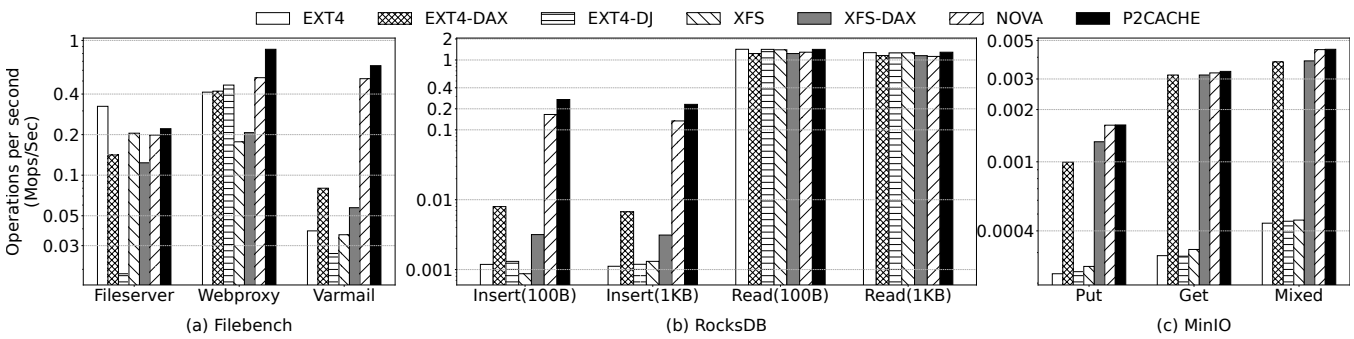

Figure 11: Performance comparisons of using real-world applications (a) Filebench, (b) RocksDB, and (c) MinIO.

cept for P^{2}CACHE, NOVA, and `tmpfs`, the performance of all other approaches drops significantly, where P^{2}CACHE outperforms them by up to *200x*. Noticeably, the performance of P^{2}CACHE and NOVA drops with `fsync` (Figure 7b) compared to the case without `fsync` (Figure 7a). It is because the `fsync` system call (though a no-op) incurs higher software overhead. As all the approaches rely on VFS's `dCache` for caching metadata, they achieve the same performance for read-related metadata operations (not listed).

Data operations: Next, we demonstrate how P^{2}CACHE benefits data operations. Figure 8a shows that in most cases P^{2}CACHE significantly outperforms other PM-based approaches in write performance – under both `append` (i.e., sequentially writing to the end of a file) and `overwrite` (i.e., sequentially overwriting existing content) – due to its lightweight design for the write path. Particularly, P^{2}CACHE achieves high performance for partial writes (e.g., for 100 bytes, 1 KB, and 2 KB) due to its *fined-grained, highly-efficient* data logging mechanism (Section 3.2.3). For example, the performance of `append` (for 1 KB) under P^{2}CACHE is 7.8x, 3.7x, and 3.9x as high as NOVA, Ext4-DAX, and XFS-DAX. Note that, only P^{2}CACHE and NOVA provide strong consistency, while Ext4-DAX and XFS-DAX only provide metadata consistency. Even with strong consistency, in many cases (except for the 100B case for `append` and 1KB & 2KB cases for `overwrite`), P^{2}CACHE achieves higher performance than kernel file systems (Ext4 and XFS), where the `append` and `overwrite` operations are directly applied to DRAM-based page cache. It indicates that P^{2}CACHE greatly reduces software overhead. The reason that the 100 B `append` case does not perform as well as other partial-write cases (e.g., 1 KB and 2 KB) lies in that the I/O size of 100 bytes is not aligned with PM's physical media access granularity, i.e., 256 bytes, causing write amplification and inefficiency [44].

Similarly, Figure 8b shows a strong consistency scenario by issuing `fdatasync` after each `append` or `overwrite` operation. The performance gap between P^{2}CACHE and others (except NOVA) widens significantly – e.g., P^{2}CACHE outperforms Ext4/XFS by more than *1,000x* and Ext4-DAX/XFS-DAX by more than *10x* for small writes. The poor performance of the kernel file systems is due to (1) slow SSD and

Metadata/data ops	Initial state	Steady state	Steady/initial

Table 3: Performance comparisons between the initial and steady states: metadata (Mops); data (IOPS).

(2) high overhead of file system journaling (Section 2.2).

For P^{2}CACHE's read performance, we tested Case 1 and 5, as listed in Figure 5. For Case 1, where all data was cached in the page cache, we measured the performance of sequential reads with various I/O sizes ranging from 100 B to 64 KB. For Case 5, where partial data was stored in DRAM and partial data was in PM, we randomly created numerous 1 KB or 2 KB "holes" in the data blocks of the page cache (averaging one hole per 4 KB) and measured the performance of sequential reads with the I/O size of 4 KB.

Figure 9 shows that, for case 1, P^{2}CACHE achieves the same (or slightly better) performance as (than) those which can leverage the DRAM-based page cache, e.g., Ext4, Ext4-DJ, and XFS. However, the difference is that P^{2}CACHE also provides strong consistency, while others do not. In contrast, P^{2}CACHE outperforms other PM-related approaches that bypass the page cache, e.g., by 1.5x compared to NOVA (for 4 KB reads). For case 5, P^{2}CACHE quickly assembled each 4 KB read from both DRAM and PM (Section 3.3.2). However, the read performance was limited by the slower device – e.g., PM. For example, P^{2}CACHE achieves the same read performance as NOVA, Ext-DAX, and XFS-DAX – the PM's speed limited the read performance.

Steady-state performance: We studied the steady-state performance by first simulating a steady-state scenario of P^{2}CACHE through running a mix of metadata/data operations until the persistent cache gradually reaches its 60% capacity with around 1 million files. We then measured the performance by running the above six metadata operations and append/overwrite data operations with strong consistency

(`fsync` or `fdatasync` after each operation) and compared the steady-state performance with that of the "initial state", where the persistent cache is empty. Table 3 demonstrates that the performance variation mostly falls within 15%.

Concurrency and scalability: We measured the scalability of P^{2}CACHE by running an increasing number of concurrent threads accessing different files on separate cores (up to 12 as one NUMA node has 12 cores). The results in Figure 10 show that both P^{2}CACHE and NOVA scale well as the number of threads increases until they reach the peak PM performance (for 4 KB `appends`). P^{2}CACHE achieves peak performance much faster than NOVA due to, again, its lightweight design.

Consistency checks: We developed a consistency checker to empirically generate test cases to examine whether the strong consistency property provided by P^{2}CACHE holds. The checker added "crash points" along P^{2}CACHE's persistence path (Algorithm 1) with three cases (1) inserting the crash point before the first `sfence`; (2) between the two `sfences`; and (3) after the second `sfence`. For Case 1, the operation should not be atomically persisted as the log tail is not updated; for Case 3, the operation should be persisted as the log tail is updated; for Case 2, the operation may or may not be persisted. The checker examines that if the operation is persisted, the final state should match the expected state (a priori knowledge), while if the operation is not persisted, nothing should be recorded (i.e., none or nothing). For all the microbenchmark tests, we also used the checker to perform consistency checks without observing any violations. We note that such consistency checks are incomplete and unable to explore all possible test cases. We leave the investigation of a more comprehensive method in future work.

4.2 Real-world Applications

Filebench: To evaluate the performance of P^{2}CACHE with real-world applications, we first selected three Filebench workloads [6]: (1) a write-intensive workload, *fileserver* (1:2 read/write ratio); (2) a read-intensive workload, *webproxy* (5:1 read/write ratio); and (3) a read/write balanced workload, *varmail* (1:1 read/write ratio). For all cases, the average read size was 1 MB, and the average write size was 16 KB. We added another type of write with the I/O size of 1 MB for fileserver. We fixed the thread number to 8 for all cases.

Figure 11 (a) shows that P^{2}CACHE consistently outperforms other PM-based approaches (e.g., NOVA, Ext4-DAX, and XFS-DAX), especially for read-intensive test cases, e.g., webproxy and varmail, due to P^{2}CACHE's read/write distinguishable memory hierarchy which leverages both PM and DRAM. For example, P^{2}CACHE outperforms NOVA by 60% for webproxy and 20% for varmail. P^{2}CACHE achieves lower performance than Ext4 for fileserver with intensive write operations, as Ext4 leverages faster DRAM-based page cache while P^{2}CACHE persists data in slower PM for writes. However, Ext4 does not provide strong consistency. P^{2}CACHE outperforms Ext4-DJ (with data journaling enabled) by *10x*.

RocksDB: We then used *db_bench* [1] – RocksDB's official benchmark tool – to evaluate P^{2}CACHE for RocksDB (a key-value store). RocksDB's architecture is highly concurrent for reads but not for writes [8]. Therefore, for writes, we focused on a single-threaded *synchronous* case by randomly inserting 10 million records to RocksDB; for reads, we focused on a multi-threaded random case with 8 threads to randomly read 10 million key-value records from RocksDB. We prepared a dataset with 10 million records. We fixed the key size to 20 bytes and evaluated two value sizes – 100 B and 1KB – a common case in RocksDB.

Figure 11 (b) shows that P^{2}CACHE outperforms all other approaches for small writes (i.e., `insert`) – e.g., by ∼72% to NOVA, ∼33x to Ext4-DAX, and ∼200x to Ext4. Note that, the extremely poor performance of Ext4 (though using the native page cache) is due to (1) synchronous insert operations, which persist data on slow SSD; and (2) read-modify-write caused by unaligned writes (e.g., 100 B or 1 KB are not aligned with 4 KB block size). As we purposely conducted the tests of reads after `insert` to have all records stored in the page cache, all the approaches (e.g., P^{2}CACHE, Ext4, Ext4-DJ, and XFS) that can leverage the page cache achieve the same performance – higher than PM-based approaches that bypass DRAM.

MinIO: Last, we evaluated P^{2}CACHE using an object storage, MinIO [14]. Compared to the above applications (e.g., RocksDB and Filebench), MinIO's software I/O path is much longer with extra data management (e.g., data checksum and placement). We used MinIO's official benchmark tool *warp* [16] with three workloads: `put`, `get`, and `mixed` (45% get, 30% stat, 15% put, and 10% deletion operations). We used log2 to distribute object sizes – i.e., objects are distributed in equal numbers for each doubling of the size.

Figure 11(c) shows that P^{2}CACHE and NOVA achieve the same performance under all cases and outperform other approaches by a range between 5% (over Ext4-DAX/XFS-DAX for `get`) and 10x (over Ext4/Ext4-DJ for `get`). We observed that software overhead from MinIO became dominant; neither P^{2}CACHE nor NOVA can exploit the full capacity of PM.

5 Conclusions

We have presented P^{2}CACHE, an in-kernel caching mechanism, which harnesses performance benefits and unique characteristics of fast, byte-addressable PM for legacy kernel file systems. P^{2}CACHE works upon a read/write-distinguishable memory hierarchy that leverages PM to persist writes and DRAM to handle reads, thus equipping kernel file systems with the key properties similar to PM-specialized file systems, including instant data durability, strong consistency, high concurrency, and high performance. Our evaluation with both microbenchmarks and applications shows that P^{2}CACHE significantly increases the performance of legacy kernel file systems, and even higher than PM-specialized file systems.

6 Acknowledgments

We thank our shepherd Mike Mesnier and the anonymous reviewers for their helpful feedback. This work was supported by NSF under Awards CCF-1845706 and CNS-2237966.

A Artifact Appendix

Abstract

The artifact contains the source code of P^{2}CACHE required to reproduce the results and figures presented in the paper. The code is designed to work upon Intel Optane PMem 200 series. To facilitate the reproduction of the results, we provide a collection of scripts for compiling and installing P^{2}CACHE, executing the experiments, collecting logs, and creating graphs. More details are available in the "README.md" file.

A.1 Description & Requirements

A.1.1 How to access

- **Link**: https://github.com/YesZhen/P2CACHE.git
- **Artifact license**: GNU GPL V3.0
- **Artifact version**: v0.0

A.1.2 Dependencies

For information on the hardware/software requirements needed to run P^{2}CACHE, please refer to "README.md".

A.1.3 Benchmarks

The experiments are carried out using several third-party benchmarking tools and applications, including FxMark, Filebench, db_bench/RocksDB, and warp/MinIO.

A.2 Testbed Setup

For instructions on how to set up and configure the test machine, please refer to the "README.md" file.

A.3 Evaluation

A.3.1 Major Claims

We summarize the major claims (Cx) in the paper as follows.

- (**C1**): P^{2}CACHE accelerates metadata operations, e.g., by *∼200x* against kernel file systems (e.g., Ext4) and *∼3.5x* against PM-specialized file systems (e.g., NOVA).
- (**C2**): P^{2}CACHE achieves much higher write performance especially for *small, partial* writes, e.g., by *6.8x* than NOVA and *1,000x* than Ext4 (with `fdatasync`) for 1 KB writes.
- (**C3**):P^{2}CACHE can leverage DRAM-based page cache to achieve high read performance, e.g., by *1.5x* than NOVA.
- (**C4**): The performance benefits brought by P^{2}CACHE further contribute to improved application-level performance – e.g., by *72%* to NOVA for RocksDB's `insert`.

A.3.2 Experiments

To reproduce the results presented in this paper, please refer to the "README.md" file and follow the instructions provided in the "Reproduce results from the paper" section.

Experiment (E1): Metadata Operations (without `fsync`)
Expected outcome. E1 produces the results as shown in Figure 7a, which illustrates that P^{2}CACHE significantly accelerates the speed of all six metadata operations (i.e., `create`, `link`, `mkdir`, `rename`, `rmdir`, and `unlink`) when compared to all other approaches (i.e., `Ext4`, `Ext4-DJ`, `XFS`, `Ext4-DAX`, `XFS-DAX`, and `NOVA`), except for `tmpfs`.

Experiment (E2): Metadata Operations (with `fsync`)
Expected outcome. E2 creates the results of Figure 7b. It demonstrates a strong consistency case by issuing `fsync` after each metadata operation. Except for P^{2}CACHE, `NOVA`, and `tmpfs`, the performance of all other approaches (i.e., `Ext4`, `Ext4-DJ`, `XFS`, `Ext4-DAX`, `XFS-DAX`) drops significantly.

Experiment (E3): Write Operations (no `fdatasync`)
Expected outcome. E3 generates the results as depicted in Figure 8a. It shows that in most cases (across various I/O sizes), P^{2}CACHE outperforms other PM-based approaches (i.e., `NOVA`, `Ext4-DAX`, and `XFS-DAX`) for two write operations: `append` and `overwrite`.

Experiment (E4): Write Operations (with `fdatasync`)
Expected outcome. E4 produces the results as depicted in Figure 8b. It demonstrates a strong consistency scenario by issuing `fdatasync` after each `append` or `overwrite` operation. P^{2}CACHE outperforms all other approaches in terms of higher `append` and `overwrite` performance.

Experiment (E5): Read Operations
Expected outcome. E5 creates the results as demonstrated in Figure 9. It shows that P^{2}CACHE achieves the same (or slightly better) performance as (than) those which can leverage the DRAM-based page cache (i.e., `Ext4`, `Ext4-DJ`, and

XFS). Further, P^{2}CACHE outperforms all other PM-based approaches (i.e., NOVA, Ext4-DAX, XFS-DAX) in terms of higher read performance.

Experiment (E6): Scalability
Expected outcome. E6 generates the results in Figure 10, showing that both P^{2}CACHE and NOVA scale well as the number of threads increases until reaching the peak performance, whereas P^{2}CACHE achieves the peak faster than NOVA.

Experiment (E7): Application: Filebench
Expected outcome. E7 produces the results as shown in Figure 11(a). It runs three workloads with Filebench, which are fileserver, webproxy, and varmail. The results show that P^{2}CACHE consistently outperforms other PM-based approaches (i.e., NOVA, Ext4-DAX, and XFS-DAX) in terms of higher application-level performance (operations/second).

Experiment (E8): Application: RocksDB
Expected outcome. E8 creates the results in Figure 11(b). It shows that for the insert operations (with sizes of 100 B and 1 KB), P^{2}CACHE outperforms all other approaches. All the approaches (i.e., P^{2}CACHE, Ext4, Ext4-DJ, and XFS) that can leverage page cache achieve similar read performance – slightly higher than other PM-based approaches that bypass DRAM (i.e., NOVA, Ext4-DAX, and XFS-DAX).

Experiment (E9): Application: MinIO
Expected outcome. E9 produces the results in Figure 11(c). The results show that P^{2}CACHE and NOVA achieve the same performance under all test cases and outperform other approaches (e.g., Ext4, Ext4-DJ, Ext4-DAX, XFS, and XFS-DAX).

Revisiting Secondary Indexing in LSM-based Storage Systems with Persistent Memory

Abstract

LSM-based storage systems are widely used for superior write performance on block devices. However, they currently fail to efficiently support secondary indexing, since a secondary index query operation usually needs to retrieve multiple small values, which scatter in multiple LSM components. In this work, we revisit secondary indexing in LSM-based storage systems with byte-addressable persistent memory (PM). Existing PM-based indexes are not directly competent for efficient secondary indexing. We propose PERSEID, an efficient PM-based secondary indexing mechanism for LSM-based storage systems, which takes into account both characteristics of PM and secondary indexing. PERSEID consists of (1) a specifically designed secondary index structure that achieves high-performance insertion and query, (2) a lightweight hybrid PM-DRAM and hash-based validation approach to filter out obsolete values with subtle overhead, and (3) two adapted optimizations on primary table searching issued from secondary indexes to accelerate non-index-only queries. Our evaluation shows that PERSEID outperforms existing PM-based indexes by 3-7× and achieves about two orders of magnitude performance of state-of-the-art LSM-based secondary indexing techniques even if on PM instead of disks.

1 Introduction

Log-Structured Merge trees (LSM-trees) feature outstanding write performance and thus have been widely adopted in modern key-value (KV) stores, such as RocksDB [22] and Cassandra [1]. Different from in-place update storage structures (e.g., B$^+$-Tree), LSM-trees buffer writes in memory and flush them to storage devices in batches periodically to avoid random writes, which enables high write performance and low device write amplification. Besides high write performance, many database applications also require high-performance queries on not only primary keys but also other specific values [11], thus necessitating secondary indexing techniques.

LSM-trees' attributes make it challenging to design efficient secondary indexing. Modern LSM-based storage systems typically store a secondary index as another LSM-tree [47] (e.g., a column family in RocksDB [44]). However, designed for block devices and optimized for write performance, LSM-trees are not competent data structures for secondary indexes which require high search performance. First, since secondary indexes usually only store primary keys instead of full records[1] as values, KV pairs in secondary indexes are small. LSM-trees' heavy lookup operations are inefficient for these small KV pairs. Second, secondary keys are not unique and can have multiple associated primary keys. LSM-trees' out-of-place write pattern will scatter these non-consecutive-arrived values (i.e., associated primary keys) to multiple pieces at different levels. Consequently, query operations need to search all levels in the LSM-based secondary index to fetch these value pieces. Besides the device I/O overhead, LSM-trees have non-negligible overheads of CPU and memory (i.e., indexing and Bloom filter) [17, 20, 34].

Moreover, the consistency of secondary indexes is another issue in LSM-based storage systems. As an LSM-based primary table adopts the blind-write pattern to update or delete records (appends new data without checking old data, versus read-modify-write in B$^+$-Trees) for high write performance, it is unable to delete the obsolete entry in a secondary index without acquiring the old secondary key. Consequently, when querying a secondary index, the system should validate each entry by checking the primary table before returning the results to users, which introduces many unnecessary but expensive lookups on the primary table for obsolete entries. Some systems fetch old records when updating or deleting records to keep secondary indexes up-to-date synchronously [9, 44], whereas this method discards the blind-write attribute and thus degrades the write performance.

Though many efforts have been made to optimize these predicaments [36, 40, 47, 50], they are difficult to solve the problems discussed above well, sacrificing either write per-

[1] For clarity, we use *record* to refer to a KV pair in the primary table, and *entry* to refer to a KV pair in a secondary index.

formance of the LSM-based storage systems or query performance of the secondary index.

As secondary indexing demands low-latency queries and the KV pairs of secondary indexes are small, we argue that leveraging persistent memory (PM) to provide a new solution for secondary indexing is promising. PM has many attractive advantages such as byte-addressability, DRAM-comparable access latency, and the ability of data persistency, which is well suited to secondary indexing. Though there are many state-of-the-art PM-based indexes [13, 25, 31, 33, 37, 38, 45, 46, 61, 62], none of them are designed for secondary indexing. Without considering the non-unique feature of secondary indexes and consistency in LSM-based KV stores, simply adopting existing general PM-based indexes as secondary indexes can overshadow their performance.

In this work, we propose PERSEID, a new persistent memory-based secondary indexing mechanism for LSM-based KV stores. PERSEID contains `PS-Tree`, a specifically designed data structure on PM for secondary indexes. `PS-Tree` can leverage state-of-the-art PM-based indexes and enhance them with a specific value layer, which considers the characteristics of both PM and secondary indexing. The value layer of `PS-Tree` works in a manner of blended log-structured approach and B$^+$-Tree leaf nodes, which is both PM-friendly and secondary-index-friendly. Specifically, new values are appended to value pages for efficient insertion on PM. During the value page split, multiple values (i.e., associated primary keys) that belong to the same secondary key are reorganized to store continuously for efficient querying.

Moreover, PERSEID retains the blind-write attribute of LSM-based KV stores for high write performance without sacrificing secondary index query performance. This is achieved by a lightweight hybrid PM-DRAM and hash-based validation approach in PERSEID. PERSEID uses a hash table on PM to record the latest version of primary keys. However, multiple random accesses on PM still incur high latencies. Thus, PERSEID adopts a small mirror of the validation hash table on DRAM which only contains useful information for validation. During validation, the volatile hash table absorbs random accesses to PM, and thus reduces the validation overhead. The small volatile hash table not only saves DRAM memory space but also reduces cache pollution.

PERSEID has a fairly low latency of index-only query[2] However, the overhead of non-index-only queries is still dominated by the LSM-based primary table. Therefore, we further propose two optimizations for non-index-only queries in PERSEID. First, as querying the primary table issued by the secondary index is an internal operation, we can locate KV pairs with additional auxiliary information much more efficiently, reducing cumbersome indexing operations. By matching the tiering compaction strategy [19, 41], we can further bypass Bloom filter checking. Second, as one secondary index query may need to search for multiple independent records in the primary table, we parallelize these searching operations with multiple threads. Since search latencies on the LSM-based primary table may vary largely, we apply a worker-active manner on parallel threads to avoid load imbalance among threads and improve utilization.

We implement PERSEID and evaluate it against state-of-the-art PM-based indexes and LSM-based secondary indexing techniques on PM. The evaluation results show that PERSEID outperforms exiting PM-based indexes by 3-7× for queries, and achieves about two orders of magnitude higher performance of state-of-the-art LSM-based secondary indexing techniques even if on PM instead of disks, while maintaining the high write performance of LSM-based storage systems.

In summary, this paper makes the following contributions:

- Analysis of the inefficiencies of LSM-based secondary indexing techniques and existing PM-based indexes when adopted as secondary indexes for LSM-based KV stores.
- PERSEID, an efficient PM-based secondary indexing mechanism, which includes a secondary index-friendly structure, a lightweight validation approach, and two optimizations on primary table searching issued from secondary indexes.
- Experiments that demonstrate the advantage of PERSEID.

2 Background

2.1 Log-Structured Merge Trees

The LSM-tree applies out-of-place updates and performs sequential writes, which achieves superior write performance compared to other in-place-update storage structures.

The LSM-tree has a multi-level structure on storage and each level comprises one or several sorted runs. The size of Level L_n is several times (e.g., 10) larger than Level L_{n-1}. Each sorted run contains sorted KV pairs and is further partitioned to multiple small components called *SSTables*. In LSM-trees, new key-value pairs are first buffered into a memory component called a *MemTable*. When the MemTable fills up, it turns into an immutable MemTable and gets flushed to storage as a sorted run. Since sorted runs have overlapping key ranges, a query operation needs to search multiple sorted runs. To limit the number of sorted runs and improve search efficiency, LSM-trees conduct compaction periodically to merge several components and remove obsolete KV pairs.

Two typical compaction strategy and their variants are commonly used in LSM-trees [19, 41]: The leveling strategy [22, 24] only allows each level (besides L_0) to have only one sorted run; The tiering strategy [48, 54] allows each level (besides L_0) to have multiple sorted runs to reduce the write amplification. Compared with leveling strategy, tiering strategy has a much smaller write amplification ratio and thus

[2] Index-only query is a common query technique: Users create a *covering index* that contains specific columns required by queries to avoid the cost of reading the primary table [5, 7, 44]. A non-index-only query searches the secondary index by secondary key to get primary keys and then retrieves full records from the primary table.

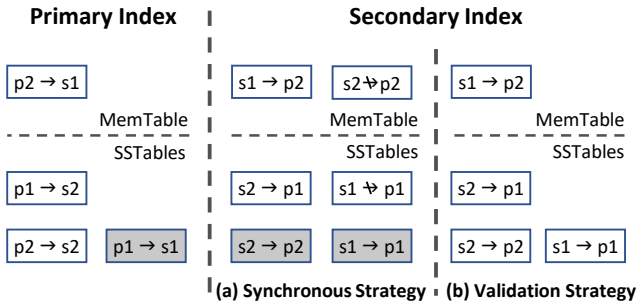

Figure 1: Stand-alone secondary indexing in LSM-based systems with Synchronous strategy and Validation strategy [47]. *The shaded entries indicate that they are invisible in the index.*

higher write performance. However, since query operations need to search multiple sorted runs in each level, LSM-trees with tiering strategy have much lower read performance.

2.2 Secondary Index in LSM-based Systems

Many applications require queries on specific values other than primary keys. Without an index based on specific values, database systems need to scan the whole table to find relevant data. Thus, secondary indexing is an indispensable technique in database systems. For example, in Facebook's database service for social graphs, secondary keys are heavily used, such as finding IDs who liked a specific photo [11, 44]. In this work, we mainly discuss stand-alone secondary indexes, which are separate index structures apart from the primary table and are commonly used in database systems [47]. A stand-alone secondary index maintains mappings from each secondary key to its associated primary keys. As secondary keys are not unique, a single secondary key can have multiple associated primary keys.

Consistency strategy. Since LSM-based KV stores update or delete records by out-of-place blind-writes, maintaining consistency of secondary indexes becomes a challenge in LSM-based storage systems. There are two strategies to handle this issue, *Synchronous* and *Validation*.

For *Synchronous* strategy, whenever a record is written in the primary table, the secondary index is maintained synchronously to reflect the latest and valid status (e.g., AsterixDB [9], MongoDB [4], MyRocks [44]). For example, as shown in Figure 1(a), when writing a new record { $p2 \rightarrow s1$ } (p denotes the primary key, s denotes the secondary key, and other fields are omitted for simplicity) into the primary table, the storage system also fetches the old record of $p2$ to get its old secondary key $s2$. Then the storage system inserts not only a new entry { $s1 \rightarrow p2$ } but also a tombstone to delete the obsolete entry { $s2 \rightarrow p2$ } in the secondary index. Nevertheless, this strategy discards the blind-write attribute and thus degrades the write performance which is the main advantage of LSM-based KV stores.
